About the Founding Editor

Michael F. L'Annunziata

Michael F. L'Annunziata, PhD, is the founding editor and coauthor of the *Handbook of Radioactivity Analysis*. He majored in chemistry with a BSc degree from St. Edward's University in 1965, and he was awarded MSc and PhD degrees from the University of Arizona, Tucson, in 1967 and 1970, respectively. His graduate thesis research in the 1960s, financed by the then US Atomic Energy Commission, dealt with the analysis of the radionuclides ^{89}Sr and ^{90}Sr and the remediation of soils contaminated with radiostrontium in the event of nuclear fallout, published as a thesis in 1967 (<https://repository.arizona.edu/handle/10150/318640>). After a short stint in the chemical industry (Amchem Products, Inc, Ambler, Pennsylvania) during 1970–71 as ^{14}C -tracer chemist, he joined the faculty at the Postgraduate College in Chapingo, Mexico, as a professor and thesis advisor during 1972–75; and during 1975–77, L'Annunziata was a senior research scientist at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico, where he served also as a thesis research advisor to graduate students of chemistry of the Autonomous University of the State of Mexico in Toluca, Mexico, in the field of radionuclide analysis and applications. During 1977–91, he was a scientific officer in the Departments of Research and Isotopes and Technical Cooperation of the International Atomic Energy Agency

(IAEA) in Vienna, Austria, where he served as IAEA Head of Fellowships and Training during 1987–91. From 1977 to 2007, he served as IAEA Expert in fact-finding, planning, and implementation assignments in peaceful applications of nuclear energy for development in more than 50 countries of the world in Asia, Africa, Europe, Latin America, and the Middle East. L'Annunziata was a member of the Board of Governors, International Science Programs at Uppsala University, between 1988 and 1991. His main research interests have been focused on the development of chemical and instrumental methods for the detection and measurement of radioactive nuclides as tracers in research. He was the first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as a source of the stereoisomers of inositol phosphates in soils (PhD dissertation, 1970, <https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum=>) and in 1975 (*SSSA Journal* 39(2), 377–379) and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–736, <https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733>). The first edition of the *Handbook of Radioactivity Analysis* was planned by L'Annunziata in 1995, and he edited and coauthored the subsequent editions, including the current fourth edition published by Elsevier in 2020. He has authored and coauthored 11 books since 1979 on radionuclide analysis and radiation physics among which his book entitled *Radioactivity: Introduction and History*, First Edition, published by Elsevier in 2007, was included on the Best Sellers List in Physics (*LibraryJournal Academic Newswire*) in 2008. His much expanded Second Edition entitled *Radioactivity: Introduction and History, From the Quantum to Quarks* (<https://www.sciencedirect.com/book/9780444634894/radioactivity>), published by Elsevier in 2016, was awarded an Honorary Mention in the 2017 PROSE AWARDS in the category of Chemistry and Physics.

Foreword

Radioactive sources play a significant role in promoting human development and health worldwide. Whether through its application to treat cancer, diagnose various diseases, develop new crop varieties, sterilize medical supplies, or provide clean energy, peaceful uses of radioactive sources are ubiquitous in our daily lives. These wide-ranging applications can only be implemented appropriately when radioactivity is measured precisely. Thus, the accurate measurement of nuclear radiation is indispensable for the peaceful applications of radioactive materials. For example, in fields such as nuclear medicine, whether for the treatment or diagnosis of disease, accurate measurements of radionuclides are essential. Dosimetric measurements are the cornerstone of safe and effective radiation therapy for the treatment of cancer whether for brachytherapy, proton beam therapy, or other sources of radiation therapy.

With more than 170 Member States in all continents of the world, the International Atomic Energy Agency (IAEA) serves as the global focal point for nuclear cooperation. The *Handbook of Radioactivity Analysis* will serve Member States as one of many tools available in the application of nuclear science and technology for peaceful purposes. The importance of this guidance is demonstrated by the wide range of areas in which the IAEA supports Member States to contribute to their well-being and development. Such examples include biological sciences research, insect pest control, health, fertilizer and water use efficiency, water resources and the environment including marine science and climate change, radiation technology, neutron diffraction, radiography and activation analysis, radiation processing in industry, radiation protection, nuclear power, nuclear safeguards, radiation preparedness and response, and research in the field of nuclear fusion, among others.

The *Handbook of Radioactivity Analysis* is now in its fourth edition since the successful first edition in 1998. Over the past two decades, this book has expanded in its scope from an initial 12 chapters to the current 22 chapters, encompassing the numerous modern applications and methods of radiation detection and measurement. The chapters in this book are written by experts from 16 countries around the world. This new edition will continue to serve as an important resource in our search to optimize radioactivity measurements both in research and in its applications, leading to the peaceful utilization of radioactive sources for health and development.

May Abdel-Wahab, MD, PhD, FACR

Director, Division of Human Health
Department of Nuclear Sciences and Applications
International Atomic Energy Agency, Vienna

Preface to the fourth edition

In 1996, I proposed to Academic Press the idea of a book that would provide readers with a reference source to state-of-the-art radiation detectors and methods of analysis of radionuclides and other sources of nuclear radiation. Thus, the first edition of this book was published in 1998 as a single volume with only 12 chapters, and the book has expanded in scope and depth over the past two decades with the current fourth edition and its 22 chapters in two volumes.

The numerous advances that have been made since the publication of the previous third edition warranted the partition of the *Handbook of Radioactivity Analysis* into two volumes. It was decided to separate the chapters into two categories, namely, Volume 1, *Radiation Physics and Detectors* and Volume 2, *Radioanalytical Applications*. The two volumes of this book were expanded greatly to provide material, which would serve as a valuable resource in teaching and a reference source to the researcher in his or her unique analytical requirements in the measurement of radioactive materials.

The first chapter in Volume 1, which was previously entitled *Radiation Physics and Radionuclide Decay*, was expanded to almost double in volume with a corresponding change in the chapter title to *The Atomic Nucleus, Nuclear Radiation, and the Interaction of Radiation with Matter*, which includes additional material helpful to supplement the academic curricula and aid in the decisions and calculations made by researchers in their measurement of nuclear radiation and radionuclide analysis. Current principles of operation of all classes of radiation detectors and their applications have been expanded and updated, including semiconductor detectors, gas ionization detectors, liquid and solid scintillation detectors, solid-state nuclear track detectors, Cherenkov detectors, calorimeters and bolometers, as well as advances in atom counting (i.e., mass spectrometry) for the measurement of radioactive and stable nuclides and radiation from other sources such as cosmic radiation, synchrotron radiation, and particle emissions from nuclear reactions.

In light of increased concern for radioactivity in the environment, a chapter was added on the *Analysis of Environmental Radionuclides* in Volume 2. Also, all chapters in Volume 2 have been expanded and updated with material required in the analysis of radionuclides and radiation in our land, air, and water resources, including the marine environment, as well as particle identification and measurement by Cherenkov counting, radiation counting statistics, radionuclide standardization, imaging techniques required in the applications of radionuclides in biological research and nuclear medicine, flow-cell analytical techniques, automation in radiochemical analysis together with analytical techniques required in the fields of nuclear safeguards and nuclear forensics.

Again, we have completed this book as an international effort by drawing upon the expertise of researchers and teachers from 16 countries of the world. Although coming from many branches of science, chapter authors all share one common objective, that being the most accurate measurement of radiation sources and radionuclides both natural and man-made, vital to all branches of science and human development. Readers interested in radiation physics, the applications of radionuclides and radiation sources, and how these have been vital to our well-being and development may refer to another text by the writer entitled “*Radioactivity: Introduction and History, From the Quantum to Quarks*” (ISBN: 978-0-444-63489-4), published in 2016 by Elsevier (<https://www.elsevier.com/books/radioactivity/lannunziata/978-0-444-63489-4>).

Women are the senior authors of three chapters in this new edition, which is evidence of the increasing role of women as leaders in this field of science. We may expect to see yet in the future an ever-increasing number of women, who will make great advances in this field of science following the pioneering examples of Marie Curie, Lise Meitner, Maria Goeppert-Mayer, Rosalind Franklin, Marietta Blau, and Chien-Shiung Wu, among others.

Mention of commercial products in this book does not imply recommendation or endorsement by the chapter authors or editor. Other or more suitable products may be available. Names of products are included for convenience or information purposes only.

I would like to thank the authors of each chapter, who have covered their fields of expertise with an unwavering commitment to meet the objectives of this book. Acknowledgment is extended to Kathryn Eryilmaz (nee Morrissey),

Aquisition Editor, at Elsevier in Cambridge for approaching me with the suggestion that we consider a fourth edition and for working with me during the planning stage of this book. Many thanks go to Hilary Carr, Elsevier Editorial Project Manager, for her constant support and advice throughout the writing and production of this book. I thank also Ashwathi P. Aravindakshan of Elsevier for her assistance in completing the legal requirements for the publication of this book. Appreciation is also extended to Prem Kumar Kaliamoorthi, Elsevier Production Project Manager, for his meticulous attention to every detail throughout the production process of this book. Thanks are also extended to Susan Dennis, Publisher of Elsevier Chemistry and Chemical Engineering Books, and Mona Zahir, Elsevier Editorial Project Manager, for their guidance and support during this project. Above all, I thank my wife Maria del Carmen (aka Reyna) for her understanding, encouragement, and unflagging patience.

Michael F. L'Annunziata, PhD

L, l Liters	LS Liquid scintillation, liquid scintillator, “linear-to-square” curve
LA Linear anode	LSA Liquid scintillation analysis (analyzer)
LAAPD Large area avalanche photodiode	LSC Liquid scintillation counting (counter)
LAB Linear alkyl benzene, dodecylbenzene	LSO Cerium-activated lutetium oxyorthosilicate ($\text{Ce:Lu}_2\text{SiO}_5$)
LA-ICP-MS Laser ablation inductively coupled plasma mass spectrometry	LSS Liquid scintillation spectrometer
LA-MC-ICP-MS Laser ablation multiple collector ICP-MS	LTC Live-time correction
λ Wavelength, decay constant, microliter (10^{-6} L), free parameter	LuAP Cerium-activated lutetium aluminum perovskite (Ce:LuAlO_3)
λ_{nr} Nonrelativistic wavelength	LY Light yield
λ_{r} Relativistic wavelength	LXe Liquid xenon
LAMMA Laser microprobe mass analysis	M Molar (solution concentration)
LAN Local area network	m Particle mass
LANL Los Alamos National Laboratory	m_0 Particle rest mass
LAr Liquid argon	m_r Speed-dependent particle mass
LARA laser-assisted isotope ratio analysis	m Mass, meters, minutes
LAW Low-activity waste	mA Milliampere (10^{-3} ampere)
LBD Ligand-binding domain	Ma Megayear (10^6 years)
BNL Lawrence Berkeley National Laboratory	mAbs Monoclonal antibodies
LC Liquid chromatography	MACS Magnetically assisted chemical separations
LCDW Lower circumpolar deep water	MALDI Matrix-assisted laser desorption/ionization
LCMS Liquid chromatography mass spectrometry	MAPD Micropixel avalanche photodiode
LD₅₀ Median lethal dose	MAPMT Multianode photomultiplier tube
LED Light-emitting diode	MARG Microautoradiography
LEGE Low-energy germanium detector	MARIS Marine information system
LENA Low-energy neutrino astrophysics detector	MARSSIM Multi-Agency Radiation Survey and Site Investigation Manual
LET Linear energy transfer	MATLAB MATrix LABoratory (numerical computing and programming language)
LEU Low enriched uranium	mb Millibarn (10^{-3} b)
LHCb RICH Large Hadron Collider beauty experiment detector at CERN	mBq Millibecquerels (10^{-3} Bq)
LHD Large Hadron Collider	MBq Megabecquerels (10^6 Bq)
LiI(Eu) Europium-activated lithium iodide	mCi Millicurie (10^{-3} Ci) = 2.22×10^9 dpm = 3.7×10^7 dps = 37 MBq
LIMS Laboratory Information Management System	MC Multiple ion counting
LINAC or linac Linear accelerator	MCA Multichannel analyzer
LIST Laser ion source trap	MCF Moving curve fitting
LL Lower level	MC-ICP-MS Multiple ion collector-ICP-MS
LL-BSS Large $^6\text{LiI(Eu)}$ Bonner sphere spectrometer	MCN Microconcentric nebulizer
LLC Liquid (mobile)—liquid (on solid phase) chromatography	MCNP Monte Carlo N-Particle code
LLCM Low-level count mode	MCNP-CP Monte Carlo N-Particle-Correlated Particle code
LLD Lower limit of detection, lower level discriminator	MCP Microchannel plate
LLE Liquid—liquid extraction	MCP-PM Microchannel plate photomultiplier
LLNL Lawrence Livermore National Laboratory	MC-TIMS Multiple collector thermal ionization mass spectrometry
LLR Long-lived radionuclide	MD Molecular dynamics
LMD Laser microdissection	MDA Minimal detectable activity
LM-OSL Linear modulation optically stimulated luminescence	MDOA Methyl dioctylamine
LN₂ Liquid nitrogen	METAS Federal Institute of Metrology, Berne-Wabern, Switzerland
LNE Laboratoire National de Métrologie et de Essais, France	METEPC Multielement tissue-equivalent proportional counter
LNGS Laboratori Nazionali del Gran Sasso, Italy	MeV Megaelectron volts
LNHB Laboratoire National Henri Becquerel, Saclay	MeVee Electron equivalent energy
LNMRI National Metrology Laboratory of Ionizing Radiation, Brazil	MHSP Microhole and strip plate (imager)
LOD Limit of detection	MHz Megahertz (10^6 Hz)
LOV lab-on-valve (system)	MIBK Methyl isobutyl ketone
lp Line pairs	MICAD Microchannel Array Detector
LPB Low-pressure Bridgman	MICM Modified integral counting method
LPI low-pressure cascade impactor	MICROMEGAS Micromesh gas detector
LPRI Laboratoire Primaire des Ionizants, Paris	mg Milligram (10^{-3} g)
LPS Lipopolysaccharide	mGy Milligray
LRAD Long-range alpha detector	

MIBK Methyl isobutyl ketone	n Neutron
min Minutes	<i>n</i> Index of refraction
mK MilliKelvin (10^{-3} K)	NA Avogadro's constant ($6.022 \times 10^{23}/\text{mol}$)
mL, ml Milliliter (10^{-3} L)	nA Nanoampere (10^{-9} A)
MLR Multiple linear regression	NAA Neutron activation analysis
mM Millimolar (10^{-3} M)	NAC <i>N</i> -acetylcystein
mm Millimeter (10^{-3} m)	NADW North Atlantic Deep Water
MM Magnetic monopoles	NaI(Tl) Thallium-activated sodium iodide
MMAD Mass median aerodynamic diameter	NARC Neutrino Array Radio Calibration
MMC Metallic magnetic calorimeter	NASA National Aeronautics and Space Administration, Washington, D.C.
mmol Millimole (10^{-3} mol)	NBL New Brunswick Laboratory of the US DOE
MNP Magnetic nanoparticle	NBR Natural background rejection
mol Mole (gram-molecular weight)	NBS National Bureau of Standards (now NIST)
MΩ Megaohm (10^6 Ω)	NC Neutral current (interaction)
MOX Mixed oxide fuel	NCD Neutral current detector
MP Multipurpose	nCi Nanocurie (10^{-9} Ci)
M-P Mandel and Paule mean	NCM Normal count mode
MPa Megapascal (10^6 Pa)	NCRP National Council on Radiation Protection and Measurements
MPGD Micropattern gas detector	NDA Nondestructive analysis
MPPC Multipixel photon counter	NEA Nuclear Energy Agency of the OECD
mrad Millirad (1 mrad = $10 \mu\text{Gy}$)	N_{eh} Number of electron–hole pairs
MRI Magnetic resonance imaging	NEMO Nautic Environment Marine Observatoire
mRNA Messenger RNA	NE-OBT Nonexchangeable organically bound tritium
MS Mass spectrometry	NF-LA-ICP-MS Near-field laser ablation inductively coupled plasma mass spectrometry
ms, msec Milliseconds (10^{-3} s)	ng Nanograms (10^{-9} g)
MSAP Microscale sample automation platform	NHMRC National Health and Medical Research Council, Australia
MSB Methylstyrylbenzene	NIDW North Indian Deep Water
MSC Microplate scintillation counting	NIM Nuclear instrument module
MSD Mean standard deviation	NIMH Nickel metal hydride
MSE Multisite events	NIST National Institute of Standards and Technology, Gaithersburg
MSGC Microstrip gas counter	nm Nanometer (10^{-9} m)
MSI Mass spectrometry imaging	NMI National Metrology Institute
MS/MS Tandem mass spectrometry	NMM Neutron moisture meter
mSv Millisievert	NMR Nuclear magnetic resonance
MW Megawatt (10^6 W)	NNDC National Nuclear Data Center
Mt Megaton (10^6 t)	NOI Nuclide of interest
MTO Magneto-optical trap	NORM Naturally occurring radioactive materials
μ^+, μ^- Muons	NP Nanoparticle
μ Attenuation coefficient	NPD 2-(1-Naphthyl)-5-phenyl-1,3,4-oxadiazole
μA Microampere (10^{-6} A)	NPE Nonyl phenol ethoxylate
μCi Microcurie (10^{-6} Ci) = 2.22×10^6 dpm = 3.7×10^4 dps = 37 kBq	NPL National Physical Laboratory, UK
μg Microgram (10^{-6} g)	NPO 2-(1-Naphthyl)-5-phenyloxazole
μL Microliter (10^{-6} L)	NPP Nuclear power plant
μm Micrometer (10^{-6} m)	NRC United States Nuclear Regulatory Commission
μPIC Micropixel gas chamber	ν Neutrino, photon frequency, particle velocity
μs, μsec Microseconds (10^{-6} s)	$\bar{\nu}$ Antineutrino
$\mu\text{-XANES}$ Microfocused X-ray absorption near edge structure	$0\nu\beta\beta$ Neutrinoless double-beta decay
$\mu\text{-XRF}$ Microfocused X-ray fluorescence	$2\nu\beta\beta$ Two-neutrino double-beta decay
MEK Methyl ethyl ketone	nM Nanomolar (10^{-9} M)
MW Megawatt (10^6 W)	nm Nanometer (10^{-9} m)
MWe Megawatt electrical	NMM Neutron moisture meter
m.w.e. Meter water equivalent	NMR Nuclear magnetic resonance
MWPC Multiwire proportional chamber	NNDC National Nuclear Data Center, BNL, Upton, New York
MV Megavolts (10^6 V)	NNFL National nuclear forensics library
MVC Multivariate calibration	NORM Naturally occurring radioactive material
N Newton = 1 kg m/s^2	
<i>N</i> Neutron number	

NPT Nonproliferation Treaty	pF Picofarad (10^{-12} F)
NRC Nuclear Regulatory Commission	PF Polar front
ns, nsec Nanosecond (10^{-9} s)	PFA Perfluoroalkoxy
NSTAR Neutron sandwich transmitter/activation- γ radiator	PFZ Polar frontal zone
NT200 Neutrino telescope, Lake Baikal, Siberia	pg Picogram (10^{-12} g)
NTD-Ge Neutron transmutation-doped Ge	PGA Pulse gradient analysis
N-TIMS Negative ion thermal ionization mass spectrometry	ph Photons
NTP Normal temperature and pressure	PHA Pulse height analysis
NTS Nevada test site	PHITS Particle and heavy ion transport code system
NU Natural uranium	PHOSWICH PHOSphor sandWICH (detector)
NUDAT Nuclear Database of the NNDC	π Pi constant = 3.14159
NWT Nuclear weapons test	π^+ , π^- , π^0 Pions or pi mesons
N/Z Neutron/proton ratio	PI Polyimide, pressurized injection
OC Organic carbon	PID Particle identification
OD or o.d. Outer detector, outer diameter	PIM Parallel ionization multiplier
OECD Organization for Economic Cooperation and Development	PIMS Positive-ion mass spectrometry
OES Optical emission spectrometry	PIPS, PIPSi Passivated implanted planar silicon
OFHC Oxygen-free high thermal conductivity	PIXE Proton-induced X-ray emission
OGE Optogalvanic effect	PKC Protein kinase C
OHM National Office of Measurement, Budapest	PLC Proportional long counter
OLLSC Online liquid scintillation counting	PLI Pulse length index
OM Optical module	PLS Partial least squares
OSL Optically stimulated luminescence	PLS-DA Partial least squares discriminant analysis
OTPC Optical time projection chamber	PLSR Partial least squares regression
P Parity quantum number	PM Photomultiplier, particulate matter
p Particle momentum	PMM Power-moderated weighted mean
p, p⁺ Proton	PMBP 1-Phenyl-3-methyl-4-benzoylpyrazolone-5
Pa Pascal = $1 \text{ N/m}^2 = 1 \text{ kg/m} \cdot \text{s}^2$	pMC Percent modern carbon
PAC Pulse amplitude comparison (comparator)	PMMA Polymethylmethacrylate
PADC Polyallyldiglycol carbonate	PMP 1-Phenyl-3-mesityl-2-pyrazoline
PAGE Polyacrylamide gel electrophoresis	PMT Photomultiplier tube
PAN Polyacrylonitrile	PN Pneumatic nebulizers
PANDA Particles and nondestructive analysis	PNNL Pacific Northwest National Laboratory
PAW Physics Analysis Workstation	PNX Pacific Northwest eXtraction system
PAZ Partial annealing zone	POM Polyoxymethylene
PBBO 2-(4'-Biphenyl)-6-phenylbenzoxazole	POPOP 1,4-Bis-2-(5-phenyloxazolyl)benzene
PBD 2-Phenyl-5-(4-biphenyl)-1,3,4-oxadiazole	PPAC Parallel plate avalanche chamber
PBO 2-(4-Biphenyl)-5-phenyloxazole	ppb Parts per billion
PBq Petabecquerel (10^{15} Bq)	PPC P-type point contact
PBS Phosphate buffered saline	PPD 2,5-Diphenyl-1,3,4-oxadiazole
PC Proportional counter(ing), personal computer, paper chromatogram, polycarbonate	PPE Personal protective equipment
PCA Principal component analysis	ppm Parts per million
PCB Polychlorinated biphenyl	ppmw Parts per million by weight
pCi Picocurie (10^{-12} Ci)	PPO 2,5-Diphenyloxazole
PCR Principle component regression	PS Plastic scintillator, polystyrene
PD Photodiode	ps Picosecond (10^{-12} s)
PDA Pulse decay analysis	PSA Pulse shape analysis
PDB Pee Dee Belemnite (standard)	PSD Pulse shape discrimination
PDD Pulse decay discriminator	PSf Plastic scintillator foils
PE Phosphate ester, polyethylene	psi $6.895 \times 10^3 \text{ Pa} = 68.95 \times 10^{-3} \text{ bar} = 51.715 \text{ torr}$
PEC Power and event controller	PSL Photostimulable light (or luminescence)
PENELOPE PENetration and Energy Loss of Positrons and Electrons Monte Carlo code	PSm Plastic scintillator microspheres
PERALS Photon Electron Rejecting Alpha Liquid Scintillation	PSPC Position-sensitive proportional counter
PET Positron emission tomography, polyethylene terephthalate	PSr Plastic scintillator resins
PETAC Pentaerythritol tetrakis allyl carbonate	PSUP Photomultiplier SUPport structure
PeV Petaelectron volts (10^{15} eV)	P/T Peak-to-total ratio
	PTB Physikalisch-Technische Bundesanstalt, Braunschweig
	PTBT Partial Test-Ban Treaty

PTFE Polytetrafluoroethylene	RSF Relative sensitivity factor
P-TIMS Positive ion thermal ionization mass spectrometry	RST Reverse spectral transform
PTP <i>p</i> -Terphenyl	s Seconds
PUR Pileup rejector	SAF Subantarcticfront
PUREX Plutonium URanium EXtraction	SAH <i>S</i> -adenosyl-homocysteine
PVC Polyvinyl chloride	SalSa Salt sensor array
PVD Physical vapor deposition	SAM Standard analysis method, <i>S</i> -adenosyl-methionine
PVDF Polyvinylidifluoride	SAMAD Surface area mean aerodynamic diameter
PVT Polyvinyl toluene	SAS Semiconductor α -spectrometry
PWR Pressurized water reactor	SBD Surface barrier detector
PXE Phenyl-ortho-xylylethane	SCA Single channel analyzer
<i>Q</i> <i>Q</i> value of nuclear reactions	SCC Software coincidence counting, squamous cell carcinoma
QA Quality assurance	SCI Science Citation Index
QC Quality control	SCR Sample channels ratio, solar cosmic rays
QC-CPM Quench-corrected count rate	SCX Strong cation exchange
QCD Quantum chromodynamics	SD Standard deviation
QD Quadrupole	SDCC Simplified digital charge comparison
QDC Charge-to-digital converter	SDD Silicon drift detector
QE Quantum efficiency	SDP Silicon drift photodiode
QIP Quench-indicating parameter	SDT Shared dead time
QWBA Quantitative whole-body autoradiography	SE Single escape, secondary electron
<i>R</i> Roentgen ($1R = 2.58 \times 10^{-4} \text{ C/kg}$)	sec Seconds
RAC Radon activity concentration	SEC Size exclusion chromatography
rad Radiation-absorbed dose (1 rad = 10 mGy = 100 erg/g)	SEGe Standard electrode coaxial Ge detector
RAD Radon-in-air monitor	SEM Scanning electron microscopy
RAST Radioallergosorbent test	SF Spontaneous fission
RBE Relative biological effectiveness	SFC Supercritical fluid extraction
RDC Remote detector chamber	SFD Scintillation fiber detector
RDD Radiological dispersal device ("dirty bomb")	SF-ICP-MS Sector field—inductively coupled plasma mass spectrometry
RE Recovery efficiency	SFU Stacked filter unit
REE Rare earth elements	SGD Submarine groundwater discharge
REFIT Radialelectron fluence around ion tracks	SHE Superheavy elements
REGe Reverse-electrode coaxial Ge detector	SHOTS Southern Hemisphere Oceans Tracer Studies
REL Restricted energy loss	SHRIMP Sensitive high mass resolution ion microprobe
rem Roentgen equivalent mammal (1 rem = 10 mSv)	SI International System of Units, sequential injection, spray ionization
RF Radiofrequency	SIA Sequential injection analysis
R_F Feedback resistor	SIE Spectral index of the external standard
RFQ Radiofrequency quadruple	σ Reaction cross section, thermal neutron cross section
RH Relative humidity	Si(Li) Lithium-compensated silicon
ρ Density (g cm^{-3}), neutron absorption cross section, resistivity	SIMS Secondary ionization mass spectrometry
RIA Radioimmunoassay	Si PIN Silicon p-i-n diode
RICE Radio Ice Cherenkov Experiment	SiPM Silicon photomultiplier
RICH Ring imaging Cherenkov (counters/detectors)	SIR International Reference System (Système Internationale de Référence)
RIMS Resonance ionization mass spectrometry	SI-RSC Sequential injection renewable separation column
RIS Resonant ionization	SIS Spectral index of the sample
RM Reference material	SJD Silicon junction detector
RMS Rosette multibottle samplers	SLAC Stanford Linear Accelerator Center
RMT Radiometric technique	SLIM System for Laboratory Information Management
RNA Ribonucleic acid	SLM Standard laboratory module
Ro5 Ring of Five (European radionuclide monitoring labs)	SLSD Scintillator-Lucite sandwich detector
ROI Region of interest (spectral)	SMAD Surface median aerodynamic diameter
ROSEBUD The Rare Objects Search with Bolometers Under-ground collaboration	SMDA Specific minimum detectable activity
ROV Remotely operating vehicle	S/N Signal-to-noise
RPC Resistive plate chamber	SNAP Systems Nuclear Auxiliary Power
RPH Relative pulse height	SNICS Source of Negative Ions by Cesium Sputtering
RSC Renewable separation column, relative sensitivity coefficient	
RSD Relative standard deviation	

SNF Spent nuclear fuel	TDCR Triple-to-double coincidence ratio (method)
SNM Special nuclear material	TDS Total dissolved solids
SNMS Secondary neutral mass spectrometry	TEA Triethylamine
SNO Sudbury Neutrino Observatory, Canada	TEM Transmission electron microscopy
SNR Signal-to-noise ratio	TENORM Technologically enhanced naturally occurring radioactive materials
SNS Spallation neutron source	TEPC Tissue-equivalent proportional counter
SNTS Semipalatinsk nuclear test site, Eastern Kazakhstan	TES Transition edge sensor
SOA Secondary organic aerosol	TBAB Tetrabutylammonium bromide
SOI Silicon-on-insulator	TeV Teraelectron volts (10^{12} eV)
SOP Standard operating procedure	Tf Transfer factor (radionuclide)
SPA Scintillation proximity assay	TFTR Tokamak fusion test reactor
SPC Single photon counting	TFWT Tissue-free water tritium
SPD Self-powered detector	THGEM Thick gas electron multiplier
SPE Single photon event, solid phase extraction, solid polymer electrolyte	THM Traveling heater method
SPECT Single photon emission computed tomography	tHM y⁻¹ Metric tons of heavy metal per year
SPME Solid phase microextraction	TI Transfer instrument
SQM Strange quark matter	~ Approximately
SQP(E) Spectral quench parameter of the external standard	TIMS Thermal ionization mass spectrometry
SQP(I) Spectral quench parameter of the isotope	TINCLE Track-in-cleavage (technique)
SQS Self-quenched streamer	TINT Track-in-track (technique)
SQUID Superconducting quantum interference device	TIOA Triisooctylamine
SR Superresolution, synchrotron radiation	TL Thermoluminescence
sr Steradian	TLA Trilaurylamine
SRAM Static random access memory	TLC Thin-layer chromatography (chromatogram)
SRM Standard reference material	TLD Thermoluminescence dosimeter
SRS Savannah River Site	TMA Trimethylamine
SSB Silicon surface barrier detector	TMI Three Mile Island
SSDD Segmented silicon drift detector	TMOS Tetramethoxysilane
SSE Single site events	TMS Tetramethylsilane
SSM Standard service module, selective scintillating microsphere	TNOA Tri- <i>n</i> -octylamine
SSNTD Solid-state nuclear track detector	TNSA Target normal sheath acceleration
ST Supersensitive	TNT Trinitrotoluene
STD Shared dead time concept	TOA Top of the atmosphere, trioctyl amine
STE Self-trapped excitation	TOF Time-of-flight
STF Subtropical front	TOP Time-of-propagation
STM Scanning tunneling microscope	TOPO Trioctylphosphine oxide
STNTD Solid-state nuclear track detection (detectors)	torr 133.3224 Pa
STP Standard temperature and pressure	TP <i>p</i> -Terphenyl
STS Semipalatinsk test site	TPPS Triphenylphosphine sulfide
STUK Radiation and Nuclear Safety Authority, Finland	TR Tritium sensitive
Sv Sievert (1 Sv = 1 Gy = 100 rem = 1 J/kg)	TRACOS Automatic system for nuclear track evaluations
SVOC Semivolatile organic carbon	TRE 12-O-Tetradecanoyl phorbol-13-acetate responsive element
t Ton(s)	TRI Toxic release inventory
<i>t</i>_{1/2}, <i>T</i>_{1/2} Half-life	TR-LSC Time-resolved liquid scintillation counting
<i>T</i> Particle kinetic energy	TR-PDA Time-resolved pulse decay analysis
T Tritium, tesla = 1 V s/m ²	TRPO Trialkyl phosphine oxide
TAEK Turkish Atomic Energy Authority	TSC Task sequence controller
TALSPEAK Trivalent Actinide—Lanthanide Separation by Phosphorus Extractants and Aqueous Complexants process	TSCA Toxic Substance Control Act
TAR Tissue—air ratio	TSEE Thermally stimulated exoelectron emission
TAT Targeted alpha therapy	tSIE Transformed spectral index of the external standard
TBP Tributyl phosphate	tSIS Transformed spectral index of the sample
TBq Terabecquerel (10^{12} Bq)	TSP Total suspended particle
TC Total carbon	TTA Tenoyl-tri-fluoro acetone
TCA Trichloroacetic acid	TTL Transistor—transistor logic
TCS True coincidence summing	TU Tritium unit (0.119 Bq ³ H kg ⁻¹ H ₂ O or 7.14 DPM of ³ H L ⁻¹ H ₂ O or ratio of 1 atom ³ H:10 ¹⁸ atoms of ¹ H)
TD Time discriminator	

u Atomic mass unit ($1/12$ mass of $^{12}\text{C} = 1.66054 \times 10^{-27}$ kg), up quark	WBA Whole-body autoradiography
\bar{u} Antiup quark	WBEC Weak base extraction chromatography
u Particle speed	WCVB Waste concentration vapor body
u_{nr} Nonrelativistic particle speed	WDS Wavelength dispersive spectrometer
u_r Relativistic particle speed	WDX Wavelength dispersive X-ray (analyzer)
UCN Ultracold neutrons	WHO World Health Organization
UHE Ultrahigh energy	WIMP Weakly interacting massive particle
UL Upper level	WIPP Waste Isolation Power Plant
ULB Ultralow background	WM Weighted mean
ULD Upper level discriminator	WMO World Meteorological Organization, Geneva
ULEGE Ultralow-energy Ge	WNO World Nuclear Organization, London
UNSCEAR UN Scientific Committee on the Effects of Nuclear Radiation	WOCE World Ocean Circulation Experiment
UOC Uranium ore concentrate	WOMARS Worldwide Marine Radioactivity Studies
U.S.A.E.C. US Atomic Energy Commission (now NRC)	WRA Warfare radioactive agent
U.S. DOE US Department of Energy	WSF Wavelength shifting fiber
USEPA US Environmental Protection Agency	WSOC Water-soluble organic carbon
USN Ultrasonic nebulizers	wt% Weight percent
UV Ultraviolet	XAF X-ray absorption spectroscopy
V Volts	XANES X-ray absorption near edge structure
V_0 Step voltage	XRD X-ray diffraction
VAX Digital Equipment Corporation trade name	XRF X-ray fluorescence
VCCI Variable configuration cascade impactor	XtRA Extended range
VHPLC Very-high-pressure liquid chromatography	y Years
VMEbus Versa Module Europa bus	YAG:Yb Yb-doped $\text{Y}_3\text{Al}_5\text{O}_{12}$
VSIPMT Vacuum silicon photomultiplier tube	YAP:Ce Cerium-activated yttrium aluminum perovskite (Ce:YAlO_3)
VUV Vacuum ultraviolet (spectral region)	YG Yttrium glass
VYNS Vinyl acetate and vinyl chloride copolymer	YSi(Ce) Cerium-activated yttrium silicate
W Watt ($1 \text{ W} = 1 \text{ J/s}$)	Z Atomic number
w/w Weight/weight	Z_2 Average atomic number
WAK Wiederaufarbeitungsanlage (nuclear fuel reprocessing plant), Karlsruhe	Z_{ef} or Z_{eff} Effective atomic number
	ZCH Central Analytical Laboratory, Jülich
	ZnS(Ag) Silver-activated zinc sulfide

The atomic nucleus, nuclear radiation, and the interaction of radiation with matter

Michael F. L'Annunziata

The Montague Group, Oceanside, CA, United States

Chapter outline

I. Introduction	2		
II. Discovery and characterization of the atomic nucleus and radioactivity	3		
III. Basic units and definitions	17		
A. Properties of atomic constituents	17		
B. Nuclides, isotopes, isobars, isomers, and isotones	18		
C. Mass and energy	20		
D. <i>Q</i> value	20		
IV. Naturally occurring radionuclides	22		
A. Radionuclides of cosmogenic origin	22		
B. Long-lived radionuclides	22		
C. Natural radioactive decay chains	22		
V. Artificially produced radionuclides	23		
VI. Properties of the nucleus	27		
A. Nuclear radius and density	27		
B. Nuclear forces, quarks, gluons, and mesons	28		
C. Binding energy	31		
1. Nuclear fission	33		
2. Nuclear fusion	34		
3. Nuclear fusion as an energy source	35		
D. Nuclear models	38		
1. Liquid drop model	39		
2. Shell model	41		
3. Collective model	44		
E. Superheavy nuclei	46		
F. Cluster radioactivity	49		
VII. Relativistic properties of nuclear radiation	50		
A. Relativity	50		
B. Relativistic length contraction and time dilation	51		
1. Length contraction in relativity	52		
2. Time dilation in relativity	53		
C. Relativity in cosmic-ray muon detection and measurement	54		
D. Relativistic measurements of particle lifetimes	56		
1. Bubble chamber measurements	56		
		2. Measurements in CERN muon storage ring	57
		E. Energy and mass in relativity	57
		F. Relativistic mass calculations	58
		G. Relativistic particle wavelength calculations	58
		VIII. Nuclear decay modes	60
		IX. Nuclear reactions	61
		A. Reaction types	61
		B. Notation	63
		C. Energy of reactions (<i>Q</i> value)	64
		D. Reaction cross section	65
		X. Particulate radiation	67
		A. Alpha decay	67
		1. Alpha decay energy	68
		2. Alpha decay energy and half-life relationship	70
		3. Alpha-particle interactions with matter	71
		B. Beta decay	76
		1. Negatron (β^-) emission	76
		2. Positron (β^+) emission	82
		3. Electron capture	86
		4. Branching β^- , β^+ and EC decay	90
		5. Double beta ($\beta\beta$) decay	92
		6. Parity violation in beta decay	95
		7. Beta-particle interactions with matter	100
		8. Beta particle absorption and transmission	104
		C. Internal conversion electrons	106
		D. Auger and Coster-Kronig electrons	107
		E. Neutron radiation	111
		1. Discovery of the neutron	111
		2. Neutron classification	111
		3. Neutron sources	116
		4. Interactions of neutrons with matter	126
		5. Neutron attenuation	129
		6. Neutron decay	134
		F. Proton and neutron radioactivity	134
		1. Proton radioactivity	135

2. Neutron radioactivity	139	C. Sample calculations	182
G. Neutrino interactions with matter	142	1. Nuclear recoil from alpha emissions	182
XI. Electromagnetic radiation — photons	146	2. Nuclear recoil from beta emissions	182
A. Dual nature: wave and particle	146	3. Nuclear recoil from gamma-ray photon, X-ray photon, or neutrino emissions	183
B. Gamma radiation	148	D. Radioactive recoil effects	184
C. Annihilation radiation	150	1. Szilard—Chalmers process	184
D. Line-spectra X-radiation and bremsstrahlung	151	2. Radioactive disequilibrium	186
1. X-rays characterized by discrete spectral lines	151	XIV. Cosmic radiation	186
2. Bremsstrahlung	153	A. Classification and properties	188
3. Bremsstrahlung and line spectra X-rays from beta- particle emitters	158	B. Showers of the cosmic radiation	191
E. Cherenkov radiation	159	C. Cosmic-ray muon detection and measurement	194
1. Origin and characteristics	160	D. Cosmic rays underground	194
2. Threshold condition	162	E. Origins of cosmic radiation	196
3. Threshold energies	163	F. Cosmic microwave background radiation	196
4. Applications	163	XV. Radiation dose	197

I. Introduction

Radioactivity is the emission of radiation originating as a result of the spontaneous decay of unstable atomic nuclei or from a nuclear reaction. The term radioactive decay refers to the process whereby unstable atomic nuclei decay with the loss of energy by the emission of elementary particles (*e.g.*, alpha particles, beta particles, neutrons, gamma ray photons) directly from the nucleus or the atomic electron shells (*e.g.*, Auger electrons and X-ray photons). The rate of decay or disintegration rate of a radionuclide (*i.e.*, a specific radioisotope of an element), as we shall see in this chapter, is directly proportional to the mass of the radionuclide. Thus, radioactivity analysis is essentially the quantitative analysis of radionuclides. Methods of radioactivity analysis have, for the most part, two approaches, namely, the determination of the disintegration rate of a radionuclide by counting the radiation emissions from the atoms of a radionuclide disintegrating per unit time or by measuring the mass of a radionuclide, such as is done using

mass spectrometry also referred to as atom counting. Thus, radioactivity analysis is synonymous to radionuclide analysis whereby we can calculate the mass of the radionuclide from its disintegration rate and vice versa.

The analysis of radioactivity is a challenging field. Both the sources of radioactivity (*i.e.*, radionuclides) and the media within which the radionuclides may be found can present themselves in a wide range of complexities. Also, nuclear radiation resulting from the decay of radionuclides can occur in various types, percent abundances or intensities, and energies. Furthermore, a given radionuclide may have more than one mode of decay. The presence of appreciable activities of more than one radionuclide in a sample can further complicate analysis. In addition, the different parent—daughter nuclide decay schemes, equilibria between parent and daughter radionuclides, and the rates of decay that radioactive nuclides undergo may facilitate or complicate the analysis of a given radionuclide. The problem of radioactivity analysis may be confounded

further by the wide range of chemical and/or physical media (*i.e.* sample matrices) from which the nuclear radiation may emanate.

As we will find in this book, there are many modern methods of radioactivity analysis. The types of detectors available for the measurement of radioactivity are numerous, and they may be designed in the gaseous, liquid, or solid state. They will differ not only in their physical state but also in chemistry. The instrumentation and electronic circuitry associated with radiation detectors will also vary. As a result, the detectors and their associated electronic instrumentation will perform with varying efficiencies of radiation detection depending on many factors, including the characteristics of the instrumentation, the types and energies of the radiation, as well as sample properties.

The proper selection of a particular radiation detector or method of radioactivity analysis requires a good understanding of the properties of nuclear radiation, the mechanisms of interaction of radiation with matter, half-life, decay schemes, decay abundances, and energies of decay. This chapter will cover these concepts as a prelude to the various chapters that follow on radioactivity analysis. Throughout the book reference will be made to the concepts covered in this introductory chapter. For the experienced radioanalytical chemist, this chapter may serve only as a review. However, the newcomer to this field should find this introductory chapter essential to the understanding of the concepts of radiation detection and measurement. He or she will find that the concepts covered in this introductory chapter will facilitate the selection of the most suitable radiation detector and instrumentation required for any particular case.

The properties of nuclear radiation and the mechanisms whereby nuclear radiation dissipates its energy in matter, dealt with in this chapter, form the basis for the methods of detection and measurement of radionuclides.

II. Discovery and characterization of the atomic nucleus and radioactivity

A brief history of radioactivity and the pioneers, who have contributed much to our understanding of this fascinating field of science, is presented here. The history of the science is important to our understanding of how we have arrived to where we are today in this science, and it serves as a source of motivation to future pioneers in this field. For a more detailed treatment of the history of the discoveries that led to our current knowledge of radioactivity, the structure of the nucleus, and nuclear stability and decay, the reader is invited to peruse a previous work by the author ([L'Annunziata, 2016](#)).

Radioactivity was discovered in 1896 by Henri Becquerel. At the beginning of 1896, on the very day that news

reached Paris of the discovery of X-rays, Henri Becquerel thought of carrying out research to see whether or not natural phosphorescent materials emitted similar rays. He was then Professor of the École Polytechnic in Paris where he went to work on some uranium salts that he had inherited from his father, who had previously studied phosphorescence as Professor of Applied Physics at the Polytechnic. Henri Becquerel placed samples of uranium sulfate onto photographic plates, which were enclosed in black paper or aluminum sheet to protect the plates from exposure to light. After developing the photographic plates, he discovered that the uranium salts emitted rays that could pass through the black paper and even a metal sheet or thin glass positioned between the uranium salts and the photographic plates. Becquerel reported his findings to the French Academy of Sciences in February and March of 1896 ([Becquerel, 1896a,b](#)) and summarized his discovery in 1901 in the journal *Nature* as follows:

At the commencement of the year 1896, in carrying out some experiments with the salts of uranium ..., I observed that these salts emitted an invisible radiation, which traversed metals and bodies opaque to light as well as glass and other transparent substances. This radiation impressed a photographic plate and discharged from a distance electrified bodies—properties giving two methods of studying the new rays.

At first he thought the rays were a result of phosphorescence, that is, excitation of the crystals by sunlight forcing the crystals to give off their own rays. However, Henri Becquerel carried out further tests demonstrating that the rays emanating from the uranium salts were independent of any external source of excitation including light, electricity, or heat, and the intensity of the rays did not diminish appreciably with time. “We were thus faced with a spontaneous phenomenon of a new order”, which were his words during his Nobel Lecture ([Becquerel, 1903](#)) given on December 11, 1903.

Becquerel provided evidence that all uranium salts emitted the same radiation, and that this was a property of the uranium atom particularly since uranium metal gave off much more intense radiation than the salts of that element. The new radiation produced ionization and the intensity of the radioactivity could be measured by this ionization. Not only did these rays produce ionization, but he was able to demonstrate that a large portion of these rays could be deflected by a magnetic field and were charged particles of property similar to cathode rays. It was J. J. Thomson, Cavendish Professor of Experimental Physics at Trinity College, Cambridge, who discovered in 1897 that the cathode rays were electrons ([Thomson, 1897](#)). Thus, Becquerel was the first to provide evidence that some of the radiation emitted by uranium and its salts were similar in properties to electrons. It would be years later that

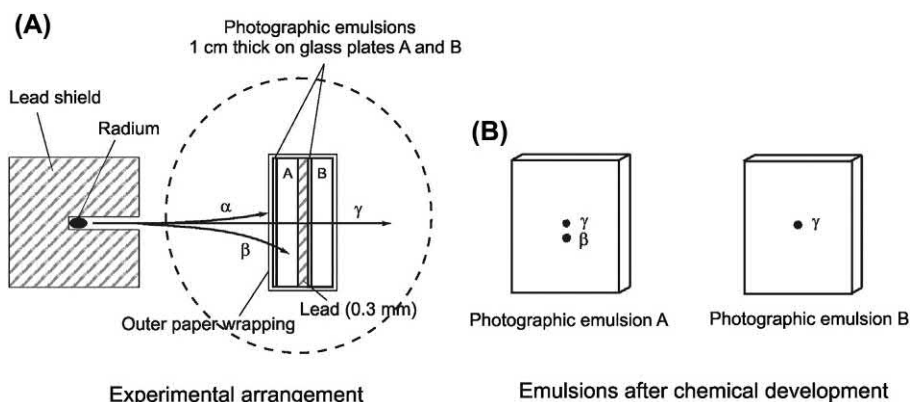

FIGURE 1.1 Paul Villard's (A) experimental arrangement and (B) experimental results that led to his discovery of gamma rays in 1900. Photographic plates A and B consisting of emulsion set on 1-cm-thick glass supports were separated from each other by a 0.3-mm-thick lead barrier and wrapped in an envelope of light-tight paper. The dashed circle represents the pole of a magnet from which the lines of force are directed into the plane of the page perpendicular to the path of radiation emitted by the radium source.

Rutherford (1903) would name the electrons originating from nuclear decay as beta particles.

Following Becquerel's discovery of spontaneous radiation from uranium, Marie Curie, who was born Maria Salomea Skłodowska in Warsaw, Poland, decided to study the mysterious rays emitted by uranium and to apply the work for a doctorate degree in the laboratory of her husband Pierre Curie, who was Professor of the Municipal School of Industrial Physics and Chemistry in Paris, France. In 1898 Marie Curie discovered that not only uranium gave off the mysterious rays discovered by Becquerel, but thorium did as well; this was independently discovered by Gerhard Schmidt in Germany the same year. Pierre and Marie Curie observed that the intensity of the spontaneous rays emitted by uranium or thorium increased as the amount of uranium or thorium increased. They concluded that these rays were a property of the atoms or uranium and thorium; thus, they decided to coin these substances as "radioactive". The emanation of such spontaneous rays from atoms would now be referred to as "radioactivity". Through tedious chemical separations and analyses, Marie and Pierre Curie worked as a team and found that another radioactive element with chemical properties similar to bismuth was present in pitchblende. She named this new element "polonium" in honor of her native country. They found yet a second new radioactive element in the pitchblende ore with chemical properties close to that of barium, and they named that new element "radium" from the Latin word *radius* meaning "ray" (Curie, 1905, 1911).

The discovery of a highly penetrating radiation that was nondeviable in an external magnetic field, which we now know to be gamma radiation, was discovered by Paul Villard at the Ecole Normal in Paris, France in 1900. Villard's discovery of gamma radiation was reported to the French Academy of Sciences (Villard, 1900a,b) and at the

Meetings of the French Society of Physics (1900c). Villard did not provide any diagrams of his experimental arrangements, which led to the discovery of gamma rays; however, the writer sketched Fig. 1.1 to facilitate the description of his experiment. Villard placed a sample of barium chloride containing radium sealed in a glass ampoule within a lead shield that contained an opening, which essentially provided a collimated beam of the radiation from the radium source as illustrated in Fig. 1.1.

To the radiation beam he exposed two photographic plates wrapped in black light-tight protective paper. Between the two plates was sandwiched a 0.3-mm-thick lead barrier. A magnetic field was applied to the collimated beam to deflect the deviable rays. Alpha particles emitted by the radium are ignored because these are absorbed by the outer protective paper wrapping. The magnetic field caused a deviation of the beta particles whereas a very penetrating radiation remained unaffected or undeivable by the magnetic field as evidence from the images produced by the radium emanations on the developed photographic emulsions. The developed photographic emulsion A, which was the first to receive the nuclear radiations from the radium, showed two spots produced by two types of radiation, one deviable (marked β) and the other undeivable (marked γ) in the magnetic field. The second photographic emulsion B, which was placed behind a 0.3-mm-thick lead barrier, yielded only one spot produced by a highly penetrating radiation unaffected by the magnetic field. The intensity of the spot on emulsion B was the same as that on emulsion A, indicating that its intensity remained unaffected to any observable extent by the lead barrier. The spot was also more clearly discernible because it was not clouded by the deviable beta particles. Villard concluded that his experimental evidence demonstrated a radiation of property similar to X-rays, but with a greater penetrating power than X-radiation. In the journal *Nature* Becquerel

(1901) acknowledged Villard's discovery of gamma rays, which had not yet been named as such, with the following statement (with the writer's comments in brackets):

... there exists two kinds of radiations, one not capable of deviation [in a magnetic field] and of which the nature is still unknown, the other capable of deviation, which later experiments have identified with the cathode rays [later identified as beta-particles] ... I might add that recently Mr. Villard has proved the existence in the radium radiation of very penetrating rays, which are not capable of deviation.

Villard did not venture to name this newly discovered highly penetrating radiation. He was a modest person possibly uninterested in fame or in the highly competitive pursuits of his fellow scientists in this new frontier.

Rutherford (1903), who is considered by many as the best experimental physicist of the 20th century, was first to name the highly penetrating radiation discovered by Villard, as gamma rays. A few years prior to Villard's discovery, Rutherford (1899) had already named two types of nuclear radiation as "alpha" and "beta", which he characterized on the basis of their relative penetrative power in matter, that is, alpha radiation would be more easily absorbed by matter than beta radiation. In harmony with this nomenclature, Rutherford assigned the term gamma rays to the yet more penetrating radiation. In the *Philosophical Magazine* Rutherford (1903) named and characterized the three types of nuclear radiation on the basis of their penetration power in matter as follows:

Radium gives out three distinct types of radiation:

1. The α rays, which are very easily absorbed by thin layers of matter, and which give rise to the greater portion of the ionization of the gas observed under the usual experimental conditions.
2. The β rays, which consist of negatively charged particles projected with high velocity, and which are similar in all respects to cathode rays produced in a vacuum tube.
3. The γ rays, which are nondeviable by a magnetic field, and which are of a very penetrating character.

These rays differ very widely in their power of penetrating matter. The following approximate numbers, which show the thickness of aluminum traversed before the intensity is reduced to one-half, illustrate this difference:

Radiation	Thickness of aluminum
α rays	.0005 cm
β rays	.05 cm
γ rays	8 cm

As noted by Rutherford in the above quotation, ionization in a gas was one of the principle properties of nuclear radiation, which helped distinguish the radiation type.

It was well understood at the time that the three rays possessed different powers of ionization in matter. The number of ion pairs formed in a gas by α , β , and γ rays of given energy per path length of travel would differ according to the relationship α rays $>$ β rays $>$ γ rays. Consequently the property of ionization power of a given radiation was used to also measure the intensity of that radiation.

In addition to the different penetrating and ionization powers of α -, β -, and γ -radiation, other properties were used to identify these mysterious radiations, such as the differing deflections that the three radiations undergo in electric or magnetic fields. Rutherford (1903) contributed much to the understanding of these properties during the early years of research on radioactivity. Alpha radiation was known to possess a positive charge because it would be deflected toward the negative electrode in an electric field potential, while beta particles were known to be negatively charged due to their deflection in the opposite direction toward the anode or positive electrode. Whereas gamma radiation would not undergo any deflection whatsoever as illustrated in Fig. 1.2. Likewise, the alpha and beta radiations, when traveling in a path perpendicular to the lines of force of a magnetic field, will be deflected in opposite directions, which is a characteristic of charged particles. Gamma radiation, which carries no electric charge, would continue along a straight undeviating path in either electric or magnetic fields.

After 3 years at the Cavendish Laboratory, University of Cambridge, Ernest Rutherford, originally from New

FIGURE 1.2 Paths of travel of collimated beams of alpha, beta, and gamma radiation in (A) electric and (B) magnetic fields. Beam collimation is provided by placing the radiation source in a hole drilled within shielded containers (e.g., lead) of which cross sections are illustrated. The electric field in (A) is illustrated by positively and negatively charged electrodes separated by a space through which the radiations pass, and the magnetic field in (B) is illustrated by the circle to depict the pole of a magnet through which the lines of force of magnetic flux (marked by the symbol x) are directed into the plane of the page (z-axis) perpendicular to the radiation paths in the xy-axis.

Zealand, moved in 1898 to McGill University in Montreal at the age of 27 to take on the position of Professor of Physics. It is at McGill University where he began to make his major discoveries in the field of nuclear physics. The first of these was the discovery that radioactive atoms emitting α -particles or β -particles disintegrate into atoms of lighter weight, in other words, atoms of an element, such as radium, that emit α -particles undergo transformations to atoms of a lighter and consequently different element. In 1907 Rutherford transferred to the University of Manchester in the UK where he and his assistant Thomas Royds (Rutherford and Royds, 1908a,b) and other coworkers demonstrated that alpha particles emanating from radium would turn into atoms of helium, and that helium gas would accumulate or be entrapped in minerals that contained radium. Thus, the alpha particle would later be determined to be equivalent to a nucleus of helium. Furthermore, Rutherford demonstrated that the lighter atom produced as a product of the decay of radium would likewise be radioactive, and in turn, decay to another even lighter atom, and so on until the final product atom was stable. It was for this work that Rutherford received the 1908 Nobel Prize in Chemistry (Rutherford, 1908). Together with another assistant Hans Geiger, who is best known for the development of the Geiger counter or Geiger–Muller tube, Rutherford (Rutherford and Geiger, 1908a,b) provided experimental evidence confirming the double positive charge on the alpha particle, thus confirming that the alpha particle was equivalent to a nucleus of helium.

Rutherford's work with numerous collaborators, including Frederick Soddy (Rutherford and Soddy, 1902), led to the conclusion that one chemical element can transform into other elements, which was previously only a centuries-old belief of alchemists, who tried to change lead into gold. Prof. Hasselberg (1908) in his speech of the 1908 Nobel Prize presentation, had foresight when he added further

[Rutherford's] disintegration theory [of atoms] and the experimental results upon which it is based, are synonymous with a new department of chemistry.

We can thus give credit to Rutherford for giving birth to the field of radiochemistry. It was, however, Frederick Soddy, who established the “displacement law” or “periodic law” of radionuclides. While at Glasgow University in 1913, he published in the journal *Nature* (Soddy, 1913a) the law in the following words:

The successive expulsion of one α and two β particles in three radioactive changes in any order brings the interatomic charge of the element back to its initial value, and the element back to its original place in the (Periodic) Table, though its atomic mass is reduced by four units.

FIGURE 1.3 Soddy's displacement or periodic law as illustrated with thorium and radium isotopes.

An example of Soddy's displacement law can be taken from a part of Fig. 1.8 of the Thorium Decay Series, which is illustrated here in Fig. 1.3.

As illustrated in Fig. 1.3, Soddy demonstrated that the emission of an α -particle would produce an element that is two atomic numbers lower, while the emission of a negative β -particle would displace an atom one atomic number higher. In the illustration above we see that the radioactive atom of thorium-232 emits an α -particle to become an atom of radium-228, which in turn decays by the emission of a β -particle to become radioactive actinium-228. The actinium atom also decays by the emission of a negative β -particle to become thorium, the same element of atomic number 90 from which it had originated, but with a mass number of four units less. The emission of an α -particle from the thorium-228 brings the atom back to the element radium with four mass units less than the atom of radium-228. The parent and product atoms of atomic number 90 are of the same element thorium, but of different mass. These two distinct atoms of thorium ($^{232}_{90}\text{Th}$ and $^{228}_{90}\text{Th}$) and radium ($^{228}_{88}\text{Ra}$ and $^{224}_{88}\text{Ra}$) illustrated above are today known as “isotopes” because Soddy (1913a,b) coined the word “isotopes” to refer to such atoms that occupy the same place (from the Greek) in the periodic table. Isotopes have the same atomic number (*i.e.*, the number of protons in the nucleus), but different mass number (*i.e.*, number of protons plus neutrons in the nucleus).

One of Ernest Rutherford's greatest discoveries came in 1919 when he reported the first evidence of a man-made nuclear reaction, that is, the splitting of the atom. This he was able to demonstrate when a high-speed alpha particle would strike the nucleus of an atom and rearrange it into two different atoms. Rutherford observed that when alpha particles would strike air, he could detect scintillation on a zinc sulfide screen produced at a distance well beyond the distance of alpha-particle range of travel, which corresponded to the range of travel of hydrogen atoms (protons). He demonstrated that the production of high-speed protons, by collision of alpha particles with air, arose from the collision of the alpha particles with only the nitrogen atoms of the air because the effect would not occur with other constituents of air such as oxygen or carbon dioxide. Furthermore, when pure nitrogen was the target, the scintillations produced by the product hydrogen nuclei

(protons) were greater than when air was bombarded with alpha particles (air contains 79% nitrogen). Rutherford was also able to show that the number of swift atoms of oxygen produced by the alpha particle collisions was about the same as the corresponding number of hydrogen nuclei (protons). This first man-made nuclear reaction is written as follows:

The historic nuclear reaction occurs when the colliding alpha particle, equivalent to a nucleus of helium (${}^4_2\text{He}$), interacts with an atom of nitrogen-14 (the most abundant isotope of nitrogen, denoted as ${}^{14}_7\text{N}$ because its nucleus contains 7 protons and 7 neutrons). In the collision, a proton (${}^1_1\text{H}$) is ejected and two protons and two neutrons from the alpha particle coalesce with the remaining nucleons of the original nitrogen to yield a nucleus having 8 protons and 9 neutrons, namely, the isotope oxygen-17 denoted above as ${}^{17}_8\text{O}$. This was the very first artificial transformation of one element into another, which was the age-old dream of alchemists.

As a result of the above man-made nuclear reaction where protons were emitted as a product, Rutherford has been given the honor of discovering the third elementary particle in matter, the proton. To put this discovery in perspective, the first elementary particle to be discovered was the electron from the work of J.J. Thomson in 1897, and the second elementary particle to be discovered was the photon from the work of Albert Einstein (Einstein, 1905a). Einstein's discovery of the photon came on the heels of Max Planck's quantum theory of radiation (Planck, 1900), which was presented by Planck on 14 December 1900 at a meeting of the Physikalische Gesellschaft in Berlin. Thus, the world came to know that radiation is emitted at discrete energies corresponding to differences in energy states of a body. Planck defined the discrete energies of emitted radiation as the product of Planck's constant, h , and the radiation frequency, ν , or

$$E = h\nu \quad (1.2)$$

Planck referred to this discrete radiation energy as "the quantum" from the Latin *quantus* meaning "how great". Thus, Planck's discovery of the energy quantum in 1900 led to Einstein's interpretation of the photoelectric effect in 1905, where he explained that light not only traveled as waves of electromagnetic radiation but also as discrete packets of energy, namely "light quanta" or photons. This opened a new door to radiation physics, referred to as quantum physics, and Eq. (1.2) is now often referred to as the Planck–Einstein relation (Woan, 2000). If electromagnetic radiation, such as X-rays, gamma rays and visible light rays, had the properties of particles, that is, the energy quanta or photons, Louis Victor de Broglie at Paris

University reasoned, in turn, that all particles in motion would have properties of a wave (de Broglie, 1923a,b,c, 1924, 1925). He reasoned that all particles of known rest mass would, in motion, have a dual nature, that of a particle and that of a wave. Thus the electron, neutron, proton, and alpha particle, etc could display this dual nature. He derived the fundamental relation for the wavelength of a particle in motion as

$$\lambda = h/p \quad (1.3)$$

where, λ is the wavelength of the particle, that is, the distance between two consecutive peaks of the particle wave, h is Planck's constant, and p is the particle momentum. This dual nature of particles (matter and wave) has been proven many times over and remains vital to applications in particle diffraction.

Another contribution, among many others made by Rutherford, deserves mention. This is the development, together with Hans Geiger, of the electronic means of detecting and counting individual alpha particle emissions from radioactive atoms. The alpha particle emissions were allowed to travel through a small opening or window into a vessel containing air or other gas exposed to an electric potential. The vessel is referred to today as an ionization chamber. Upon entering the vessel the alpha particle, which carries a double positive charge, would cause ionization of the gas, and the ions produced by the alpha particle would accelerate toward electrodes of the chamber thereby magnifying the ionization within the gas. The positive and negative ions produced by the alpha particle would be collected by their apposing electrodes and thereby produce a pulse that would cause a deflection of an electrometer needle. This instrument was the precursor of more modern Geiger counters, but it served its purpose, as Rutherford and Geiger were able to count each alpha particle emission from a radium sample and calculate its specific activity, in the words of Rutherford on his 1908 Nobel Lecture, "In this way it was shown that 3.4×10^{10} alpha-particles are expelled per second from 1 gram of radium." This was very close to the real value of 3.7×10^{10} , which is used today to define the unit of radioactivity known as the Curie (Ci), where $1 \text{ Ci} = 3.7 \times 10^{10}$ disintegrations per second.

Rutherford's best work was yet to come after his receipt of the Nobel Prize. In 1907 he moved to England to fill the position of Professor of Physics at Manchester University. It was at Manchester where Rutherford had a list of research topics to explore, and one of these was the deflection that alpha particles would undergo when passing through thin foils (approx. 5×10^{-5} cm thick) of materials such as mica, aluminum, gold, etc. He knew that the alpha particles, as they travel at high speed, would traverse the very thin foils as if the foil material was not even in the alpha particle path, and that the flux of alpha particle radiation would undergo

only a very slight dispersion upon exiting the foils. This was understandable to him as strong electrical charges, expected to occur in atoms, could cause the slight dispersion of the positively charged alpha particles.

The story goes that Rutherford was approached by one of his students at Manchester, Dr. Hans Geiger (best known as the person who developed the Geiger counter still used today for the monitoring of radioactivity). Geiger had asked Rutherford “What do you suggest we give the new student Ernest Marsden to do?” Rutherford proposed that they try to see if any alpha particles would bounce back, that is, not traverse the foil but be deflected by over 90 degrees back toward the particle direction of travel. Rutherford did not expect to see any such deflection, but it had to be investigated. They could discern the alpha particle direction of travel and count the deflections by means of a zinc sulfide screen that would produce a microscopic fluorescence (flash of light scintillation) in the dark when each individual alpha particle hit the screen. They used radium as the source of the alpha particle beam to bombard a thin foil of gold. Geiger later informed Rutherford that they could see the occasional deflection by greater than 90 degrees of one alpha particle for every 8000 particles traversing the gold foil. In a presentation given by Rutherford years later, he described his reaction to this discovery by stating

It was quite the most incredible event that ever happened to me in my life. It was as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you.

Rutherford grasped this discovery to conclude that there had to be a massive core or nucleus in the atoms of materials that would cause colliding alpha particles to bounce back. By using high-energy (7.7 MeV) alpha particles, that would travel at highest speeds available at that time, Rutherford was able to calculate the distance of closest approach and consequently the radius of the atomic nucleus to be approx. 5×10^{-15} m (Rutherford, 1906, 1913, 1919, 1920a,b).

In a Letter to the Editor of *Nature*, concerning the structure of the atom, published on December 11, 1913, Rutherford postulated correctly the atomic nucleus as the origin of α - and β -radiation. In his letter he stated the following:

There appears to me no doubt that the α particle does arise from the nucleus, and I have thought for some time that the evidence points to the conclusion that the β particle has a similar origin. This point has been discussed in some detail in a recent paper by Bohr (Philos. Mag., September 1913). The strongest evidence in support of this view is, to my mind, (1) that the β ray, like the α ray transformations, are independent of physical and chemical conditions, and (2) that the energy emitted in the form of β and γ rays by the transformation of an atom of radium C is much greater

than could be expected to be stored up in the external electronic system.

From here on Rutherford was able to begin to formulate the structure of atoms with a central massive nucleus (Rutherford, 1929, 1936). Rutherford’s findings were the initial step that provided the foundation upon which other physicists such as Niels Bohr, Werner Heisenberg, and others were able to elaborate the structure of the atom.

Following Rutherford’s alpha scattering experiment, which provided evidence for a massive central nucleus, Bohr (1913, 1914, 1921a,b, 1922) formulated the structure of the atom, known as the Bohr atom, consisting of a positively charged nucleus with electron orbitals about the nucleus, the number of which were sufficient to neutralize the positive charge on the nucleus (i.e., the number of electrons in each neutral atom equaled the number of protons in the nucleus or its atomic number). Also, the dimensions of the nucleus were very small in comparison to the size of the atom defined by the electron orbitals, and almost all of the mass of the atom was concentrated in the nucleus. By taking Rutherford’s atom, Max Planck’s quantum theory of energy, and the simplest of all atoms hydrogen, Niels Bohr was able to launch his quantum theory of atomic structure, referred to as the Bohr atom. With his quantum theory of atomic structure, Bohr was able to explain the spectra of radiation emitted by atomic electrons and the chemical properties of the elements based on electron groupings in quantum orbitals. Bohr proposed that electrons would exist in orbitals about the nucleus at discrete distances; and each orbital would represent specific quantized energies. Thus, when an atom absorbs energy, from an external form of excitation, an atomic electron would jump from one orbital to another further away from the atomic nucleus. Energy absorbed by the atom could be emitted from the atom as radiation when an electron falls from an outer to an inner orbital. Bohr explained that energy can be absorbed or emitted by an atom only as a single quantum of energy or light photon ($h\nu$) equal to the energy differences of specific orbitals. The difference between two such energy levels ($E_2 - E_1$), divided by Planck’s constant h , would define the oscillation frequency of a spectral line that can be emitted by the atom, as described by the following

$$\nu = \frac{E_2 - E_1}{h} \quad (1.4)$$

With his quantum theory of atomic structure, Bohr derived and explained fully the Rydberg formula, which was a formula devised by the Swedish physicist Janne Rydberg (1854–1919) to calculate and predict the wavelengths of light photons emitted by hydrogen and later applied to the other elements of the periodic table to include, in addition to visible light, other types of electromagnetic radiation emitted by atoms.

The use of electron orbitals about a central atomic nucleus, as depicted by Bohr (*i.e.*, the Bohr atom), was not considered or intended as an accurate depiction of the atom; however, it remains to this day a very didactic method to illustrate the atom and explain radiation emission and absorption of electron origin and the chemical properties of the elements. Because electrons have properties of both particles and waves, that is, a dual nature as described by de Broglie, Heisenberg (1926a–c, 1929) demonstrated that we cannot always assign to an electron a position in space at a given time, nor follow it in its orbit, so therefore, we cannot assume that the planetary orbits postulated by Niels Bohr actually exist. Heisenberg thus established the Uncertainty Principle (Heisenberg, 1927), which states that it is not possible to accurately measure both the atomic particle (*e.g.*, electron) velocity or momentum and its location. Heisenberg's derivation from quantum mechanics showed that it is not possible to determine, in any given instant in time, both the velocity and the position of an atomic particle. It was demonstrated that the more accurately one tries to determine the velocity of the particle, the more uncertain becomes the determination of its position, and vice versa. Bohr (1928) presented his complementarity argument that the clearest analysis that can be derived from quantum mechanics must include both the corpuscular and wave nature of atomic particles, that is, both the particulate and wave nature of the electron are needed to complement each other in providing a complete description of the atomic particle.

Schrödinger (1926a–e) took the dual nature of the electron to describe the electron and its properties with wave equations. Schrödinger's wave mechanics provided scientists with a visual picture of the space coordinates occupied by the electron, which Heisenberg's mathematical matrix equations could not provide. Thus, we may also picture atomic electrons as possessing energy levels, rather than occupying definite orbits. Schrödinger had interpreted his wave function Ψ as the electron's matter–wave density distribution, that is, he wanted to dispense with the particulate properties of the electron and consider them to possess a continuous density distribution $|\Psi|^2$ meaning that the electron as a wave could have a high density in some regions of space and lower density in other regions. Max Born, however, interpreted the wave function Ψ as providing a picture of the electron with its coordinates in space, and $|\Psi|^2$ as the probability density of the electron (Born, 1926a,b,c,d; Born et al., 1926; Born and Oppenheimer, 1927; Born and Fock, 1928). Born's probability density interpretation is widely accepted today as that which gives the probability of finding the electron particle at particular coordinates in space.

At the time that Heisenberg, Schrödinger, and Born were studying the atomic electron, the Austrian physicist Wolfgang Pauli postulated the Exclusion Principle for which he received the 1945 Nobel Prize in Physics, as this

proved to be a vital contribution to nuclear and atomic physics. The Exclusion Principle (Pauli, 1924, 1925, 1946) stated that no two electrons in an atom could exist in the same quantum or energy state. Pauli's Exclusion Principle enabled the assignment of electrons to different quantum levels K, L, M, N , etc., and our subsequent understanding of X-ray spectra that often follows nuclear decay. The Pauli Exclusion Principle also proved to be a vital tool decades later to explain the structure of protons and neutrons in the nucleus, particularly what is referred to as the shell structure of the nucleus, and the stability of particular nuclei to decay. Like the electrons, which are assigned to various quantum levels or orbitals on the basis of Pauli's Exclusion Principle, no two nucleons may possess the same quantum or energy state and are assigned to specific shells. Certain filled shells of protons and neutrons in the nucleus were found by Maria Goeppert-Mayer at the Argonne National Laboratory and J. Hans D. Jensen at the University of Heidelberg (Goeppert-Mayer and Jensen, 1955a,b) to be unusually stable. Maria Goeppert-Mayer and J. Hans D. Jensen were awarded the 1963 Nobel Prize for Physics for their work on nuclear structure, which they shared with Eugene Wigner for his work on the mechanics of proton–neutron interaction.

One of the greatest conundrums of modern physics was beta decay. It was understood that the kinetic energy of a particle emitted by a decaying nucleus was a manifest of the decay energy of that nucleus. However, it was observed that beta particles are emitted from decaying nuclei with a broad spectrum of energies over a range between zero and a maximum energy or E_{\max} . In other words, it was observed that most of the beta particles emitted possessed an energy less than the nuclear decay energy. Only a very small number of the beta particles of the maximum energy of the beta-particle energy spectrum would correspond closely to the nuclear decay energy. In desperation for an answer, some physicists proposed that possibly the laws of conservation of energy did not apply in this particular case. However, Wolfgang Pauli could not agree to any exceptions to the laws of energy conservation, and he took a bold step. He proposed, that during beta decay, there should exist another particle of zero charge and very small rest mass that would be created at the time of beta decay, and this particle would share the decay energy with the beta particle. While he was Professor of Theoretical Physics at the Swiss Federal Institute of Technology in Zurich (Eidgenössische Technische Hochschule or ETH, Zurich) Pauli sent an Open Letter dated 4 December 1930 to the Radioactivity Group at their Regional Meeting at Tübingen, Germany. In this letter Pauli wrote

Dear Radioactive Ladies and Gentleman,

I beg you to most favorably listen to the carrier of this letter. He will tell you ... of the continuous beta spectrum, I

have hit upon a desperate remedy to save ... the law of conservation of energy. There is the possibility that electrically neutral particles exist ... in nuclei, which have a spin $\frac{1}{2}$ and obey the exclusion principle, and which differ from the photons also in that they do not move with the velocity of light. The continuous beta spectrum would then be understandable if one assumes that during beta decay with each electron a [neutrino]¹ is emitted in such a way that the sum of the energies of the [neutrino]¹ and electron (i.e., beta-particle) is constant.

I admit that my remedy may seem incredible ... But only he who dares can win and the difficult situation caused by the continuous beta spectrum ... Henceforth every possible solution must be discussed. So, dear radioactive people, because I am indispensable here due to a ball which will take place in Zurich during the night from December 6 to 7. With my best regards to you...

Your humble servant,

W. Pauli

The writer believes that Wolfgang Pauli used the ball in Zurich as an excuse not to attend the scientific conference because he wanted his letter to be read to the participants of the conference, and it is very understandable that he would not want to listen to any ridiculous arguments against his theory, particularly any that would suggest an exception to the law of conservation of energy.

Wolfgang Pauli's prediction in 1930 of the neutrino as a particle, that would be produced in beta decay and share the decay energy with the beta particle, was only the beginning of the elucidation of a more complex scheme for beta decay. Two years earlier Paul A.M. Dirac, as a Fellow at St. John's College in Cambridge and a researcher at the Cavendish Laboratory, published the quantum theory of the electron (Dirac, 1928a,b, 1933). A result of Dirac's quantum theory of the electron was the prediction of the electron spin and the occurrence of a new electron, one of positive charge, known as the positron, the antiparticle of the negatron or negative electron. Dirac also predicted the phenomenon of annihilation, when a particle and its antiparticle (e.g., negatron and positron) come into contact and are annihilated by the conversion of their electron masses into electromagnetic radiation. He also predicted pair production, which would be the converse of annihilation, that

is, the creation of a positron and negatron pair from electromagnetic radiation. In his Nobel Lecture Dirac explained

From our theoretical picture, we should expect an ordinary electron, with positive energy, to be able to drop into a hole and fill up this hole, the energy being liberated in the form of electromagnetic radiation. This would mean a process in which an electron and a positron annihilate one another. The converse process, namely the creation of an electron and a positron from electromagnetic radiation, should also be able to take place. Such processes appear to have been found experimentally, and are at present being more closely investigated by experimenters.

The existence of the positron was experimentally discovered in 1932 by Carl D. Anderson while carrying out research on cosmic rays for which he was awarded the Nobel Prize in Physics 1936 (Anderson, 1932, 1933a,b). Anderson also demonstrated together with his graduate student, Seth Neddermeyer, that gamma rays from "ThC" (i.e., ^{212}Bi) would generate positrons, by pair production, after passing through substances such as lead (Anderson and Neddermeyer, 1933). Pair production, as predicted by Dirac, is the creation of an electron and positron pair by the conversion of the energy of electromagnetic gamma radiation into the masses of two electrons of opposite charge. A cloud chamber photograph of positron–negatron pair production is illustrated in Fig. 1.4.

If negative and positive electrons (i.e., beta particles) were known to exist and these were products of beta decay, the mystery remained how beta particles, which are

FIGURE 1.4 Photograph of cloud chamber tracks of positrons (curved tracks on the right) and negatrons (curved tracks on the left) originating from a common point of origin where gamma-ray photons of cosmic origin were absorbed by a lead barrier. The magnetic field was applied in the direction of the page of this book. The photograph was presented as a stereoscopic pair, and the direct image is at the left. A drawing to the right illustrates pair-production, that is, the production of a negatron–positron pair from the energy of a gamma ray photon in the region of the nucleus of an absorber material such as lead. The curved tracks illustrate the bending of the direction of travel of the negatron–positron pair as a result of the magnetic field. From Anderson and Neddermeyer (1936). 1. The actual naming of the particle as the neutrino, while not included in Pauli's letter, is included here for clarification with the reader as to the real particle referred to by Pauli. Enrico Fermi later coined the name of this neutral particle of near-zero rest mass as the "neutrino" from the Italian meaning "little neutral one". Due to the particle's neutral charge and near-zero rest mass, it was very difficult to detect the neutrinos, so difficult, that it was not until over 25 years later (June 1956) did technology permit Frederick Reines and Clyde Cowan, Jr. to finally achieve the detection of the neutrino.

equivalent to electrons, could originate and be expelled from an atomic nucleus. The beta decay process of radioisotopes, often referred to as “Fermi Beta Decay”, was elaborated in 1934 by Enrico Fermi (1934a,b) only 2 years following the discovery of the neutron by Chadwick (1932a,b). Fermi proposed, that within the nucleus of a radioactive atom, the neutron may decay to a proton or vice versa, a proton into a neutron. He proposed the existence of a Weak Interaction as a new force, within the nucleus, that permits a neutron to decay into a proton and a negatively charged electron (*i.e.*, negatron) and antineutrino ($n \rightarrow p^+ + e^- + \bar{\nu}$) or vice versa, a proton could decay into a neutron and a positively charged electron (*i.e.*, positron) and neutrino ($p^+ \rightarrow n + e^+ + \nu$). The Weak Interaction would allow a nucleon (proton or neutron) to transform itself into the other to achieve nuclear stability. This force would be weaker than the Strong Nuclear Force or Strong Interaction that binds the nucleons together in the nucleus. The weak interaction proposed by Fermi advanced into a Unified Electroweak Theory for which the Nobel Prize in Physics 1979 was awarded to Sheldon L. Glashow, Abdus Salam, and Steven Weinberg “for their contributions to the theory of unified weak and electromagnetic interaction between elementary particles ...”, as it has subsequently been discovered that the weak interactions and electromagnetic interactions are of similar strengths at short distances typical of nucleons (10^{-18} m). These two forces can thus be combined into what is called the Electroweak Force.

Fermi’s original manuscript on the transformations of nucleons within the nucleus was rejected by the editors of the journal *Nature* because of its theoretical nature, and therefore his first reports on the beta decay theory were published in the Italian and German languages (Fermi, 1934a,b). Evidence for these transformations was provided years later by Snell and Miller (1948), who demonstrated that the neutron when outside the protective confines of a nucleus would decay to a proton and an electron with a lifetime of ~ 15 minutes according to the scheme

Although Fermi is well remembered for his beta decay theory, the Nobel Prize was awarded him in 1938 for his contribution to the application of neutron radiation to the production of many new radioactive isotopes and to his discovery that certain nuclear reactions are brought about by slow neutrons. In his Nobel Lecture (December 12, 1938) Fermi acknowledged that Rutherford was the first to start the technique of nuclear bombardments using high-energy alpha particles to enable the transmutation of one element into another in 1919. Fermi further noted that immediately after the discoveries of the artificial production of radioactive elements (radioisotopes) by the Joliot-Curies in 1934 via alpha particle–induced nuclear reactions

(Joliot-Curie and Joliot (1934a–c)), he thought that alpha particles might not be the only type of bombarding projectiles that could produce artificial radioactivity, particularly for atoms with atomic number greater than 20, and began then to investigate the effects of bombarding various elements with neutrons.

Fermi observed that neutrons having no electric charge should be able to reach the nuclei of all atoms without having to overcome the Coulombic barrier of the target nucleus. He knew that the neutron would not be hindered by the atomic electrons or the positive charge of the atomic nucleus, and that the probability of nuclear collisions by neutrons would be higher than that achievable with charged projectiles such as alpha particles or protons. The initial results obtained by Fermi in early 1934 (Fermi, 1934c,d; Fermi et al., 1934) and his coworkers during 1934–40 including H. Anderson, E. Amaldi, O. D’Agostino, F. Rasetti, E. Segré, and L. Szilard (Amaldi and Fermi, 1935, 1936a,b; Amaldi et al., 1935; Anderson et al., 1939a,b; Fermi and Amaldi, 1936; Fermi, 1940a,b; Fermi et al., 1934, 1938) yielded 63 artificial radioisotopes.

Only about 6 months after their first experiment with neutron bombardment Fermi made a great discovery. He found that the neutron irradiation of elements became more effective in producing new radioisotopes when the neutrons were made to slow down, by allowing the neutron beam to pass through a given barrier of water or paraffin. By so doing, the fast neutrons are slowed down to become thermal neutrons or in other words, neutrons corresponding to thermal agitation. In his Nobel Lecture, Fermi explained the properties of thermal neutrons

After their energy is reduced to a value corresponding to thermal agitation, the neutrons go on diffusing without further change of their average energy. All of the processes of capture of slow neutrons by any nucleus are generally accompanied by the emission of gamma rays: Immediately after the capture of the neutron, the nucleus remains in a state of high excitation and emits one or more gamma-quanta, before reaching the ground state.

The idea of slowing down neutrons to improve the efficiency of neutron capture was contrary to what one would believe at that time, because previously only charged particles were used to bombard atomic nuclei and the higher the speed of the charged particle, the greater the probability of penetrating the Coulombic barrier of the target atom. Because neutrons, due to their neutral charge, have no difficulty diffusing into close proximity of atomic nuclei, Fermi and his coworkers were able to produce more than 400 new radioisotopes using slow neutron bombardment of all known elements with the exception of hydrogen and helium.

The work of Enrico Fermi on neutron reactions up to 1938 was the final precursor needed for the discovery of nuclear fission by Otto Hahn and Fritz Strassmann in 1939 with the collaboration and interpretation by Lise Meitner (Hahn and Strassman, 1939a,b; Meitner and Frisch, 1939; Meitner et al., 1938). Fermi's next great achievement would be the construction of the first nuclear reactor.

Enrico Fermi collaborated with Leo Szilard and a team of scientists in the construction of the first nuclear reactor. Leo Szilard was a renowned theoretical physicist and life-long friend of Albert Einstein. Fermi's great knowledge of neutron physics and Szilard's determination to beat Germany to the production of a nuclear fission chain reaction was an excellent combination for the successful working reactor. In the words of Richard Rhodes (1999).

In 1939, still official enemy aliens, Fermi and Szilard co-invented the nuclear reactor at Columbia University, sketching out a three-dimensional lattice of uranium slugs dropped into holes in black, greasy blocks of graphite moderator, with sliding neutron-absorbing cadmium control rods to regulate the chain reaction.

As soon as it became known that neutron-induced fission of Uranium-235 would yield more than one neutron per fission Fermi, Szilard and others knew that a fission chain reaction would be possible, which would release large amounts of energy. Walter Zinn and Leo Szilard (1939) determined that 2.4 neutrons were emitted on the average for neutron-induced ^{235}U fission, and it was understood that each fission reaction would yield a high amount of energy, ~ 200 MeV. The reactor, that was built under the direction of Enrico Fermi, was given the name of an "atomic pile", coined by Fermi because the unique apparatus had the appearance of a pile of uranium fuel, graphite moderator, and cadmium control elements. Fermi knew from his previous work with neutrons that cadmium has a very high efficiency for absorbing slow (thermal) neutrons and should serve to control the chain reaction, and that fission in ^{235}U is optimal at thermal incident neutron energies. They assembled the pile in such a way that neutrons would be produced with the correct energy needed to create fission in the uranium whereby the splitting of uranium nuclei would create additional neutrons and keep the chain reaction going to produce energy with the application of cadmium rods to control the reaction. The reactor "pile" was assembled by Fermi and his team on a squash court under the stands of the University of Chicago's Stagg (football) Field in late 1942. On December 2, 1942, under the direction of Enrico Fermi, the reactor went critical, that is, the chain reaction was sustained with the production of a neutron for every neutron absorbed by the uranium nucleus. Fermi allowed the reactor to continue as a carefully controlled chain reaction for 4.5 minutes at one-half Watt of power. A plaque, at the site of the first "atomic pile",

commemorates this historic event with the words "On December 2, 1942, man achieved here the first self-sustaining chain reaction and thereby initiated the controlled release of nuclear energy."

On December 19, 1944 Enrico Fermi and Leo Szilard jointly filed for a highly classified patent as coinventors of the atomic pile, describing how the self-sustained nuclear chain reaction had been achieved. The patent (US Patent No. 2,708,656 entitled "Neutronic Reactor") was not issued until May 18, 1955. Detailed illustrations of the nuclear reactor patented by Fermi and Szilard are provided in a book by the writer (L'Annunziata, 2016) The invention of the nuclear reactor for the peaceful application of nuclear energy capable of providing electric power to cities was declared by some to be one of the most significant inventions of all time comparable to those of communication, the telegraph and telephone, by Samuel Morse and Alexander Graham Bell.

The first nuclear reactor was a giant step for mankind, as it has had since Fermi's "atomic pile" and continues to have a vital role in development with peaceful applications including (1) the production of isotopes for medical, biological, and other vital sciences, (2) the production of heat that can drive steam turbines and generate enormous amounts of electricity, and (3) the production of neutrons for research. A fourth ominous application of the nuclear reactor is, of course, for the production of plutonium for nuclear weapons.

The peaceful applications of nuclear power have an enormous impact on our daily lives. This is underscored in an article by Yukiya Amano (2013), IAEA Director General, where he noted

Many countries with existing nuclear power programmes plan to expand them. Many new countries, both developed and developing, plan to introduce nuclear power.

The factors contributing to this growing interest include increasing global demand for energy, as well as concerns about climate change, volatile fossil fuel prices, and security of energy supply. It will be difficult for the world to achieve the twin goals of ensuring sustainable energy supplies and curbing greenhouse gases without nuclear power.

As noted by Yukiya Amano, the number of nuclear power plants worldwide is expanding. The number of operating nuclear power reactors worldwide has increased to 448 in 2016, and by the end of 2016, there were 61 new power reactors under construction (IAEA, 2016).

About the same time that Enrico Fermi was producing radionuclides by nuclear reactions with neutrons, Ernest O. Lawrence at the University of California, Berkeley, invented the cyclotron, which could accelerate charged particles to high energies capable of penetrating the

coulombic barrier of atoms resulting in nuclear reactions that produced numerous radionuclides. Lawrence visualized an accelerator, not consisting of a large number of accelerating electrodes in a straight line, but one that had only two electrodes, which would be used over and over again by sending the positive ions back and forth through the electrodes in a circular fashion in a magnetic field. He concluded that two hollow electrodes would be needed with a relatively low voltage (e.g., 4000 V) and oscillating positive and negative potential so that each instant the accelerating ions exit one electrode and enter the other, the charges on the electrodes would change in accord with the proper frequency providing a “push” to the ions as they exit an electrode and thereby increase their energy and velocity.

The experimental work on the development of the cyclotron began in 1930 and, in the Spring of that year, Lawrence’s first graduate student at Berkeley, Nels Edlefsen, constructed a crude model, which gave evidence of working. In September of 1930 they gave a preliminary report before a meeting of the National Academy of Sciences (Lawrence and Edlefsen, 1930). In the fall of the same year another graduate student, M. Stanley Livingston, improved on the model, which was only 4.5 inches (11.43 cm) in diameter. The diameter of the accelerator refers to the size of the chamber in which the ions move in a circular path of increasing radius. The first working cyclotron produced 0.08 MeV protons with less than 1000 V applied to the semi-circular accelerating electrode.

This was reported before the American Physical Society (Lawrence and Livingston, 1931a) as a demonstration of the cyclotron as a practical apparatus for the acceleration of ions. The same year Lawrence and Livingston (1931b) reported the acceleration of protons to 0.5 MeV with only 5000 V potential applied to the electrodes.

Lawrence and Livingston (1932) described the basic design and principle of the cyclotron, with a simple diagram such as that illustrated in Fig. 1.5. The cyclotron utilizes the principle of repeated acceleration of ions by means of resonance with an oscillating field. The ions circulate from the interior of one electrode to the interior of another back and forth with increasing speed in a circular fashion. The hollow electrodes *A* and *B* of Fig. 1.5 are placed between the poles of a magnet, and the magnetic field normal to the plane of the hollow plates causes the ions to deflect in a circular fashion with a radius of curvature dependent on the mass, charge and velocity of the ions.

The oscillating electric field between the electrodes is vital to the operation of the cyclotron. For example, as Lawrence and Livingston (1932) explained, if at one instant there is an ion in the region between the electrodes, and if electrode *A* is negative with respect to electrode *B*, the ion will be “pushed” and accelerated to the interior of electrode (*A*). Within the hollow electrode the ion will travel along a circular path under the effect of the magnetic field. After completing a semi-circular path in electrode *A*, as illustrated by the arc *a ... b* in Fig. 1.5, the ion emerges again between

FIGURE 1.5 Diagrams illustrating the cyclotron method of multiple acceleration of ions. On the left is a drawing of the top or bottom of the cyclotron electrodes and on the right is a drawing of a view from the side with the electrodes between the poles of a magnet. Two electrodes *A* and *B* in the form of semi-circular hollow plates (called Dees because they have the shape of the letter D) are mounted in a vacuum chamber with their diametral edges adjacent. The electrodes of the early cyclotron of Lawrence and Livingston measured only 24 cm in diameter, and their hollow semi-circular chambers, through which the ions traveled, had a width of only 1 cm. The system is placed between the poles of a magnet whereby the magnetic field *H* is introduced normal to the plane of the plates. High frequency electric oscillations are applied to the plates so that there results an oscillating electric field in the diametral region between them. A filament placed above the diametral region creates a stream of electrons that produce the needed positive ions, which are pulled out sideways by the oscillating electric field. The electrons are not drawn out into the cyclotron electrodes because of their very small radii of curvature in the magnetic field. The positive ions (e.g., protons, deuterons, or helium nuclei) are accelerated by the oscillating electric field and travel with increasing speed and energy in a circular fashion of increasing radius in the magnetic field. The beam of positive ions emerges from the cyclotron to collide with specific targets creating new elements, stable isotopes, and radioisotopes, etc. Adapted from Lawrence and Livingston (1932).

the electrodes. If the time consumed in the travel of this semi-circular path (e.g., from point *a* to point *b* of Fig. 1.5) is equal to the half-period of the electric oscillations, the electric field will have reversed and the ion will receive a second “push” and be accelerated into the interior of electrode *B* with higher velocity. The ion continues to travel in a circular path in electrode *B* and completes another semi-circular path with greater velocity and greater radius of curvature. Upon completion of the semi-circular path in electrode *B* at point *c*, the ion again emerges between the electrodes, and the ion is again accelerated by the oscillating electric field to travel at a greater speed into the interior of the opposing electrode with a path of greater radius of curvature. The process of acceleration repeats itself over and over until the ion achieves a radius of curvature whereby it emerges from the cyclotron.

A vital characteristic of the cyclotron principle is that the time of travel of an ion to complete a semi-circular path is independent of the ion's velocity and thus independent of the radius of the ion path. This was demonstrated and explained by Lawrence and Livingston (1932) following their demonstration of an 11-inch (28-cm) diameter cyclotron:

... the radius of the path is proportional to the velocity, so that the time required for the travel of a semi-circular path is independent of the ion's velocity. Therefore, if the ion travels its first half-circle in a half-cycle of the oscillations, it will do likewise on all succeeding paths. Hence it will circulate around on ever widening semi-circles from the interior of one electrode to the interior of the other, gaining an increment of energy on each crossing of the diametral region that corresponds to the momentary potential difference between the electrodes. Thus, if, as was done in the present experiments, high frequency oscillations having peak values of 4000 volts are applied to the electrodes, and protons are caused to spiral around in this way 150 times, they will receive 300 increments of energy, acquiring thereby a speed corresponding to 1,200,000 volts.

The 1.2 million-volt hydrogen ions produced by Lawrence and Livingston in their early 11-inch (28-cm) diameter accelerator were of sufficient energy to disintegrate the light lithium nucleus; but much higher energies would be needed to penetrate larger atomic coulombic barriers and disintegrate the heavier elements. Larger diameter cyclotrons would require larger magnets, because the spiraling path taken by the ions in the cyclotron are produced by a uniform magnetic field normal to their plane of travel. Thus the pole faces of the magnets had to be at least as large as the diameter of the cyclotron vacuum chamber.

With a larger magnet at hand, Lawrence then proceeded to build a 27-inch (69 cm) diameter cyclotron with the electrodes (“dees”) measuring 20 inches (51 cm) having a width of 1.12 inches (2.8 cm). With the new and larger

cyclotron, Lawrence and Livingston (1934) were able to accelerate protons (${}^1\text{H}$) to 5 MeV energy. With yet further modification by essentially increasing the size of the electrodes (i.e., dees) to a diameter of 24.5 inches (62 cm) and width of 1.75 inches (4.4 cm) Lawrence and Cooksey (1936) produced deuterons (heavy hydrogen, ${}^2\text{H}$) ions and helium ions (${}^4\text{He}$) of 5- and 10-MeV energy, respectively. The helium ions would be accelerated to twice the energy of the deuterons, explained by Lawrence and Cooksey (1936) as follows:

... The helium ions having twice the charge and mass relative to deuterons, receive twice the increments in energy each time they pass between the dees and arrive at the periphery with twice as much energy. Thus, apart from difficulties of producing doubly charged helium ions at the center, the cyclotron produces 10 MeV alpha particles as readily as 5 MeV deuterons.

The most significant outcome of the new and improved cyclotron demonstrated by Lawrence and Cooksey (1936) was the production of neutrons and artificial radioactive isotopes. Neutron fluxes higher than ever achieved were reported. For example, the neutron flux by the deuteron bombardment of various elements including beryllium was 10^5 times greater than that produced by a mixture of 1 Ci of radon and beryllium. Lawrence began to produce many new radioisotopes as noted by Lawrence and Cooksey (1936).

With 5 MeV deuterons, it has been found possible (Lawrence, 1935) to produce radioactive isotopes of many of the elements throughout the periodic table. In many cases, the yields of the radioactive substances are quite large; as for example, a day's bombardment of sodium metal with 20 microamperes of 5 MeV deuterons produces more than 200 milligrams—equivalent of radio sodium.

By 1939, the year Lawrence received the Nobel Prize, he and coworkers (Lawrence et al., 1939) at the Berkeley lab completed the construction of a larger 60-inch (1.5 m) cyclotron that produced 16 MeV deuterons. It had a magnet weighing 200 tons. In his Nobel Lecture at Stockholm, Lawrence (1951) commented about the larger cyclotron

... the cyclotron for the first time began to look like a well-engineered machine. It was with this machine that the discoveries of the transuranium elements were made, which have been rewarded this year by the award of the Nobel Prize in Chemistry [1951] to Edwin M. McMillan and Glenn T. Seaborg.

Using the 60-inch cyclotron at the University of California, Berkeley, Edwin McMillan and Philip Abelson (McMillan and Abelson, 1940) created neptunium (Np) a new element of atomic number 93. McMillan moved to the Massachusetts Institute of Technology, and Glenn T.

Seaborg continued research on the creation of new radioactive elements with the 60-inch cyclotron. By bombarding U-238 with 16-MeV deuterons from the 60-inch cyclotron, Seaborg and coworkers (Seaborg et al., 1946a,b) discovered element 94 (*i.e.*, atomic number 94). The new element was named plutonium after the planet Pluto, because McMillan had suggested the name neptunium after the planet Neptune, the planet immediately beyond Uranus. Thus, Seaborg noted that it would be proper to name the new element plutonium (Pu) after what was then considered the next planet Pluto. In the summer of 1944, Seaborg and coworkers bombarded ^{239}Pu with 32 MeV helium ions (equivalent to alpha particles) in the Berkeley 60-inch cyclotron and created the new radioactive element 96, named curium, according to the reaction $^{239}\text{Pu}(\alpha, n)^{242}\text{Cm}$, which is an abbreviation for the nuclear reaction that reads “target nucleus(projectile, particle emitted)product nucleus”. A few months later they identified a new element 95, named americium, created by the bombardment of ^{239}Pu with neutrons produced in a nuclear reactor. The resulting ^{241}Pu would decay by negative beta emission to yield ^{241}Am . By December of 1949 they were able to identify new elements 97 and 98 created by bombarding americium and curium with 37 MeV helium ions in the 60-inch cyclotron according to the reactions $^{241}\text{Am}(\alpha, 2n)^{243}\text{Bk}$ and $^{242}\text{Cm}(\alpha, 2n)^{244}\text{Cf}$, respectively. The new elements berkelium (Bk) and californium (Cf) were named after the city and the university and state, respectively, where the discovery was made. This work laid the foundation for Seaborg’s formulation of the “actinide” transition series of elements in the Periodic Table, which begins with the radioactive element actinium with a tripositive oxidation state. Included in the series are elements 99 to 103, namely, einsteinium, fermium, mendelevium, nobelium, and lawrencium. In recognition of this work, element 106 among the transuranium elements, was named “seaborgium” in 1997, which was the first time an element was named after a living person, less than 2 years before the passing of Glenn T. Seaborg. For a detailed description of this work, see Seaborg’s Nobel Lecture (Seaborg, 1951) and a more recent paper published by him 4 years before his passing (Seaborg, 1995).

The cyclotron remains to this day an invaluable instrument for the production of radionuclides. Many short-lived nuclides are needed for the diagnosis and treatment of various types of cancer. Particularly the radionuclides used by medical physicians for positron emission tomography (PET) are short-lived, and only with the cyclotron is it possible to produce these radionuclides on-site at hospitals where patients can be diagnosed and treated. There are currently more than 350 cyclotrons in 39 countries of the world (Cantone and Hoeschen, 2011; IAEA, 2006, 2007), many of these are in hospitals, which produce short-lived radionuclides for medical use.

During the late 1950s, when the author of this chapter started to study chemistry, it was taught in all of the schools and widely accepted that the proton and neutron were elementary particles, that is, it was generally thought that the proton and neutron could not be broken down into smaller subatomic particles. However, by bombarding nucleons with high-energy electrons with an electron accelerator at the Stanford Linear Accelerator Center (SLAC), Robert Hofstadter and coworkers (Hofstadter et al., 1953a,b; Hofstadter and McAllister, 1955; McAllister and Hofstadter, 1956; Chambers and Hofstadter, 1956; Yearian and Hofstadter, 1958a,b) determined that internal magnetic and charge forces of an individual proton or neutron would scatter the high-energy electrons of varying energies in different directions. From these experiments they could conclude that the proton and neutron are not elementary particles, but that they contain an inner structure that exhibit strong electric and magnetic forces. In his Nobel Lecture Hofstadter (1961) stated the following:

In concluding this discussion it may be appropriate to return to the theme introduced earlier in the paper and raise the question once again of the deeper, and possibly philosophical, meaning of the term “elementary” particle. As we have seen, the proton and neutron, which were once thought to be elementary particles are now seen to be highly complex bodies. It is almost certain that physicists will subsequently investigate the constituent parts of the proton and neutron ...

Then in 1964 George Zweig, as a visiting theoretical physicist at CERN, wrote a lengthy treatise that contained a model for the internal structure of the nucleons to explain the strong interaction and its breaking (Zweig, 1964). His model depicted the proton and neutron to consist of three subatomic particles, which we now call quarks. He had called them aces. Zweig also proposed that the three quarks were held together within the proton or neutron by a force, which we now know to be mediated by gluons. He further proposed the yet unthinkable, that these subatomic particles (*i.e.*, quarks) possess a fractional charge. At the time, it was a general belief that the smallest charge a particle could possess was unitary (+1 or −1). Zweig predicted the proton to consist of two up (u) quarks of charge +2/3 and a down (d) quark of charge −1/3 attributing the overall charge of +1 to the proton. In turn, the neutron would consist of two down (d) quarks and one up (u) quark giving the neutron its overall neutral charge. The same year in a very short paper, Gell-Mann (1964) also proposed the possibility that nucleons might be made up of three quarks similar to the model described by George Zweig.

The model presented by Zweig and Gell-Mann described above remained unconfirmed until the work of Jerome I. Friedman, Henry W. Kendall, Richard E. Taylor and their collaborators at MIT and SLAC, which yielded

data demonstrating deep inelastic scattering of electrons on protons and bound neutrons obtained with a two-mile (3.2 km) electron accelerator buried underground at SLAC on the campus of Stanford University. Their deep inelastic scattering experiments with electrons demonstrated the presence of dense matter within the proton and neutron, which caused the scattering. More accurate measurements could be correlated to the fractional charges of the quark composition of the proton (with its two up quarks and one down quark, uud) and neutron (with its one up quark and two down quarks, udd). In addition, the electron deflections corresponded to only a fraction of the mass of the nucleons; the remaining fraction could be attributed to the mass of neutral gluons, which would not interact with the bombarding charged electrons. For this work, Friedman, Kendall, and Taylor were awarded the 1990 Nobel Prize in Physics. Most convincing was visible evidence for the presence of quarks and gluons, which was provided by high-energy positron–electron collisions produced by the large electron-positron (LEP) collider of 27 km circumference and built by CERN near Geneva, Switzerland. The LEP was operated as a synchrotron to accelerate positrons and electrons to travel close to the speed of light with energies as high as 209 GeV. Electrons and positrons colliding at such high energies would result in the annihilation of both particles, which can generate the emission of a quark and antiquark pair together with the radiation of a gluon traveling in three different directions terminating in the production of three jets of hadrons, as illustrated in Fig. 1.6. The LEP was dismantled in 2001 and replaced in 2012 with the Large Hadron Collider (LHC) capable of

accelerating proton beams to energies of 4 TeV. A more complete description of these studies is provided in a book by the writer (L'Annunziata, 2016).

Our current understanding of the quark and gluon composition of protons and neutrons and the forces binding quarks have helped us understand the strong interaction or strong nuclear force between the nucleons that hold them together in the atomic nucleus. With this understanding, we can now explain both positron emission and electron capture (EC) when a proton changes to a neutron with the transformation of an up (u) quark into a down (d) quark. Likewise, we can now explain negatron emission when a neutron changes into a proton with a transformation of a down (d) quark into an up (u) quark within the decaying atomic nucleus, as illustrated in Fig. 1.7.

Since Max Planck's quantum theory of radiation (Planck, 1900) whereby he explained the emission of radiation in discrete packets of energy referred to as "the quantum" ($E = h\nu$) and Albert Einstein's explanation in 1905 of the photoelectric effect as the result of the photon quantum to consist of a distinct particle that can knock out atomic electrons from atoms to produce electricity, we have considered this as sufficient evidence to adhere to the concept of the particulate nature of photons. Finally in 2012, the Nobel Prize in Physics was awarded to Serge Haroche and David J. Wineland for their measurement and manipulation of individual quantum systems. As a result, science has taken us to the stage where an individual photon particle could be trapped and measured.

The previous paragraphs in this section provide a brief overview of a few key highlights of the historical

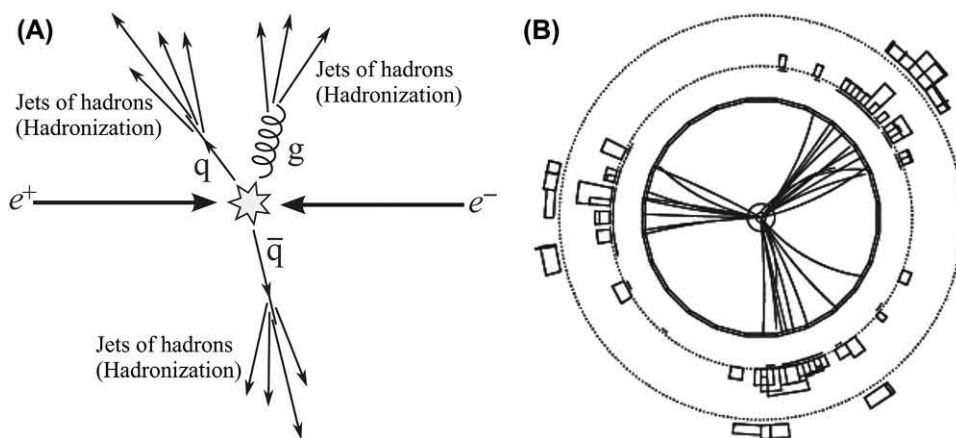

FIGURE 1.6 Hadron jets formed as a result of a high-energy collision and annihilation of a positron and electron produced in an electron–positron collider. (A) On the left is illustrated a collision of a high-energy positron and electron in a positron–electron collider producing a quark (q) and antiquark (\bar{q}) traveling apart in opposite direction, and a gluon (g) resulting in the production of three jets of hadrons traveling away from the point of collision. (B) On the right is an example of recordings of three hadron jets from a e^+e^- annihilation recorded in the jet chamber of a particle detector. The three jets include two jets produced by a quark–antiquark pair and the emission of a gluon by the separated quark–antiquark pair. The jets of hadrons are shown in the plane perpendicular to the direction of the e^+ and e^- , which annihilated in the center of the detector. Charged particles produce curved jets, bent by a solenoidal magnetic field, and uncharged particles produce straight lines. The boxes outside of the circular region represent recordings of the energy deposited by the neutral and charged particles in the outer components of the particle detector. FIGURE 1.7 Feynman diagram illustrating negatron (β^-) emission in beta decay. A down quark (d) of a neutron (lower left of the figure) is transformed into an up quark (u) whereby the neutron changes into a proton (upper left of figure) with the emission of a W^- boson, which transforms into a negative electron (β^-) and antineutrino ($\bar{\nu}$). The W^- boson serves as a carrier of the weak interaction of elementary particles that occurs in beta decay. The quark transformation is depicted in red color, and the quarks that undergo no change are in black. The transformation of a neutron to a proton in the decaying nucleus results in an increase in atomic number of the nucleus; however, as in all forms of beta decay, the mass number of the nucleus does not change. For the color version of this figure the reader is referred to the electronic version of this book. From *L'Annunziata (2016)*; reprinted with permission from Elsevier © 2016.

developments that have brought us to our current understanding of nuclear stability and decay. A more comprehensive coverage of the historical discoveries starting with the discovery of radioactivity to modern scientific findings that have helped us understand the structure of matter, and nuclear stability and decay can be obtained by the reader in a previous lengthy treatise by the writer (*L'Annunziata, 2016*).

III. Basic units and definitions

A. Properties of atomic constituents

The properties of the atomic constituents that are relevant to topics dealt with in this chapter are rest mass, charge, spin, magnetic moment, and stability. The atomic constituents in this section will be limited to the proton, neutron, and electron (see *Table 1.1*). The properties of particles that are found in the underlying structure of protons and neutrons, namely quarks and gluons, will be discussed further on in this chapter. Several units of rest mass are given in *Table 1.1*, as these are used throughout the chapter, including the expression of mass in terms of energy, the electron volt (eV) or joule (J) the unit of energy established by the International System of units (SI). A brief description of the terms used for the properties of the atomic constituents is as follows:

Rest Mass: The rest mass, which is the mass of the particle at rest relative to an observer, is expressed in four units, namely, kilograms (kg) or atomic mass units (u), and the energy equivalence of the rest mass ($E = m_0c^2$) in joules (J) or electron volts (eV). The atomic mass unit (u) is defined in terms of the stable carbon nuclide ^{12}C , which is assigned an atomic mass of exactly 12 u where $1 \text{ u} = 1.660540 \times 10^{-27} \text{ kg}$. The rest mass of the proton or neutron is approximately 1840 times that of the electron.

Charge: The charge on the particle is expressed on the basis of the unit electron charge $+e$ or $-e$ or in units of the Coulomb (C). The neutron is neutral or without charge. A **neutral atom** would be one that possesses a number of external electrons equal to the number of protons in the nucleus. It may be expressed as ^A_ZX , where Z is the **nuclear charge** or **atomic number**, i.e., the number of protons in the nucleus, A is the **mass number** of the nucleus or the sum of the number

TABLE 1.1 Properties of atomic constituents.

Property	Proton	Neutron	Electron
Rest mass	$1.67262 \times 10^{-27} \text{ kg}$ $1.50327 \times 10^{-10} \text{ J}$ 938.271 MeV 1.007276466 u	$1.67492 \times 10^{-27} \text{ kg}$ $1.50534 \times 10^{-10} \text{ J}$ 939.565 MeV 1.008664915 u	$9.10938 \times 10^{-31} \text{ kg}$ $8.18710 \times 10^{-14} \text{ J}$ 0.510998 MeV 0.0005485799 u
Charge	$+e$ $+1.602 \times 10^{-19} \text{ C}$	Zero	$-e$ $-1.602 \times 10^{-19} \text{ C}$
Spin	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
Magnetic moment	$1.410 \times 10^{-26} \text{ J/T}$	$-0.966 \times 10^{-26} \text{ J/T}$	$928.476 \times 10^{-26} \text{ J/T}$
Stability	Stable	10.2 minutes half-life	Stable

of protons and neutrons in the nucleus. The number of electrons that the atom possesses is assumed to equal that of Z when the atom is a neutral atom.

Spin: In 1920, Otto Stern and Walter Gerlach observed two spin states of the electron, that is, the electron possessed a magnetic dipole moment, which may be quantized in either of two directions, namely with or against an external magnetic field, i.e., spin-up or spin-down. These spin states are assigned the values $+\frac{1}{2}\hbar$ or $-\frac{1}{2}\hbar$ where \hbar is Planck's constant reduced or $\hbar/2\pi$. The spin states are abbreviated as $+\frac{1}{2}$ and $-\frac{1}{2}$. The proton, neutron and electron possess half-integer spin states. Particles with half-integer spins belong to a class of particles called **fermions** (named after Enrico Fermi). Fermions obey the Pauli Exclusion Principle, which states that no two identical fermions can occupy the same quantum state (energy state) at any given time, as described further on in this chapter. The property of spin and the Pauli Exclusion Principle enable the assignment of protons and neutrons to specific quantum levels or shells within the nucleus and electrons to specific orbitals away from the nucleus.

Magnetic moment: The nuclear magnetic moments of the proton and neutron are about a thousand-fold smaller than that of the electron. Although the neutron is of neutral charge, it possesses a magnetic moment due to its underlying quark constituents that possess charge. The positive or negative signs designated to the magnetic moments indicate that the spin vectors and the magnetic moments are in opposite direction. The magnetic moments are important properties that establish the basis for magnetic resonance imaging and spectroscopy.

Stability: The neutron is unstable outside the confines of the nucleus. Once outside the nucleus, a neutron has a mean half-life of 10.2 minutes.

B. Nuclides, isotopes, isobars, isomers, and isotones

Ernest Rutherford (1911) discovered that the atom contains a massive center following experiments that revealed the backscattering of α -particles by atoms of gold, which was discussed previously in Section II of this chapter. Reference to the "nucleus" as a massive positively charged center of the atom was proposed by Rutherford (1913) and Niels Bohr (1913) in their classic papers on the structure of the atom. However, it was not until James Chadwick (1932a,b, 1935) discovered the neutron and determined its mass, could the structure of an atomic nucleus be explained to

contain a definite number of protons and neutrons. Consequently the term nuclide and radionuclide could then be derived, which are defined as follows:

Nuclide: A nuclide is a species of an atom that is characterized by the number of protons (Z) and number of neutrons (N) in its nucleus. A symbol for a nuclide can be written in the form ${}^A_Z\text{X}_N$, where X is the symbol for the chemical element, Z is the atomic number or number of protons in the nucleus, A is the mass number or the number of protons plus neutrons in the nucleus, and N is the number of neutrons in the nucleus. Generally when A and Z are noted with the nuclide symbol, the neutron number N is not written, as it is deduced (i.e., $N = A - Z$). For example, the nuclide written as ${}^{90}_{38}\text{Sr}$ represents an atom of the element strontium with a nucleus containing 38 protons and 52 neutrons and a mass number of 90. The nuclide may also be written in a more abbreviated form as ${}^{90}\text{Sr}$, since the atomic number of the element strontium is known and an invariable number for that element.

There are 266 stable nuclides and 83 unstable or radioactive nuclides that exist naturally on earth. More than 3000 radioactive nuclides are known, that are artificially produced. The radioactive nuclides are referred to as **radionuclides**. All of the nuclides, both stable and radioactive, are organized in "The Chart of the Nuclides". The Chart provides a block containing the properties of each nuclide, which is plotted according to its Z versus N . A small part of the Chart of the Nuclides is illustrated in Fig. 1.50 in this chapter. The entire Chart of the Nuclides and the nuclear data for each nuclide can be viewed online on the website of the National Nuclear Data Center (NNDC, 2018a,b) of the Brookhaven National Laboratory (<http://www.nndc.bnl.gov/nudat2/>), or on the website of the International Atomic Energy Agency (<http://www-nds.iaea.org/relnsd/vcharthtml/VChartHTML.html>).

Isotopes: Nobel Laureate Frederick Soddy coined the word "isotopes" (Soddy, 1913a,b) to refer to such atoms that have the same atomic number (i.e., the number of protons in the nucleus) but different mass number (i.e., number of protons plus neutrons in the nucleus). Soddy recognized that these are atoms of the same element in the periodic table but of different mass. In his words Soddy (1913a) explained

I call (them) "isotopes" or "isotopic elements", because they occupy the same place (from the Greek) in the periodic table. They are chemically identical, and save only as regards the relatively few physical properties which depend on atomic mass directly, physically identical also.

Soddy went further by alluding to the fact that many, if not most, of the stable elements actually consist of a

mixture of isotopes. In his Nobel Lecture, [Soddy \(1922\)](#) gave credit to the Swedish scientists [Strömholtz and Svedberg \(1909a,b\)](#) by quoting them as follows:

Perhaps, one can see, as an indication in this direction, the fact that the Mendeleev scheme (Periodic Table of Elements) is only an approximate rule as concerns the atomic weight, but does not possess the exactitude of a natural law; this would not be surprising if the elements of the scheme were mixtures of several homogeneous elements of similar but not completely identical atomic weight.

Thus, **isotopes** are nuclides that have the same atomic number (Z), that is, the same number of protons; but they differ in their number of neutrons (N). Thus, they differ in their mass number (A), which is the sum of the number of protons and neutrons in the nucleus. Because isotopes have the same atomic number, they are nuclides of the same chemical element. For example, the following are isotopes of the chemical element carbon: $^{10}_6\text{C}$, $^{11}_6\text{C}$, $^{12}_6\text{C}$, $^{13}_6\text{C}$, $^{14}_6\text{C}$, where the subscript and superscript represent the atomic number Z and mass number A , respectively, whereby the number of neutrons in the nucleus, N , is calculated as $A - Z$. Among the five isotopes of carbon listed above $^{10}_6\text{C}$, $^{11}_6\text{C}$ and $^{14}_6\text{C}$ are radioactive, and thus referred to as **radioisotopes**. The other two isotopes of carbon listed above, namely, $^{12}_6\text{C}$ and $^{13}_6\text{C}$ are stable isotopes of carbon. The natural isotopes that make up the element of carbon are $^{12}_6\text{C}$, $^{13}_6\text{C}$, and $^{14}_6\text{C}$.

Isotope natural abundance: Isotopes of the elements, that are found in nature, occur at a particular **natural abundance**. The term natural abundance refers to the relative abundance of an isotope that occurs naturally on earth. For example, among the five isotopes of carbon listed above, $^{12}_6\text{C}$ and $^{13}_6\text{C}$ occur naturally at natural abundances of 98.90%, and 1.10%, respectively. The isotope $^{14}_6\text{C}$ is naturally occurring in only a small trace ($\sim 10^{-10}\%$ natural abundance), as it is formed continuously by the interaction of cosmic-ray protons with nuclides in the upper atmosphere. The isotope $^{14}_6\text{C}$ is radioactive, and thus a radioisotope of carbon. The percent natural abundances of the isotopes for each element should add up to 100%. Another example is the naturally occurring isotopes of potassium, namely, $^{39}_{19}\text{K}$, $^{40}_{19}\text{K}$, and $^{41}_{19}\text{K}$, which occur at natural abundances of 93.2581%, 0.0117% and 6.7302%, respectively. The isotopes $^{39}_{19}\text{K}$ and $^{41}_{19}\text{K}$ are stable isotopes; however, the isotope $^{40}_{19}\text{K}$ is a radioisotope that decays with a half-life of 1.26×10^9 years. Since the naturally occurring isotopes are remnants of the nucleosynthesis of the earth, which is 2.54×10^9 years of age ([Dalrymple, 1991](#)), the isotope $^{40}_{19}\text{K}$ has had time to decay since the earth's creation. When only one isotope of an element exists naturally on earth, its

natural abundance is expressed as 100%. Examples are $^{19}_9\text{F}$, $^{27}_{13}\text{Al}$, $^{31}_{15}\text{P}$, $^{45}_{21}\text{Sc}$, $^{55}_{25}\text{Mn}$, $^{59}_{27}\text{Co}$, $^{89}_{39}\text{Y}$, $^{127}_{53}\text{I}$, $^{133}_{55}\text{Cs}$, $^{209}_{83}\text{Bi}$, and $^{232}_{90}\text{Th}$.

Further up the Chart of the Nuclides are found the last of the natural isotopes, namely, isotopes of uranium. Three of the isotopes of uranium are found naturally on earth, namely, $^{234}_{92}\text{U}$, $^{235}_{92}\text{U}$, and $^{238}_{92}\text{U}$, at abundances of 0.0055%, 0.720% and 99.2745%, respectively. The isotope $^{238}_{92}\text{U}$, which is the most abundant, has a half-life of 4.5×10^9 years. It has not undergone even a half-life of decay since the formation of the earth. However, the isotopes $^{234}_{92}\text{U}$ and $^{235}_{92}\text{U}$ with half-lives of 2.4×10^5 years and 7.1×10^8 years, respectively, have undergone considerable decay since the formation of the earth. All nuclides of atomic number greater than that of uranium do not occur naturally, and have been produced artificially by man as described in [Section II](#) of this chapter.

Isobars: Isobars are nuclides that possess the same mass number (A), but different atomic number (Z). For example, $^{56}_{28}\text{Ni}$, $^{56}_{27}\text{Co}$, $^{56}_{26}\text{Fe}$, $^{56}_{25}\text{Mn}$, and $^{56}_{24}\text{Cr}$ are isobars. In mass spectrometry where nuclides are separated and analyzed according to their mass, isobars can cause interference, and special techniques may be required to discriminate between nuclides of the same mass number ([Kusnir et al., 2004](#); [Litherland et al., 2007](#); [Pläß et al., 2008](#)). In beta decay, discussed further on in this chapter, the parent and daughter nuclides are always isobars.

Isomers: Nuclear isomers are different energy states of the same nucleus, having different half-lives and even different modes of decay. A well known example is that of $^{99}_{43}\text{Tc}$, which may have two isomeric states. The isomers of $^{99}_{43}\text{Tc}$ are the following: $^{99}_{43}\text{Tc}$, which decays by negatron emission to $^{99}_{44}\text{Ru}$ with a half-life of 2.14×10^5 years, and $^{99m}_{43}\text{Tc}$, which decays by gamma emission to $^{99}_{43}\text{Tc}$ with a half-life of 6.00 hours. Isomeric states of nuclides other than the ground state are represented with a superscript “ m ” following the mass number. The isomer $^{99m}_{43}\text{Tc}$ is commonly used in the field of nuclear medicine as a diagnostic imaging source injected into the human body ([L'Annunziata, 2016](#)). When more than two excited isomeric states of a nuclide exist, the nuclear isomers are labeled as m_1 , m_2 , etc, in order of increasing excitation energy. For example, the isomers of $^{152}_{63}\text{Eu}$ are identified as follows: $^{152}_{63}\text{Eu}$ of 13.2 year half-life, $^{152m1}_{63}\text{Eu}$ of 9.3 hours half-life, and $^{152m2}_{63}\text{Eu}$ of 1.6 hours half-life. There are over 950 isomeric states known to exist among the nuclides. They are not considered as individual nuclides, but rather as isomers of individual nuclides.

Isotones: Nuclides that have the same number of neutrons, but different mass numbers are isotones. For example, $^{33}_{15}\text{P}$, $^{34}_{16}\text{S}$, $^{35}_{17}\text{Cl}$, $^{36}_{18}\text{Ar}$, and $^{37}_{19}\text{K}$ are isotones;

their nuclei all contain 18 neutrons. Isotones may be found in the Chart of the Nuclides, which plots the nuclides according to their Z versus N , as the column of nuclides having the same number N .

C. Mass and energy

The rest masses of the proton and neutron are of the order of 10^{-27} kg (see Table 1.1). Due to the small masses, most calculations involving atomic nuclei, such as nuclear decay energy, binding energy, and energies of nuclear reactions, make use of a more convenient scale of unit, namely, the atomic mass unit (u).

The atomic mass unit is defined in terms of the stable carbon nuclide ^{12}C , which is assigned an atomic mass of exactly 12.000000 u. Thus, the atomic mass unit is by definition exactly $1/12$ the rest mass of ^{12}C or

$$1 \text{ u} = 1.66053873 \times 10^{-27} \text{ kg.} \quad (1.6)$$

The mass of all of the nuclides in atomic mass units are available in reference tables, such as those listed in the Handbook of Chemistry and Physics (Rumble, 2017) and the following NIST website: <https://www.nist.gov/pml/atomic-weights-and-isotopic-compositions-relative-atomic-masses>.

The International System of units (SI) for energy is the joule (J); however, the electron volt (eV) remains a very popular unit for expressing energy in nuclear decay, nuclear reactions, nuclear binding, etc. The electron volt (eV) is, by definition, the amount of kinetic energy gained by an electron when accelerated through a potential difference of 1 V. The electron volt is equivalent to the following units:

$$\begin{aligned} 1 \text{ eV} &= 1.602176462 \times 10^{-19} \text{ J} \\ &= 1.602176462 \times 10^{-12} \text{ erg} \end{aligned} \quad (1.7)$$

The erg is a unit of energy in the centimeter-gram-second (CGS) system of units, and less commonly used in nuclear energy calculations. From the above relation, the erg is equivalent to 10^{-7} J or 6.2415097×10^{11} eV.

Calculations concerning nuclear decay energy, nuclear reaction energy or nuclear binding energy, etc. generally require the conversion of mass to energy. A common factor that is used in such calculations is one that can convert atomic mass units (u) to the units of the electron volt (eV). The conversion factor is found using Einstein's equation of equivalency of energy and mass to convert the mass of 1 u to energy or

$$E = m_0 c^2 \quad (1.8)$$

where E is energy in joules, m_0 is the rest mass in kilograms, and c is the velocity of light in a vacuum or 2.99792458×10^8 m/s. If by definition, the mass of 1

u = $1.66053873 \times 10^{-27}$ kg, the energy equivalent to 1 u is calculated as

$$\begin{aligned} E &= (1.66053873 \times 10^{-27} \text{ kg/u}) (2.99792458 \times 10^8 \text{ m/s})^2 \\ &= 14.92417783 \times 10^{-11} \text{ J/u} \end{aligned} \quad (1.9)$$

The energy in units of joules is then converted to units of electron volts, as $1 \text{ eV} = 1.602176462 \times 10^{-19} \text{ J}$ or

$$\begin{aligned} E &= \frac{14.92417783 \times 10^{-11} \text{ J/u}}{1.602176462 \times 10^{-19} \text{ J/eV}} \\ &= 9.31494013 \times 10^8 \text{ eV/u} \\ &= 931.494013 \text{ MeV/u} \end{aligned} \quad (1.10)$$

Thus $1 \text{ u} = 931.494013 \text{ MeV}$ or $931.494013 \text{ MeV}/c^2$. The latter units of MeV/c^2 are used conveniently when converting atomic mass units to MeV energy in Einstein's equation according to the following

$$\begin{aligned} E = mc^2 &= [(\text{atomic mass units}) \\ &\times (931.494013 \text{ MeV} / c^2)] c^2 \end{aligned} \quad (1.11)$$

Eq. (1.11) is used to convert conveniently atomic mass units (u) to units of energy in MeV. Examples are given throughout this chapter in calculations of nuclear decay energy, nuclear reaction energy and nuclear binding energy.

D. Q value

The Q value of a nuclear reaction is a measure of the energy "released" or "absorbed" by the reaction. When the Q value is positive ($Q > 0$), energy is "released" by the reaction with a conversion of the rest mass of the reactants into kinetic energy of the products. When the Q value is negative in magnitude ($Q < 0$), an input of energy is needed for the reaction to proceed, as energy is consumed in the reaction. In other words, when Q is negative, kinetic energy must be added to one or more of the reactants (*i.e.*, bombarding particles) up to a threshold (*i.e.*, required) energy for the reaction to proceed. When the value of $Q = 0$, kinetic energy is neither consumed nor released. In this case, no reaction occurs with the exception of an elastic collision.

The energy released in a nuclear reaction is a function of the kinetic energies of the initial reactants K_i and final products K_f and, because the total energy (E) of the reactants or products is the sum of their rest energies (E_0) and kinetic energies (K), that is

$$E = E_0 + K \quad (1.12)$$

Because the rest energies and kinetic energies are conserved, the Q value is calculated as the difference between the initial and final rest masses

$$Q = E_{0, \text{ initial}} - E_{0, \text{ final}} = (m_i - m_f)c^2 = (m_R - m_P)c^2 \quad (1.13)$$

where $E_{0, \text{ initial}}$ and $E_{0, \text{ final}}$ are the initial and final rest energies, m_i and m_f are the initial and final rest masses, and m_R and m_P are the rest masses of the reactant and products, respectively.

Thus, the Q value of a nuclear reaction is calculated by the difference in rest masses of the nuclear reactants and nuclear products or

$$Q = E_{0, \text{ Reactants}} - E_{0, \text{ Products}} = (m_R - m_P)c^2 \quad (1.14)$$

where m_R and m_P are the rest masses of the reactants and products of the nuclear reaction.

If we know the Q value of a nuclear reaction and we know the kinetic energies of the reactants, we can calculate the kinetic energies of the products according as

$$K_{\text{Products}} = Q + K_{\text{Reactants}} \quad (1.15)$$

Examples of the application of Eqs. (1.14) and (1.15) to a nuclear reaction is provided in the following paragraphs.

As nuclear reactions involve the reactions between nuclear particles and nuclei of atoms, we would need to know the rest masses of the nuclei or nuclear particles involved in the reaction to calculate a reaction Q value. In lieu of using rest masses of the atomic nuclei, it is common to use the atomic masses (u) which are available in reference tables, such as that of the Handbook of Chemistry and Physics or the Internet, such as data available from NIST, <https://www.nist.gov/pml/atomic-weights-and-isotopic-compositions-relative-atomic-masses>. However, it is important to keep in mind that atomic masses include the masses of the atomic electrons. To eliminate error that might occur from the added masses of the atomic electrons, it is important to assure that the number of electrons added to either side of the reaction is equal, whereby the difference of the electron masses of the reactants and products would be zero when utilizing Eq. (1.14). Let us take an example and calculate the Q value of the first man-made nuclear reaction whereby Ernest Rutherford discovered the proton described earlier in Part II of this Chapter. The reaction is as follows:

In this reaction the alpha particle interacts with an atom of ${}^{14}\text{N}$ to form an atom of ${}^{17}\text{O}$ with the ejection of a proton from the nucleus. The atomic masses may be used to calculate the Q value of the reaction as follows:

$$\begin{aligned} Q &= (M_{{}^4\text{He}} + M_{{}^{14}\text{N}}) - (M_{{}^{17}\text{O}} + M_{{}^1\text{H}}) \\ &= (4.002603254 \text{ u} + 14.003074004 \text{ u}) \\ &\quad - (16.999131756 \text{ u} + 1.007825032 \text{ u}) \\ &= -0.00127953 \text{ u} \end{aligned} \quad (1.17)$$

By using atomic masses, we have added nine electron masses to each side of the reaction, and their difference is zero. Converting atomic mass units to energy according to Eq. (1.11) gives the Q value in units of MeV energy or

$$\begin{aligned} Q \text{ value} &= (m_R - m_P)c^2 \\ &= [(-0.00127953)(931.494013 \text{ MeV}/c^2)]c^2 \\ Q \text{ value} &= -1.19187 \text{ MeV} = -1191.87 \text{ keV} \end{aligned} \quad (1.18)$$

Atomic masses are conveniently used in such calculations, in lieu of nuclear masses, provided an equal number of electrons are added to either side of Eq. (1.14). The negative energy value above demonstrates that the reaction is endoergic or endothermic, that is, the reaction requires a net energy input of 1.192 MeV. When the Q value is positive, the nuclear reaction is exoergic or exothermic, resulting in a net release of energy. There are small differences in the binding energies of the electrons when using atomic masses; however, the differences in the binding energies are negligible and ignored.

The Q value for nuclear reactions or nuclear decays can be obtained using the QCALC computer program via the Internet on the website of the National Nuclear Data Center (NNDC, 2018a,b) of the Brookhaven National Laboratory in Upton, NY, USA (<http://www.nndc.bnl.gov/qcalc/>). In the case of a nuclear reaction, all that is required is to input on the website the symbols for the reactants and that of a product. For example, we can take the above reaction 1.16 and, on the NNDC website, we can input the symbol for the **target** nucleus as 14N (without superscript for the mass numbers), the symbol for the **projectile** 4He and the symbol for the **ejectile** 1H. The QCALC computer program can then calculate instantly the Q value to be -1191.87 keV , which is equivalent to the value calculated above by Eqs. (1.17) and (1.18).

When the reaction has a negative Q value, as in the example provided above, energy must be added for the reaction to proceed. According to the calculation of Eq. (1.18), a minimum energy of 1.19 MeV of kinetic energy must be added to the bombarding particle for the reaction to proceed. In the reaction described by Eq. (1.16), Ernest Rutherford (1919) used alpha-particles from ${}^{214}\text{Po}$, which

emits alpha particles with a kinetic energy of 7.69 MeV. This is well above the threshold energy for the reaction to proceed. The kinetic energy of the reaction products (K_{Products}) when 7.69 MeV alpha particles are bombarded onto ^{14}N nuclides at rest are calculated according to Eq. (1.15) as

$$\begin{aligned} K_{\text{Products}} &= Q + K_{\text{Incident alpha-particle}} \\ &= -1.19 \text{ MeV} + 7.69 \text{ MeV} \\ &= 6.5 \text{ MeV} \end{aligned} \quad (1.19)$$

The 6.5 MeV is shared between the product nuclides of reaction (1.16), namely the ^{17}O and ^1H .

IV. Naturally occurring radionuclides

If we take into account the age of the earth, which is 4.5×10^9 years, and the characteristic property of radionuclide half-life decay, one of the following conditions would have to be met for a natural radioactive nuclide to occur on earth: (1) the radionuclide would be produced continuously on earth or in its atmosphere by a natural phenomenon, (2) the radionuclide would be very long-lived, that is, it would have a half-life of the order of $\geq 10^9$ years, or (3) the radionuclide would be a short-lived radionuclide in equilibrium with a naturally occurring long-lived parent radionuclide. The above categories of naturally occurring radionuclides will be subsequently discussed.

A. Radionuclides of cosmogenic origin

A number of radionuclides are produced on a continuous basis by the interaction of cosmic-ray particles with nuclei in the earth's atmosphere. The cosmogenic isotopes are created by the interactions of high-energy primary and secondary particles of cosmic radiation with nuclei of gaseous molecules of the atmosphere (*e.g.*, N_2 , O_2 , Ar, etc.) resulting in the fragmentation of the target nuclei or by the capture of thermal neutrons of the cosmic radiation showers with target nuclei of the atmosphere (see Section XIV.B for additional information on cosmic-ray interactions in the earth's atmosphere). As reported by Lal (2009), most of the cosmic-ray energy (>98%) is dissipated in the earth's atmosphere. Secondary particles of cosmic radiation produce nuclear reactions at a much-reduced rate with the earth's superficial reservoirs including the hydrosphere, cryosphere and lithosphere. Cosmogenic radionuclides are produced, therefore, to the greatest extent in the earth's atmosphere. Table 1.2 provides a list of cosmogenic nuclides, their half-lives, rate of production in the atmosphere, and the global mass of these naturally occurring nuclides. Short-lived radionuclides are not included here. Once produced in the

atmosphere, radionuclides, such as ^3H , ^7Be , ^{10}Be , ^{26}Al , and ^{36}Cl , will find their way to the earth's surface; whereas, radionuclides in gaseous form, such as $^{14}\text{CO}_2$, ^{37}Ar , ^{39}Ar , and ^{81}Kr find their way into oceans and rivers via air exchange.

B. Long-lived radionuclides

Based on the age of the earth (4.5×10^9 years), we can expect that all noncosmogenic radionuclides with a half-life $< 10^8$ years, that were formed during the formation of the earth and are not in equilibrium with a parent nuclide in a naturally occurring decay chain (see Section IV.C below), would have decayed to an undetectable level. Table 1.3 lists the naturally occurring long-lived radionuclides according to increasing atomic number (Z) together with their half-lives, relative isotope abundances, decay modes, and decay products. Two decay products are listed when there are two modes of decay. All of the decay products are stable with the exception of the decay products of ^{148}Sm and ^{152}Gd , which decay to the very long-lived ^{144}Nd and ^{148}Sm , respectively, and ^{232}Th , ^{235}U , and ^{238}U , which are long-lived parent radionuclides of the Thorium, Uranium and Actinium decay chains described in the following Section IV.C). Not listed in the table are 10 radionuclides that are exceptionally long-lived. These decay via a double-beta ($\beta\beta$) decay mode with half-lives ranging between 10^{18} and 10^{24} years. Double-beta decay is the rarest form of nuclear decay discussed further on in this chapter.

C. Natural radioactive decay chains

There are three naturally occurring decay chains, which begin with one of three long-lived parent nuclides. The three decay chains, namely, the ^{232}Th or Thorium Decay Chain ($4n$), the ^{238}U or Uranium Decay Chain ($4n + 2$), and the ^{235}U Decay Chain or also referred to as the Actinium Decay Chain ($4n + 3$) are illustrated in Figs. 1.8–1.10, respectively. The notations $4n$, $4n + 2$, and $4n + 3$ refer to the mass number A for all nuclides in the respective decay chains where n is a positive integer between 50 and 60. The notations are derived from the fact that the mass number (A) for all radionuclides in a given decay chain are multiples of 4, because α -decay results in a mass reduction of 4, whereas the mass number between parent and daughter does not change in β -decay. Thus, the mass numbers in the respective series agree with the relations $4n = A$, $4n + 2 = A$, and $4n + 3 = A$ where n is an integer between 50 and 60. There are radionuclides in the decay chains with very short half-lives (of the order of minutes and seconds). These short-lived nuclides have survived the billions of years since the formation of the earth due to an equilibrium that develops between a long-lived parent and its shorter-lived daughter.

TABLE 1.2 Production rates of several isotopes in the earth's atmosphere, arranged in order of decreasing half-lives.^a

Isotope	Half-life	Production rate (atoms/cm ² s)		Global inventory
		Troposphere	Total atmosphere	
³ He	Stable	6.7×10^{-2}	0.2	3.2×10^3 tons ^b
¹⁰ Be	1.5×10^6 y	1.5×10^{-2}	4.5×10^{-2}	260 tons
²⁶ Al	7.1×10^5 y	3.8×10^{-5}	1.4×10^{-4}	1.1 tons
⁸¹ Kr ^c	2.3×10^5 y	5.2×10^{-7}	1.2×10^{-6}	8.5 kg
³⁶ Cl	3.0×10^5 y	4×10^{-4}	1.1×10^{-3}	15 tons ^d
¹⁴ C	5730 y	1.1	2.5	75 tons
³⁹ Ar ^e	268 y	4.5×10^{-3}	1.3×10^{-2}	52 kg
³² Si	~150 y	5.4×10^{-5}	1.6×10^{-4}	0.3 kg
³ H	12.3 y	8.4×10^{-2}	0.25	3.5 kg
²² Na	2.6 y	2.4×10^{-5}	8.6×10^{-5}	1.9 g
³⁵ S	87 d	4.9×10^{-4}	1.4×10^{-3}	4.5 g
⁷ Be	53 d	2.7×10^{-2}	8.1×10^{-2}	3.2 g
³⁷ Ar	35 d	2.8×10^{-4}	8.3×10^{-4}	1.1 g
³³ P	25.3 d	2.2×10^{-4}	6.8×10^{-4}	0.6 g
³² P	14.3 d	2.7×10^{-4}	8.1×10^{-4}	0.4 g

^aBased on Lal and Peters (1967).^bThe inventory of this stable nuclide is based on its atmospheric inventory, which includes an appreciable contribution from crustal degassing of ³He.^cBased on atmospheric ⁸¹Kr/Kr ratio of $(5.2 \pm 0.4) \times 10^{-13}$.^dIncludes a rough estimate of ³⁶Cl produced by the capture of neutrons at the earth's surface.^eBased on atmospheric ³⁹Ar/Ar ratio of (0.107 ± 0.004) dpm/L Ar (STP).

From Lal (2009), reprinted with permission from Elsevier Publishers.

Equilibrium between parent and daughter nuclides is discussed in detail further on in this chapter. All radionuclides in the Thorium, Uranium, and Actinium decay chains terminate with a stable isotope of lead, namely, ²⁰⁸Pb, ²⁰⁶Pb, and ²⁰⁷Pb, respectively.

V. Artificially produced radionuclides

There are over 1300 artificially produced radionuclides. These are made by nuclear reactions often facilitated by a nuclear reactor or particle accelerator. A brief historical account of the development of man-made radionuclides including the synthetic elements, all of which are radioactive, will be provided here.

Frédéric Joliet and Irène Joliet-Curie (daughter of Pierre and Marie Curie) in 1934 were the first to produce artificially a radioactive nuclide, ³⁰P. The nuclide emits positrons, which are electrons of positive charge and the antiparticle of the negative electron. Positrons were discovered in cosmic radiation only 2 years earlier by Carl D. Anderson (1932, 1933a).

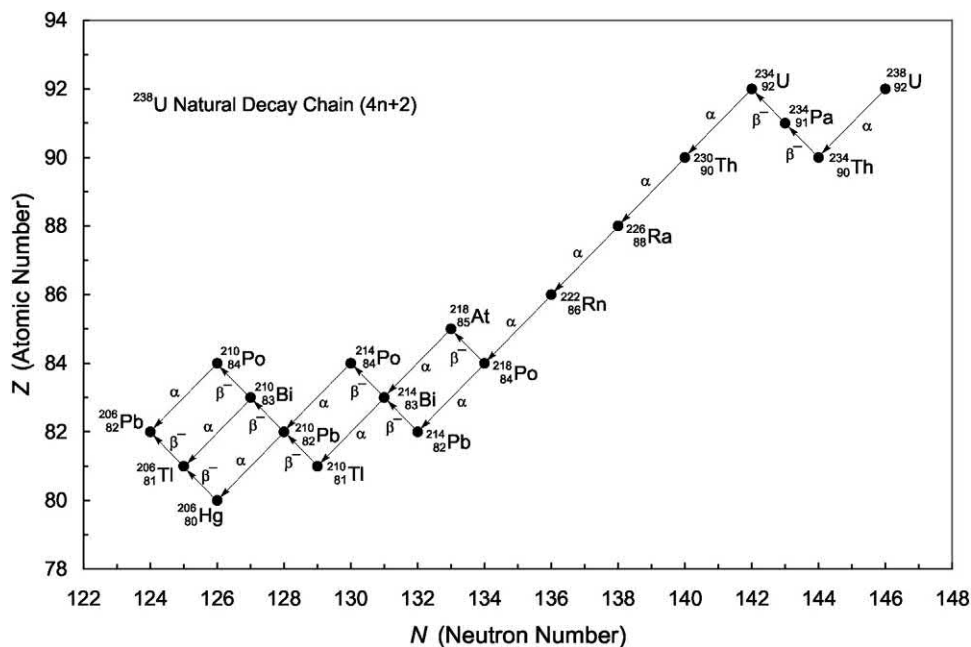

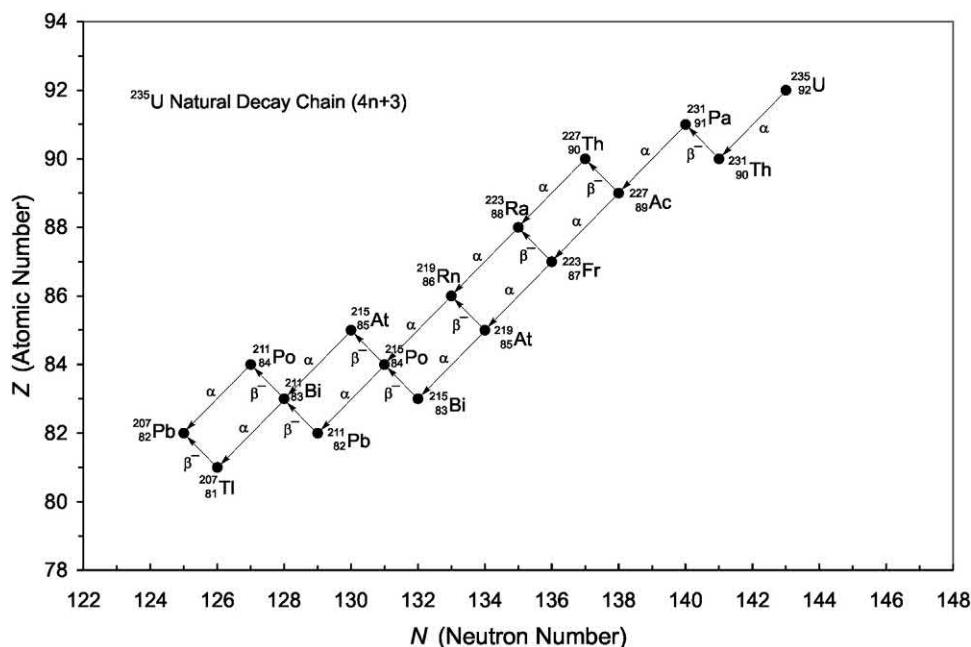

The discovery of the Joliet-Curies of artificially produced radioisotopes came about when they began their

search for positrons. They decided to irradiate various metals with alpha particles of different energies to see if the result would be the production of a predominance of neutrons or positrons. They irradiated aluminum foil with alpha particles from a polonium source. The energy of the alpha particles colliding with the aluminum could be controlled by placing the polonium at various distances from the aluminum. The irradiation of aluminum foil by the polonium alpha particles produced neutrons and positrons. When the polonium source was moved away from the aluminum to a distance beyond the reach of the alpha particles (The alpha particles from polonium-216 have an energy of 6.78 MeV and these cannot travel beyond 5.3 cm in dry air as calculated according to Eq. (1.166).), the neutron emission from the alpha-irradiated aluminum would cease; however, to their amazement, the Joliet-Curies discovered that the positron emission would continue. They measured the positron emission with a Geiger counter and found that the number of positrons emitted would diminish with time with an average lifetime of less than 5 minutes. The interaction of the alpha particles with the aluminum foil produced a new radioactive isotope of short half-life, yet unknown to mankind.

TABLE 1.3 Long-lived naturally occurring radionuclides.^a

Nuclide	Half-life (years)	Isotope abundance (%)	Decay mode(s)	Decay product(s)
⁴⁰ ₁₉ K	1.26×10^9	0.0117	β^- , EC	⁴⁰ ₂₀ Ca (β^-), ⁴⁰ ₁₈ Ar (EC)

The Joliot-Curies were able to demonstrate that the new isotope was chemically equivalent to elemental phosphorus, and it was radioactive phosphorus. By balancing the transformation of the nuclear reaction between alpha particles and aluminum yielding neutrons they could write the reaction

They used the equal sign rather than an arrow for the above reaction to demonstrate that the sum of the mass

numbers and atomic numbers on one side of the nuclear reaction should equal those on the other side, *i.e.*, $27 + 4 = 30 + 1$ for the mass numbers and $13 + 2 = 15 + 0$ for the atomic numbers. Expressing nuclear reactions was not a practice at that time. The Joliot-Curies were one of the first to introduce the practice.

The Joliot-Curies demonstrated that the new radioactive isotope of phosphorus emitted positrons. The new radioisotope, phosphorus-30, decays to stable silicon-30 with

positron emission and a short half-life of 2.5 minutes according to the following:

Thus, the Joliot-Curies not only produced a previously nonexistent radioisotope, but they were the first to produce positrons in the laboratory. The neutrino included in the above decay equation accompanies positron emission; however, this particle was yet to be discovered at the time of the Joliot-Curies.

By irradiating other metals, such as boron and magnesium, with alpha particles the Joliot-Curies were able to produce radioactive nitrogen and radioactive silicon according to the following reactions (Joliot-Curie and Joliot, 1934a,b,c):

The radioisotopes of nitrogen and silicon above decay by positron emission.

The Joliot-Curies were awarded the Nobel Prize in Chemistry the very year following the report of these discoveries. The rapid award of the Nobel Prize underscored the impact this discovery had on the scientific community and the advancement of science. Their work established firmly a new branch of chemistry called “radiochemistry”. As explained by Frédéric Joliot in his part of the Nobel lecture

The succession of radioactive transformations provides numerous examples in which the quantities of radio-elements are extremely small and not capable of being weighed, yet nevertheless, by the methods of radiochemistry it has been possible to examine correctly their chemical properties, and identify some of them as being isotopes of elements ... This special kind of chemistry in which one handles unweighable quantities, sometimes of the order of 10^{-16} g, is made possible thanks to the fact that one can determine and follow by measuring the radiation emitted, infinitesimal traces of radioactive matter dispersed in the midst of other matter.

While this work established firmly “radiochemistry” as a new branch of chemistry, the Joliot-Curies were the first to coin the terminology, which we are very accustomed to, when referring to radioactive elements. In their Nobel Lecture Frédéric Joliot stated

We have proposed that these new radio-elements (isotopes, not found in nature, of known elements) be called radio-nitrogen (for radioactive isotopes of nitrogen), radio-phosphorus (for radioactive isotopes of phosphorus), ...

Only 2 years after the Joliot Curies reported the synthesis of radionuclides by the alpha particle bombardment of nuclei, Enrico Fermi and his coworkers reported the synthesis of new radionuclides by neutron bombardment

of nuclei. This work, which was cited earlier in this chapter, yielded 63 previously unknown artificial radionuclides by the following three nuclear reactions:

where ${}^A_Z\text{X}$ is a symbol for any element X with atomic number Z and mass number A, and n is the symbol for the neutron. Fermi found reactions (1) and (2) to occur chiefly among the light elements, and the reaction of type (3) was found to occur most often among the heavy elements. More than one of the above reactions would sometimes occur when elements were bombarded with neutrons. In Fermi's words at his Nobel Lecture

In many cases the three processes are found at the same time in a single element. For instance, neutron bombardment of aluminum that has a single isotope ${}^{27}\text{Al}$, gives rise to three radioactive products: ${}^{24}\text{Na}$, with a half-life of 15 hours by process (1); ${}^{27}\text{Mg}$, with a period (half-life) of 10 minutes by process (2), and ${}^{28}\text{Al}$ with a period (half-life) of 2–3 minutes by process (3).

In addition to the above three neutron reactions described by Fermi, he and his coworkers were also able to observe the production of artificial radioactive isotopes by a fourth process that he described:

The primary neutron does not remain bound in the nucleus, but knocks off instead, one of the nuclear neutrons out of the nucleus; the result is a new nucleus, that is isotopic with the original one and has an atomic weight less by one unit.

This fourth neutron interaction, where the mass number is reduced by one (loss of a neutron) and the atomic number remains unaltered, can be written as follows:

Fermi knew that neutrons, because of their neutral charge, did not have to overcome the Coulombic barrier to penetrate the nucleus of an atom. Furthermore, he discovered, that reducing the neutron energy or slowing the neutron down by placing a water or paraffin barrier between a neutron source and its target nuclei, the energy of the neutrons could be reduced to that corresponding to thermal agitation. At this energy state, the slow neutrons could diffuse through target atoms and be captured by the target nuclei. Thus, using slow neutron bombardment, Fermi and his coworkers were able to produce more than 400 new radioisotopes of all known elements with the exception of hydrogen and helium.

At the same time that Enrico Fermi was producing radionuclides by means of neutron bombardment of target nuclei, Ernest Lawrence was developing the cyclotron

capable of accelerating protons, deuterons, and helium nuclei to very high energies. This work, discussed previously in this chapter, yielded many new artificial radionuclides, as the high energy of the accelerated ions could easily penetrate the Coulombic barrier of target nuclei.

The discovery of nuclear fission by Otto Hahn and Fritz Strassman with the interpretation of Lise Meitner in 1939 led to the discovery of the first nuclear reactor in 1942 by Enrico Fermi and coworkers. This work was discussed previously in more detail in [Section II](#) of this chapter. Today, the nuclear reactor and the cyclotron are the main instruments for the artificial production of radionuclides. There are now more than 1300 artificially produced radionuclides. Many of these radionuclides are vital for medical diagnosis and treatment, the sterilization of medical implements and supplies, and peaceful applications in industry and scientific research.

Elements with atomic number $Z > 92$, which are elements with atomic number higher than that of uranium, are artificially produced. They are all radioactive. By means of the cyclotron Glenn T. Seaborg pioneered the synthesis of many artificial elements. This work is described in detail in [Section II](#) of this chapter. There are no natural elements beyond $Z = 92$, because they all have half-lives too short to have survived since the formation of the earth. Also, there is the $4n + 1$ naturally occurring decay chain. The $4n + 1$ decay chain, illustrated in [Fig. 1.11](#), consists of artificially produced radionuclides. It is called the Neptunium Decay Chain after ^{237}Np , which is the longest-lived nuclide of the chain with a half-life of 2.1×10^6 years. There are currently over 25 artificially produced elements. All of the elements are listed according to atomic number in Appendix B of this book.

VI. Properties of the nucleus

A. Nuclear radius and density

[Rutherford \(1911, 1919, 1920a,b\)](#) was the first to discover the atomic nucleus and to measure the size of the nucleus of an atom. A detailed accounting of this work is given in previous books ([L'Annunziata, 2007, 2016](#)). In brief, Rutherford bombarded very thin gold foil (4×10^{-5} cm thick) with alpha particles. Most of the alpha particles traversed the gold foil almost as if the foil was not in the path of the alpha particles; however, 1 alpha particle for every 20,000 particles would bounce back from the foil by more than 90 degrees from the direction of travel. From this work, Rutherford concluded that within much empty space of the atom there exists a massive central nucleus upon which the alpha particle would collide and consequently cause the alpha particle to ricochet back toward the direction from which it came. Rutherford expressed his reaction to the observed alpha particle back scattering with the following statement, related by [Feather \(1940\)](#) in a biographical essay a few years following Rutherford's death:

On consideration, I realized that the scattering backwards must be the result of a single collision, and when I made calculations I saw that it was impossible to get anything of that order of magnitude unless you took a system in which the greater part of the mass of the atom was concentrated in a minute nucleus.

Rutherford went even further to make use of this interaction to determine the nuclear radius of aluminum. By selecting a metal foil of low Z (aluminum, $Z = 13$) and thus low Coulomb barrier to alpha penetration, and

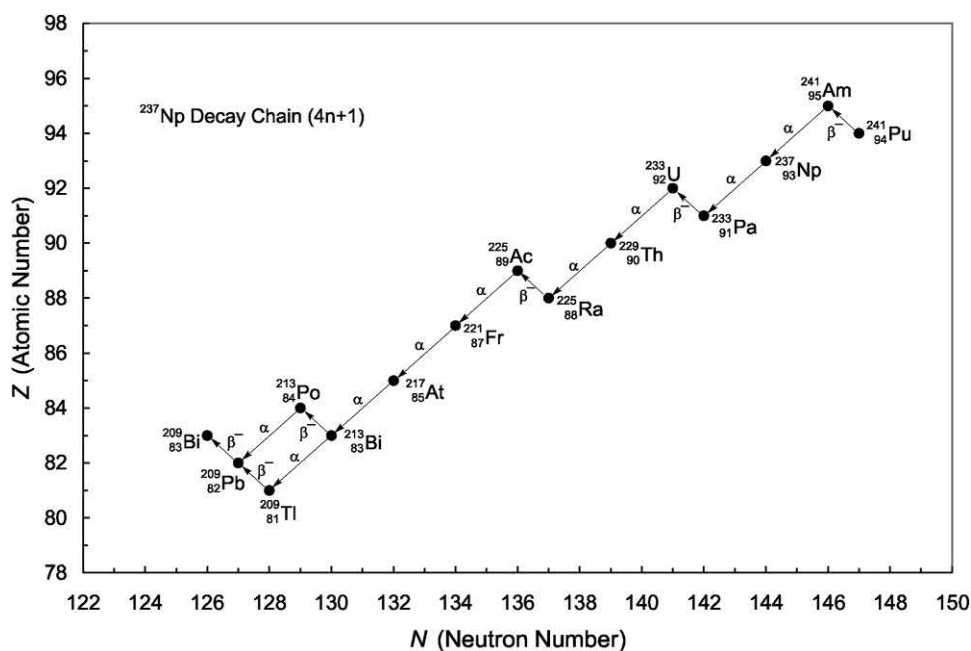

FIGURE 1.11 The Neptunium decay chain.

applying alpha particles of high energy (7.7 MeV) whereby defined alpha particle scattering at acute angle due to Coulombic repulsion would begin to fail, [Rutherford \(1919, 1920a,b\)](#) was able to demonstrate that the distance of closest approach of these alpha particles to the atom center according to Coulomb's law was equivalent to the nuclear radius of aluminum, $\sim 5 \times 10^{-15}$ m or five fm (*i.e.*, 5 fm or five fermi).

Since Rutherford's pioneering alpha-particle scattering experiment, numerous nuclear scattering experiments have been carried out to measure the size of atomic nuclei including electron scattering ([Jansen et al., 1971](#); [Sick, 1982](#)), electron–proton scattering ([Klarsfeld et al., 1986](#)), electron–deuteron scattering ([Sick and Trautmann, 1998](#)), and high-energy beam interactions ([Tanihata et al., 1985](#); [Suzuki et al., 1999](#)). The radius of an atomic nucleus obeys the general empirical formula

$$R = r_0 A^{1/3} \quad (1.28)$$

where r_0 is a constant, referred to as the radius parameter, and A is the mass number of the nucleus ([Tolhoek and Brussaard, 1954](#); [Elton, 1958](#); [Angeli and Csatlós, 1977](#)). A detailed derivation of Eq. (1.28) is provided by [Elton \(1958\)](#). The value of the radius parameter r_0 , was calculated by [Royer \(2008\)](#) to be within the range of 1.22–1.23 fm. Obviously the radius of the nucleus will increase with mass number. For a small nucleus, such as the nucleus of ${}^4_2\text{He}$ (equivalent to an alpha particle), the radius is calculated to be 1.9×10^{-15} m or 1.9 fm. For larger nuclei, such as ${}^{27}_{13}\text{Al}$, ${}^{197}_{79}\text{Au}$ and ${}^{235}_{92}\text{U}$, the nuclear radii calculate to be 3.6, 6.9 and 7.4 fm, respectively.

Treating the nucleus as a sphere permits the calculation of the nuclear volume, and from the mass of the nucleus, we can calculate the nuclear density ρ_N as

$$\rho_N = \text{mass/volume} = m_n A / \left(\frac{4}{3} \pi R^3 \right) \quad (1.29)$$

where m_n is the mass of a nucleon (proton or neutron), A is the mass number, and R is the nuclear radius. The mass of either nucleon (the proton or neutron) may be used, as the two nucleons are very similar in mass and may be considered equal in mass, when only three significant figures are used, namely, 1.67×10^{-27} kg. Substituting $r_0 A^{1/3}$ for R in Eq. (1.29) gives

$$\rho_N = m_n / \left(\frac{4}{3} \pi r_0^3 \right) \quad (1.30)$$

The value of the nuclear density calculated according to Eq. 1.29 or 1.30, gives the value of $\rho_N = 2.3 \times 10^{17}$ kg/m³. Treating the nucleus as a sphere facilitates the density calculation and provides a good estimate as provided in current textbooks; however, most nuclei are not spherical and some may exhibit oscillations such as depicted by the liquid-drop model of the nuclei. Some nuclei described by

[Gould et al. \(2004\)](#) exhibit football-shaped quadrupole deformations and even pear-shape octupole deformations ([Krappe and Wahsweiler, 1967](#); [Vogel, 1967, 1968](#); [Aponick et al., 1970](#); [Cline, 1993](#)). [Gould et al. \(2004\)](#) describe the interior of a large nucleus as uniform (0.17 nucleons/fm³); but that the density falls off smoothly at the surface of the nucleus, dropping from 90% to 10% of the interior density over a distance of ~ 2.5 fm.

The density of the nucleus is extraordinarily high when compared with elements and materials consisting of atoms. For example, the atomic nucleus is 2.0×10^{13} times the density of lead (11.3×10^3 kg/m³) or 1.2×10^{13} times the density of depleted uranium (19.1×10^3 kg/m³). While the density of the nucleus is amazingly high, the nucleus consists of closely packed nucleons and thus, the nucleons themselves and even subnuclear particles, particularly leptons, would even have higher densities.

Subnuclear particles are classified into two groups, the leptons and hadrons. The word leptons comes from the Greek “lepto” meaning “refined” or “thin”. **Leptons** are particles with no apparent substructure and thus considered to be truly elementary or point particles, such as, the electron, muon, and their respective neutrinos and quarks. Leptons, with the exception of quarks, participate in electromagnetic and weak interactions. **Hadrons**, on the other hand, are more complex in subnuclear structure and they participate in the strong nuclear force. Hadrons are classified into two groups, namely, the **mesons** containing two quarks (*e.g.*, pion and kaon) and the **baryons** (from the Greek “barys” meaning “heavy”), which are of higher mass and contain three quarks (*e.g.*, proton and neutron). The role of mesons as particles, that mediate the strong nuclear force between the nucleons, is discussed in the next section of this chapter.

The high density of the nucleus underscores the importance of a strong short-range nuclear force that exists between the nucleons (*i.e.*, protons and neutrons) keeping them closely packed regardless of the repulsive forces of the positively charged protons or the Z/N ratios of the nucleus among the thousands of nuclides that exist.

B. Nuclear forces, quarks, gluons, and mesons

In the 1930s question arose concerning the force that was capable of holding the protons and neutrons together in the nucleus. It was unusual to find that the like positive charge of the protons did not force them to repel each other; but rather, they were held tightly together into a very dense nucleus in association with the neutrally charged neutrons. It was expected that the force holding the nucleons together would be a strong force. Nobel Laureate Hideki [Yukawa \(1935, 1949\)](#) first postulated the strong force between nucleons. Before doing this, Yukawa understood that charged particles would interact through the exchange of

FIGURE 1.12 Feynman diagram illustrating the photon as a particle that mediates the electromagnetic force between two electrons. The electromagnetic interaction results in the absorption of the photon particle by an electron providing it with momentum to be repelled. The illustration can be read as follows: An electron (lower left) emits a photon and undergoes recoil (upper left). The photon, illustrated as a dashed wave, is absorbed by an electron (lower right) and it is repelled (upper right). The photon is referred to as a virtual photon, because it is emitted and absorbed without being detected. From *L'Annunziata* (2016); reprinted with permission from Elsevier © 2016.

photon particles. He noted that such a force, known as the electromagnetic force, would become manifest when the particles collide. For example, electrons would interact via the exchange of virtual photons as illustrated by the Feynman diagram² of Fig. 1.12. Yukawa explained the strong force between nucleons by proposing a new particle, which would mediate the strong force between the nucleons. He predicted that the new particle would have a mass inversely proportional to the force between the nucleons, and that the mass of the particle would be intermediate of the proton and electron masses ($\sim 200 \times$ the electron mass). The new particle was named the meson, which was taken from the Greek “meso” meaning “middle”. The prediction of Yukawa was verified by the discovery of the π meson or pion by *Occhialini and Powell* (1947, 1948). The strong force keeping the nucleons together is mediated by the exchange of π mesons between the nucleons. The pion is the carrier of Yukawa’s nuclear force. It is found in three charge states, π^+ , π^- , and π^0 . They have the mass predicted by Yukawa and are unstable, e.g., the π^+ has a mass of $139.5 \text{ MeV}/c^2$ and a mean

FIGURE 1.13 A Feynman diagram illustrating the mediation of the strong nuclear force between nucleons in the nucleus. A neutron (lower left) is transformed into a proton (upper left) and a proton (lower right) is transformed into a neutron (upper right) via the intermediary pi meson. From *L'Annunziata* (2016); reprinted with permission from Elsevier © 2016.

lifetime of 2.6×10^{-8} seconds (*Sundaeson, 2001*). The mediation of the strong force between a neutron and a proton in the nucleus is illustrated by the Feynman diagram in Fig. 1.13, which illustrates a neutron converting into a proton and a proton converting into a neutron and, in the process, a π^+ is exchanged between the two nucleons.

Pion exchange between nucleons, as the particle mediating the strong force, is explained on the basis of the subnuclear quark structure of the proton, neutron, and meson. George *Zweig* (1964) and Murray *Gel-Mann* (1964) independently proposed the idea of a substructure to mesons and baryons. This substructure is now universally referred to as quarks, which would possess quantum numbers and fractional charge, which are subsequently described. The mesons (e.g., pion and kaon), which are of intermediate mass between that of the electron and proton, consist of two quarks; whereas, the baryons (e.g., proton, neutron, lambda, etc.), which are of higher mass, contain three quarks. The quark compositions of pi mesons (pions) and of the nucleons (proton and neutron), and the properties of the quarks are provided in Table 1.4. In the table, it is seen that the π^+ is composed of an up quark (u) with charge of $+\frac{2}{3}e$ and an antidown (\bar{d}) quark with charge of $+\frac{1}{3}e$ yielding a total charge on the π^+ of $+1$. The π^- consists of a down quark (d) of charge $-\frac{1}{3}e$ and antiup quark (\bar{u}) of charge $-\frac{2}{3}e$ yielding an overall particle charge of -1 . The π^0 is a mixture or superposition of $u\bar{u}$, $d\bar{d}$ quark pairs referred to as mixing of quark pairs with overall neutral charge.

The proton, neutron, and all of the baryons, which are particles of higher mass than the mesons, contain three quarks. The quark content of the proton, as listed in Table 1.4, is two up quarks and one down quark (uud) with respective charges of $+\frac{2}{3}e$, $+\frac{2}{3}e$ and $-\frac{1}{3}e$ or a total charge of $+1$; whereas, the neutron contains two down quarks and one up quark (ddu) with a total charge of zero.

2. A convenient way to illustrate the interactions and exchange forces between the elementary particles is with Feynman diagrams, which were used frequently by Nobel laureate Richard Feynman (1918–88). When he was a young scientist, he utilized the diagrams as a means of depicting, through sketches, the interactions among nuclear particles as shorthand for the equations that are used to put the interactions into more complex mathematical terms. Feynman diagrams show particle interactions in coordinates of space and time. The axis is not quantitative, that is, the length of the lines or spacing between particles is not a measure of relative time or distance. Particles are illustrated by solid lines with arrows giving the particle direction. Virtual particles are illustrated as dashed waves for particles with zero rest mass (i.e., photons or gluons) and dashed straight lines for particles with a rest mass.

TABLE 1.4 Quark compositions and properties of quark components of pi mesons and nucleons.

Particle	Quark composition	Properties of quarks			
		Name ^a	Symbol	Charge	Mass
Mesons					
π^+	$u\bar{d}$	up	u	$+\frac{2}{3}e$	2.3 MeV/ c^2
π^-	$d\bar{u}$	down	d	$-\frac{1}{3}e$	4.8 MeV/ c^2
π^0	$u\bar{u}, d\bar{d}$	antiup	\bar{u}	$-\frac{2}{3}e$	$m_{\bar{u}} = m_u$
Nucleons/Baryons		antidown	\bar{d}	$+\frac{1}{3}e$	$m_{\bar{d}} = m_d$
p	uud				
n	udd				

^aOther quarks exist, such as the strange (s), charmed (c), bottom (b), and top (t) quarks, which are component quarks of other mesons and baryons.

Quarks possess another property called color or color charge. The property of color or color charge has no relation to visible radiation as we see color; but rather, color charge is a quantum number and source of force that quarks and antiquarks possess. Color charge was proposed as a quantum number by [Greenberg \(1964\)](#) at the University of Maryland, and as a source of force between quarks by Mo-Young Han at Duke University and [Nambu \(1966\)](#) at the University of Chicago ([Han and Nambu, 1965](#)). To satisfy the Pauli Exclusion Principle, that states that no two fermions can exist simultaneously in the same energy or quantum state, the concept of color charge was introduced as a quantum state and force between quarks. Three color-charge quantum states carried by quarks are red, blue, and green, and those carried by antiquarks are antired, antiblue, and antigreen. In the baryons, all of which possess three quarks such as the proton (uud) and the neutron (ddu), there would exist three quarks of color charge, red, blue, and green. Quarks of different color charge possess an attractive force between each other, whereas quarks of like color would repel each other. Mesons, which possess only two quarks, a quark and antiquark (see [Table 1.4](#)), would display red and antired, blue and antiblue, or green and antigreen quantum states. There is an attractive force between quarks of a given color and its anticolor quantum state in mesons.

There are yet other particles in addition to quarks, called gluons, which exist in baryons and mesons. A gluon is a field particle like the electromagnetic photon, which has zero rest mass. Gluons differ from photons because they interact directly with quarks and with each other, and they carry, similar to quarks, a color charge quantum state. Quarks emit and absorb gluons. When a quark either emits or absorbs a gluon, the quantum state of the quark changes and thus, the color charge of the quark also changes. The process of emission and absorption of gluons by quarks, which is discussed subsequently, is part of the mechanism by which the strong nuclear forces keep the protons and

neutrons closely packed in the atomic nucleus. The force that exists between quarks of different quantum color states is called color force, and the theory that these forces play in the strong interactions is called quantum chromodynamics (QCD).

In summary, mesons mediate the strong forces between the protons and neutrons in the nucleus; and it is the energy exchange or quantum state changes between quarks and gluons of the mesons and nucleons, that enable the strong nuclear forces to hold the protons and neutrons together in the nucleus. An example of a process, whereby the strong nuclear forces between the nucleons come into play, is illustrated by the Feynman diagram of [Fig. 1.14](#). The figure illustrates the involvement of quarks and gluons in the transformation of a proton into a neutron and a neutron into a proton within an atomic nucleus via the mediation of a pi meson (π^+).

The mass of the nucleons as well as that of the mesons arise from the interaction of their quarks with the gluon field particles. Because gluons have a zero rest mass, the creation and absorption of gluons is a constant process in the nucleons attributing mass to the nucleons. As described by [Gould et al. \(2004\)](#), the mass of the nucleons comes from the interaction of the quarks with the nucleon field, and the nucleon is described as consisting of a core of three quarks confined within a sphere of radius $\sim 0.5\text{--}1.0$ fm. Surrounding the core is a cloud of pions (pi mesons), which are themselves composed of quark–antiquark pairs.

The range of the strong nuclear force is very close to that of the radius of the nucleon core. We can use Heisenberg's Uncertainty Principle to calculate the range of interaction of the strong nuclear force mediated by the pi meson or pion. Nobel Laureate Werner Heisenberg published the Uncertainty Principle ([Heisenberg, 1927](#)), which is a basic concept of quantum physics. In terms of energy and time variables, Heisenberg's Uncertainty principle can be expressed as

FIGURE 1.14 A Feynman diagram illustrating the mediation of a π^+ meson of the strong nuclear force between a proton and a neutron in the atomic nucleus with the interaction of quarks and gluons as follows: An up quark (u, colored red) in the proton on the lower left of the figure emits a gluon (g) illustrated by a helice in the left center of the figure resulting in pair production of a $d\bar{d}$ pair. The down quark (d, colored green) is captured (green line) changing the proton on the lower left to a neutron (upper left). The antidown quark (\bar{d} , colored purple) created in the pair production is annihilated by a down quark (d, colored brown) of the neutron at the lower right of the figure. The purple arrow of the antidown quark points in the opposite direction, because it is an antiparticle, and according to Feynman rules antiparticles are identified by arrows in the opposite direction. The $d\bar{d}$ annihilation results in the destruction of the down quark of the neutron on the lower right with the emission of a gluon (g, helice) in the right center of the figure, and the up quark (u, red colored) originating from the proton at the lower left is captured by the neutron on the lower right converting it into a proton on the upper right hand of the figure. For the color version of the figure, the reader is referred to the electronic version of the book. From *L'Annunziata (2016)*; reprinted with permission from Elsevier © 2016.

$$\Delta E \Delta t \geq \frac{h}{4\pi} \geq \frac{\hbar}{2} \quad (1.31)$$

which states that the precision with which we measure the energy of an atomic particle (ΔE) is limited by the time available (Δt) to measure the particle energy, where h is Planck's constant ($h = 6.626 \times 10^{-34}$ J s) and \hbar is a reduced form of Planck's constant ($\hbar = h/2\pi = 1.055 \times 10^{-34}$ J s = 6.582×10^{-22} MeV s). We can accurately calculate the energy of the pion from its mass, and from the Heisenberg Uncertainty Principle expressed by Eq. (1.31), we can state that the pion would violate the conservation of energy if it lasted for a period of time exceeding

$$\Delta t \approx \frac{\hbar}{2\Delta E} \quad (1.32)$$

where ΔE is the energy needed to create a pion of mass m_π defined by Einstein's equation of mass and energy as

$$\Delta E = m_\pi c^2 \quad (1.33)$$

And Δt is the time it would take for the pi meson to travel from one nucleon to the other (e.g., from a proton to a

neutron or vice versa). The mass m_π of the π^+ or $\pi^- = 139.5$ MeV/ c^2 . Since the pi meson cannot travel faster than the speed of light c , its distance (d) of travel is defined as

$$d = c\Delta t \quad (1.34)$$

Thus, the maximum distance, that the pi meson could travel, is calculated as

$$\begin{aligned} d &= c\Delta t = c \left(\frac{\hbar}{2m_\pi c^2} \right) \\ &= 2.99 \times 10^8 \text{ m/s} \left(\frac{6.582 \times 10^{-22} \text{ MeV s}}{2(139.5 \text{ MeV}/c^2)c^2} \right) \\ &= 7.0 \times 10^{-16} \text{ m} \approx 1 \times 10^{-15} \text{ m} \approx 1 \text{ fm} \end{aligned} \quad (1.35)$$

The range of the strong nuclear force mediated by the pion is thus ~ 1 fm similar to that of the radius of the proton or neutron.

For a more in-depth reading on subnuclear structure and its role in the strong nuclear force, see books by [Serway et al. \(2005\)](#), [Martin \(2011\)](#), and [Taylor et al. \(2015\)](#).

C. Binding energy

The difference in the total energy of the nucleus with its bound nucleons is always less than the total energy of the separate protons and neutrons, and this difference in energy is the binding energy (E_b) of the nucleus. The binding energy is equivalent to the energy required to pull a bound system apart, such as a bound nucleus, leaving its component protons and neutrons free of attractive forces. The binding energy is described by the equation

$$E_b = \sum_{i=1}^n m_i c^2 - M c^2 \quad (1.36)$$

where m_i are the free component particles (protons and neutrons) of the nucleus numbered $i = 1$ to n , and M is the mass of the bound nucleus. We may use atomic mass units (u) to calculate the nuclear binding energies according to the above Eq. (1.36) for any nuclide, ${}^A_Z\text{X}$, of Z number of protons, A number of protons + neutrons, and $N = A - Z$ number of neutrons as follows:

$$E_b = [(Zm_{\text{H}} + Nm_n - M_{\text{X}})931.494 \text{ MeV}/c^2]c^2 \quad (1.37)$$

where m_{H} is the atomic mass of hydrogen, m_n is the neutron mass, and M_{X} is the atomic mass of the nuclide of atomic number Z and mass number A , i.e., ${}^A_Z\text{X}$, and by definition $1 \text{ u} = 931.494 \text{ MeV}/c^2$. Atomic mass units are used in Eq. (1.37) because the number of electrons of the Z hydrogen atoms are the same as the electrons included in the atomic mass of the nuclide ${}^A_Z\text{X}$. The differences in electron binding energies of the hydrogen atoms and that

of the nuclide are negligible and ignored. Let us take an example and use atomic mass units to calculate the binding energy for the helium nucleus, i.e., ${}^4_2\text{He}$, which is equivalent to an alpha particle, as follows:

$$\begin{aligned}
 E_b &= [(2m_{\text{H}} + 2m_n - M_{{}^4_2\text{He}})931.494 \text{ MeV}/c^2]c^2 \\
 &= [((2)(1.007825032 \text{ u}) + (2)(1.008664915 \text{ u}) \\
 &\quad - 4.00260325 \text{ u})931.494 \text{ MeV}/c^2]c^2 \\
 &= 28.2956
 \end{aligned} \tag{1.38}$$

Because nuclei vary in their number of nucleons or mass number (A), it is common to express the nuclear binding energy in terms of the number of nucleons in the nucleus, that is, the binding energy per nucleon or E_b/A . In the case of the nuclide, ${}^4_2\text{He}$, the binding energy per nucleon is

$$E_b/A = 28.2956 \text{ MeV}/4 = 7.0739 \text{ MeV} \tag{1.39}$$

The values of the binding energies per nucleon for all of the nuclides provides a measure of how tightly bound the

nucleons are within a particular nucleus. Fig. 1.15 illustrates graphically the difference in the values of the binding energy per nucleon (E_b/A) as a function of the mass number (A) of the nucleus for nuclides over the entire range of mass numbers.

From Fig. 1.15 it is seen that the highest nuclear stability is found in the region of mass number $A = 50$ to 70 , and the most stable nuclei, that is, those nuclei that are most tightly bound belong to the “iron group” including ${}^{62}\text{Ni}$, ${}^{58}\text{Fe}$, and ${}^{56}\text{Fe}$ with binding energies per nucleon at a maximum of approximately 8.8 MeV . On either side of this maximum, illustrated in Fig. 1.15, are (1) the smaller nuclei in the range of $A = 2$ to 20 with lower binding energies per nucleon, which could fuse to yield larger and more stable nuclei with the release of energy or (2) the very large nuclei in the range of about $A \geq 120$, which could break apart into approximately equal mass number by fission to form smaller and more stable nuclei with the release of energy. Consequently the size of the nucleus and its binding energy per nucleon will govern whether nuclear fusion or fission would be feasible, and the energy released in both cases can be estimated directly from Fig. 1.15 or by calculation. Let us take examples of both cases, fission and fusion.

FIGURE 1.15 Binding energy per nucleon as a function of mass number. The scale between mass number 0 and 30 is broader than that illustrated for mass numbers 30–270. Several nuclides are identified along the curve. The most stable nuclei are ${}^{62}\text{Ni}$, ${}^{58}\text{Fe}$, and ${}^{56}\text{Fe}$ with E_b/A values of 8.794 , 8.792 and 8.790 MeV , respectively. Notice the small peak of highest stability at the top of the curve.

1. Nuclear fission

The nuclide ^{236}U , which results from the capture of a slow neutron by ^{235}U , is unstable. It takes on the characteristic of an unstable oscillating droplet. The nuclear droplet, which oscillates with the opposing forces of two positively charged nuclides, splits into two fragments with the liberation of an average energy of 193.6 MeV (Koch, 1995). The mass numbers of the fission fragments vary between 70 and 160, and the following is just one example, illustrating the fission of ^{236}U into the nuclide fragments ^{90}Sr and ^{143}Xe with the emission of 3 neutrons:

The binding energy (E_b) of the ^{236}U nucleus, *i.e.*, the difference in mass of the ^{236}U nucleus and the combined mass of its free component nucleons, is calculated as follows:

$$E_b = (M_{92 \text{ protons}} + M_{144 \text{ neutrons}}) - M_{^{236}\text{U}} \quad (1.41)$$

where $M_{92 \text{ protons}}$ is the mass of 92 protons, $M_{144 \text{ neutrons}}$ is the mass of 144 neutrons, and $M_{^{236}\text{U}}$ is the mass of the bound nucleus of ^{236}U . Using atomic mass units for the masses of the ^{236}U nucleus and its constituent nucleons, we calculate the binding energy (E_b) in atomic mass units (u) as

$$\begin{aligned} E_b &= [92(1.007825032 \text{ u}) + 144(1.008664915 \text{ u}) \\ &\quad - 236.0455682 \text{ u} \\ &= 237.9676507 \text{ u} - 236.0455682 \text{ u} = 1.9220825 \text{ u} \end{aligned} \quad (1.42)$$

Although the masses of the electrons are included in the atomic masses, the electron masses can be ignored since these are the same for the ^{236}U and the 92 hydrogen atoms. Values of the relative atomic masses are available from the National Institute of Standards database (<https://www.nist.gov/pml/atomic-weights-and-isotopic-compositions-relative-atomic-masses>). Using Einstein's equation for the equivalence of mass and energy we can convert the binding energy to MeV or

$$\begin{aligned} E &= mc^2 = [(1.9220825 \text{ u}) (931.494 \text{ MeV}/c^2)] c^2 \\ &= 1790.41 \text{ MeV} \end{aligned} \quad (1.43)$$

Dividing the binding energy by the number of nucleons in the nucleus (mass number, $A = 236$) will provide the binding energy per nucleon for ^{236}U or

$$(E_b/A)_{^{236}\text{U}} = 1790.41 \text{ MeV}/236 = 7.58 \text{ MeV/nucleon} \quad (1.44)$$

Similar calculations for the binding energies of the fission fragments ^{90}Sr and ^{143}Xe yield $E_b/A = 8.69 \text{ MeV/nucleon}$ for ^{90}Sr and 8.19 MeV/nucleon for ^{143}Xe . The calculated binding energies per nucleon for all of the isotopes of atoms may be obtained from the website <http://www.periodictable.com/Isotopes/054.132/index2.p.full.html>. Estimated values for the binding energies per nucleon (E_b/A) as a function of mass number (A) can be obtained from Fig. 1.15. Because the binding energies per nucleon for the two fission products are slightly different, we could average the two values simply to get an estimated figure for the amount of energy released. We can now estimate the energy released from ^{236}U fission or the Q value, using as an example, the fission reaction of Eq. (1.40) as follows:

$$\begin{aligned} ^{236}_{92}\text{U} &\rightarrow ^{90}_{38}\text{Sr} + ^{143}_{54}\text{Xe} + 3^1_0\text{n} \\ Q &= [(E_b/A)_{\text{fission products}} - (E_b/A)_{^{236}\text{U}}] \times 236 \text{ nucleons} \\ Q &= \left[\left(\frac{(E_b/A)_{^{90}\text{Sr}} + (E_b/A)_{^{143}\text{Xe}}}{2} \right) - (E_b/A)_{^{236}\text{U}} \right] \\ &\quad \times 236 \text{ nucleons} \\ Q &= \left[\left(\frac{8.69 \text{ MeV/nucleon} + 8.19 \text{ MeV/nucleon}}{2} \right) \right. \\ &\quad \left. - 7.58 \text{ MeV/nucleon} \right] \times 236 \text{ nucleons} \\ Q &= 202 \text{ MeV} \end{aligned} \quad (1.45)$$

Thus, approximately 200 MeV is the amount of energy released from ^{236}U fission, *i.e.*, neutron-induced fission of ^{235}U . The magnitude of the energy released from neutron-induced fission of ^{235}U would be an average figure because the actual amount of energy released would depend on the fission reaction, and there are many possible ways that the ^{236}U could break into two nuclides.

There are about 100 radionuclides of high mass number $A \geq 230$, which decay by spontaneous fission (SF), which involves the spontaneous noninduced splitting of the nucleus into two nuclides or fission fragments. A rough estimate of the energy released by fission reactions can be estimated quickly from Fig. 1.15. For example, ^{252}Cf undergoes SF in 3% of the decay events as an alternative to alpha decay. A rough estimate of the energy released in the SF is found by simply reading from Fig. 1.15 the binding energy per nucleon for a nuclide of mass number $A \approx 250$, which would be about 7.5 MeV, and the binding energy per nucleon for fission fragments that would have a mass number (A) in the range of 80–150, which varies between

8.5 and 8.3 or an average of ~ 8.4 MeV. The following calculation, in accord with Eq. (1.45), would give the approximate energy released as

$$Q \approx [(8.4 \text{ MeV/nucleon}) - (7.5 \text{ MeV/nucleon})] \\ \times 252 \text{ nucleons} \approx 230 \text{ MeV} \quad (1.46)$$

Nuclear fission is discussed in more detail further on in this chapter.

2. Nuclear fusion

Nuclides of very low mass number ($A < 20$) have nuclei (see Fig. 1.15) with relatively low binding energies, and if these nuclei could coalesce, a larger more tightly bound nucleus would form, and the overall process would release energy as described by Eq. (1.36). For Example, if two nuclei of deuterium (${}^2_1\text{H}$) were to fuse into a nucleus of helium (${}^4_2\text{He}$), equivalent to an alpha-particle, the energy released by the nuclear fusion could be estimated from Fig. 1.15. Taking the values of binding energy per nucleon (E_b/A) from Fig. 1.15 for ${}^2_1\text{H}$ to be ~ 1 MeV and that for ${}^4_2\text{He}$ to be ~ 7 MeV, the energy released would be estimated from the following as

$$Q = [(E_b/A)_{\text{He}} - (E_b/A)_{\text{H}}] \times 4 \text{ nucleons} \\ Q \approx [(\sim 7 \text{ MeV/nucleon}) - (\sim 1 \text{ MeV/nucleon})] \\ \times 4 \text{ nucleons} \approx 24 \text{ MeV} \quad (1.47)$$

The energy released is more precisely determined by calculating the binding energy, E_b , for the ${}^4_2\text{He}$ nucleus and for the ${}^2_1\text{H}$ nucleus according to Eq. (1.47). The nuclear binding energy for ${}^4_2\text{He}$ was previously calculated (see Eq. 1.38) to be 28.2956 MeV, and the precise binding energy per nucleon for ${}^4_2\text{He}$ would be $(E_b/A)_{\text{He}} = 28.2956 \text{ MeV}/4 = 7.0739 \text{ MeV}$. The nuclear binding energy for ${}^2_1\text{H}$ according to Eq. (1.37) is calculated as

$$E_b = [(m_{\text{H}} + m_n - M_{\text{H}})931.494 \text{ MeV}/c^2]c^2 \\ = [(1.007825032 \text{ u} + 1.008664915 \text{ u} - 2.014101778 \text{ u}) \\ 931.494 \text{ MeV}/c^2]c^2 \\ = 2.2245 \text{ MeV} \quad (1.48)$$

The binding energy per nucleon for ${}^2_1\text{H}$ would be $(E_b/A)_{\text{H}} = 2.2245 \text{ MeV}/2 = 1.11225 \text{ MeV}$. The

energy released in the fusion of two nuclei of deuterium to a nucleus of helium would be calculated according to Eq. (1.47) as

$$Q = [7.0739 \text{ MeV} - 1.11225 \text{ MeV}] \times 4 \text{ nucleons} \\ = 23.846 \text{ MeV} \quad (1.49)$$

The above calculated energy of 23.846 MeV for deuterium fusion agrees with the online computer calculated value of 23.846 MeV provided by the Brookhaven National Laboratory (BNL) of the National Nuclear Data Center (NNDC, 2018a,b): <http://www.nndc.bnl.gov/qcalc>. The deuterium fusion reaction is written as

The energy released in the deuterium fusion may be calculated according to Eq. (1.14) as

$$Q = (m_R - m_P)931.494 \text{ MeV/u} \quad (1.51)$$

where m_R and m_P are the rest masses of the reactants and products, respectively, in atomic mass units (u). Thus, the energy released in the fusion of two deuterium nuclei is calculated according to the above Eq. (1.51) as

$$Q = [2(2.014101778 \text{ u}) - 4.00260325 \text{ u}]931.494 \text{ MeV/u} \\ = 23.846 \text{ MeV}$$

The nuclear fusion reaction described by Eq. (1.50) is one that releases a relatively large amount of energy; but it has a low reaction cross-section or low probability of occurrence, and the energy not easily captured because most of the energy would be carried off by the gamma radiation. A more practical source of energy by nuclear fusion would be the fusion of deuterium and tritium nuclei according to the reaction:

When comparing the energy released from neutron-induced fission of ${}^{235}\text{U}$ (~ 200 MeV, See Eq. 1.45) and that produced by the fusion of deuterium and tritium nuclei (17.6 MeV, See Eq. (1.52) above), we can immediately see that there is more than a 10-fold greater magnitude of energy released by the neutron-induced fission reaction. However, if we evaluate the reactions in terms of fuel mass, we will find that the above deuterium-tritium fusion reaction is the most efficient for energy production. For example, let us now calculate and compare the energy yields per kilogram of fuel for both nuclear fission and nuclear fusion.

Neutron-induced ^{235}U Fission energy yield:

$$\begin{aligned}
E_{\text{yield}_{^{235}\text{U fission}}} &= \frac{\text{Reaction energy release}}{\text{Fuel mass}} \\
&= \frac{200 \text{ MeV}}{(M_{^{235}\text{U}} + M_{\text{neutron}})(1.660 \times 10^{-27} \text{ kg/u})} \\
&= \frac{200 \text{ MeV}}{(235.04392 \text{ u} + 1.00866 \text{ u})(1.660 \times 10^{-27} \text{ kg/u})} \\
&= 0.5104 \times 10^{27} \text{ MeV/kg}
\end{aligned} \tag{1.53}$$

Deuterium-Tritium (D-T) Fusion:

$$\begin{aligned}
E_{\text{yield}_{\text{D-T fusion}}} &= \frac{\text{Reaction energy release}}{\text{Fuel mass}} \\
&= \frac{17.6 \text{ MeV}}{(M_{^2\text{H}} + M_{^3\text{H}})(1.660 \times 10^{-27} \text{ kg/u})} \\
&= \frac{17.6 \text{ MeV}}{(2.01410 \text{ u} + 3.016049 \text{ u})(1.660 \times 10^{-27} \text{ kg/u})} \\
&= 2.1077 \times 10^{27} \text{ MeV/kg}
\end{aligned} \tag{1.54}$$

In the above Eqs. (1.53) and (1.54) the notation $M_{^{235}\text{U}}$, M_{neutron} , $M_{^2\text{H}}$, and $M_{^3\text{H}}$ refer to the masses of ^{235}U , the neutron, deuterium, and tritium in atomic mass units (u). Taking the ratio of energy yields of nuclear fusion over fission yields

$$\frac{E_{\text{yield}_{\text{D-T fusion}}}}{E_{\text{yield}_{^{235}\text{U fission}}}} = \frac{2.1077 \times 10^{27} \text{ MeV/kg}}{0.5104 \times 10^{27} \text{ MeV/kg}} = 4.13 \tag{1.55}$$

Thus, deuterium-tritium (D-T) nuclear fusion is more than four times as efficient than neutron-induced nuclear fission in terms of energy yield per mass of fuel consumption.

3. Nuclear fusion as an energy source

D-T fusion offers great promise as a future energy source, which would be more efficient and more environmentally friendly than neutron-induced fission. There are 448 nuclear power plants in 30 countries of the world operating on the basis of nuclear fission, which provides 16% of the energy needs of the world (IAEA, 2017). However, nuclear fusion is still in the developmental stage. The fusion of light nuclei is not possible under normal temperature and pressure because the repulsive Coulombic forces between atomic electrons and between positive charges of atomic nuclei prevent the nuclei from mingling into the required

close proximity for them to coalesce into one nucleus. However, at temperatures of about 100×10^6 °C, the nuclei of atoms become plasmas in which nuclei and electrons move freely with high kinetic energy sufficient for the nuclei to overcome their repulsive forces and combine. Because of the high temperatures required, the process is referred to as thermonuclear fusion.

In summary, the fusion of the light nuclei, such as those of deuterium (^2H) and tritium (^3H), release an energy per nucleon (MeV/u) or energy per unit of material considerably greater than can be achieved by nuclear fission as calculated above. Thermonuclear fusion requires a large energy input to achieve high temperatures and maintain nuclear plasma; but once achieved, the energy output is greater than the input. An additional advantage of the nuclear fusion of deuterium and tritium is that no hazardous radioactive wastes are direct products of the reaction. The products of the thermonuclear fusion of deuterium and tritium nuclei are alpha particles and neutrons. The neutrons can produce some radioactive isotopes in the surrounding reactor shielding material, but most would be short-lived and there would be no need to store radioactive waste in geological deposits for long periods of time as is the custom with nuclear fission.

a. Advances in fusion reactor development

Nuclear fusion reactors or controlled thermonuclear reactors (CTRs) are under development to achieve nuclear fusion as a practical energy source. The reactors are based on maintaining plasmas at high temperature through magnetic confinement in a tokamak. The word “tokamak” is derived from the Russian “toroidal kamera ee magnetnaya katushka” meaning “torus-shaped magnetic chamber”, which was initially designed in 1951 by Russian physicists and Nobel Laureates Andrei Sakharov and Igor Tamm (UIC, 2005). The reactors are based on maintaining plasmas through magnetic or inertial confinement. A deuterium-tritium (D-T) plasma burning experiment was performed with 0.2 g of tritium fuel with the Joint European Torus (JET) reactor in the UK in 1991 (JET Team, 1992), and a higher power D-T experimental program with 20–30 g of tritium was continued on the Tokamak Fusion Test Reactor (TFTR) at Princeton in 1993. The European device, JET, achieved 16 MW of fusion power over approximately 1s in 1997, and a long-duration plasma of 4.5 minutes was sustained with a heating power of 3 MW in the Tore Supra device at Cadarache, France in 2002 (Magaud et al., 2004). The Experimental Advanced Superconducting Tokamak (EAST) in China had a successful plasma test in 2006 (Wan et al., 2007; Xiao et al., 2008). The EAST tokamak was an advanced design for toroidal and poloidal magnetic confinement of plasma,

which is a design currently undergoing construction in Cadarache, France by the international project ITER described in the following paragraphs. In addition, a plasma function with diagnostic tests was conducted on the Korea Superconducting Tokamak Advanced Research (KSTAR) fusion reactor in 2008 (Park et al., 2010).

Under the auspices of the International Atomic Energy Agency, the international project ITER, meaning “The Way” in Latin, to signify “the way to new energy” was given birth in 1988 with the purpose of designing and constructing a fully operational prototype fusion reactor. There are seven signatories of ITER including China, the European Union, India, Japan, Russian Federation, Republic of Korea, and the United States, all of which will provide the financial input and technical cooperation required for the construction and operation of the reactor. In addition, 35 nations are collaborating in the construction of this large-scale Tokamak. The design of the ITER Tokamak fusion reactor was approved by the signatory members in 2001, and the site where the reactor would be constructed was agreed in 2005 to be in Southern France at Cadarache near Aix-en-Provence. The fusion reactor now under construction will begin plasma experimentation in 2025, and the reactor is expected to be fully functional with deuterium-tritium fusion by the year 2035 (<https://www.iter.org/>). The prototype reactor has the purpose of demonstrating that fusion can produce relatively safe energy with a high net energy yield, that is, more energy output than energy put into the system. Fusion energy production via a large-scale commercial reactor with the capacity to produce electric power and with the capacity of producing its own tritium fuel will be the next step after ITER. This full-scale commercial fusion reactor is planned with the project DEMO or Demonstration Power Plant. DEMO is expected to begin operation with connection to the electrical grid in the year 2050 (<https://www.euro-fusion.org/programme/>).

b. Fusion power reactor

A schematic cutaway view of a fusion power reactor, based on magnetic confinement of the hot plasma, is illustrated in Fig. 1.16. Five major components of the reactor are identified by the encircled letters (A) through (E). Firstly, deuterium and tritium fuel ($D + T$) are introduced into an inner vacuum chamber at (A). This is a closed chamber having the shape of a torus. The deuterium and tritium are heated in excess of 150 million $^{\circ}\text{C}$ and enter into the plasma state (B). Heating, which is required to take the deuterium and tritium to the plasma state, illustrated at (A) in Fig. 1.16, is accomplished by three means, which are the following (1) Ohmic heating, which is the result of the changing magnetic fields used to confine the plasma within the center of the vacuum chamber. These magnetic fields create a very intense electrical current through the plasma causing the charged particles to travel and collide creating a resistance and heat, referred to as ohmic heating; (2) neutral beam injection and (3) high-frequency electromagnetic waves. As described by ITER (<http://www.iter.org/sci/plasmaheating>), neutral beam injection involves accelerating high-energy particles into the plasma. Deuterium particles are accelerated to the required energy level and subsequently are stripped of their electrons with an “ion beam neutralizer”. Upon entering the plasma at high velocity, the high-energy deuterium nuclei undergo collisions and thus transfer their energy to the plasma particles. This process brings the temperature of the plasma close to that required for deuterium-tritium fusion. Irradiation with high-frequency electromagnetic radiation increases the temperature of the plasma to the desired ~ 150 million $^{\circ}\text{C}$, which is more than sufficient for fusion to occur. The hot plasma is kept within the central region of the inner chamber by magnetic confinement by means of toroidal and poloidal field coils. The plasma produces energy from the fusion of deuterium and tritium with the emission of 3.52 MeV

FIGURE 1.16 Schematic and cutaway view of a fusion reactor based on a magnetic confinement of plasma: (A) vacuum chamber, (B) plasma, (C) plasma radiation, (D) blanket, and (E) electricity production. For the color version of the figure, the reader is referred to the online or electronic version of the book. From Magaud et al. (2004), printed with permission from Elsevier © 2004.

helium nuclei and 14.06 MeV neutrons according to the fusion reaction

The high-energy 14.06 neutrons account for 80% of the energy liberated from the above nuclear fusion. The high-energy neutrons possess no charge and thus can penetrate the magnetic confinement and deposit energy into the outer blanket of the chamber. The energy liberated is absorbed by an outer chamber blanket illustrated at (C) of Fig. 1.16, and the heat is utilized to produce steam to operate a turbine and generate electricity at (E). The neutrons thus lose energy and are absorbed by lithium nuclei in a breeding blanket at (D). The breeding blanket contains a high concentration of lithium to produce tritium according to the reaction

With the breeder blanket, The ITER fusion reactor will be equipped to produce more tritium fuel than it consumes to produce power. The tritium produced by the fusion reactor can be introduced together with deuterium as fuel when required. Ash, consisting of helium ions and unconsumed deuterium and tritium, are extracted from the inner chamber, as illustrated in Fig. 1.16 and separated to collect the helium; and the unconsumed deuterium and tritium are reintroduced into the inner chamber. The cryostat, illustrated in Fig. 1.16, is the cooling system and physical enclosure surrounding the vacuum chamber providing thermal insulation for the superconducting magnets required for plasma confinement.

c. Advantages of fusion over fission for power

Fusion is the energy of the future, and we may state optimistically that fusion is the energy of the relatively near future. The fusion of tritium and deuterium in a tokamak reactor has been demonstrated. As described previously, the ITER reactor will begin plasma experimentation in the year 2025, and the DEMO reactor, which will be the first full-scale fusion power plant, is planned to begin operation with connection to the electric power grid in year 2050. In 3 decades, we should witness a functioning full-scale fusion power plant producing relatively safe electric power and more power output than the energy consumed by the reactor. By the next century, we should expect and hope that fusion will be the energy of choice over power reactors based on nuclear fission that now produce considerable radioactive waste. Thus, fusion reactors together with solar and wind power would constitute sources of electric power that produce neither greenhouse gases nor long-lived radioactive waste.

Current optimism over fusion reactors for electric power is based on overwhelming advantages that deuterium-tritium fusion offers over current nuclear fission power

reactors. These advantages are listed and described briefly as follows:

(i) No danger of a runaway nuclear chain reaction.

Unlike nuclear fission, any misfortune such as a tsunami, earthquake, or simple negligence would not result in any out-of-control chain reaction that could spew radioactive contamination into the environment. Nuclear chain reactions are not involved in a fusion reactor. Any misfortune, that could break down the reactor, would automatically and immediately shut the fusion reactor down, because the continuous heating and feeding of deuterium and tritium into the plasma would be disrupted. As noted by Magaud et al. (2004) the slightest uncontrolled interference with the environment of a fusion reactor causes the rapid cooling and automatic shutdown of the fusion reaction.

(ii) No long-lived radioactive waste. Fusion reactors do not use or produce long-lived radioactive materials. Fusion reactors do not produce long-lived fission products. The fusion of deuterium and tritium produce alpha particles and high-energy neutrons. The neutrons would produce heat, more tritium fuel upon reaction with Li-6, and mostly short-lived radionuclides when neutrons are absorbed by nuclei of the materials with which the fusion reactor is constructed. These materials would have a relatively short half-life and would not require deep underground storage facilities for long-lived radioactive waste now necessitated by current fission reactor waste. In point of fact, if we compare an equal amount of energy produced by a fusion reactor and a coal-burning plant, the burning of coal would produce more long-term radioactive waste, as the ash from coal burning contains long-lived radioactive uranium and thorium (Magaud et al., 2004). Fig. 1.17 illustrates the relative amounts of long-lived radioactive waste that result from fission, coal, and fusion. Fission and coal burning leave behind significant radioactive waste beyond 500 years; whereas, after only 50 years of fusion reactor shutdown, there is no significant long-lived radioactive waste and no need for deep underground waste storage.

(iii) No radioactive fuel is required. The fuel required for fusion is deuterium and lithium, both of which are not radioactive. Although the fusion of deuterium with tritium is the reaction liberating energy for power, the elements considered as fuel components for fusion, are deuterium and lithium, which are the elements required in relatively large quantities. Tritium is needed only in relatively small quantities for the startup of the fusion reaction. The tritium, which is radioactive with a relatively short

FIGURE 1.17 Radiotoxicity of fusion waste after reactor shutdown. The green shaded area shows the significant difference between coal and fusion with respect to long-term radioactive waste production. For the color version of the figure, the reader is referred to the online or electronic version of the book. Figure from Magaud et al. (2004), reprinted with permission from Elsevier © 2004.

half-life, would be produced by the neutrons emitted during fusion and subsequently fed into the fusion chamber when needed. All of the tritium needed for power would be produced by the fusion reactor.

- (iv) **The only fuel elements deuterium and lithium, required for fusion, are abundantly available.** Deuterium is readily extracted from seawater, which contains inexhaustible amounts of deuterium (33 g of deuterium/m³ of seawater), and lithium would be used in the reactor to breed the required tritium for the fusion reaction. Magaud et al. (2004) note that < 1 kg of deuterium and < 10 kg of naturally occurring lithium would be required for a day's generation of 1000 MWe of power. Lithium deposits are massive with global deposits totaling 31.1 Mt (million tons) of Li (Kesler et al., 2012). In addition, the world's oceans contain 44.8 billion tons of recoverable lithium (Yaksic and Tilton, 2009).
- (v) **Extraction of fuel for fusion will have minimal effect on the environment.** Obtaining deuterium and lithium fuel for fusion from seawater will cause minimal effect on the environment; whereas, the mining of uranium deposits for fission reactor fuel causes significant effect on the environment.
- (vi) **The fusion reactor will yield more power than energy input.** The ITER prototype fusion reactor will require 50 MW of input power and it is designed to produce 500 MW of output power. The reactor

will have a Q value ≥ 10 , that is, it is designed to produce 10 times the power it will consume. This will be the first reactor to produce net energy (<https://www.iter.org/proj/itermission>).

- (vii) **Not necessary to evacuate population in event of severe accident.** The overall radioactivity at a fusion reactor would be minimal. The only radioactive isotope involved in the production of fusion energy is tritium, and because tritium is not a fuel component but produced in the lithium breeding blanket to be fed into the plasma as needed, the tritium inventory on site would be minimal. Also, as noted by Magaud et al. (2004), to minimize emission there would be "three confinement barriers: the vacuum vessel, the cryostat, and the reactor building itself ... there is no accident sequence that could impugn reactor integrity. Even in the event of a severe accident, it would not be necessary to evacuate the population."
- (viii) **Overall costs of fusion energy would be comparable to those of renewable resources.** Magaud et al. (2004) provides an excellent review of the overall costs of fusion power relative to other sources, such as fossil fuel, fission, and renewable resources such as solar and wind power. A brief summary will be provided here. The principle direct costs in the utilization of all energy sources are the investment, operation, maintenance, replacement of components, and fuel. Fuel costs of fusion account for less than 1% of the total kilowatt-hour costs; whereas, in the case of nuclear fission, fuel costs amount to $\sim 35\%$ of direct costs. Other costs, referred to as externalities, are measured in terms of the cost of effects on our environment and health, which includes fuel extraction, plant construction, operation, accident, dismantlement, and disposal of a dismantled power source. For example, the nuclear fuel cycle, required for nuclear fission, involves mining and nuclear enrichment, which have an effect on our environment. So does the mining and burning of coal. Fusion is predicted to have one of the lowest costs per kilowatt hour of energy produced similar to that of the renewable resources such as wind and solar, as determined by the European Union (ExternE Studies: http://www.externe.info/externe_d7/).

D. Nuclear models

Since Ernest Rutherford's alpha-scattering experiment that led to the discovery of the atomic nucleus (Rutherford, 1911), physicists have used experimental and empirical data to establish nuclear models to describe the nucleus. The nuclear models, that have been established, provide insight into the stability of the atomic nucleus and an understanding of the processes of nuclear decay.

1. Liquid drop model

During a meeting of the Royal Society in London on February 7, 1929, the Russian-born physicist George Gamow (1904–68) presented his thoughts on the properties of the nucleus and that the nucleus would possess forces similar to those of a liquid drop (Gamow et al., 1929). A very complete and detailed account of Gamow's conception of the liquid-drop model of the nucleus is given by Stuewer (1997). The writer will give here a small portion of this historical account, which provides the reasoning used by Gamow. At the time Gamow first presented his ideas on the liquid-drop characteristics of the nucleus, the neutron had not been discovered, and the alpha particle was thought to be the building block of the nucleus. In the discussion, Gamow et al. (1929) commented

Such an assembly of alpha particles with attractive forces between them, which vary rapidly with the distance may be treated somewhat as a small drop of water in which the particles are held together by surface tension.

Gamow (1930) continued his development of the liquid-drop model, even before the neutron was discovered by Chadwick (1932a,b) to be a component particle of the nucleus. After the discovery of the neutron, Heisenberg (1934) presented his analysis of exchange forces and general theory of nuclear structure at the 7th Solvay Conference in Brussels in October 1933. At the meeting, Heisenberg reported his theory on nuclear structure, which could be “considered as corresponding to a form of Gamow's drop model made precise by the neutron hypothesis” (Stuewer, 1997). Only a year later, Heisenberg's student von Weizsäcker (1935) derived an empirical equation that would yield the binding energy of the nucleus as a function of its mass number (A), incorporating into the equation the various properties of the nucleus characteristic of a liquid drop. Von Weizsäcker's equation for the liquid-drop model of the nucleus gained notoriety when Hans Bethe and Robert Bacher (Bethe and Bacher, 1936; Bethe, 1937) from Cornell University reworked Weizsäcker's equation to include a pairing energy, which was referred to subsequently as the Bethe–Weizsäcker mass formula.

Gamow's original conception of the nucleus with the physical properties of a liquid drop soon became useful in the interpretation of nuclear fission. In December of 1938, Otto Hahn and Fritz Strassmann (Hahn and Strassman, 1939a,b) had confirmed that barium ($Z = 56$) was a product of neutron bombardment of uranium ($Z = 92$). Hahn could not arrive at an explanation of how a nuclide of lower atomic number would result from the reaction of a neutron with a nucleus of much higher atomic number. Hahn asked his former colleague and collaborator, Lise Meitner for an explanation. Meitner and Frish (1939) considered the recently developed concept of the nucleus having the properties of a liquid drop. They arrived at the conclusion

FIGURE 1.18 Neutron capture by uranium-235 and subsequent fission of unstable uranium-236. The capture of a slow neutron by uranium-235 yields the nuclide uranium-236, which is unstable, capable of oscillating like a liquid drop and breaking into two smaller nuclides X and Y generally of different masses and of atomic numbers that add up to $Z = 92$ (the atomic number of the parent uranium) plus the emission of an average of 2.4 neutrons and energy (approximately 200 MeV). The emission of three neutrons is illustrated. The uranium-236 nuclides break into two fission fragments in as many as 30 different possible ways producing, therefore, 60 different nuclide fission fragments.

that the capture of a neutron by the uranium nucleus attributes to the nucleus a degree of instability, whereby it would oscillate like a liquid drop forming a dumbbell shape (see Fig. 1.18) and that the apposing Coulomb forces of the fat sections of the dumbbell would cause the nucleus to split apart into two nuclides (fission fragments) of smaller atomic number, and that the sum of the atomic numbers of the two fission fragments would equal that of the original uranium ($Z = 92$). Meitner and Frisch concluded that if barium ($Z = 56$) was a product (fission fragment) of neutron bombardment of uranium ($Z = 92$), the other fission fragment would be krypton ($Z = 36$), as described by the following reaction:

They coined the word “fission” by borrowing the word from biology, a word used to describe the splitting of bacteria cells. The liquid-drop model remains to this day an excellent means of describing nuclear fission, and the liquid-drop model formula has been used to predict spontaneous fission half-lives (Ronnen, 2004).

Today the liquid-drop model formula is referred to often as the Weizsäcker liquid-drop model formula or the semi-empirical mass formula. It has been refined by many researchers to include theory with empirical measurements

including those described by Evans (1955), Friedlander et al. (1964), Ronen (2004), Serway et al. (2005), Mahboub (2008) and Royer (2008), and the formulas vary slightly among research reports; however, all have the basic mathematical structure as the equation first reported by von Weizsäcker. The liquid-drop formula described by Evans (1955), Friedlander et al. (1964), Choppin et al. (2002), Gould et al. (2004), and Serway et al. (2005) is basically the following:

$$E_b = a_v A - a_s A^{2/3} - a_c \frac{Z(Z-1)}{A^{1/3}} - a_{sy} \frac{(N-Z)^2}{A} \pm \delta_p(Z, N) \quad (1.59)$$

where E_b is the nuclear binding energy in MeV, A is the mass number, N is the neutron number, Z is the atomic number, a_v , a_s , a_c , and a_{sy} are coefficients for the volume energy, surface energy, Coulomb energy, and the symmetry energy, respectively, and $\delta(Z, N)$ is a pairing energy term described subsequently. The values of the coefficients a_v , a_s , a_c , and a_d reported by Woan (2000) are $a_v \approx 15.8$ MeV, $a_s \approx 18.0$ MeV, $a_c \approx 0.72$ MeV, and $a_{sy} \approx 23.5$ MeV. The coefficients vary slightly among research reports depending on the data used to obtain the mathematical best fit of the equation to measured values of nuclear binding energy, and the equation generally agrees with measured values to within a few percent for nuclides of $A > 40$. The various terms of the liquid-drop equation (Eq. 1.59) are described as follows:

Volume Energy, $a_v A$. The volume energy term assigns a direct proportionality of the nuclear volume to the total binding energy of the nucleus, i.e., the nuclear volume increases in proportion to the number of nucleons. The extension of the binding energy throughout the entire volume of the nucleus is a consequence of the short range and saturation characteristics of the nuclear forces. The strong nuclear forces binding neutrons and protons in the nucleus extend throughout the nuclear volume.

Surface Energy, $a_s A^{2/3}$. The surface energy term is negative, as the nuclear forces binding the nucleons are unsaturated at the surface similar to the surface tension effect that occurs with a liquid drop (see Fig. 1.19) and there is thus a reduction of binding at the surface. The nucleons at the surface have fewer neighboring nucleons with which to bind resulting in a reduction in binding energy as a function of surface area. The surface effect will increase with surface area, and surface area of a sphere is defined as πr^2 . Since the radius of the nucleus is proportional to the mass number ($r \propto A^{1/3}$) as defined by Eq. (1.28), the surface area term can be written as being proportional to $A^{2/3}$.

Coulomb Energy, $a_c (Z(Z-1)/A^{1/3})$. The Coulomb energy term takes into account the repulsive Coulomb

FIGURE 1.19 Nuclear forces (arrows) binding a nucleon at the nuclear surface (A) and a nucleon within the nucleus (B). The binding forces of the nucleon at the surface are unsaturated, as there are fewer neighboring nucleons with which to bind compared to nucleons within the nucleus. The phenomenon is similar to that which occurs in the binding of molecules of a liquid drop resulting in surface tension.

forces of the protons in the nucleus. The nucleus contains Z protons and their long-range Coulomb forces interact with the remaining $Z-1$ protons. The Coulomb force therefore extends throughout the nucleus with radius proportional to $A^{1/3}$ (see Eq. 1.28), which is included in this Coulomb energy term of the liquid-drop model.

The strong nuclear binding forces between neutrons and protons in the nucleus, which are of short range, counteract the Coulomb repulsive forces. Thus, throughout the Chart of the Nuclides among the stable nuclei with $Z > 20$, we will find that their nuclei contain more neutrons than protons. If we look throughout The Chart of The Nuclides, we will notice that the stable nuclides of low atomic number ($Z \leq 20$) will have an N/Z ratio of ~ 1 . However, as the atomic number increases ($Z > 20$), the N/Z ratio of the stable nuclides increases gradually and reaches as high as ~ 1.5 (e.g., $^{209}_{83}\text{Bi}$, $Z = 83$, $N/Z = 1.518$). Furthermore, there are no stable nuclides of atomic number greater than 83.

In brief, the importance of the N/Z ratio to nuclear stability is explained on the basis of the existence of strong short-range nuclear binding forces, which are charge independent, and the long-range repelling Coulomb forces between protons. The short-range strong nuclear forces extend to a distance of ≈ 2 fm (2 fermi or 2×10^{-15} m), which is close to the radius of a small nucleus, such as that of ^4_2He (see Section VI.A). These attractive strong nuclear forces are binding exchange forces that have charge independence (see Section VI.B). The binding exchange forces exist therefore, regardless of charge on the particles, between two protons, two neutrons, and a proton and neutron. Thus, at short distances within 2 fm, the strong forces between n-n, n-p, and p-p are equal and charge

independent. However, at distances beyond 2 fm there exists repelling Coulombic forces between the positively charged protons that act to force them apart. For nuclides of low Z , the attractive nuclear forces exceed the repelling Coulombic forces when $N \approx Z$. However, increasing the number of protons (e.g., $Z > 20$) further increases the strength of the repelling Coulombic forces over a larger nucleus, which will tend to force the nucleus apart. Therefore, additional neutrons, $N > Z$, provide additional strong attractive nuclear forces needed to overcome the repelling forces of the larger proton population. Fig. 1.20 illustrates a plot of the stable nuclides as a function of their N and Z numbers. The N/Z ratio of the stable nuclides (dots on the graph), illustrated in Fig. 1.20, increases significantly as a function of Z for nuclides of $Z > 20$. As the atomic number increases further, $Z > 83$, all nuclides are unstable. Nuclear stability is not achieved, when the number of protons in the nucleus exceeds 83.

Volume Symmetry, $a_{sy}((N - Z)^2 / A)$. The volume symmetry term quantifies the contribution of nuclear symmetry to the binding energy. Among the light nuclei, the unstable nuclei reside on either side of the symmetrical term $N = Z$. Thus, a negative sign is assigned to this symmetry term, which increases according to $(N - Z)$. Nuclear stability among the larger nuclei is achieved by an increase in the N/Z ratio (see Fig. 1.20), as the strong short-range binding nuclear forces between neutrons and protons (see Section VI.B) are needed to hold the nucleus together over the entire volume of the nucleus. As these short-range n-p binding forces do not reach throughout the volume of the nucleus, the probability of occurrence of n-p binding within a nucleus would be inversely proportional to the nuclear volume or A^{-1} .

Pairing Energy, $\pm \delta_p(Z, N)$. The pairing energy term may have a positive sign whereby the term adds to the nuclear binding energy, or a negative sign diminishing the nuclear binding energy. Nuclei that have an even numbers of protons and even number of neutrons (even Z , even N) are known to be the most stable of all nuclei due to proton-proton spin coupling and neutron-neutron spin coupling (see Section VI.D.2 below). The pairing energy term for the binding energy of these nuclei are assigned a value of $+34/A^{3/4}$ MeV. Nuclides with even Z , odd N or odd Z , even N are generally less stable than even-even nuclides, and thus the even-odd and odd-even (i.e., odd A) nuclides are assigned a value of zero to the pairing energy term. The least stable of the nuclides are those with odd Z and odd N (i.e., odd-odd nuclides), and these are assigned a pairing energy term of $-34/A^{3/4}$ MeV. The negative value of this term would diminish the total binding energy of Eq. (1.59) for the liquid-drop model.

FIGURE 1.20 Plot of stable nuclides (dots). The number of neutrons (N) is plotted against the number of protons (Z) in the nuclei of the stable atoms. The straight line represents $N = Z$. Only 13 nuclides in the region $Z \leq 20$ are stable with an equal number of neutrons and protons ($N = Z$).

Thus, the pairing energy term would have the following values as summarized by Woan (2000) and Gould et al. (2004):

$$\pm \delta_p(Z, N) \approx \frac{34}{A^{3/4}} \begin{cases} +1 & \text{for even - even} \\ 0 & \text{for } A \text{ odd} \\ -1 & \text{for odd - odd} \end{cases} \quad (1.60)$$

The liquid-drop model is useful in describing certain properties that may attribute stability or instability to atomic nuclei, and it has proven successful in explaining nuclear fission in large nuclei. However, the liquid-drop model does not provide insight into the fine organized structure and spin coupling of protons and neutrons in the nucleus that attribute stability to certain nuclei as provided by the shell model described subsequently.

2. Shell model

Our knowledge of the shell structure of the atomic nucleus has its beginnings with the independent work of Maria Goeppert-Mayer while at the Argonne National Laboratory in the US (Goeppert-Mayer, 1948a; b, 1949) and J. Hans D. Jensen, from the University of Heidelberg, Germany (Haxel et al., 1949). They subsequently collaborated with a book on nuclear shell structure (Goeppert-Mayer and Jensen, 1955a,b). For this work they were awarded the 1963 Nobel Prize in physics, which they shared with Eugene Paul Wigner. This award made Maria Goeppert-Mayer the second woman to receive the Nobel Prize in physics since Marie Curie.

Maria Goeppert-Mayer's opportunity for discovery came while voluntarily collaborating at the University of Chicago's Institute for Nuclear Studies (now known as the Enrico Fermi Institute). At the institute she collaborated with Edward Teller in a search for the cosmological model of the

origin of the universe. While compiling data she studied the abundance of the elements and found that there were certain elements that were highly abundant, and she found a correlation between the abundance of these elements and specific numbers of neutron and protons in their nuclei. J. Hans D. Jensen at the Institute of Theoretical Physics in Heidelberg together with his collaborators Otto Haxel at the Max Planck Institute in Göttingen and Hans E. Suess of the Institute of Physical Chemistry at Hamburg came to a similar conclusion that certain elements with particular numbers of neutrons and protons were particularly stable. It is interesting to note, that at both sides of the globe, the discoveries were made simultaneously and independently. When the stage is set, the discoveries will be made.

The numbers of protons and neutrons, correlated to particularly stable nuclei, were called the “magic numbers”. In the words of Goeppert-Mayer in her Nobel Lecture

What makes a number magic is that a configuration of a magic number of neutrons, or of protons, is unusually stable whatever the associated number of the other nucleons. The magic numbers, as we know them today, are: 2, 8, 20, 28, 50, 82, 126 and most importantly, they are the same for neutrons and protons.

Nuclides containing a magic number of neutrons and/or protons are listed in Table 1.5. Goeppert-Mayer (1963) pointed out that Sn ($Z = 50$) is the element with the largest

number of stable isotopes among all of the elements in the Periodic Table. There are six stable nuclides with 50 neutrons and 7 stable nuclides with 82 neutrons, whereas normally one will find only 2 or 3 stable nuclei in the Chart of the Nuclides having identical numbers of neutrons.

Some nuclides are called “doubly magic” because they have equal numbers of protons and neutrons that are magic numbers. The nuclide ${}^4_2\text{He}$ has a high binding energy, *i.e.*, it is very tightly bound (see Fig. 1.15), and an extra proton or neutron cannot be attached to its nucleus, as evidenced by the fact that ${}^4_3\text{Li}$ and ${}^5_2\text{He}$ do not exist. In addition, ${}^{16}_8\text{O}_8$, which is also “doubly magic”, is very stable. A large amount of energy would be required to remove a neutron from the ${}^{16}_8\text{O}_8$ nucleus; whereas, the addition of an extra neutron to its nucleus to form ${}^{17}_8\text{O}_9$ would result in a weakly bound neutron, which is evidenced by the low natural abundance of ${}^{17}\text{O}$ (0.04%) compared to ${}^{16}\text{O}$ (99.76%).

The breakthrough in the development of the nuclear shell model came with the conclusion that the protons and neutrons in the nucleus exhibit nuclear spin coupling effects, which result in shifts in their energy levels within the nucleus, similar to what occurs with electrons in their orbitals about the atom. Pauli’s Exclusion Principle, which was applied to atomic electrons, is also applied to the nucleons in the nucleus. The Exclusion Principle states that no two protons or two neutrons in a nucleus could exist in the same quantum or energy state. The proton or

neutron can exist in two spin quantum states, namely $+1/2$ (i.e., spin-up) or $-1/2$ (i.e., spin-down). Goeppert-Mayer explained in her Nobel lecture that there is a strong interaction between spin and orbital angular momentum, whereby spin-up and spin-down refers to the spin being parallel or antiparallel to the orbital angular momentum. She provided evidence that this spin interaction raised considerably the energy levels of nuclei that contained 9, 21, 29, 51, or 83 protons or neutrons, or 127 or 128 neutrons, thereby attributing a high degree of stability to nuclei that contain 8, 20, 28, 50, 82 protons or neutrons, or 126 neutrons. The numbers 8, 20, 28, 50, 82, and 126 refer to closed shells of protons or neutrons attributing a high degree of stability to nuclei with these nucleon numbers. The closed shells of nucleons in the highly stable nuclei is analogous to the closed electron shells of the noble gases, which attribute to these gases a high degree of chemical inertness. Thus, protons and neutrons exist in the nucleus in different energy states in structured orbitals similar to the external electron orbitals of the atom. In Section VI.D.1 it was discussed how stability is achieved in the light nuclei ($Z < 20$) when $Z = N$, and this was illustrated previously in Fig. 1.20. In accord with the Exclusion Principle the nucleons are packed in the nucleus according to energy levels with two protons of opposite spin and two neutrons of opposite spin per energy level. As a proton or neutron is added to the nucleus, it will occupy the next highest energy state, and the increase in energy state of the nucleus can decrease its stability. Fig. 1.21 illustrates how the additional proton in ^{12}N compared to ^{12}C attributes a higher energy state to the ^{12}N nucleus, whereby it decays to the stable ^{12}C by the conversion of a proton to a neutron via positive beta decay. Also, an extra neutron in the nucleus of ^{12}B places that nucleus in a higher energy state compared to ^{12}C . The ^{12}B achieves stability by conversion of the excess neutron to a proton to form stable ^{12}C via negative beta decay.

In her Nobel lecture Maria Goeppert-Mayer provided evidence for the increased instability of nuclei when additional neutrons are added to nuclei above the magic numbers, which represent closed shells at 2, 8, 20, 28, 50, 82, and 126 neutrons. Fig. 1.22 illustrates the β^- -decay energies of various nuclides with $N-Z=3$. Maria Goeppert-Mayer explained the curve as follows:

One would expect to find a smooth curve, sloping downward. Except for one point it is indeed so, This point is ^{39}Ar with 21 neutrons and 18 protons. A smooth interpolation of the curve would predict ^{39}Ar to be stable ... However, ^{39}Ar is unstable against β^- emission by about 0.5 MeV. The explanation of this anomaly is the low binding energy of the 21st neutron, while the 19th proton into which it is transformed has the higher binding energy of the proton shell which closes at 20. That the energies drop again sharply is due to the fact that now $Z=20$ is involved. These types of discontinuity occur at all magic numbers.

FIGURE 1.21 Nuclear potential energy-well illustrations of the pairing of nucleons in the isobars ^{12}N , ^{12}B , and ^{12}C . The neutrons and protons are illustrated with arrows to represent opposite spin states, spin up (\uparrow) and spin down (\downarrow). Only two nucleons of opposite spin state are allowed per energy level (E) in accord with the Pauli Exclusion Principle. The protons are illustrated at a higher energy level than the neutrons because of the added positive Coulomb potential of the protons. The ridge, at energy levels above those occupied by the protons, represents the Coulomb potential barrier to charged particles from entering or escaping the nucleus. The nuclear radius is represented by r .

A similar discontinuity of the β^- -decay energies in the neighborhood of $N=50$ is illustrated in Fig. 1.23. The addition of a single neutron to the nucleus of $N=50$ increases the energy state of that nucleus illustrated by the higher decay energy of the nucleus of ^{89}Sr with $N=51$ compared to ^{85}Kr with $N=49$. This is only one of several examples given by Goeppert-Mayer (1972) of nuclear stability attributed to the closing of a neutron shell at $N=50$.

The highest magic number of 126 occurs only for the closing of a neutron shell. Thus, it would be expected that the 127th and 128th neutrons would be less tightly bound, and that these nuclides would be at higher and less stable energy states compared to nuclides with 126 neutrons. This is just the case, as illustrated in Fig. 1.24. In the case of α -decay there is the emission of two neutrons together with two protons. As illustrated in Fig. 1.24, the α -particle decay energy is the highest for nuclides with 128 neutrons, and

FIGURE 1.22 Beta decay energies in the neighborhood of $N = 20$. [Goeppert-Mayer \(1963\)](#); reprinted with permission © The Nobel Foundation 1958.

this drops sharply when the 128th and 127th neutron is removed from the nucleus.

For further information on this subject matter the reader is invited to peruse works by [Goeppert-Mayer and Jensen \(1955a,b, 1965\)](#), [Goeppert-Mayer \(1964\)](#), [Choppin et al. \(2002\)](#), and [Rowe and Wood \(2010\)](#).

3. Collective model

The collective model of the nucleus combines aspects of the liquid-drop and shell models, which provides a description of the collective properties of the nucleus. The oldest model was the liquid-drop model described previously. This model was very useful in describing

certain nuclear reactions, such as nuclear fission. After the liquid-drop model came the shell model, which gave an organized picture of the nucleons in different energy states in structured orbitals. This provided an explanation for the stability of nuclei with certain “magic numbers”. However, neither model could provide an explanation for excited states of the nucleus, which are a result or consequence of the collective action of the nucleons. The collective model, for which Aage Bohr (son of Niels Bohr), Ben Mottelson, and James Rainwater received the 1975 Nobel Prize in physics, depicts the nucleus with both the properties of a liquid drop and the ordered structure of the nucleons providing an explanation of excited states of the nucleus as a consequence of its rotations and vibrations.

FIGURE 1.24 Energy release in alpha decays. *Goeppert-Mayer (1963); reprinted with permission © The Nobel Foundation 1958.*

Certain nuclei, particularly heavy nuclei ($A > 150$), exhibit large electric quadrupole moments. This property, which is a charge distribution that deviates from what one would encounter with a symmetrical spherical nucleus. This property clearly indicated that certain nuclei were not spherical in shape, but that they were deformed or ellipsoidal in shape. *Rainwater (1950)* provided a solution by considering that there was an interaction between an inner core and outer surface of valence nucleons whereby the valence nucleons could influence the shape of the nucleus. The movement of the valence nucleons with respect to the core would cause a polarizing effect resulting in a deformed nucleus as what would be expected in the liquid-drop model. *Bohr (1951)* published ideas similar to those of Rainwater in a paper that was submitted prior to the publication of Rainwater's paper demonstrating their independent discoveries. Bohr linked the movement of nucleons on the nuclear surface to oscillations of the nuclear shape, which would account for the large nuclear quadrupole moments. Bohr predicted collective excitations of the nucleus, namely vibrational excitations resulting in the periodic change in the shape of the nucleus and rotational excitations, which entails the rotation of the entire nucleus not as a single body, but that the motion consists of a surface wave of nucleons that propagates. In his words during his Nobel address, Aage Bohr stated "The rotational motion resembles a wave traveling across the nuclear surface and the moment of inertia is much smaller than for a rigid rotation." The moment of inertia of the nucleus will change as its shape changes. This is analogous to the actions of a figure skater, who with outstretched arms will pull in his or her arms thereby reducing their moment of inertia resulting in a faster spin. In his Nobel lecture *Bohr (1975)* illustrated the differences between the rotation of a rigid nucleus and one which has a nonrigid surface as depicted in *Fig. 1.25*.

Thus, nuclear excitations would be expected from the nucleus rotating not as rigid body, but resulting from the movement of a surface wave of nucleons propagating about and around the surface of the nucleus. The nuclear deformations (ellipsoidal shapes) would result from numerous nucleons acting in a collective manner as a wave about the surface of a more rigid inner nuclear core. The differing ellipsoidal shapes or rotational states of the nucleus are manifested as rotational bands in gamma emission spectra as subsequently discussed.

Bohr and Mottelson (1953a,b) were able to correlate the energy of rotational states with gamma ray emission spectra. The energy (E) of the rotational states for even-even nuclei would be defined by the equation

$$E = \hbar^2 \frac{I(I+1)}{2\vartheta} \quad (1.61)$$

where I is the nuclear spin and ϑ is the moment of inertia. Some of the first examples of energy spectra proportional to $I(I+1)$ are illustrated in *Fig. 1.26*. For example, the ratio of spin-state 4 to spin-state 2 is $4(4+1)/2(2+1) = 3.33$, and the product of this ratio and the observed energy at spin-state 2 yields $(3.33)(93 \text{ keV}) = 310 \text{ keV}$ as given in parenthesis for the calculated energy at spin state 4 in *Fig. 1.26*.

Similar calculations can be made to arrive at the calculated energy levels of 651 and 1116 keV of ^{180}Hf illustrated in *Fig. 1.26*. In his Nobel Lecture Bohr stated

The spectrum of ^{238}Pu was established by Asaro and Perlman (1953) from measurements of the fine structure in the α -decay of ^{242}Cm . Subsequent evidence showed the spin-parity sequence to be $0^+, 2^+, 4^+$, and the energies are seen to be closely proportional to $I(I+1)$.

These findings were the first to demonstrate that certain nuclear energy states can be explained on the basis that they

FIGURE 1.25 Velocity fields for rotational motion. For the rotation generated by irrotational flow, the velocity is proportional to the nuclear deformation (amplitude of the traveling wave). Thus for a spheroidal shape, the moment of inertia is $\vartheta = \mathfrak{I}_{\text{rig}}(\Delta R/R)^2$ where $\mathfrak{I}_{\text{rig}}$ is the moment for rigid rotation, while R is the mean radius and ΔR (assumed small compared to R) is the difference between major and minor semi-axes. From Bohr (1992); reprinted with permission © The Nobel Foundation 1958.

FIGURE 1.26 Rotational spectra for ^{238}Pu and ^{180}Hf . The spectrum of ^{180}Hf was deduced from the observed γ lines associated with the decay of the isomeric state. The nuclear spin states (0, 2, 4 ...) and parity (+) are given at the left of each energy plateau of ^{180}Hf , and the energies in keV are given to the right of each energy plateau. The vertical arrows pointing downward in the decay of ^{180}Hf represent the energy differences between plateau and the magnitudes of the gamma ray photon energies. The numbers in parenthesis are calculated from the energy of the first excited state, assuming the energies to be proportional to $I(I+1)$. From Bohr (1992); reprinted with permission © The Nobel Foundation 1958.

constitute a nuclear rotational spectrum; thus providing convincing evidence for the collective model of the nucleus.

E. Superheavy nuclei

The superheavy elements (SHE), also referred to as “superheavies” or SHEs, are those elements that contain nuclei with atomic number $Z > 104$. These do not occur naturally, and SHEs of atomic number $Z = 105$ to $Z = 118$ have been produced artificially. The quest to produce superheavy elements reached a seemingly scientific and political impasse

during the period of 1965–74, which is described in an interesting historical account by Dunn (2013) in the *National Geographic*. During this period the Lawrence Berkeley National Laboratory in California and Flerov Laboratory of Nuclear Reactions of the Joint Institute for Nuclear Research in Dubna, Russia, both laid claim to the production of elements 102, 103, 104, 105, and 106. As Dunn (2013) describes, a dispute arose over which laboratory (at Berkeley or Dubna) was the first to produce these elements. This dispute got ugly as it was during the Cold War between the US and Soviet Union. Dunn (2013) related, compromise prevailed and “nuclear war” was averted by the naming of element 105 as dubnium (Db), after the city of Dubna, Russia, and element 106 seaborgium (Sg) after Glenn T. Seaborg, who was codiscoverer of the transuranium elements 94 through 103 and element 106.

The isotopes of the superheavy elements ($Z > 104$), which have been produced so far, are unstable with increasingly diminishing half-lives from elements 105 to 118. For example, the half-lives of these elements are measured in units of hours for element 105, minutes for elements 106 and 107, seconds for elements 108 to 114, and milliseconds for elements 115 to 118. While the superheavy elements, that have been produced so far (up to element 118), have very unstable nuclei, current theory of shell structure of the atomic nucleus predicts certain “magic numbers” of protons and neutrons that would attribute a relatively high stability to yet much heavier elements.

The shell structure of the atomic nucleus with its “magic numbers” of protons and neutrons in the nucleus, first discovered by Maria Goeppert-Mayer and Hans Jensen during 1948–49, was described earlier in this chapter. The shell structure described the stable atomic nuclei as having magic numbers of 2, 8, 20, 28, 50, and 82 protons or neutrons or 126 neutrons, which comprised closed shells of protons or neutrons in the nucleus of an atom that attribute to the atom exceptional stability. Atomic nuclei that were “doubly magic” that is, those nuclei that contained magic numbers of closed shells for both protons and neutrons (e.g., ^4He with $Z = 2$ and $N = 2$, ^{16}O with $Z = 8$ and $N = 8$, ^{40}Ca with $Z = 20$ and $N = 20$, ^{48}Ca with $Z = 20$ and $N = 28$, and ^{208}Pb with $Z = 82$ and $N = 126$), were shown to be most stable.

The concept of the shell structure and magic numbers of protons and neutrons in the nucleus has been extended to the theory and synthesis of the superheavy elements (SHE), also referred to as “the superheavies” or SHEs. New magic numbers are predicted that would constitute closed shells of protons and neutrons in an atomic nucleus that would attribute stability to superheavy nuclei with $Z = 114$ and $N = 184$, or $Z = 120$ (Bender et al., 2001) or $Z = 126$ (Ćwiok et al., 1996). These magic numbers of closed shells of protons and neutrons are predicted to yield one or more

FIGURE 1.27 Cutout from the Chart of Nuclides in the region of the heaviest known elements. The underlying contour plot shows the magnitude of shell stabilization according to microscopic–macroscopic calculations (Patyk et al., 1997). The predicted Island of Stability is clearly visible as a dark area close to $N = 184$ and $Z = 114$. Note that other calculations favor a closed proton shell at $Z = 120$ (Bender et al., 2001), or $Z = 126$ (Ćwiok et al., 1996) instead. Known nuclei are indicated with color coded boxes according to their decay properties. The region of neutron-rich isotopes accessible via multinucleon transfer reactions is highlighted. For the color version of the figure, the reader is referred to the online or electronic version of the book. From Dvorak et al. (2011); reprinted with permission from Elsevier © 2011.

elements with unusual stability, which could be measured with half-lives in the thousands of years. These superheavy nuclides would have decayed, if they were produced at the time of the formation of the earth 4.5 billion years ago. Their predicted numbers of closed shells of protons and neutrons place them in the Chart of the Nuclides in a separate region referred to as the “Island of Stability”, surrounded by a “Sea of Instability” composed of known and unstable radionuclides of very short half-life. Fig. 1.27 illustrates where the predicted “Island of Stability” would be found in the Chart of the Nuclides. The dark blue area and dark blue blocks of Fig. 1.27 (color visible in the electronic version of this book) in the region of $Z = 114$ to 126 and $N = 177$ to 186 identify the “Island of Stability” surrounded by light blue and yellow and green blocks representing the locations of very short-lived nuclides comprising a “Sea of Instability”.

Currently, element 114, namely Flerovium (Fl), has been produced as isotopes with mass numbers in the range $A = 285$ to 289 . Thus, its heaviest known isotope (Fl-289) contains $A - Z = 289 - 114 = 175$ neutrons, which is below the predicted magic number of $N = 184$. Its measured half-life is reported to be 2.6 seconds. The difficulty lies in finding the mechanism of producing an isotope with the magic number of 184 neutrons, which would require adding an additional 9 neutrons to Flerovium-289, an isotope of Element 114.

The predicted magic number of $Z = 120$, which would be Element 120 with its predicted filled shell of protons, is yet to be produced. In a review on the shell structure of superheavy nuclei, Greiner (2008) notes that research utilizing meson field theory and other approaches indicates that the proton number $Z = 120$ should prove to be as much a magic number as $Z = 114$ (Rutz et al., 1997; Papazoglou (1998); Papazoglou et al., (1999) Beckmann et al., 2002).

The corresponding magic number of neutrons for Element 120 is predicted to be $N = 172$ and to a lesser degree, $N = 184$ (Greiner, 2008). Work by R. A. Gherghescu, Greiner, and coworkers (Poenaru et al., 1987, 1989) calculated the potential energy surface of the $Z = 120$ nucleus; and the charge distribution of the $Z = 120$, $N = 184$ nucleus points to a hollow interior of that nucleus. This work indicates that such a nucleus would have a structure similar to the fullerene “buckyball” molecule that consists of 60 carbon atoms (C_{60}) in a spherical structure with hollow interior, as illustrated in Fig. 1.28. Greiner (2008) notes that these studies suggest that the nucleus with predicted doubly magic numbers $Z = 120$, $N = 184$ would consist of 60 α -particles (${}^4_2\text{He}$ nuclei) with one additional binding neutron per α -particle, as illustrated in Fig. 1.28. These studies point to a new frontier where elements beyond $Z = 118$ will be produced, and some with an exceptional stability with long half-lives measured to have magnitudes in the thousands of years. When the writer was a university student in the early 1960s, the shell structure of

FIGURE 1.28 On the left is the typical molecular structure of the C_{60} carbon molecule fullerene. On the right is the nuclear case where the Carbon atoms are replaced by α -particles and the double bondings by the additional neutrons. Such a structure would immediately explain the semi-hollowness of that superheavy nucleus, which is revealed in the mean-field calculations within meson-field theories. For the color version of the figure, the reader is referred to the online or electronic version of the book. From Greiner (2008); reprinted with permission from Elsevier © 2008.

the atomic nucleus and the existence of magic numbers of protons and neutrons in the nucleus was an altogether new field. The buckyball structure of carbon molecules was unknown then. In years to come, amazing discoveries are expected with the production of new superheavy elements beyond Element 118.

The current goal is to find the ways and means of producing neutron-rich superheavy elements within the Island of Stability. Dean (2008) describes the methods used by Yuri Oganessian and his team of the Flerov Laboratory of Nuclear Research at the Joint Institute for Nuclear Research in Dubna, Russia, and methods utilized at the Lawrence Livermore National Laboratory (LLNL) in California. Also Hofmann (2009) describes the fusion reactions based on lead and bismuth targets, which were utilized by the Gesellschaft für Schwerionenforschung mbH (GSI) in Darmstadt, Germany, and/or at RIKEN in Wako, Japan, for the synthesis of neutron-deficient isotopes of the elements from 107 to 113, and the fusion reactions of ^{48}Ca projectiles with actinide targets whereby more neutron-rich isotopes of the elements from 112 to 116 and even 118 were produced at the Flerov Laboratory of Nuclear Reactions (FLNR) at the Joint Institute for Nuclear Research (JINR) in Dubna, Russia. Also, the Lawrence Livermore National Laboratory in California produced elements 113 through 118 in a joint collaboration between the Flerov Laboratory at the JINR in Dubna, Russia. Elements 114 and 116 were named flerovium (Fl) and livermorium (Lv) in honor of the two laboratories.

The production of the superheavy elements 113 through 118 involved fusion reactions of “doubly magic” neutron-rich ^{48}Ca with massive actinide target elements (Oganessian and Utyonkov, 2015). The ^{48}Ca stripped of its electrons is a highly stable nucleus containing both magic numbers of protons and neutrons ($Z = 20$ and $N = 28$). These nuclei are accelerated in a cyclotron against an actinide target resulting in the fusion of the ^{48}Ca projectile and actinide according to the following examples:

A new approach to the production of neutron-rich elements that reside in the Island of Stability is the application of multinucleon transfer reactions reviewed by Dvorak et al. (2011) and Corradi et al. (2013). These reactions usually are carried out at lower projectile energies whereby one or more nucleons are transferred between the projectile and target nuclei (Götz et al., 2017). As described by

Dvorak et al. (2011), these are deeply inelastic reactions whereby the projectile and target nuclei come into contact and exchange a large number of nucleons, before they separate. Dvorak et al. (2011) note that these reactions can yield a broad spectrum of products including the neutron-rich isotopes of the heaviest elements. This technique requires lower and more gentle projectile energies than those used in the fusion reactions, which can tend to “break up” target nuclei. A large source of neutron-rich isotopes that may be used in future multinucleon transfer reactions is highlighted in Fig. 1.27 in the region of the Chart of the Nuclides labeled “transfer reactions”.

The acceleration of a beam of charged nuclei onto an actinide target for the production of superheavy elements can produce numerous nuclear reaction products in addition to the superheavy elements (Roberto et al., 2015). In addition, the superheavy elements produced to date all have short half-lives. The separation, detection, and measurement of newly produced superheavy elements require, after the beam irradiation of target nuclei, the separation of the beam nuclei and the scattered product ions, which emerge from the target, followed by their detection and measurement (Theisen et al., 2015; Popeko, 2016). An instrumental design used to separate, detect, and measure reaction products of this type, referred to as a quadrupole (QD) separator/spectrometer, is designed to contain a combination of magnetic quadrupoles (multipoles) and a magnetic dipole, as described by Dvorak et al. (2011) and illustrated in Fig. 1.29.

When the beam of projectile nuclei strikes the actinide target, reaction products (*e.g.*, transfer products) are scattered in many directions from the target material. These ions will enter the separator where quadrupole or multipole magnets will focus the product nuclei toward a central area in the first stage of the separator. The transfer products as well as nuclei of the original nuclear beam, which had not

FIGURE 1.29 Schematic drawing of a separator based on the QD design. Ions are focused in a pair of quadrupole magnets before they enter the dipole magnet, where they are separated according to their magnetic rigidity. The beam, which leaves the target without a nuclear interaction has a low magnetic rigidity and is deflected to the inner wall of the dipole magnet. The intensity of the dipole field is tuned to guide the neutron-rich heavy transfer products into the focal plane detector (spectrometer mode) or into the gas cell (products collection mode). For the color version of the figure, the reader is referred to the online or electronic version of the book. From Dvorak et al. (2011); reprinted with permission from Elsevier © 2011.

undergone any nuclear reaction, enter into the field of the dipole magnet, which will separate the ions according to their momentum rigidity (i.e., their momentum-to-charge ratios). Ions of the nuclear beam, which had passed through the target material without reaction, are of low mass compared to the heavy transfer products. These ions thus have a lower magnetic rigidity and are deflected easily in the dipole magnetic field away from the detector and land onto the inner wall of the dipole magnet. These ions are, in a sense, discarded. The dipole magnetic field is tuned to focus the superheavy transfer products onto a detector, which serves as a spectrometer for the determination of the particle mass and proton number for particle identification (Dvorak et al., 2011). An alternative mode of the separator is to remove the detector and replace it with a gas cell, as illustrated in Fig. 1.29, for the collection of the neutron-rich isotopes of the heaviest elements. The heavy elements are stopped in the gas cell, that is, the gas medium serves as a collector of the neutron-rich transfer products. The neutron-rich heavy elements in the collection gas can then be transferred to another experimental arrangement for the measurement of their physical and chemical properties. Single or double charged ions are extracted from the gas via RF and DC electrical fields through a nozzle with extraction times as short as 0.1 s (Dvorak et al., 2011). Another type of ion separator/spectrometer used to collect, detect, and measure the heavy ions is a solenoid-based design, which utilizes a solenoid magnet to focus the transfer-product ions according to momentum and charge onto a detector and/or gas cell collector. This design is described by Dvorak et al. (2011).

The future offers great promise for discoveries in the ways and means of producing neutron-rich superheavy elements with very long half-lives. P. Roy Chowdhury of the Saha Institute of Nuclear Physics in Kolkata, India and coworkers (Chowdhury et al., 2008) have modeled the decay modes of numerous isotopes of the superheavy elements, which indicate that a few isotopes could have half-lives, which would measure from a few hundred years to as long as 100 million years. If these elements existed at the time of the creation of the earth, they would not be found, as such isotope lifetimes would be too short compared to the age of the earth (4.5 billion years). If such elements are produced eventually, Dvorak et al. (2011) note that our knowledge of the isotopes in this region would open new fields in nuclear chemistry, nuclear and atomic physics, and nuclear astrophysics of which the latter includes particularly nuclear processes that occur in supernovae.

F. Cluster radioactivity

Cluster radioactivity is nuclear decay with the spontaneous emission of a particle heavier than an alpha particle with $Z \geq 6$. It is included in this part of the chapter, because cluster radioactivity is an important phenomenon that

contributes to our understanding of the properties of the nucleus, in particular, nuclear stability and magic numbers.

Cluster radioactivity was first predicted by Sandulesco and Greiner (1977) and discovered by Rose and Jones (1984), who were the first to observe the emission of ^{14}C from the nucleus of ^{223}Ra . Since the discovery in 1984, intense experimental research at numerous institutions (see reviews by Price, 1989, 1994; Ronen, 1997; Bonetti and Guglielmetti, 1999; Santhosh et al., 2010; Santhosh and Biju, 2013; Soylu and Evlice, 2015; Mirea et al., 2017) have uncovered numerous radionuclides of high mass number ($A \geq 221$) that emit clusters including ^{14}C , ^{20}O , ^{23}F , ^{24}Ne , ^{28}Mg , or ^{32}Si . Radionuclides, that exhibit cluster radioactivity, are listed in Table 1.6 with their cluster decay modes and decay properties.

Cluster decay is a rare event that competes with alpha particle emission, i.e., alpha decay. The probabilities of cluster decay for observed decay modes (i.e., branching ratios) range from 10^{-9} to 10^{-17} of the alpha decay probability. All of the decay modes listed in Table 1.6 yield product nuclei that possess magic numbers of protons ($Z = 82$) and/or neutrons ($N = 126$) with the exception of ^{211}Bi ($Z = 83$, $N = 128$), which is accompanied with the ^{14}C cluster in the decay of ^{225}Ac . However, in this exceptional case, the ^{14}C cluster has the highest binding energy (BE) per cluster. Ronen (1997) compared the magic numbers, binding energies per cluster and Q values of the cluster decays as listed in Table 1.6. From these comparisons, Ronen (1997) concluded the following:

1. *The most likely mode of cluster radioactivity is when the light cluster has the highest BE per cluster and the daughter product is the doubly magic nucleus ^{208}Pb .* We can see from Table 1.6 that, among the isotopes of Ra, which yield the ^{14}C cluster, the decay mode yielding the doubly magic ^{208}Pb has the highest Q value. Also, among the isotopes of U and Pu, the decay modes that yield the doubly magic ^{208}Pb also have high Q values.
2. *Nuclei that decay by cluster radioactivity have either a daughter that is magic ($N = 126$ or $Z = 82$) or a light emitted cluster with the highest BE per cluster. Nuclei that obey both conditions (magic number and highest BE per cluster for the emitted cluster) have shorter half-lives).*

Due to the rarity of cluster radioactivity in comparison to alpha decay, the detection of emitted clusters must be done with a relatively high alpha activity. Certain solid state nuclear track detectors insensitive to alpha particles (Durrani and Bull, 1987; Ilić and Durrani, 2003) serve as good means of detecting cluster radioactivity. However, Bonetti et al. (2001) point out that track detectors may not have enough A resolution to offer unambiguous identification. Thus, to decide in favor of one of the most probable Ne clusters, Bonetti et al. (2001) resorted to theoretical calculations.

TABLE 1.6 Cluster decay modes and properties.^a

Decay mode ^b	Magic number(s) ^c	E Or Q value (MeV)	Half-life (log $T_{1/2}$ (s))
$^{221}\text{Fr} \rightarrow ^{207}\text{Tl} + ^{14}\text{C}$	$N = 126$	29.28	14.5 ± 0.12

$^{238}\text{Pu} \rightarrow ^{208}\text{Pb} + ^{30}\text{Mg}$	$Z = 82, N = 126$	67.00	25.7 ± 0.25
$^{238}\text{Pu} \rightarrow ^{206}\text{Hg} + ^{32}\text{Si}$	$N = 126$	78.95	25.3 ± 0.16

^aDecay mode, energy (E), and half-life data are from Price (1994) and Ronen (1997).

^bOther cluster decays, not listed in the table, are $^{236}\text{U} \rightarrow ^{206}\text{Hg} (N = 126) + ^{30}\text{Mg}$, $^{236}\text{Pu} \rightarrow ^{212}\text{Pb} (Z = 82) + ^{24}\text{Mg}$, and $^{242}\text{Cm} \rightarrow ^{208}\text{Pb} (Z = 82, N = 126) + ^{34}\text{Si}$ reported by Tretyakova (1995) and $^{230}\text{U} \rightarrow ^{208}\text{Pb} (Z = 82, N = 126) + ^{22}\text{Ne}$ and $^{226}\text{Th} \rightarrow ^{208}\text{Pb} (Z = 82, N = 126) + ^{18}\text{O}$ reported by Bonetti et al. (2001). The magic numbers of the product nuclei are in parenthesis where the nucleus of ^{208}Pb is "doubly magic".

^cThe magic numbers are those of the cluster-decay product nuclei.

Several of the cluster decays listed in Table 1.6 are illustrated in Fig. 1.30 together with sections of the Chart of the Nuclides (Z vs. N). This illustrates how cluster radioactivity competes with alpha particle emission and results in large leaps in the Chart of the Nuclides from parent to daughter nuclides.

An important outcome of the discovery of cluster radioactivity was the reconfirmation of the magic numbers of closed shells of protons and neutrons in the nucleus that yield exceptional stability to atomic nuclei discussed previously in this chapter. Numerous works have been devoted to explaining the cluster decay process. These are summarized by Santhosh et al. (2010). There are two approaches to explaining the cluster decay process, namely, that it is (1) fission-like and (2) alpha-like. In the fission model (Sandulescu et al., 1985; Greiner et al., 1985; Poenaru et al., 1985, 1986; Shi and Swiatecki, 1985; Shanmugam and Kamalaharan, 1988) the nucleus deforms continuously as the cluster penetrates the nuclear barrier. This would be somewhat similar to the nuclear fission process discussed previously in this chapter. In the alpha-like or cluster model of decay (Blendowske et al., 1987; Landowne and Dasso, 1986; Buck and Merchant, 1989;

Malik and Gupta, 1989), the cluster is assembled in the nucleus in a similar fashion as the alpha particle is assembled (see alpha decay in this chapter.) before the cluster penetrates the nuclear potential barrier.

VII. Relativistic properties of nuclear radiation

A. Relativity

Einstein's theory of relativity is sometimes utilized in the measurement and detection of nuclear radiation and subatomic particles. In this part of the chapter, examples are provided on how relativity is taken into account in the measurement of muons traveling close to the speed of light in the cosmic radiation showers, the measurement of the lifetime of short-lived subatomic particles originating in the cosmic radiation showers, and the measurement of the mass and de Broglie wavelengths of particles, such as electrons and neutron radiation, traveling at relativistic speeds.

In the third of Einsteins' papers submitted to *Annalen der Physik* (Einstein, 1905a,b,c) he proposed his theory of special relativity. Einstein's *Principle of Relativity* is based

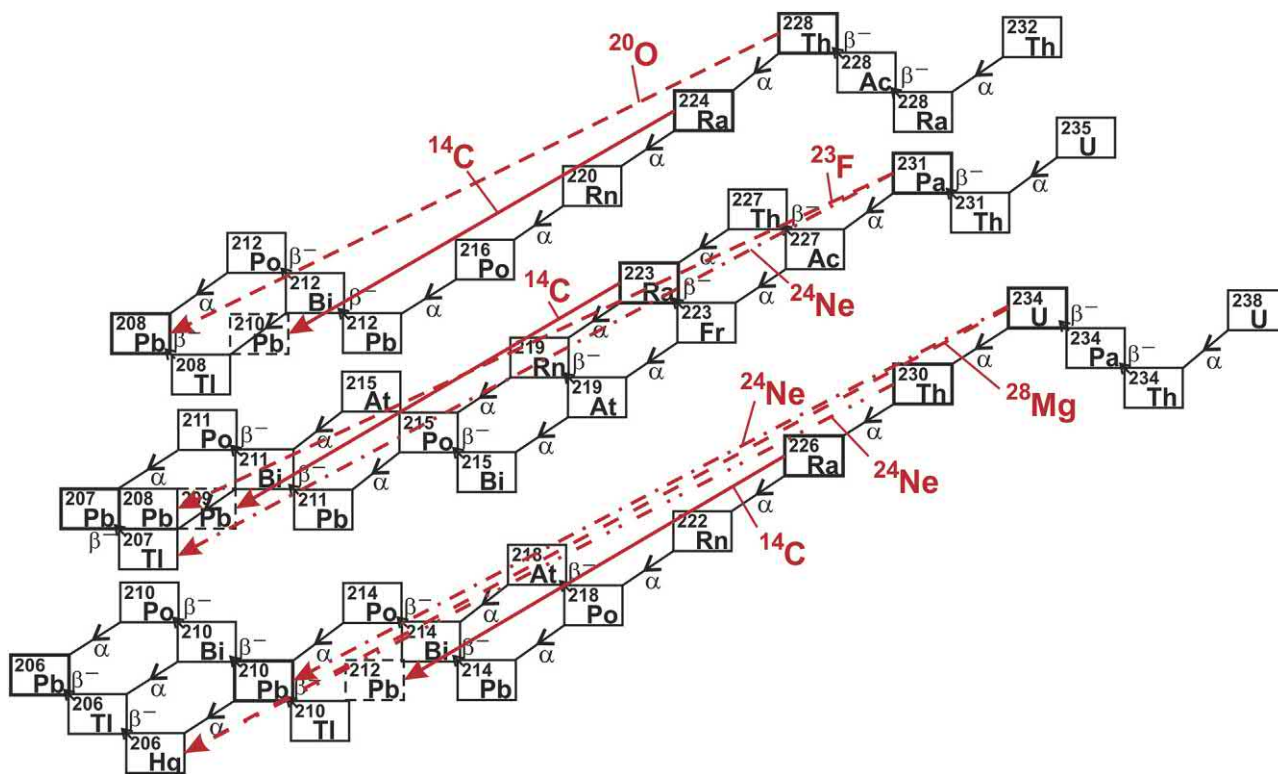

FIGURE 1.30 Cluster radioactivity of actinide nuclei. By emission of ^{14}C , ^{20}O , ... “big leaps” in the periodic system can occur, just contrary to the known α -, β -, γ -radioactivities, which are also partly shown in the figure. (Caption and figure are from Greiner, 2008 with red color added by the writer; reprinted with permission from Elsevier © 2008.) For the color version of the figure, the reader is referred to the online or electronic version of the book.

on two postulates, which are namely, (1) that in making observations or measurements in physics, there should be no preferred inertial (nonaccelerating) frame. In other words, for all inertial observers, the laws of physics are the same. (2) The speed of light in a vacuum is a constant ($c = 2.99 \times 10^8$ m/s) for all inertial observers, regardless of the velocity of travel of the source. Einstein developed his principle of relativity into what would be referred to later as the special theory of relativity that would provide an analysis of space and time. The special theory of relativity can be used to explain changes of length, time, and mass when an observer in one inertial frame makes measurements of length, time, and mass of another body or clock in another inertial frame. A person in one inertial frame of reference can make measurements of length, time, and mass on another inertial frame and vice versa. Space, time, mass, and speed are all relative depending on which inertial frame of reference is used. In his Nobel Lecture on the theory of relativity delivered to the Nordic Assembly of Naturalists at Gothenburg on July 11, 1923 (<http://www.nobelprize.org>), Einstein underscored the two principles upon which the special theory of relativity is based (Einstein, 1923) as follows:

The special theory of relativity is an adaption of physical principles to Maxwell–Lorentz electrodynamics. From earlier physics it takes the assumption that Euclidian

geometry is valid for the laws governing the position of rigid bodies, the inertial frame and the law of inertia. The postulate of the equivalence of inertial frames for the formulation of the laws of Nature is assumed to be valid for the whole of physics (special relativity principle). From Maxwell–Lorentz electrodynamics it takes the postulate of invariance of the velocity of light in a vacuum (light principle).

B. Relativistic length contraction and time dilation

In Einstein’s treatise on relativity (Einstein, 1916a,b) he explained that, when making measurements of events from frames of reference that are in uniform motion, we must define the events by four coordinates, namely the space coordinates x , y , and z as well as the time coordinate t . Thus, any event wherever it takes place would be fixed in space by the perpendicular space coordinates x , y , and z and a fixed time t (see Fig. 1.31). The same event, relative to another frame of reference, is also fixed in space and time according to the space–time coordinates x' , y' , z' , t' . In his treatise on relativity, Einstein (1916a,b) explained that the world we live in should be considered as a four-dimensional space–time continuum.

Einstein (1916a,b) demonstrated that, when events measured from one frame of reference (e.g., O , where the events are measured by an observer at O) on another frame of reference (e.g., O' , where the same events are measured by an observer at O'), which is traveling at a velocity v relative to the observer at O , will yield different measurements of time (e.g., time dilation) and length (e.g., length contraction), which is dependent on the frame of reference from which the measurements are taken and the velocity (v). The differences in measurement of time and length taken from the two frames of reference will be greater as the velocity v approaches the unattainable speed of light c (i.e., speed of light in a vacuum = 2.9979×10^8 m/sec).

The problem of relativity was presented by Einstein (1916a,b) with a question, which may be worded as follows: What are the values of x' , y' , z' , and t' of an event with respect to frame O' , when we know the values of x , y , z , and t , of the same event with respect to reference frame O ? He explained that the solution to the problem must satisfy a law of the transmission of light in a vacuum, abbreviated by the symbol c , as a constant. Einstein indicated that for the coordinate systems illustrated in Fig. 1.31, the problem is solved by the following Lorentz transformations (Eqs. 1.68 and 1.69), named after Nobel Laureate Hendrik A. Lorentz:

Length:

$$x' = \frac{x - vt}{\sqrt{1 - (v^2/c^2)}}, \quad y' = y \quad \text{and} \quad z' = z \quad (1.68)$$

Time:

$$t' = \frac{t - \frac{v}{c^2}x}{\sqrt{1 - (v^2/c^2)}} \quad (1.69)$$

where the variables are those defined in the previous paragraph. In his treatise, Einstein (1916a,b) provided a derivation of Eqs. (1.68) and (1.69). The detailed derivation is provided in the Appendix of a previous book by the writer (L'Annunziata, 2016).

FIGURE 1.31 Two frames of reference in space and time. An event in space and time in reference frame O' is defined by space-time coordinates x' , y' , z' , and time t' , traveling at a velocity v relative to reference frame O , defined by coordinates x , y , z , and t .

1. Length contraction in relativity

Fig. 1.32 illustrates an observer (with waving hands) in reference frame O' , who takes a measurement in his or her own frame of reference, and measures the length of an object at time t' along the x -axis to extend from x'_a to x'_b . Since the object is measured by an observer at O' in his or her own frame of reference, the object is at rest with respect to the observer at O' . At the same time, another observer in reference frame O takes a measurement of the same object in the reference frame O' to extend from x_a to x_b . Reference frame O' is traveling at a velocity v with respect to reference frame O . The measurement of the length of the object made by the observer in reference frame O will be smaller than that made by the observer in reference frame O' according to the Lorentz transformation defined in Eq. (1.68) above.

Let us look at Eq. (1.68) of the Lorentz transformation with respect to the specific example provided in the previous paragraph. The Lorentz transformation that defines changes in length along the x -axis (Eq. 1.68) is the following:

$$x' = \frac{x - vt}{\sqrt{1 - (v^2/c^2)}} \quad (1.70)$$

where x' is a coordinate along the x axis measured at time t' in reference frame O' as measured by an observer in the

FIGURE 1.32 Two frames of reference in space and time. An event in space and time in reference frame O' is defined by space-time coordinates x' , y' , z' , and time t' , traveling at a velocity v relative to reference frame O , defined by coordinates x , y , z , and t . An observer at O (with hands on hips) may take measurements of length and time on the frame of reference at O' (where there is an observer with hands waving) and measure length to be contracted (i.e., shorter) and time dilated (i.e., longer interval of time) than the length and time measured by the observer at O' . The observer at O' , who makes measurements of an event in his or her own reference frame would experience different measurements, because the measurements would be made of an event that would be at rest with respect to the observer. A rod is illustrated in the reference frame O' , which would measure 1 m by the observer at O' , because the rod would be at rest with respect to the observer at O' . However, the rod measured by the observer in the reference frame O would measure the rod to be contracted or shorter than 1 m in length, and the amount of contraction would be a function of the velocity v at which the reference frame O' is traveling with respect to reference frame O . From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.

same reference frame, which is traveling at the velocity v with respect to another reference frame O . The variable x is the coordinate along the x axis measured by an observer in reference frame O at time t , and c is the invariable speed of light in a vacuum. With respect to the example given in the previous paragraph, we can express the two measurements taken by the two observers in the two reference frames with the Lorentz transformation Eq. (1.68) as follows:

$$x'_b - x'_a = \frac{(x_b - x_a) - v(t' - t)}{\sqrt{1 - (v^2/c^2)}} \quad (1.71)$$

where $x'_b - x'_a$ are the measurements along the x -axis (length of an object) in reference frame O' taken by an observer in the same reference frame where the object would be at rest with respect to the observer, which we can now call L_r ; and $x_b - x_a$ are the measurements of the same object made by an observer in reference frame O , which we may call L . If the measurements are made by the two observers in the two reference frames at the same time, $t' = t$ and $t' - t = 0$ and Eq. (1.71) becomes

$$L_r = \frac{L}{\sqrt{1 - (v^2/c^2)}} \quad (1.72)$$

where L_r is the length of the object that is at rest with respect to the observer (at O') traveling at the velocity v with respect to an observer at O in another reference frame, L is the length of the object in reference frame O' measured by an observer in reference frame O . Eq. (1.72) may be written as

$$L = L_r \sqrt{1 - (v^2/c^2)} \quad (1.73)$$

The above Eq. (1.73) states that an observer in a reference frame, who measures an object (L) in another reference frame that is traveling at a velocity v with respect to the observer will be contracted (*i.e.*, smaller) with respect to the measurement L_r taken by another observer, who make the measurement in the reference frame where the object is at rest with respect to that observer. Thus, L is always smaller than L_r (*i.e.*, $L < L_r$) by the factor $\sqrt{1 - (v^2/c^2)}$, and the degree of contraction is dependent on the velocity v . As the velocity v increases and approaches the unattainable speed of light c , the value of L decreases, that is, contraction increases.

Einstein (1916a,b) provided examples of how measurements from one frame of reference on another frame of reference will yield different measurements of time and length dependent on the frame of reference from which the measurements are taken and the velocity v at which one frame of reference is traveling with respect to the other. As an example, he chose a meter-rod situated in Fig. 1.32 in the coordinate system (reference frame) O' at $x' = 0$ at one end and $x' = 1$ m at the other end of the rod. He then proceeded to calculate the length of the meter-rod relative to system O at a particular time t . Using Eq. (1.70) of the Lorentz transformation reduced to Eq. (1.73), Einstein shows that at time $t = 0$, the value of $x = 0$ for the beginning of the rod, that is,

$$x = 0 \left(\sqrt{1 - (v^2/c^2)} \right) \quad (1.74)$$

and the end of the rod would measure

$$x = 1 \text{ m} \left(\sqrt{1 - (v^2/c^2)} \right) \quad (1.75)$$

Thus, when the meter rod is traveling at the speed v relative to O , the meter-rod is shorter as judged from O according to the factor $\sqrt{1 - (v^2/c^2)}$, and the faster that the rod is traveling relative to O , the shorter will be the rod as measured from O . The degree of rod contraction is a function of the velocity v , and it is significant at relativistic speeds, that is, when v approaches c , the unattainable speed of light.

A specific example of relativistic length contraction in the detection of cosmic-ray muons on earth is provided subsequently in Part C.

2. Time dilation in relativity

Another example proposed by Einstein (1916a,b) in his treatise on relativity included a clock, which is permanently situated at the origin ($x = 0$) of the frame of reference O , which travels at the velocity v relative to the reference frame O' (see Fig. 1.33). He then assigned two successive ticks of the clock as $t = 0$ for the first tick and $t = 1$ second for the following tick. Using the Lorentz transformation provided by Eq. (1.69) above, Einstein (1916a,b) calculated that the time for the two ticks measured from the frame of reference O' to be $t = 0$ for the start and $t = 1 / \sqrt{1 - (v^2/c^2)}$ for the following tick of the clock. Thus, from the reference frame of O' , Einstein demonstrated that the time between two ticks of the clock is not one second, but rather the dilated time of $t = 1 / \sqrt{1 - (v^2/c^2)}$ seconds. Thus, when measured from the frame of reference O' , the time is enlarged, and the greater the velocity v relative to the observer at O' , the longer will be the time measured from O' . As explained by Einstein (1916a,b), the value of v can never reach c , which remains an unattainable limiting velocity.

In the above example, Einstein (1916a,b) used the Lorentz transformation provided in Eq. (1.69), namely,

$$t' = \frac{t - \frac{v}{c^2}x}{\sqrt{1 - (v^2/c^2)}} \quad (1.76)$$

and

$$\Delta t' = \frac{(t_2 - t_1) - \frac{v}{c^2}(x_2 - x_1)}{\sqrt{1 - (v^2/c^2)}} \quad (1.77)$$

where x_2 and x_1 are the positions of the clock at the origin of reference frame O . The clocks remain at rest with respect to the observer in frame O , and thus $x_2 - x_1 = 0$. The above Eq. (1.77) is then written as

FIGURE 1.33 An observer in reference frame O measures two events with a clock situated at the origin. In reference frame O , the clock remains at the origin, that is, it does not move with respect to the observer in that reference frame. The reference frame O travels at a velocity v with respect to the frame of reference O' . However, the clock in reference frame O is at rest with respect to the observer in that reference frame, who measures the time interval between the two events to be 1 seconds. An observer in the frame of reference O' sees the two events as occurring in two locations and measures the time interval between these events to be $t' > 1$ seconds. From *L'Annunziata (2016)*; reprinted with permission from Elsevier © 2016.

$$\Delta t' = \frac{\Delta t_r}{\sqrt{1 - (v^2/c^2)}} \quad (1.78)$$

where $\Delta t_r = t_2 - t_1$, that is, the time interval measured by the observer in reference frame O where the clocks are at rest with respect to the observer. Thus, the time interval measured by the observer at O' is the time interval

$$\Delta t' = \frac{1 \text{ s}}{\sqrt{1 - (v^2/c^2)}}, \quad (1.79)$$

which is a dilated or longer time interval than 1 seconds, that is $\Delta t' > \Delta t_r$. The length of the time interval is greater than 1 seconds by the factor $1/\sqrt{1 - (v^2/c^2)}$, and this dilated time will be greater as the velocity v increases and approaches c , the unattainable velocity of light in a vacuum.

The above results would be the same if we were to consider the reference frames O and O' in reverse, that is, if the reference frame O' would be moving with the velocity v with respect to O , the observer at O would measure the same results with the following Lorentz transformation with the expression Δt rather than $\Delta t'$:

$$\Delta t = \frac{\Delta t_r}{\sqrt{1 - (v^2/c^2)}} \quad (1.80)$$

Real examples of relativistic calculations involving time dilation and length contraction with respect to the

measurement of muons in the showers of cosmic radiation are provided in the following section.

C. Relativity in cosmic-ray muon detection and measurement

Muons are produced high in the atmosphere at an altitude of ~ 15 km where high-energy cosmic-ray nucleons encounter and undergo collision with nuclei of the atmospheric gases. The muons produced high in the atmosphere are components of the showers of cosmic radiation, and these muons travel toward the earth reaching the ground (sea level) with a mean energy of ≈ 4 GeV at speeds close to the speed of light ($>0.99c$).

One might ask at this point the following question: If muons of the cosmic radiation showers are produced high in the earth's atmosphere (at altitudes of $\sim 15,000$ m or higher), travel at speeds close to the speed of light, and have an average lifetime of only 2.2×10^{-6} seconds, how could such muons be detected to reach the earth's surface? The question is an obvious one, as it would appear with classical mathematics that, with such a short lifetime, muons would never be expected to reach the earth. Let's say, for example, a muon is produced at the altitude of 15,000 m and it travels at the speed v of $0.9993c$, which would correspond to a speed in units of m/s as

$$\begin{aligned} 0.9993c &= (0.9993)(2.9979 \times 10^8 \text{ m/s}) \\ &= 2.9958 \times 10^8 \text{ m/s}. \end{aligned} \quad (1.81)$$

The classical calculation of its average distance d of travel during its lifetime would be

$$\begin{aligned} d &= (v)(t) = (2.9958 \times 10^8 \text{ m/s})(2.2 \times 10^{-6} \text{ s}) \\ &= 659.1 \text{ m} \end{aligned} \quad (1.82)$$

Thus, the muon would be expected to decay, according to classical transformations, after traveling only 659 m on the average and, therefore, never be detected on earth. However, for such a muon viewed by an observer on earth, he or she would view the following two events: A, the creation of the muon and B, the decay of the muon, to occur in two locations in space-time coordinates. Einstein's theory of relativity utilizing the Lorentz time transformations demonstrate that the two events, A and B, separated by the time interval Δt , will be dilated to the time interval Δt_{earth} , when viewed by an observer on earth. The time dilation, as described by [Einstein \(1916a,b\)](#), is calculated according to the following:

$$\Delta t_{\text{earth}} = \frac{\Delta t_r}{\sqrt{1 - (v^2/c^2)}} \quad (1.83)$$

where v is the velocity of the particle, and c is the invariable speed of light in a vacuum. For the muon traveling at

$0.9993c$, we can calculate Δt_{earth} or the observed dilated lifetime of the muon as follows:

$$\Delta t_{\text{earth}} = \frac{\Delta t_r}{\sqrt{1 - (v^2/c^2)}} = \frac{2.2 \times 10^{-6} \text{ s}}{\sqrt{1 - (0.9993)^2}} = \frac{2.2 \times 10^{-6} \text{ s}}{0.0374} = 58.8 \times 10^{-6} \text{ seconds} \quad (1.84)$$

According to the dilated time of 58.8×10^{-6} seconds, the observer on earth will determine that the muon would travel, before it decays, a distance of

$$d = (v)(\Delta t_{\text{earth}}) = (2.9958 \times 10^8 \text{ m/s})(58.8 \times 10^{-6} \text{ s}) = 17615 \text{ meters}, \quad (1.85)$$

which is well beyond the distance of 15,000 m elevation when it was created, permitting its detection on earth. The distance is only an average figure, because the muon lifetime of 2.2×10^{-6} seconds is an average lifetime. For thorough treatments of relativistic space–time measurements and the applications of Lorentz transformations to these measurements see books by [Einstein \(1916a,b\)](#), [Wolfson \(2003\)](#), [Gautreau and Savin \(1999\)](#) and [Serway et al. \(2005\)](#).

The example provided here is a realistic one, and the relativistic time dilation has been demonstrated by [Bailey et al. \(1977, 1979\)](#) based on the historical tests of [Rossi and Hall \(1941\)](#). The historical work of Rossi and Hall entailed the measurement of the muon flux on Mt. Washington in New Hampshire at the altitude of 1900 m and at the mountain base, as illustrated in [Fig. 1.34](#). They found that the muon flux at both altitudes did not differ greatly, only by the ratio of 1.4, that is, the muon flux was 1.4 times as high at the altitude of 1900 m compared to the ground level. Calculations based on a muon half-life of 1.5×10^{-6} seconds (*i.e.*, average lifetime of $1.5 \times 10^{-6} \text{ seconds} / \ln 2 = 2.2 \times 10^{-6} \text{ seconds}$), the muon flux ratio for the two altitudes, should have been approximately 22 even when attributing the highest unrealistic speed of light to the muons. The actual low ratio of 1.4 could only be explained by applying the time dilation calculations for muons traveling at the speed of $0.994c$, which are the following:

$$\Delta t_{\text{earth}} = \frac{\Delta t_r}{\sqrt{1 - (v^2/c^2)}} = \frac{2.2 \times 10^{-6} \text{ sec}}{\sqrt{1 - (0.994)^2}} = \frac{2.2 \times 10^{-6} \text{ s}}{0.1094} = 20.1 \times 10^{-6} \text{ seconds} \quad (1.86)$$

The dilated muon lifetime of 20.1×10^{-6} seconds measured by observers in the space–time reference frame of earth demonstrates that the muons measured at the 1900 m mountain peak altitude and at the base of the mountain, have a measured lifetime long enough to

travel ~ 6000 m well beyond the base of the mountain, calculated as follows:

$$\begin{aligned} d &= (v)(\Delta t_{\text{earth}}) \\ &= (0.994c)(\Delta t_{\text{earth}}) = (.994)(2.9979 \times 10^8 \text{ m/sec}) \\ &\quad (20.1 \times 10^{-6} \text{ sec}) = 5989 \text{ meters} \end{aligned} \quad (1.87)$$

The above calculation demonstrated the time dilation for the decay of the muon when observing the muon travel from the reference frames of observers on earth ([Fig. 1.34](#)), which explains why the muon of short lifetime (2.2×10^{-6} seconds) created high in the atmosphere can be observed (*i.e.*, detected) at sea level.

There is yet another aspect of relativity providing evidence for the observation of cosmic-ray muons at sea level. As noted by Einstein, when traveling at relativistic speeds (*i.e.*, speeds approaching the speed of light), measurements made in the space–time reference frame where they occur in different places will yield a contraction of objects compared to their sizes when measured in a reference frame where they occur at the same place. For example, an observer on the mountain would measure its altitude to be 1900 m; however, if an observer could travel with the muon at $0.994c$, he or she would take two separate measurements, namely, one of the peak and one of the base of the mountain (two events) and find the height of the mountain to be contracted by the factor $\sqrt{1 - (v^2/c^2)}$ previously described by [Einstein \(1916a,b\)](#)

FIGURE 1.34 Observers at the peak of Mt. Washington measure the intensity of muons in the atmosphere at A at the altitude of 1900 m (mountain peak) and at (B) the base of the mountain. To the left of the figure a path of travel taken by a cosmic-ray muon is illustrated. Only one muon path of travel is illustrated for simplicity, although numerous muons are produced in the showers of cosmic radiation. The muon is illustrated traveling toward the earth at the relativistic speed of $0.994c$. Relativistic calculations show that the mountain height would be squeezed or contracted in space to only 208 m when measured from the reference frame of the muon. From [L'Annunziata \(2016\)](#); reprinted with permission from Elsevier © 2016.

and discussed earlier in this section. The measured height of the mountain (x), from the reference frame of the muon, would be squeezed or contracted in space according to the following:

$$\begin{aligned} x &= (1900 \text{ meters}) \left(\sqrt{1 - (v^2/c^2)} \right) \\ &= (1900 \text{ m}) \sqrt{1 - \frac{(0.994c)^2}{c^2}} = 208 \text{ meters} \quad (1.88) \end{aligned}$$

Thus, the muon in the atmosphere traveling at $0.994c$ at the height of the mountain peak encounters a mountain squeezed in space to only 208 m from the mountain peak to its base (Fig. 1.34), which is more than enough distance for it to reach earth. One might question these calculations by asking “What is the true height of the mountain, 1900 m or 208 m?” Both calculations are correct relative to which inertial frame of reference the measurements are taken; the height of the mountain will depend on the reference frame (space–time coordinates) of an observer, who makes the measurement, namely, an observer located at the mountain, who measures the height to be 1900 m or an observer traveling close to the speed of light ($0.994c$) in the reference frame of the muon, who measures the height (208 m from peak to base) of the mountain while traveling past the mountain at this relativistic speed.

D. Relativistic measurements of particle lifetimes

1. Bubble chamber measurements

An interesting example of the application of relativistic time dilation can be taken from the work of Nobel Laureate Luis Alvarez. He was awarded the Nobel Prize in Physics in 1968. Luis Alvarez pioneered the development of the hydrogen bubble chamber, which enabled the discovery of subatomic particles produced by the collision of high-energy protons accelerated to energies reaching a billion electron volts in a proton synchrotron against hydrogen nuclei of the bubble chamber. The nuclear reactions that occurred would result in the production of very short-lived particles, and some would have lifetimes less than 10^{-10} seconds. Particles that possessed a positive or negative charge would produce tracks in the bubble chamber, which were photographed at the time of their production. Neutral particles would not produce any track; rather these would leave a gap in the bubble chamber from the time of their production to their decay into a charged particle. An example of the tracks produced by such short-lived particles can be seen in one of Alvarez’s bubble chamber photographs illustrated in Fig. 1.35.

The particles produced in the bubble chamber would travel close to the speed of light ($0.99c$). Alvarez and his coworkers could measure the lengths of the tracks stored in photographs, and from the particle speed, they could calculate the particle lifetimes. The smallest track length,

that Alvarez could measure accurately, was $1 \mu\text{m}$ or 10^{-6} m. In making such measurements of particle lifetimes in the laboratory, Alvarez would take into account that the particles travel at close to the speed of light, and from the reference frame of the laboratory, he would be measuring the dilated lifetime of the particle that travels in another reference frame. This is similar to the example presented in Fig. 1.33 where a measurement made by an observer in one frame of reference (e.g., the laboratory) on the time transpired for an event that occurs over time in another frame of reference traveling at a velocity v with respect to the observer. Serway et al. (2005) distinguishes the dilated measurement of time made by the observer in the lab as t_{lab} , according to the previously described Eq. (1.80) as follows

$$t_{\text{lab}} = \frac{t_{\text{proper}}}{\sqrt{1 - (v^2/c^2)}}. \quad (1.89)$$

where t_{proper} is the proper lifetime of the particle (i.e., the lifetime of the particle in the reference frame of the particle). Serway et al. (2005) calculated the dilated lifetime of a particle traveling at $0.99c$ for a distance of only $1 \mu\text{m}$ in the bubble chamber as

$$t_{\text{lab}} = \frac{d}{v} = \frac{10^{-6} \text{ m}}{(0.99)(2.99 \times 10^8 \text{ m/s})} = 0.33 \times 10^{-14} \text{ s} \quad (1.90)$$

and the proper lifetime of the particle as

$$\begin{aligned} t_{\text{proper}} &= (t_{\text{lab}}) \sqrt{1 - (v^2/c^2)} \\ &= (0.33 \times 10^{-14} \text{ s}) \sqrt{1 - \frac{(0.99c)^2}{c^2}} \\ &= 4.6 \times 10^{-16} \text{ s} \end{aligned} \quad (1.91)$$

FIGURE 1.35 Left: photograph of particle tracks produced by high-energy proton collision with hydrogen nuclei in a hydrogen bubble chamber, <https://doi.org/10.1103/PhysRevLett.2.215>, reprinted with permission by the American Physical Society © 1959; right: sketch of specific particle tracks traced out of the photograph illustrating kaon (K^+ , K^0), xi (Ξ^0), lambda (Λ^0), pion (π^+ , π^0 , π^-), and a proton (p) track. From Alvarez et al. (1959).

Thus, the proper lifetime of the particle traveling only 1 μm in the bubble chamber is much shorter than the lifetime measured in the reference frame of the laboratory (t_{lab}). If we consider a particle traveling at a yet faster speed of $0.9995c$ and apply the same calculations, we will arrive at the proper lifetime of the particle (t_{proper}) to be more than fourfold shorter or 1.0×10^{-16} seconds.

2. Measurements in CERN muon storage ring

Measurements made by [Bailey et al. \(1977, 1979\)](#) on relativistic muons in a large muon storage ring of the European Center for Nuclear Research (CERN) in Geneva provided very precise evidence for Einstein's special relativity. They found that the Einstein time dilation factor agreed with experiment with a fractional error of only 2×10^{-3} at a 95% confidence level. They calculated the proper lifetime (t_{proper}) of the negative muon (μ^{-1}) to be 2.2×10^{-6} seconds from a measured dilated lifetime (t_{lab}) of 64.4×10^{-6} seconds. The speed of the muon within the storage ring was found to be $0.9994c$ and the dilated lifetime of the muon as measured in the reference frame of the laboratory was found to be 64.4×10^{-6} seconds. This is the dilated lifetime according to Einstein's special relativity described by [Eq. \(1.89\)](#). The proper lifetime of the muon (i.e., its lifetime as measured in the reference frame of the muon or in other words the lifetime of the muon at rest) was calculated to be

$$\begin{aligned} t_{\text{proper}} &= (t_{\text{lab}}) \sqrt{1 - (v^2/c^2)} \\ &= (64.4 \times 10^{-6} \text{ s}) \sqrt{1 - \frac{(0.9994c)^2}{c^2}} \\ &= 2.2 \times 10^{-6} \text{ s} \end{aligned} \quad (1.92)$$

At the speed of 0.9994 times the speed of light, measurements of particle lifetimes made in the laboratory are highly dilated in accord with Einstein's special relativity. In the case of the muon, the measured lifetime at a muon speed of $0.9994c$ is close to 30-fold longer than its proper lifetime or

$$\frac{t_{\text{lab}}}{t_{\text{proper}}} = \frac{64.4 \times 10^{-6} \text{ s}}{2.2 \times 10^{-6} \text{ s}} = 29.3 \quad (1.93)$$

This test of time dilation, provided by the muon lifetime measurements, is discussed in papers by [Thompson \(2004\)](#) and [Tomaschitz \(2004\)](#).

E. Energy and mass in relativity

In Einstein's treatise on relativity ([1916a,b](#)), he wrote on the relationship of energy and mass. He explained that, in

the theory of relativity, the kinetic energy of a body of mass m is not given by the conventional expression

$$E = \frac{1}{2}mv^2, \quad (1.94)$$

rather by the expression

$$E = \frac{mc^2}{\sqrt{1 - (v^2/c^2)}} \quad (1.95)$$

where the energy E approaches infinity, as the velocity v of the body approaches the speed of light c . Thus, the velocity v always remains below the unattainable speed of light c .

[Einstein \(1916a,b\)](#) elucidated that if a body, which he referred to as a material point (e.g., nuclear particle), takes up energy, its energy will increase by an amount

$$E_0 = mc^2 \quad (1.96)$$

The increase in energy also represents an increase in mass. Thus, [Einstein \(1916a,b\)](#) wrote the increase in energy of the particle E_0 into the above [Eq. \(1.95\)](#) to give

$$E = \frac{mc^2 + E_0}{\sqrt{1 - (v^2/c^2)}} \quad (1.97)$$

or

$$E = \frac{(m + E_0/c^2)c^2}{\sqrt{1 - (v^2/c^2)}}, \quad (1.98)$$

which expresses that the body, to which energy is added, has the energy of a body of mass $(m + E_0/c^2)$ moving at a velocity v .

The above [Eq. \(1.98\)](#) may be written as

$$mc^2 = \frac{m_0 c^2}{\sqrt{1 - (v^2/c^2)}} \quad \text{where } m_0 = m + E_0/c^2 \quad (1.99)$$

and

$$m = \frac{m_0}{\sqrt{1 - (v^2/c^2)}} \quad (1.100)$$

where m is the relativistic mass of the body, sometimes written as m_r ; and m_0 is the rest mass of the body or, in other words, the mass of the body as measured in the coordinates of the observer, which would be at rest with respect to the observer, because the body and the observer in the same coordinates are traveling at the same velocity.

The expression of [Eq. \(1.100\)](#) is used further on in this chapter to define the energy of particles that travel at speeds approaching the speed of light (i.e., relativistic speeds). The equation is expressed as

$$E = \gamma mc^2 \quad \text{where } \gamma = \frac{1}{\sqrt{1 - (u^2/c^2)}} \quad \text{and } u = v \quad (1.101)$$

The symbol u is often used in place of v when particle speeds are relativistic. Einstein (1916a,b) explained in the above Eq. (1.101) that as the energy of a body (*e.g.*, nuclear particle) is increased, so is its mass increased. He expounded on this by clarifying that the law of conservation of energy must hold not only for one coordinate system O , but also for all coordinate systems, such as O' , that are in uniform motion relative to O (see Fig. 1.31). Einstein (1916a,b) elaborated that when the energy of a body is increased by an amount E_0 , its mass increases by the amount E_0/c^2 . He stated that the inertial mass of a body is a variable; namely, the inertial mass of the body will vary according to the change in energy of the body. In turn, the inertial mass of a body is also a measure of its energy.

F. Relativistic mass calculations

In the above Eq. (1.100) Einstein described that the rest mass of a body (*i.e.*, the mass of a body at rest with respect to the observer), m_0 , would be measured to possess a higher mass, m , when the body is observed traveling at a velocity, v , relative to an observer, and the value of m is referred to the relativistic mass.

The relativistic speed of a 100 GeV cosmic-ray proton is calculated from its kinetic energy to be 0.999956c (see Eq. (1.493) in Part XIV.A of this chapter). As noted in Einstein's Eq. (1.100), we may calculate the relativistic mass, m , of the proton from its known rest mass (1.67262×10^{-27} kg) and its velocity, to be

$$m = \frac{m_0}{\sqrt{1 - (v^2/c^2)}}$$

$$m = \frac{1.67262 \times 10^{-27} \text{ kg}}{\sqrt{1 - ((0.999956c)^2/c^2)}}$$

$$m = \frac{1.67262 \times 10^{-27} \text{ kg}}{\sqrt{1 - (0.999956)^2}} = 178.3038 \times 10^{-27} \text{ kg} \quad (1.102)$$

The ratio of the relativistic mass to the rest mass (m/m_0) of the proton traveling at 0.999956c is

$$m/m_0 = 178.3038 \times 10^{-27} \text{ kg} / 1.67262 \times 10^{-27} \text{ kg} = 106.6 \quad (1.103)$$

which is calculated to be over 100-fold greater than its mass at rest.

Einstein's relativity calculations can be applied to photons of light, which are also particulate in nature. We know from Einstein's interpretation of the photoelectric effect, for which he was awarded the Nobel Prize, that the energy of a photoelectron is directly proportional to the

energy of the photon, which had collided with the electron to cause its emission from an atom. The greater the energy of the photon, that is, the shorter its wavelength, the greater will be the energy of the photoelectron. Einstein demonstrated that the energy of the photoelectron depended on the energy of the photon that collided with the atomic electron or, the product of Planck's constant times the photon frequency according to the formula

$$E_{\text{photon}} = mc^2 = h\nu = \frac{hc}{\lambda} \quad (1.104)$$

and from the above equations, the effective mass of the photon can be written as

$$m = \frac{h}{\lambda c} \quad (1.105)$$

where m is the photon mass, c is the speed of light in a vacuum (2.9979×10^8 m/s), h is Planck's constant (6.626×10^{-34} J s), ν is the photon frequency in units of s^{-1} , and λ is the photon wavelength in meters. From Eq. (1.105), the effective mass of the photon as a function of its wavelength can be calculated. For example, the effective mass of a photon of 450 nm wavelength, which is in the visible blue wavelength of light, is calculated as

$$m = \frac{6.626 \times 10^{-34} \text{ J} \cdot \text{s}}{(4.50 \times 10^{-7} \text{ m})(2.9979 \times 10^8 \text{ m/s})} = 4.91 \times 10^{-36} \text{ kg} \quad (1.106)$$

The above units of $\text{J} \cdot \text{s}^2/\text{m}^2$ convert to kilograms or kg as follows:

$$\frac{\text{J} \cdot \text{s}^2}{\text{m}^2} = \frac{\text{Nm} \cdot \text{s}^2}{\text{m}^2} = \frac{\text{N} \cdot \text{s}^2}{\text{m}} = \frac{\text{m kg/s}^2 \cdot \text{s}^2}{\text{m}} = \text{kg} \quad (1.107)$$

where N is the Newton, a unit of force, which is equivalent to m kg/s^2 . As seen from Eq. (1.105), the energy and consequently the effective mass of the photon is wavelength dependent.

G. Relativistic particle wavelength calculations

As described previously in accord with Einstein's theory of relativity, the mass of a particle will increase according to its energy. The change in mass and speed of a particle as a function of its energy must be accounted for in calculations of particle radiation wavelength. This is particularly relevant in studies of particle radiation diffraction.

The first documented application of relativistic particle wavelength calculations is that of Nobel Laureate George Thomson (1927, 1928, 1929), who demonstrated the diffraction of an electron beam thereby demonstrating the de Broglie matter wave theory as well as Einstein's theory of relativity. As a result of this work, George Thomson was awarded the 1937 Nobel prize in physics for his demonstration of the wave property of the electron, which he shared with Clinton Davisson. At the time of the 1937 Nobel prize

award, the following joke spread throughout the scientific community: “Joseph Thomson, the father, was awarded the Nobel prize in physics in 1906 for demonstrating that the electron was a particle; and George Thomson, the son, won the Nobel prize in 1937 for demonstrating that the electron was a wave rather than a particle”. This was only in jest because the scientific community finally had evidence for the de Broglie particle-wave duality, that is, particles not at rest will have a dual nature of particle and wave.

Thomson and coworkers (1927, 1928, 1929) calculated the wavelength of the electron beam according to the de Broglie matter-wave theory defined previously in Eq. (1.3) after correcting for the relativistic mass of the electron or

$$\lambda = \frac{h}{p} = \frac{h}{mv} \quad (1.108)$$

where m , the relativistic mass of the electron, is defined as

$$m = \frac{m_0}{\sqrt{1 - (v^2/c^2)}} \quad (1.109)$$

and m_0 is the electron rest mass, v is the speed of the electron, and c is the speed of light in a vacuum. Eq. (1.108) can then be written as

$$\lambda = \frac{h}{[m_0/\sqrt{1 - (v^2/c^2)}]v} \quad (1.110)$$

and

$$\lambda = \frac{h\sqrt{1 - (v^2/c^2)}}{m_0v} \quad (1.111)$$

Thomson (1928) used Eq. (1.111) from the de Broglie matter wave theory to calculate the wavelength of the electron beam produced in their electron diffraction apparatus. He only needed to know the speed of the electron, v , which was calculated from the electron kinetic energy. The following expression for the electron kinetic energy permits the calculation of the speed of the relativistic electron:

$$K = mc^2 - m_0c^2 \quad (1.112)$$

where m is the relativistic mass of the electron and m_0 its rest mass. From the expression of m of Eq. (1.109), the particle kinetic energy can be written as

$$K = \frac{m_0c^2}{\sqrt{1 - (v^2/c^2)}} - m_0c^2 \quad (1.113)$$

The electron rest energy in units of MeV is calculated as

$$\begin{aligned} E = m_0c^2 &= (9.109 \times 10^{-31} \text{ kg})(2.9979 \times 10^8 \text{ m/sec})^2 \\ &= 8.186 \times 10^{-14} \text{ J} \end{aligned} \quad (1.114)$$

The electron rest energy in joules is converted to units of MeV as

$$8.186 \times 10^{-14} \text{ J} / 1.602 \times 10^{-19} \text{ J/eV} = 0.511 \text{ MeV} \quad (1.115)$$

The known constant value of the electron rest energy, 0.511 MeV, can be inserted into Eq. (1.113) to calculate the electron velocity, v , from the measured value of its kinetic energy, K , as

$$K = \frac{0.511 \text{ MeV}}{\sqrt{1 - (v^2/c^2)}} - 0.511 \text{ MeV} \quad (1.116)$$

Thomson measured the kinetic energy of the electron beam produced in his apparatus in units of eV from an accurate measurement of the potential difference used to accelerate the electron toward the anode. From the measured value of K , he calculated the velocity of the electron according to Eq. (1.116).

Thomson (1938) used electron beams over the range of 20,000 to 60,000 V energy, which he reports to have wavelengths varying according to energy over the respective range of $0.8 \times 10^{-9} \text{ cm}$ to $0.5 \times 10^{-9} \text{ cm}$. For example, in his early detailed report of electron diffraction, Thomson (1928) used an electron beam of 25,000 V energy and calculated the wavelength of the electron beam according to Eq. (1.111) to be about $0.75 \times 10^{-9} \text{ cm}$. To arrive at the value of the electron wavelength, the velocity of the 25 keV electron is first calculated according to Eq. (1.113) as

$$\begin{aligned} K &= \frac{m_0c^2}{\sqrt{1 - (v^2/c^2)}} - m_0c^2 \quad \text{or} \\ 0.025 \text{ MeV} &= \frac{0.511 \text{ MeV}}{\sqrt{1 - (v^2/c^2)}} - 0.511 \text{ MeV} \end{aligned} \quad (1.117)$$

which is transposed to solve for the electron velocity, v , as follows:

$$\sqrt{1 - (v^2/c^2)} = 0.953 \quad (1.118)$$

and

$$1 - (v^2/c^2) = (0.953)^2 \quad (1.119)$$

and

$$\frac{v^2}{c^2} = 1 - 0.90821 \quad (1.120)$$

and

$$v^2 = 0.09179c^2 \quad (1.121)$$

or

$$v = 0.3029c \quad (1.122)$$

Thus, the calculated value of $v = 0.3029c$ is the velocity of the electrons of 25,000 V energy, which is 0.3029 times the speed of light in a vacuum.

From the calculated value of v , the wavelength λ of the 25 keV electrons is calculated as

$$\begin{aligned}\lambda &= \frac{h\sqrt{1 - (v^2/c^2)}}{m_0v} \\ &= \frac{6.626 \times 10^{-34} \text{ J sec} \sqrt{1 - \frac{[(.3029)(2.9979 \times 10^8 \text{ m/sec})]^2}{(2.9979 \times 10^8 \text{ m/sec})^2}}}{(9.109 \times 10^{-31} \text{ kg})(.3029)(2.9979 \times 10^8 \text{ m/sec})} \\ &= 0.076 \times 10^{-10} \text{ m} = 0.076 \text{ \AA}\end{aligned}\quad (1.123)$$

The above results agree closely with the calculated value of $0.75 \times 10^{-9} \text{ cm}$ reported by Thomson (1928).

Section X.E.2 provides a treatment of neutron velocity and wavelength as a function of neutron energy within the context of neutron classification. In that section, the following equation is derived for the calculation of the relativistic de Broglie wavelength:

$$\lambda_r = \frac{hc}{pc} = \frac{hc}{[2m_0c^2K(1 + (K/2m_0c^2))]^{1/2}} \quad (1.124)$$

where the constant hc , Planck's constant times the speed of light in a vacuum, is calculated in Section XI.A to have the value

$$hc = 12.4 \text{ keV} \cdot \text{\AA} = 12.4 \times 10^{-4} \text{ MeV} \cdot \text{nm}, \quad (1.125)$$

m_0c^2 is the particle rest energy, and K is the particle kinetic energy. We can take the example of Thomson's electron accelerated to 0.025 MeV described in the previous paragraphs and use Eq. (1.124) to calculate the electron's relativistic wavelength as follows:

$$\begin{aligned}\lambda_r &= \frac{hc}{pc} = \frac{12.4 \times 10^{-4} \text{ MeV} \cdot \text{nm}}{\{\sqrt{2(0.51 \text{ MeV})(0.025 \text{ MeV})[1 + (0.025 \text{ MeV}/2(0.51 \text{ MeV})]}\}} \\ &= \frac{12.4 \times 10^{-4} \text{ MeV} \cdot \text{nm}}{0.162 \text{ MeV}} \\ &= 7.6 \times 10^{-3} \text{ nm} = 0.076 \times 10^{-10} \text{ m} = 0.076 \text{ \AA}\end{aligned}$$

which is equivalent to the value calculated by Thompson (1928) according to Eq. (1.123) in his discovery of the electron de Broglie matter-wave. The application of Eq. (1.124) to the calculation of the relativistic de Broglie wavelength of the neutron as a function of neutron energy is provided in Section X. E.2 of this chapter.

VIII. Nuclear decay modes

Throughout this book numerous decay modes of atomic nuclei are described. These decay modes are manifested in general through the emission of nuclear radiation, such as α -particles, β -particles, γ -ray photons, protons, neutrons, neutrinos, and heavy cluster emissions. We also refer to the modes of nuclear decay as radioactive decay modes. The modes of nuclear decay are given specific nomenclature for reason of identification, such as (1) alpha-decay (α), (2) beta decay including negatron emission (β^-), positron emission (β^+), and electron capture (ϵ or EC), (3) isomeric transition (IT resulting in γ emission), (4) proton emission (p), (5) neutron emission (n), (6) spontaneous fission (SF), and (7) heavy cluster emission (^{14}C , ^{20}O , ^{23}F , ...). Most nuclear decay modes result in a transformation (*i.e.*, transmutation) of an atom of one element into another, as illustrated in Fig. 1.36. This figure depicts nuclear decay transitions that occur between blocks occupied by the various radionuclides in the Chart of the Nuclides, which is the "Periodic Table" of the nuclides (both stable and radioactive) separated in blocks

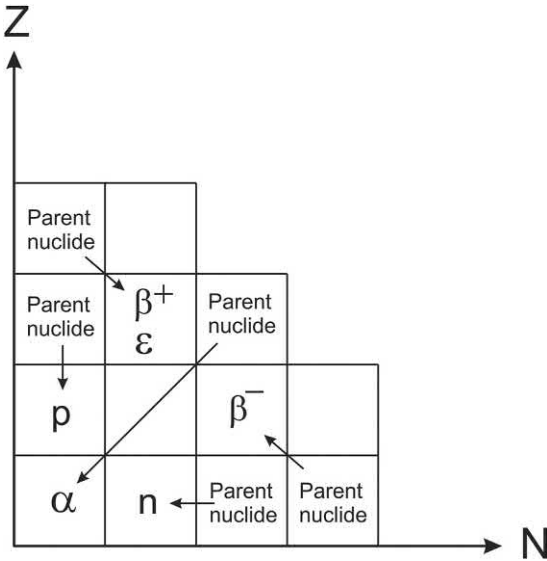

FIGURE 1.36 Nuclear decay mode transitions according to blocks occupied by the various nuclides in the Chart of the Nuclides plotted according to their number of protons (Z) and number of neutrons (N) in the nucleus. Various nuclear decay modes are illustrated that result in changes in the number of protons (atomic number, Z) or neutrons (neutron number, N) between parent and daughter nuclides. The radiation emitted or the decay modes are written in the blocks occupied by the daughter nuclides. For example, positron (β^+) emission or EC (ϵ) decay results in a reduction in proton number ($Z - 1$) and increase in neutron number ($N + 1$); whereas, negatron emission results in the opposite, that is, an increase in the number of protons in the nucleus ($Z + 1$) and reduction in the number of neutron ($N - 1$). Alpha (α) decay results in twofold reductions in the proton and neutron numbers in the nucleus ($Z - 2$ and $N - 2$). Proton (p) and neutron (n) radioactivity result in loss of only one or more protons or neutrons, respectively.

according to their atomic number (Z) and neutron number (N). The nuclear decays generally lead to a change in the atomic number (Z) and consequently a change from one element to another. The emission of a neutron (n) from the nucleus, also illustrated in Fig. 1.36, results in no change in atomic number and thus no change of element between parent and daughter nuclides; rather, the emission of one or more neutrons from the nucleus results in a change in the mass number of the same element resulting in an isotope of the same element. Also, another mode of nuclear decay, which does not result in a change in chemical elements between parent and daughter atoms, is the isomeric transition (IT) decay mode, not illustrated in Fig. 1.36. The IT decay results in a change from one energy state of an atomic nucleus to a lower energy state with the emission of gamma (γ) radiation. Heavy cluster emission is the emission of nuclei larger than the helium nucleus (*e.g.*, ^{14}C , ^{20}O , etc.) from a heavy nucleus, which for reasons of space, is not illustrated in Fig. 1.36.

Table 1.7 provides a list of nuclear decay modes together with their description and examples of each.

IX. Nuclear reactions

A nuclear reaction is an interaction between two nuclear particles or two nuclei that yields products which are

different from the reactants, that is, new nuclei are formed. If the interacting particles or nuclei only collide and separate without change, the process is referred to as **elastic scattering**. When a nuclear particle collides with a nucleus, but the nucleus only undergoes excitation to a higher energy state, the process is referred to as an **inelastic collision**.

A. Reaction types

The term nuclear reaction generally refers to the interaction of a projectile particle and a target nucleus that results in the production of a residual (product) nucleus and an ejected particle.

An example of a nuclear reaction is the following:

In the example provided by Eq. (1.126) a neutron, ${}_0^1\text{n}$, collides with the target nucleus ${}_{5}^{10}\text{B}$, whereby they coalesce to form an excited and unstable compound nucleus (abbreviated as CN*). The compound nucleus generally is not written, as it is very short-lived ($\sim 10^{-16}$ seconds). In this example the compound nucleus decays to yield the product nucleus ${}_3^7\text{Li}$ and an ejected alpha particle, ${}_2^4\text{He}$. The sum of the proton numbers and mass numbers must be equal on both sides of the reaction. For example, in Eq. (1.126) the proton numbers $0 + 5 = 3 + 2$ and mass numbers $1 + 10$ and $7 + 4$ are equal on both sides of the reaction. As illustrated in Eq. (1.126), there is kinetic energy released in this reaction to the amount of 2.8 MeV. This nuclear reaction is a very practical one because it is used for the detection of thermal neutrons. The nuclide ${}^{10}\text{B}$ has a high natural abundance of 20%, and when incorporated into the crystalline structure of a solid scintillation detector, the crystal becomes a sensitive detector for thermal neutrons. The alpha particles ejected as a product of the reaction have a very short range of travel in the crystalline detector. The kinetic energy of the alpha particles is in the MeV range, and the alpha particles dissipate their energy close to the point of neutron interaction. Solid scintillators of this type serve as good thermal neutron detectors.

Nuclear reactions between a specific projectile and target nucleus may result in more than one set of reaction products. For example, in his Nobel lecture, Enrico Fermi noted the following:

Neutron bombardment of aluminum, that has a single isotope ${}^{27}\text{Al}$, gives rise to three radioactive products: ${}^{24}\text{Na}$, with a half-life of 15 h ...; ${}^{27}\text{Mg}$, with a half-life of 10 min ...; and ${}^{28}\text{Al}$ with a half-life of 2 to 3 min ...

The three reactions described by Fermi (1938) may be written as follows:

TABLE 1.7 Nuclear decay modes.

Mode	Designation and description	Example
α	α emission. A nucleus of helium (${}^4_2\text{He}$) is emitted from the nucleus of the decaying atom.	${}^{241}_{95}\text{Am} \rightarrow {}^{137}_{93}\text{Np} + {}^4_2\text{He}$
β^-	β^- or negatron emission. A neutron is converted to a proton with the emission of a negative electron and an antineutrino. There is no change in mass number.	${}^3_1\text{H} \rightarrow {}^3_2\text{He} + \beta^- + \bar{\nu}$
β^+	β^+ or positron emission. A proton is converted to a neutron with the emission of a positive electron and a neutrino. There is no change in mass number.	${}^{11}_6\text{C} \rightarrow {}^{11}_5\text{B} + \beta^+ + \nu$
ϵ or EC	Electron capture. An atomic electron (e.g., K shell) is captured by a nuclear proton, and the proton is converted to a neutron with the emission of a neutrino. This is another form of beta decay, and there is no change in mass number. EC decay competes with positron emission.	${}^{65}_{30}\text{Zn} \rightarrow {}^{65}_{29}\text{Cu} + \nu$
IT	Isomeric transition. The transition of a nucleus from an excited elevated energy state to that of a lower energy state with the emission of gamma (γ) ray photons. There is no change in atomic number or mass number. The mass number of the parent nuclide is designated with the letter <i>m</i> to signify a metastable state when the gamma-ray emission is not immediate or a “prompt gamma”.	${}^{119m}_{50}\text{Sn} \rightarrow {}^{119}_{50}\text{Sn} + \gamma$
SF	Spontaneous fission. The spontaneous splitting of a nucleus into two nuclear fragments with the emission of neutrons. The possible nuclear fission fragments vary, and there are numerous fragment combinations possible.	${}^{252}_{98}\text{Cf} \rightarrow {}^{101}_{40}\text{Zr} + {}^{148}_{58}\text{Ce} + 3{}_0^1\text{n}$
p	Proton emission. The consecutive or simultaneous emission of one, two, or three protons from a proton-rich atomic nucleus. When two or three protons are emitted, the decay mode is identified as 2p and 3p, respectively.	${}^{147}_{69}\text{Tm} \rightarrow {}^{146}_{68}\text{Er} + \text{p}$
n	Neutron emission. The emission of one or two neutrons from a neutron-rich nucleus. The simultaneous emission of 2 neutrons is identified as a 2n decay mode.	${}^{16}_4\text{Be} \rightarrow {}^{14}_4\text{Be} + 2\text{n}$
$\beta^+\text{p}$	Beta-delayed proton emission. The emission of a proton from a populated elevated energy state of a proton-rich atomic nucleus following β^+ decay. The emission of two protons is designated as $\beta^+2\text{p}$.	${}^{13}_8\text{O} \rightarrow {}^{13}_7\text{F} + \beta^+ + \nu \rightarrow {}^{12}_6\text{C} + \text{p}$
$\beta^- \text{n}$	Beta-delayed neutron emission. The emission of a neutron from a populated elevated energy state of a neutron-rich atomic nucleus following β^- decay. The emission of two neutrons is designated as $\beta^-2\text{n}$.	${}^{94}_{35}\text{Br} \rightarrow {}^{94}_{36}\text{Kr} + \beta^- + \bar{\nu} \rightarrow {}^{93}_{36}\text{Kr} + \text{n}$
$2\beta^-$ or $\beta^-\beta^-$	Double β^- decay. Two neutrons decay to two protons in an atomic nucleus with the emission of two β^- -particles and two antineutrinos.	${}^{82}_{34}\text{Se} \rightarrow {}^{82}_{36}\text{Kr} + 2\beta^- + 2\bar{\nu}$
${}^{14}\text{C}, {}^{20}\text{O} \dots$	Cluster radioactivity. The spontaneous emission of a particle heavier than an α -particle with $Z \geq 6$, such as the emission of ${}^{14}\text{C}, {}^{20}\text{O}, {}^{23}\text{F}, {}^{24}\text{Ne}, {}^{28}\text{Mg}, {}^{30}\text{Mg}$, or ${}^{32}\text{Si}$.	${}^{221}_{87}\text{Fr} \rightarrow {}^{207}_{81}\text{Tl} + {}^{14}_6\text{C}$

From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.

An intermediary compound nucleus is illustrated as decaying into three possible decay products. The above reactions, that leave behind the residual nuclei of ${}^{24}\text{Na}$ and ${}^{27}\text{Mg}$, have negative Q values. These reactions are endoergic or endothermic. In these two cases, the neutron projectile must possess additional kinetic energy for the reaction to proceed. The reaction that produces the ${}^{28}\text{Al}$ residual nucleus has a positive Q value. This reaction is exoergic or exothermic resulting in a release of energy. Low-energy neutrons, classified as slow or thermal neutrons, are sufficient for this reaction to proceed. The capture of slow neutrons by nuclei is accompanied generally with the immediate emission of one or more gamma ray photons. The nuclei are left in a state of excitation after the neutron capture, and their ground state is reached after the emission of the gamma ray quanta. The Q value, as a measure of reaction energy, is discussed in Parts III.D and IX.B of this chapter.

The reactions were described in Eq. (1.127) as possessing a compound nucleus, and those reactions may be referred to as **compound nuclear reactions**. Two other types of nuclear reactions are classified as **pickup** and **stripping reactions**. When high-energy nuclear projectiles are used to bombard a target nucleus, the interaction can be more direct whereby the projectile does not interact with all of the nucleons of the target and thus, does not reside in a compound nucleus; but rather, the projectile may interact only with a few nucleons in specific nuclear shell-model orbits of the target. In such cases, the projectile may pick up or gain nucleons from the target nucleus in pickup reactions; or the projectile may lose nucleons to the target in stripping reactions. Some early studies of pickup and stripping reactions that may occur in specific nuclear shell-model orbits are the works of Kaschl et al. (1970) and Brien et al. (1972). Examples of pick-up and stripping reactions

TABLE 1.8 Examples of pick-up and stripping reactions.

Reaction	Condensed notation ^a	Projectile energy	Reference
Pick-up reactions:			
$^{13}_6\text{C} + ^1_1\text{H} \rightarrow ^{12}_6\text{C} + ^2_1\text{H}$	$^{13}_6\text{C}(p, d)^{12}_6\text{C}$	12 MeV	Glover and Jones (1966)
$^{12}_6\text{C} + ^3_1\text{H} \rightarrow ^{11}_5\text{B} + ^4_2\text{He}$	$^{12}_6\text{C}(t, \alpha)^{11}_5\text{B}$	10 MeV	Honda et al. (1965)
$^{20}_{10}\text{Ne} + ^2_1\text{H} \rightarrow ^{19}_9\text{F} + ^3_2\text{He}$	$^{20}_{10}\text{Ne}(d, h)^{19}_9\text{F}$	52 MeV	Kaschl et al. (1970)
$^{89}_{39}\text{Y} + ^2_1\text{H} \rightarrow ^{87}_{38}\text{Sr} + ^4_2\text{He}$	$^{89}_{39}\text{Y}(d, \alpha)^{87}_{38}\text{Sr}$	12 MeV	Brien et al. (1972)
Stripping reactions:			
$^{12}_6\text{C} + ^2_1\text{H} \rightarrow ^{13}_6\text{C} + ^1_1\text{H}$	$^{12}_6\text{C}(d, p)^{13}_6\text{C}$	12 MeV	Glover and Jones (1966)
$^{12}_6\text{C} + ^3_1\text{H} \rightarrow ^{13}_6\text{C} + ^2_1\text{H}$	$^{12}_6\text{C}(t, d)^{13}_6\text{C}$	12 MeV	Glover and Jones (1966)
$^{27}_{13}\text{Al} + ^3_2\text{He} \rightarrow ^{28}_{14}\text{Si} + ^2_1\text{H}$	$^{27}_{13}\text{Al}(h, d)^{28}_{14}\text{Si}$	41 MeV	Munger and Peterson (1978)
$^{194}_{78}\text{Pt} + ^3_2\text{He} \rightarrow ^{195}_{79}\text{Au} + ^2_1\text{H}$	$^{194}_{78}\text{Pt}(h, d)^{195}_{79}\text{Au}$	41 MeV	Munger and Peterson (1978)

^aThe condensed form of writing nuclear reactions is discussed subsequently in this chapter.

and the projectile energies at which these reactions were observed are listed in Table 1.8.

Spallation reactions are another class of nuclear reaction, which is gaining increased interest worldwide. Spallation occurs when a high-energy (>100 MeV) charged particle, such as a proton, strikes a nucleus whereby it initially “knocks-out” several nucleons from the target nucleus within a duration of about 10^{-22} seconds leaving the residual nucleus in an excited state. The excited residual nucleus may then immediately break up into numerous smaller components of nucleons such as helium and lithium nuclei, deuterons, mesons, and individual protons and neutrons, etc. In general, numerous neutrons are emitted from each spallation reaction making this reaction a good neutron source. Nobel Laureate Glenn T. Seaborg is credited with coining the term “nuclear spallation” in his doctoral dissertation in 1937 deriving the word from the verb “spall” meaning to chip or crumble.

Nuclear spallation is a common occurrence in our atmosphere when high-energy cosmic-ray particles of energies ranging from 10^8 to $>10^{20}$ eV strike nuclei in the atmosphere resulting in the fragmentation of nuclei into smaller nucleons constituting the cosmic-ray showers discussed further on in this chapter. Spallation reactions resulting from the interaction of high-energy particles in the cosmic-ray showers colliding with nuclei in mineral deposits on the earth’s surface is attributed to the cosmogenic production of nuclides, such as, ^{36}Cl (Stone et al., 1996; Licciardi et al., 2008).

There is current worldwide interest in the artificial production of spallation reactions as neutron sources referred to as spallation neutron sources (SNS). Spallation neutron sources are accelerator driven systems whereby protons are accelerated to high-energies (1 GeV and above), which then collide with heavy metal targets resulting in nuclear spallation with the emission of neutrons useful in research (Słowiński, 2003; Mason et al., 2006; Thomsen, 2007; Zamani et al., 2008).

Two other nuclear reactions that are very important sources of energy are nuclear fission and nuclear fusion. These are discussed in much detail in other parts of this chapter.

B. Notation

The nuclear reaction, illustrated by the above in Eq. (1.126), may be abbreviated as

$$^{10}_5\text{B}(n, \alpha)^7_3\text{Li} \quad (1.128)$$

which is written in the following sequence:

target nucleus(projectile, ejected particle)product nucleus. (1.129)

This condensed form of writing the nuclear reaction, as written above in Eq. (1.128), reads as follows: a ^{10}B target nucleus bombarded by neutrons ejects an alpha-particle leaving the residual ^7Li nucleus. Particles, which are often projectiles or ejected particles, in nuclear reactions are the following in name and abbreviation in parenthesis: proton (^1_1H or p), neutron (n), deuteron (^2_1H or d), Triton (^3_1H or t), helium-3 (^3_2He or h), and helium-4, *i.e.*, the alpha particle (^4_2He or α). Neutrons as projectiles for nuclear reactions with target nuclei are easily available from alpha particle induced nuclear reactions, such as the alpha-particle bombardment of beryllium (*i.e.*, $^9_4\text{Be}(\alpha, n)^{12}_6\text{C}$), which provide neutrons with average energies of 5.5 MeV. The nuclear fission reactor is another excellent source of neutrons available as projectile particles to induce nuclear reactions. Accelerators are also good sources of neutrons via spallation reactions induced by high-energy particle collisions with target nuclei. Various sources of neutrons are described further on in this chapter. The cyclotron is an excellent source of high-energy positively charged particles and nuclei, such as protons, deuterons, triton ions, and helium-3 and helium-4 ions. In the

cyclotron, target material is placed in the path of the accelerating ion, and numerous radionuclides are made via the nuclear reactions initiated by the bombardment of the positively charged projectiles with the target nuclei.

C. Energy of reactions (Q value)

The Q value of a nuclear reaction is a measure of the reaction energy. It is the difference between the kinetic energy of the reaction products and the kinetic energy of the original particles of the nuclear reaction. The Q value for the reaction illustrated above in Eq. 1.126 is reported in the literature to be 2.8 MeV. The Q values for all nuclear reactions are readily available online at the following website of the National Nuclear Data Center, Brookhaven National Laboratory: <http://www.nndc.bnl.gov/qcalc/> (NNDC, 2018a,b). At this website it is only needed to identify, the projectile, target nucleus, and the ejected particle. There is no need to input or identify the residual nucleus on this website, because the calculator can easily deduce the proton number and mass number of the residual nucleus by difference. The calculations made at this website are based on the data maintained by the Atomic Mass Data Center and on atomic mass evaluations reported by Wang et al. (2017). Q values for nuclear reactions are easy to calculate, and the calculation of Q values will be discussed subsequently in this section. The Q value is an important property of a nuclear reaction, because it will tell us whether a reaction will release kinetic energy ($Q > 0$) or lose kinetic energy ($Q < 0$). When $Q = 0$, the reaction is referred to as **elastic scattering** whereby the projectile and target nucleus collide and exchange energy; but they do not undergo any change. When the projectile and target nucleus collide, and part of the kinetic energy of the projectile is transferred to the target nucleus leaving the target at an excited energy state, the reaction is referred to as **inelastic scattering**. There is only energy transfer, but no change in atomic or mass number of the projectile or target nucleus in inelastic scattering reactions.

To arrive at the equation for the calculation of reaction Q values let us abbreviate the nuclear reaction of Eq. (1.126) in the form

where projectile A bombards nucleus B , which leaves behind a residual nucleus C and ejected particle D . If the total energy of the reactants and products are conserved, we can write

$$E_A + E_B = E_C + E_D \quad (1.131)$$

Also, the total energy (E) of a particle or nucleus is the sum of its kinetic energy (K) and its rest energy (m_0c^2), that is

$$E = K + m_0c^2 \quad (1.132)$$

where m_0 is the particle or nuclear rest mass, and c is the speed of light in a vacuum. Furthermore, if we assume

that the target nucleus is at rest, *i.e.*, it has zero kinetic energy, we can transform Eq. (1.131) to

$$K_A + m_Ac^2 + m_Bc^2 = K_C + m_Cc^2 + K_D + m_Dc^2 \quad (1.133)$$

The total kinetic energy released or absorbed in the reaction, Q , is the difference of the kinetic energies of the products and the reactants. In other words, it is the differences in the kinetic energies gotten out of the reaction versus what was put into the reaction, or

$$Q = K_{\text{out}} - K_{\text{in}} \quad (1.134)$$

Then from Eq. (1.133) we can write

$$Q = (K_C + K_D) - K_A = (m_A + m_B)c^2 - (m_C + m_D)c^2 \quad (1.135)$$

In accord with $E = mc^2$, Eq. (1.135) simple states

$$Q = E_{0, \text{reactants}} - E_{0, \text{products}} \quad (1.136)$$

where $E_{0, \text{reactants}}$ and $E_{0, \text{products}}$ are the rest energies of the nuclear reactants and products, respectively. Eqs. (1.135) and (1.136) may be simplified to read

$$Q = (m_{\text{reactants}})c^2 - (m_{\text{products}})c^2 \quad (1.137)$$

where $m_{\text{reactants}}$ and m_{products} are the combined masses of the nuclear reactants and products, respectively.

For example, in accord with Eqs. (1.135) and (1.137), the Q value for the nuclear reaction described previously in Eq. (1.126) and rewritten here in condensed form,

would be calculated as follows:

$$Q = (M_{1\text{n}} + M_{10\text{B}})c^2 - (M_{7\text{Li}} + M_{4\text{He}})c^2 \quad (1.139)$$

where $M_{1\text{n}}$, $M_{10\text{B}}$, $M_{7\text{Li}}$ and $M_{4\text{He}}$ are the masses of the neutron and ${}^{10}\text{B}$ reactants and the ${}^7\text{Li}$ and ${}^4\text{He}$ product nuclei, respectively, and c is the speed of light in a vacuum. We may use atomic mass units (u) taken from standard reference tables since the 5 atomic electron masses of the reactants and the product nuclides are included on both sides of the equation. Thus, using atomic mass units in Eq. (1.139) gives

$$Q = \left\{ \begin{array}{l} (1.00866492 \text{ u} + 10.012937 \text{ u})(931.494 \text{ MeV/u}) \\ -(7.016004 \text{ u} + 4.00260325 \text{ u})(931.494 \text{ MeV/u}) \end{array} \right\}$$

$$Q = 2.789 \text{ MeV}$$

The Q value is positive. Thus, energy is released in the nuclear reaction. The above calculated Q value of 2.789 MeV agrees with the computer-calculated Q value provided via the QCalc website of the NNDC (<http://www.nndc.bnl.gov/qcalc/>) of the Brookhaven National Laboratory.

When Q is positive, the reaction is called **exoergic**. In such a case, the reaction releases kinetic energy by

conversion of some of the rest mass to kinetic energy according to

$$E_{\text{Total}} = E_K + m_0 c^2 \quad (1.140)$$

Reactions with a positive Q value ($Q > 0$) are also called **exothermic**, since kinetic energy is released. When the Q value is negative ($Q < 0$) the reaction is called **endoergic** or **endothermic**, as kinetic energy would be absorbed in the reaction. In such a case, the reaction could not take place unless energy is added to the reactant particle or projectile. For example, from atomic mass data of the Atomic Mass Data Center (AMDC) (<http://amdc.impcas.ac.cn/web/masseval.html>), let us calculate the Q value of the following nuclear reaction used by Ernest Rutherford (1919) whereby he discovered the proton:

$$Q = (M_{{}^4\text{He}} + M_{{}^{14}\text{N}})c^2 - (M_{{}^{17}\text{O}} + M_{{}^1\text{H}})c^2$$

$$Q = \left\{ \begin{array}{l} (4.002603254 \text{ u} + 14.003074004 \text{ u})(931.494 \text{ MeV/u}) \\ - (16.999131756 \text{ u} + 1.007825032 \text{ u})(931.494 \text{ MeV/u}) \end{array} \right\}$$

$$Q = -1.19187 \text{ MeV} = -1191.87 \text{ keV} \quad (1.142)$$

The National Nuclear Data Center (QCalc) computer-calculated Q value yields the same energy of -1191.87 keV for the above reaction (<https://www.nndc.bnl.gov/qcalc/>). The reaction is endoergic ($Q < 0$) or endothermic, that is, energy is absorbed in the reaction. The reaction would require at least 1.192 MeV of energy to occur. Since the target nucleus is at rest, it is the projectile particle or nucleus that would carry the kinetic energy needed for the reaction to take place. Furthermore, there is a threshold energy (E_{th}) energy, which is by definition the minimum bombarding energy that the projectile particle must possess when Q is negative ($Q < 0$), for the reaction to take place. The threshold energy is calculated by the following equation, derived by Evans (1955):

$$E_{\text{th}} = -Q \left(\frac{M_1 + M_2}{M_2} \right) \quad (1.143)$$

where M_1 and M_2 are the masses of the projectile particle and target nucleus, respectively, as illustrated in Fig. 1.37. Using the Q value of -1.192 MeV , we can calculate the threshold energy of the alpha-particle projectile for reaction 1.141 to take place, with atomic mass data of the AMDC used in Eq. (1.142), as follows:

$$\begin{aligned} E_{\text{th}} &= -(-1.192 \text{ MeV}) \left[\frac{(4.002603254 \text{ u} + 14.003074004 \text{ u})(931.494 \text{ MeV/u})}{(14.003074004 \text{ u})(931.494 \text{ MeV/u})} \right] \\ &= 1.533 \text{ MeV} \end{aligned} \quad (1.144)$$

FIGURE 1.37 Three stages of a nuclear reaction, namely, (I) Collision of a projectile particle of mass M_1 with a target nucleus of mass M_2 forming a (II) Compound nucleus or intermediate nucleus M_C of mass equivalent to the combined masses of the projectile and target nucleus, and (III) Dissociation of the compound nucleus resulting in an ejected particle of mass M_3 and residual nucleus of mass M_4 expelled at angles θ_3 and θ_4 , respectively.

The calculated threshold alpha-particle projectile energy of 1.533 MeV would be required for reaction 1.141 to take place. Rutherford (1919) used alpha particles from Radium C' , which is today known as ${}^{214}\text{Po}$. The alpha particles from ${}^{214}\text{Po}$ have energies of 7.8 MeV well above the threshold energy for Reaction 1.141 to take place.

The projectile particle M_1 of Eq. (1.143) is illustrated in Fig. 1.37 traveling in the direction of the target nucleus M_2 , which forms an intermediate compound nucleus M_C , which has a mass equivalent to the combined masses of the projectile particle and target nucleus. The compound nucleus then dissociates into an ejected particle M_3 and a residual nucleus M_4 . Due to the very short lifetime of the combined nucleus ($\sim 10^{-22}$ seconds) or of an intermediate system that does not consist of the formation of a compound nucleus, Evans (1955) reports that M_C loses no appreciable energy due to ionization prior to dissociation into M_3 and M_4 . When particle M_3 is ejected at an angle $\theta_3 = 0$, the energy of the projectile particle is at the minimum or threshold energy E_{th} . As the projectile particle energy is raised over the threshold energy, the ejected particles M_3 begin to appear at $\theta_3 > 0$.

D. Reaction cross section

The reaction cross section is, by definition, the measure of the probability that a nuclear reaction will occur. The cross section has units of area (cm^2), and the term reaction cross section is used, because it is a term that depicts the effective area of the target nucleus. It is not a measure of the true cross section of a target nucleus; rather, it is a measure of

the effectiveness of the target nucleus to increase or reduce the probability of a nuclear reaction with a projectile particle. The larger the measured effective area or cross section of the target nucleus, the greater will be the probability that a projectile particle will hit or interact with the target nucleus. The probability, that a projectile particle collides with a target nucleus, will depend on the rate at which the projectile particles are bombarding the target material, that is, the particle beam intensity (I = projectile particles/second), the number of target nuclei in the target material or the target nuclei density (N = # of nuclei/cm³), the effective area of the target nucleus, that is, the cross section (σ) of the target nucleus (cm²), and the thickness (x) of the target material (cm). The variables affecting the probability of a nuclear reaction and consequently the rate of the reaction are illustrated in Fig. 1.38.

The rate of a nuclear reaction is a function of the effective target area exposed to the projectile particle beam. The effective target area is a product of the total number of target nuclei in the target material and the reaction cross section (σ) of the target nuclei. The number (#) of target nuclei in the target material is dependent on the density of the target nuclei and the target volume, that is,

$$\text{\# of target nuclei} = NAx \quad (1.145)$$

where N is the target nuclei density (# of nuclei/cm³), A is the target area (cm²), and x is the target thickness (cm). The effective target area is then calculated as

$$\text{Effective target area} = (\text{\# of target nuclei})(\sigma) \quad (1.146)$$

$$= NAx\sigma \quad (1.147)$$

FIGURE 1.38 Reaction target area. A beam of projectile particles bombards a material containing target nuclei of cross section (σ). Some of the projectile particles react with the target nuclei resulting in the ejection of particles as products of the nuclear reaction. The reaction rate is measured by a detector sensitive to the ejected particles.

We can reason that the rate of the reaction is related to the particle beam intensity as the effective target area is to the total target area, or

$$\frac{\text{Rate of reaction (particles/s)}}{\text{Beam intensity (particles/s)}} = \frac{\text{Effective target area (cm}^2\text{)}}{\text{Total target area (cm}^2\text{)}} \quad (1.148)$$

or

$$\frac{R}{I} = \frac{N(Ax)\sigma}{A} = N\sigma x \quad (1.149)$$

and

$$R = IN\sigma x \quad (1.150)$$

where R is the rate of the reaction (ejected particles/s), I is the projectile beam intensity (projectile particles/s), N is the density of target nuclei (# of target nuclei/cm³), σ is the reaction cross section (cm²), and x is the target thickness (cm). The cross section may be determined experimentally from the reaction rate, projectile beam intensity, target nuclei density, and the target thickness. As described in the previous section on reaction Q value, the rate of a nuclear reaction will depend also on the energy of the projectile particles bombarding the target nuclei. Thus, reaction cross sections are reported together with the projectile particle energy (Zhou et al., 2010; Madani et al., 2010; Yigit, 2017; Ghosh et al., 2017a,b; Mosby et al., 2017). Thorough treatments of reaction cross section are given by Evans (1955), Friedlander et al. (1964), and Serway et al. (2005).

The common unit of measure for the reaction cross section is the barn where one b = 1×10^{-24} cm². This measure of cross section was first used by Baker et al. (1943) and proposed by Marshall P. Holloway and Charles P. Baker (1944) as the unit of measure for the cross section in secret technical reports of the Los Alamos National Laboratories during the Manhattan Project. Holloway and Baker (1944, 1972) reported that, while measuring reaction cross sections at Purdue University, they tried to come up with a suitable unit of measure. They thought of the word "Oppenheimer", but discarded the idea because of the word's length. They also considered the "Bethe", but discarded that, because of possible confusion with the widespread use of "beta". They also considered using the name "John" after John Manley, who headed the Purdue Project, but also discarded that because that word had widespread use for purposes other than the name of a person. One of the authors had a rural background, and on farms in the countryside, the broad side of a barn was always the largest building, which could be seen at a distance. There was then the very common colloquial term "big as a barn", and the term is still used today. It was a common saying then to sportsmen, who had poor aim such as poor marksman, archers, or golfers, that "they couldn't hit the side of a

barn". Barns were built generally longer than they were wide, and thus the broad side or length of a barn was the largest part of a barn, which could be seen from a distance. They reported then that the unit "barn" was appropriate, because a cross section of 10^{-24} cm² for nuclear processes was very large and really "as big as a barn". Submultiples and multiples of the barn are also used, such as the millibarn (mb = 10^{-3} barns) and the kilobarn (kb = 10^3 barns).

We may take an example of the practical application of Eq. (1.150) to calculate the rate of absorption of thermal neutrons via the $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction by crystalline boric acid (H_3BO_3). The nuclide ^{10}B has a high cross section for the absorption of thermal neutrons. The value of σ for the (n, α) reaction at the thermal neutron energy of 0.025 eV is 3.842×10^3 barns. According to Eq. (1.150), the rate of the (n, α) reaction as a function of the projectile beam intensity may be written as

$$R = IN\sigma x \quad (1.151)$$

The value of N , namely, the density of the ^{10}B target nuclei with units of # of target nuclei/cm³ is calculated as

$$N = \frac{\delta N_A}{A} \quad (1.152)$$

where δ is the density of the absorbing material or compound, N_A is Avogadro's number, A is the molar mass of the absorbing compound, and the value of N is

$$\begin{aligned} N &= \frac{(1.44 \text{ g/cm}^3)(6.022 \times 10^{23} \text{ molecules H}_3\text{BO}_3/\text{mol})(1 \text{ atom B/molecule})(0.199 \text{ atoms } ^{10}\text{B/atom boron})}{61.8 \text{ g H}_3\text{BO}_3/\text{mol}} \\ &= 2.79 \times 10^{21} \text{ atoms of } ^{10}\text{B}/\text{cm}^3 \end{aligned}$$

The term 0.199 atoms ^{10}B /atom B is included here, because natural boron consists of 19.9% ^{10}B . Eq. (1.151) is solved for a boric acid thickness $x = 0.01$ cm and a neutron beam intensity of 6×10^{14} neutrons/cm²·s as follows:

$$\begin{aligned} R &= IN\sigma x \\ &= (6 \times 10^{14} \text{ n/cm}^2 \cdot \text{s})(2.79 \times 10^{21} \text{ atoms } ^{10}\text{B}/\text{cm}^3)(3.842 \\ &\quad \times 10^3 \text{ barns/atom } ^{10}\text{B})(1 \times 10^{-24} \text{ cm}^2/\text{barn})(0.01 \text{ cm}) \\ &= 6.43 \times 10^{13} \text{ neutrons/cm}^2 \cdot \text{s} \end{aligned}$$

Thus, the rate of neutron capture by the 1 cm² of the pure crystalline H_3BO_3 in this example is 6.43×10^{13} neutrons/s. The ratio of the rate of neutron capture and incident neutron intensity is

$$R/I = 6.43 \times 10^{13} \text{ n/cm}^2 \cdot \text{s} / 6 \times 10^{14} \text{ n/cm}^2 \cdot \text{s} = 0.107$$

which represents 10.7% of the incident neutron flux. Elemental boron, which contains a natural abundance of 19.1 atom % of ^{10}B has a high cross section for the absorption of thermal neutrons. In pressurized water reactors (PWRs) the boric acid may be dissolved in reactor coolant at a relatively low concentration (up to 2000 ppm or 0.2%) to reduce fission. Some reactors may use boric acid enriched in ^{10}B up to a 40% atom %.

Two very important nuclear reactions, not discussed in this section and vital energy sources, are nuclear fission and fusion. These are discussed in detail in other parts of this chapter.

X. Particulate radiation

All types of nuclear radiation over all ranges of energy will have a dual nature, that of a particle and a wave. Earlier in this chapter the work of Louis Victor de Broglie was described, whereby he demonstrated, that all particles of known rest mass (*e.g.*, alpha particles, beta particles, neutrons, etc.) would, in motion, display the properties of a wave with a wavelength inversely proportional to the particle momentum. For the purpose of classifying radiation in this chapter, particulate radiation will be all types of radiation that have a known mass at rest.

A. Alpha decay

Alpha decay is the nuclear decay process whereby the parent nucleus emits an alpha particle. The alpha particle, structurally equivalent to the nucleus of a helium atom and denoted by the Greek letter α , consists of two protons and two neutrons. Alpha particles are emitted as decay products of many radionuclides that consist of relatively large nuclei predominantly of atomic number greater than 72. For example, the radionuclide americium-241 decays by alpha particle emission to yield the daughter nuclide ^{237}Np according to the following equation:

The loss of two protons and two neutrons from the americium nucleus results in a mass reduction of four and a charge reduction of two on the nucleus. In nuclear

equations such as the preceding one, the subscript denotes the charge on the nucleus (*i.e.*, the number of protons or atomic number, also referred to as the *Z* number) and the superscript denotes the mass number (*i.e.*, the number of protons plus neutrons, also referred to as the *A* number). The 5.638 MeV of Eq. (1.153) is the decay energy, which is described subsequently.

1. Alpha decay energy

The energy liberated during nuclear decay is referred to as decay energy. Many reference sources report the precise decay energies of radioisotopes. The energy released in alpha decay will be reviewed in this section and the decay of ^{241}Am will be taken as an example. The value reported by the National Nuclear Data Center (NNDC, 2018a,b) of the Brookhaven National Laboratory (<http://www.nndc.bnl.gov/qcalc>) for the decay energy of ^{241}Am , illustrated in Eq. (1.153), is 5.638 megaelectron volts (MeV).

The alpha decay equation may be described in general terms as follows:

where A_ZP is the parent nucleus of atomic number *Z* and mass number *A*, ${}^{A-4}_{Z-2}D$ is the daughter nucleus of atomic number *Z*−2 and mass number *A*−4, ${}^4_2\text{He}$ is the alpha particle equivalent to a helium nucleus, and K_T is the total kinetic energy released in the alpha-decay. The total kinetic energy released, also referred to as the decay energy (Q_α) is shared between the alpha particle, recoil daughter nucleus, and gamma radiation or

$$Q_\alpha = K_T = E_\alpha + E_{\text{recoil}} + E_\gamma \quad (1.155)$$

where E_α is the kinetic energy of the alpha particle, E_{recoil} is the kinetic energy of the recoil daughter nucleus, and E_γ is the energy lost as gamma radiation from the daughter nucleus, when the daughter nucleus is left at an excited energy state and decays to its ground state. We will use the symbol “*E*” for kinetic energy, rather than “*K*”, when referring to the kinetic energy of the radiation and recoil nuclei, as it is the symbol most commonly used, and the kinetic energy is inferred. The decay energy is represented by *Q* as the “*Q* value”. The decay energy of 5.638 MeV of Eq. (1.153) above, may be written as Q_α for alpha-decay energy, which may be composed of the energies of the alpha-particle, recoil daughter nucleus, and gamma radiation described in Eq. (1.155). Energy and mass are conserved in the decay process; that is, the energy liberated in radioactive decay is equivalent to the loss of mass by the parent radionuclide (*e.g.*, ^{241}Am) or, in other words, the difference in masses between the parent radionuclide and the product nuclide and particle.

We can calculate the energy liberated in the decay of ^{241}Am , as well as for any radionuclide decay, by

accounting for the mass loss in the decay equation. Using Einstein’s equation for equivalence of mass and energy

$$E = mc^2 \quad (1.155)$$

we can write the general equation for the energy equivalence to mass loss as

$$Q = (\text{mass of parent nuclide} - \text{mass of decay products})c^2 \quad (1.157)$$

For the decay of ^{241}Am described in Eq. (1.153) above, we can write Eq. (1.157) as

$$Q_\alpha = (M_{^{241}\text{Am}} - M_{^{237}\text{Np}} - M_\alpha)c^2 \quad (1.158)$$

where Q_α is the disintegration or alpha decay energy, $M_{^{241}\text{Am}}$, $M_{^{237}\text{Np}}$ and M_α are the masses of ^{241}Am , ^{237}Np , and the alpha particle, and *c* is the speed of light in a vacuum. We may use atomic mass units (u) for the calculation, because the electron masses included with atomic mass units may be ignored. The number of electrons on both sides of the decay Eqs. (1.153) and (1.154) are equal, and we can ignore the negligible differences in the binding energies of the electrons. When the nuclide masses are expressed in the more convenient atomic mass units (u), the energy liberated in decay equations can be calculated in units of megaelectron volts according to the equation

$$Q_\alpha = (M_{^{241}\text{Am}} - M_{^{237}\text{Np}} - M_\alpha)(931.494 \text{ MeV/u}) \quad (1.159)$$

The precise atomic mass units obtained from reference tables (Rumble, 2017) or the National Institute of Standards and Technology (NIST, <https://www.nist.gov/pml/atomic-weights-and-isotopic-compositions-relative-atomic-masses>) can be inserted into Eq. (1.159) to obtain

$$\begin{aligned} Q_\alpha &= (241.0568293 \text{ u} - 237.0481736 \text{ u} - 4.0026032 \text{ u}) \\ (931.494 \text{ MeV/u}) &= (0.0060525 \text{ u})(931.494 \text{ MeV/u}) \\ &= 5.6378 \text{ MeV} \end{aligned}$$

which corresponds to the online computer calculated value of 5637.8 keV (National Nuclear Data Center, https://www.nndc.bnl.gov/nudat2/indx_dec.jsp). The energy liberated is shared between the daughter nucleus and the α -particle. If the parent nuclide (*e.g.*, ^{241}Am) is at rest when it decays, most of the decay energy will appear as kinetic energy of the liberated less-massive α -particle and only a small fraction of the kinetic energy remaining with the recoiling massive daughter nuclide (*e.g.*, ^{237}Np). The kinetic energy of the recoiling daughter nuclide is comparable to that of a recoiling canon after a shell is fired; the shell being analogous to that of the α -particle shooting out of the nucleus, as illustrated in Fig. 1.39.

Fig. 1.40 illustrates the transitions involved in the decay of ^{241}Am . The interpretation of this figure is given in the

FIGURE 1.39 The alpha particle shoots out of a nucleus. In the decay of nuclides by alpha particle emission, the alpha particle will shoot out of the nucleus, and the daughter nucleus will recoil similar to that of a canon that recoils upon firing a shell from its barrel.

FIGURE 1.40 Decay scheme of ^{241}Am . The relative intensities of alpha-particle and gamma-ray emissions are expressed in percent beside the radiation energy values in MeV.

following paragraph. There are five major α -particle transitions in the decay of ^{241}Am , each involving an α -particle emission at different energies and relative intensities. These are illustrated in Fig. 1.40. The decay energy of 5.6378 MeV for ^{241}Am calculated above and reported in the literature is higher than any of the α -particle energies provided in Fig. 1.40. This is because there remains also the recoil energy of the daughter nucleus and any gamma ray energy that may be emitted by the daughter, when its nucleus remains at an excited state. The emission of gamma radiation often accompanies radionuclide decay processes that occur by alpha particle emission. Gamma radiation is described in Part XI.B of this chapter. The recoil energy, E_{recoil} , of the daughter nucleus can be calculated by the equation

$$E_{\text{recoil}} = (M_{\alpha} / M_{\text{recoil}})E_{\alpha}, \quad (1.160)$$

which is derived in Part XIII of this chapter, where M_{α} is the mass of the alpha particle as defined in Eqs. 1.159, M_{recoil} is the mass of the recoil nucleus, and E_{α} is the

α -particle energy. For example, the recoil energy of the ^{237}Np daughter nucleus for the transition of the 5.545 MeV alpha particle (Fig. 1.40) can be calculated according to Eq. (1.160) as

$$\begin{aligned} E_{\text{recoil}} &= (4.00260325\text{u}/237.048166\text{u})5.545\text{ MeV} \\ &= (0.0168851897)(5.545\text{ MeV}) \\ &= 0.0936\text{ MeV} \end{aligned}$$

The transition energy, E_{trans} , for the above α -particle emission is the sum of the α -particle and recoil nuclear energies or

$$\begin{aligned} E_{\text{trans}} &= E_{\alpha} + E_{\text{recoil}} \\ &= 5.545\text{ MeV} + 0.0936\text{ MeV} \\ &= 5.638\text{ MeV} \end{aligned} \quad (1.161)$$

In the above case, the transition energy turns out to be equal to the reported and calculated decay energy because as illustrated in Fig. 1.40, the ^{241}Am radionuclides decay directly to the ground state whenever 5.545 MeV α -particles are emitted. This is not the case when α -particles of other energies are emitted from ^{241}Am . If we take, for example, the 5.486 MeV α -particle transition of Fig. 1.40, the decay energy, E_{decay} , would be the sum of the transition energy plus gamma ray energy, E_{γ} , emitted from the daughter nucleus or

$$\begin{aligned} E_{\text{decay}} &= E_{\text{trans}} + E_{\gamma} \\ &= E_{\alpha} + E_{\text{recoil}} + E_{\gamma} \\ &= E_{\alpha} + (M_{\alpha}/M_{\text{recoil}})E_{\alpha} + E_{\gamma} \\ &= 5.486\text{ MeV} + (4.00260325\text{ u}/237.048166\text{ u}) \\ &\quad (5.486\text{ MeV}) + 0.059\text{ MeV} \\ &= 5.486\text{ MeV} + 0.0926\text{ MeV} + 0.059\text{ MeV} \\ &= 5.638\text{ MeV} \end{aligned} \quad (1.162)$$

The gamma ray energy emitted from the daughter nucleus for the 5.486 MeV α -particle transition in ^{241}Am decay is illustrated in Fig. 1.40. Gamma ray energy values of other radionuclides are available from reference tables (Browne et al., 1986; Firestone et al., 1996; Lederer and Shirley, 1978; Appendix A of this book and the Internet via the Interactive Chart of the Nuclides of the National Nuclear Data Center, Brookhaven National Laboratory, <http://www.nndc.bnl.gov/nudat2/index.jsp>).

As described in the previous paragraphs, alpha particles are emitted with a certain quantum of energy as the parent

nuclide decays to a lower energy state. The energy emitted from radionuclides as nuclear radiation can be described by a decay scheme such as that given in Fig. 1.40. Decay schemes are written such that the energy levels of the nuclides are plateaus along the ordinate, and these energy plateaus are distributed along the abscissa according to atomic number. The alpha particles, as the example shows (Fig. 1.40), are emitted with certain magnitudes of kinetic energy, which is most often expressed in units of kiloelectron volts (keV) or megaelectron volts (MeV). The energies of alpha particles from most nuclear decay reactions fall within the range 4–10.5 MeV.

Alpha particles are emitted from unstable nuclei with discrete quanta of energy, often leaving the daughter nuclide at an excited energy state. In such cases, when the daughter nuclide occurs at an elevated energy state, it may reach the ground state via the emission of energy in the form of electromagnetic gamma radiation as illustrated in Fig. 1.40.

The nuclei of daughter atoms of alpha particle-emitting nuclides are often unstable themselves and may decay by further alpha or beta particle emission. Thus, alpha particle-emitting nuclides may consist of a mixture of radionuclides, all part of a decay chain, as illustrated in Figs. 1.8–1.11 described previously in this chapter.

2. Alpha decay energy and half-life relationship

Alpha particles are emitted by radionuclides with distinct energies that range between 4 and 10 MeV, and half-lives of the nuclides will vary over a wide range of time from 10^{10} years to microseconds. Radionuclides, emitting alpha particles of low energy, decay with long half-lives; whereas, those emitting alpha particles of high energy, have short half-lives.

A relationship between alpha decay energy and the half-life of the nuclide was recognized very early in the history of the study of radionuclide decay. German physicist Hans (Johannes Wilhelm) Geiger, best known for the Geiger–Müller counter, and British physicist John Mitchell Nuttall (Geiger and Nuttall, 1911) were the first to measure a relationship between alpha particle energy and half-life decay of even-*Z* even-*A* radionuclides, that is, radionuclides that had an even number of protons and even atomic number. By correlating half-life measurements with the range of alpha particles emitted by several radionuclides Geiger and Nuttall (1911) determined the best-fit linear relationship between the two variables and reported the following equation, which is known as the Geiger–Nuttall Law:

$$\log \lambda = a \log R + b \quad (1.163)$$

where λ is the radionuclide decay constant, R is the alpha particle range (cm) and a and b are constants that provided the best fit to the experimental data. Since $\lambda = 0.693/t_{1/2}$, where $t_{1/2}$ is the half-life, it is clear from Eq. (1.163), that for shorter values of $t_{1/2}$ there are correspondingly increasing magnitudes of the alpha-particle range (R). The range of travel of the alpha particle is proportional to its energy. Consequently, the Geiger–Nuttall Law provided a correlation between radionuclide decay half-life and alpha decay energy. Other variations of the best fit equation were reported subsequently to the work of Geiger and Nuttall, which provided best-fit empirical equations for specific radionuclide decay series (Beckerly, 1945), but the correlation of half-life decay and decay energy remained the same.

Alpha decay energy and half-life of heavy elements of even *Z* even *A* were studied by Perlman and Ypsilantis (1950) on the basis of the shell structure of nuclei. They found a direct and exponential relationship between half-life and alpha decay energy for many even *Z* even *A* radioisotopes of the heavy elements, which is illustrated in Fig. 1.41.

Radionuclides that are not even *Z* and even *A* (*i.e.*, even *Z* odd *N*, odd *Z* even *N*, or odd *Z* odd *N*) also obey the general rule whereby nuclides with low alpha decay energy exhibit long half-lives, and nuclides with high alpha decay energy exhibit short half-lives. However, these nuclides exhibit longer half-lives than even-even nuclides, because

FIGURE 1.41 Observed values of half-life and total alpha-decay energy for each nuclide. The mass number of the radioactive parent nuclide is given at each point. The curves represent the theoretical values for radioactive parents having the same atomic number (isotopes). The range in half-life for the radionuclides, in the curves provided, is 1.6×10^{-4} seconds for ^{214}Po to 1.4×10^{10} y for ^{232}Th . The reader will note from the figure that, at the time of this report, the mass numbers were written as superscripts to the right of the element symbol. Currently mass numbers are written as superscripts to the left of the element symbol. From Perlman and Ypsilantis (1950), United States Atomic Energy Commission Report UCRL-613, February 27, 1950.

these nuclides must first transition to an excited state prior to the formation of the alpha particle, which is an even-even nucleus of two protons and two neutrons. The alpha particle must be assembled within the nucleus from proton and neutron nuclear shells, and the transition to the excited nuclear state will prolong the nuclear decay to yet longer half-lives (Perlman et al., 1950; Evans, 1955; Loveland, 2004).

The shorter half-lives exhibited by radionuclides with high alpha decay energies compared to the longer half-lives of nuclides with lower decay energies is explained on the basis of the nuclear potential barrier, that the alpha particle must overcome to penetrate or escape from the nucleus. By bombarding a thin foil of aluminum with 8.75 MeV alpha particles, Rutherford (1927) demonstrated that the high-energy alpha particles were scattered by the aluminum nuclei at a distance of 30×10^{-13} cm from the center of the nucleus, as illustrated in Fig. 1.42. A Coulomb potential barrier, which is inversely proportional to the distance from the center of the nucleus, repels incoming alpha particles as well as inhibits their escape from the nucleus. Question therefore arose as to how alpha particles, which are emitted from decaying nuclei with energies as low as 4 MeV, escape from the nucleus. Gamow (1928) and Gurney and Condon (1928) independently used Schrödinger's wave mechanics to demonstrate that, within the nucleus, the

alpha particle as a wave need not pass over the Coulomb barrier, but that the alpha particle wave could tunnel its way through the potential barrier and escape from the nucleus. The probability of the alpha-particle escape will be a function of the energy of the alpha particle and the amount of potential barrier that the alpha particle must overcome. Alpha decay energies, among all of the alpha-decaying radionuclides, vary between approximately 4 and 10 MeV. A high alpha decay energy yields alpha particles with less Coulomb barrier to overcome, which augments the probability for alpha particle escape resulting in a shorter half-life. The opposite would be the case for a low alpha decay energy, which would yield alpha particles with a greater Coulomb barrier or reduced penetrability and thus lower probability of escape, resulting in a longer decay time or half-life.

3. Alpha-particle interactions with matter

Now consider what happens to an alpha particle that dissipates its kinetic energy by interaction with matter. Alpha particles possess a double positive charge due to the two protons present. This permits ionization to occur within a given substance (solid, liquid or gas) by the formation of ion pairs due to coulombic attraction between a traversing alpha particle and atomic electrons of the atoms within the material the alpha particle travels. The two neutrons of the alpha particle give it additional mass, which further facilitates ionization by coulombic interaction or even direct collision of the alpha particle with atomic electrons. The much greater mass of the alpha particle, 4 atomic mass units (u), in comparison with the electron (5×10^{-4} u) facilitates the ejection of atomic electrons of atoms through which it passes, either by direct collision with the electron or by passing close enough to it to cause its ejection by coulombic attraction. The ion pairs formed consist of the positively charged atoms and the negatively charged ejected electrons. The alpha particle continues along its path suffering, for the most part, negligible deflection by these collisions or coulombic interactions because of the large difference in mass between the particle and the electron. An exception will be a less common (\sim one in a few thousand) deflection or scattering of the alpha particle due to a direct collision with the Coulombic barrier of an atomic nucleus. Thus, an alpha particle travels through matter producing thousands of ion pairs (see the following calculation) in such a fashion until its kinetic energy has been completely dissipated within the substance it traverses.

In air, an alpha particle dissipates an average of 35 eV (electron volts) of energy per ion pair formed. Before it stops, having lost most of its energy, an alpha particle produces many ion pairs. For example, as a rough estimate, a 5-MeV alpha particle will produce 1.4×10^5 ion pairs in air before coming to a stop:

FIGURE 1.42 Nuclear potential barrier and potential energy well based on schematics of Gamow (1930) and Evans (1955). The nuclear radius is from 0 to R , and the distance from the center of the nucleus is r . The potential energy of the bound nucleus within the well is considered constant from $-U_0$ to 0. The Coulomb potential barrier U is inversely proportional to the distance from the center of the nucleus according to $U = (Ze)(ze)/r$ or Zze^2/r where Z is the atomic number or charge on the nucleus and z is the proton number of the alpha particle ($z = 2$). Excess energy of the unstable nucleus, required for alpha-particle emission, is represented by the energy level U_1 along the potential energy scale, and the height of the potential barrier occurs at U_2 where $r = R$. For a perspective on the nuclear dimensions, data from Evans (1955) for the uranium nucleus ($Z = 92$) are the following: $R \approx 9.3 \times 10^{-13}$ cm, $U_1 \approx 4$ MeV, and $U_2 \approx 28$ MeV.

$$\frac{5 \times 10^6 \text{ eV}}{35 \text{ eV/ion pair}} = 1.4 \times 10^5 \text{ ion pairs in air} \quad (1.164)$$

The thousands of interactions between a traveling alpha particle and atomic electrons can be abstractly compared with a rolling bowling ball colliding with stationary ping-pong balls. Because of the large mass difference of the two, it will take thousands of ping-pong balls to stop a bowling ball. The additional stopping force of electrons is the binding energy of the atomic electrons.

The amount of energy required to produce ion pairs is a function of the absorbing medium. For example, argon gas absorbs approximately 25 eV per ion pair formed and a semiconductor material requires only 2–3 eV to produce an ion pair. Ionization is one of the principal phenomena utilized to detect and measure radionuclides, and it is treated in more detail in subsequent chapters. The energy threshold for ion pair formation in semiconductor materials is approximately 10 times lower than in gases, which gives semiconductor materials an important advantage as radiation detectors (see Chapter 4) when energy resolution in radioactivity analysis is an important factor.

In addition to ionization, another principle mechanism by which alpha particles and charged particles, in general, may impart their energy in matter is via electron excitation. This occurs when the alpha particle fails to impart sufficient energy to an atomic electron to cause it to be ejected from the atom. Rather, the electrons of atoms of a given material may absorb a portion of the alpha particle energy and become elevated to a higher energy state. Depending on the absorbing material, the excited atoms of the material may immediately fall back to a lower energy state or ground state by dissipating the absorbed energy as photons of visible light. This process, referred to as fluorescence, was first observed by Sir William Crookes in London in 1903 (Crookes, 1903a,b) and soon confirmed by Julius Elster and Hans Geitel the same year (Elster and Geitel, 1903) in Wolfenbüttel, Germany. They observed fluorescence when alpha particles emitted from radium bombarded a zinc sulfide screen. In darkness, individual flashes of light were observed and counted on the screen with a magnifying glass with the screen positioned a few millimeters from the radium source. The phenomenon of fluorescence and its significance in the measurement of radionuclides are discussed in subsequent chapters. Thus, as described in the previous paragraphs, alpha particles as well as other types of charged particles, dissipate their energy in matter mainly by two mechanisms, ionization and electron excitation.

Because the atomic “radius” is much larger ($\approx 10^{-10}$ m) than the “radius” of the nucleus ($\approx 10^{-14}$ m), the interactions of alpha particles with matter via direct collision with an atomic nucleus are few and far between. However, when a direct collision of an alpha particle with an atomic nucleus does occur, the large mass of the

nucleus causes deflection or ricocheting of the alpha particle via coulombic repulsion without generating any change within the atom. Such deflections were discovered in the early part of this century by Ernest Rutherford and his students Hans Geiger and Ernest Marsden in an experiment discussed previously in detail in Section II of this chapter.

Scattering of alpha particles at angles of less than 90 degrees may occur by coulombic repulsion between a nucleus and a particle that passes in close proximity to the nucleus. These deflected particles continue traveling until sufficient energy is lost via the formation of ion pairs. The formation of ion pairs remains, therefore, the principal interaction between alpha particles and matter.

The high mass and charge of the alpha particle in relation to other forms of nuclear radiation give it greater ionization power, but a poorer ability to penetrate matter. In air, alpha particles may travel only a few centimeters. This short range of travel varies depending on the initial energy of the particle. For example, a 5.5-MeV alpha particle, such as that emitted by the radionuclide ^{241}Am previously described, has a range of approximately 4 cm in dry air at standard temperature and pressure, as estimated by the empirical equation described by Lapp and Andrews (1948), namely Eq. (1.165).

$$R_{\text{air}} = (0.005E + 0.285)E^{3/2} \quad (1.165)$$

where R is the average linear range in cm of the alpha particle in air and E is the energy of the particle in MeV. The empirical formula is applied for alpha particles in the energy range 4–15 MeV. For example, Eq. (1.165) yields a value of 4.03 cm for the range of a 5.5 MeV alpha particle in dry air.

More accurate ranges are available from the following online ASTAR (Alpha Stopping Power and Range) computer program of the National Institute of Standards and Technology (NIST) <https://physics.nist.gov/PhysRefData/Star/Text/programs.html>, which utilizes the Bethe (1930) stopping-power formula for alpha-particle energies above 2 MeV and fitting formulas based on experimental stopping power data for alpha-particles below 2 MeV. The online ASTAR computer provides a projected range of $5.010 \times 10^{-3} \text{ g/cm}^2$ for the 5.5 MeV alpha particle in dry air near sea level, which divided by the density of dry air near sea level ($1.205 \times 10^{-3} \text{ g/cm}^3$) yields a range of 4.15 cm, which agrees closely with the range calculated by the empirical formula of Eq. (1.165). The online ASTAR program provides the ranges of alpha particles or helium nuclei in dry air, other gases, chemical elements, glass, synthetic polymers, inorganic and organic compounds, and biological tissue, etc over a wide energy range from 0.001 to 1000 MeV. All that is needed is to select the medium and the energy of the alpha particle.

FIGURE 1.43 Range of 5.5 MeV alpha particles in air.

According to calculations of [Fenyves and Haiman \(1969\)](#), the ranges of alpha particles with energies between 4 and 7 MeV can be estimated by using a simplified version of [Eq. \(1.165\)](#) as follows:

$$R_{\text{air}} = 0.3E^{3/2} \quad (1.166)$$

Also, ranges of alpha particles in air over a wide range of alpha particle energy can be obtained from Figure B.1 of Appendix B of Volume 2. The online ASTAR program described above yields the more accurate calculations of alpha particles ranges.

The approximate 4-cm range of 5.5-MeV alpha particles in air is illustrated in [Fig. 1.43](#). There is no abrupt drop in the number of alpha particles detected at the calculated range of 4 cm owing to statistical variations in the number of collisions that the particles may have with air molecules and to variations in the amount of energy loss by the particles for each ion pair formed. After being halted, an alpha particle acquires two free electrons through columbic attraction and is converted to helium gas.

In materials other than air, such as liquids and solids, the range of alpha particles is obviously much shorter owing to their higher densities, which enhance the number of collisions a particle may undergo per path length of travel. The range of alpha particles in liquids and solids may be approximated by comparison with ranges in air according to the empirical equation

$$R_{\text{cm}} = 0.00032(A^{1/2}/\rho)R_{\text{air}} \quad (1.167)$$

described in a previous text ([L'Annunziata, 1987](#)), where R_{cm} is the average range in cm of the alpha particle in an absorber other than air, A is the atomic weight of the absorber, ρ is the absorber density in g/cm^3 , and R_{air} is

the calculated average linear range of the alpha particle in air (from [Eq. 1.165](#) or 1.166) or more accurate values of R_{air} from the online ASTAR computer program (<https://physics.nist.gov/PhysRefData/Star/Text/programs.html>).

For example, from [Eq. \(1.167\)](#), the 5.5-MeV alpha particles emitted by ^{241}Am have a calculated range of 2.48×10^{-3} cm or 24.8 μm in aluminum ($A = 27$ and $\rho = 2.69 \text{ g/cm}^3$) utilizing a value of R_{air} of 4.03 cm calculated previously from [Eq. 1.165](#)). However, if we utilize the more accurate online ASTAR program and compute the range of 5.5 MeV alpha particles in aluminum, we obtain the value of the range to be $6.6 \times 10^{-3} \text{ g/cm}^2$, which divided by the density of aluminum (2.69 g/cm^3) yields a linear range of 2.45×10^{-3} cm or 24.5 μm , which corresponds closely to the value calculated by the empirical [Eq. \(1.167\)](#). Empirical equations should be used with caution, and it is best to compare empirical calculations to the computer calculated values such as the online ASTAR program.

The linear ranges, that is the depth to which charged particles, such as the alpha particle, will penetrate in liquids and solid materials can be too short to measure with conventional laboratory instrumentation. The alternative is to express range in units of weight of absorber material per unit area, such as mg/cm^2 , which is a measure of milligrams of absorber per square centimeter in the absorption path, or in other words, a measure of absorber thickness. If we multiply the linear range of the alpha particle measured in cm of absorber material by the density of the absorber in units of mg/cm^3 , the range of the alpha particle in an absorber will be expressed in terms of the weight of absorber per unit area (mg/cm^2) as described by [Eq. \(1.168\)](#), as follows

$$R_{\text{mg/cm}^2} = (R_{\text{cm}})(\rho) \quad (1.168)$$

where $R_{\text{mg/cm}^2}$ is the range of alpha particles of a given energy in units of mg/cm^2 , also referred to as mass thickness units or material surface density, R_{cm} is the linear range of the alpha particles, and ρ is the absorber density. For example, the linear range of the 5.5 MeV alpha particles in aluminum, calculated above with [Eq. \(1.167\)](#) is converted to range in mass thickness units according to [Eq. \(1.168\)](#) as follows

$$\begin{aligned} R_{\text{mg/cm}^2} &= (2.48 \times 10^{-3} \text{ cm}) \\ &\times (2690 \text{ mg/cm}^3) = 6.6 \text{ mg/cm}^2 \end{aligned}$$

Therefore, the mass thickness of 6.6 mg/cm^2 of aluminum absorber is sufficient to absorb alpha particles of 5.5 MeV energy. The ASTAR (Alpha Stopping Power and Range Tables, <https://physics.nist.gov/PhysRefData/Star/Text/ASTAR.html>, provide a value of $6.60 \times 10^{-3} \text{ g/cm}^2$

as the range of 5.5 MeV alpha particles in aluminum, which agrees with the calculated value of 6.6 mg/cm² calculated above.

Ranges of alpha particles as well as other charged particles such as protons and deuterons of a given energy in absorber elements of atomic number $Z > 10$ in units of absorber mass thickness can be calculated directly by comparison to the calculated range of the same charged particles of the same energy in air according to the following formula described by Friedlander et al. (1964).

$$\frac{R_Z}{R_{air}} = 0.90 + 0.0275Z + (0.06 - 0.0086Z)\log\frac{E}{M} \quad (1.169)$$

where R_Z is the range of the charged particle in mass thickness units, mg/cm², R_{air} is the range of the charged particle in air in the same mass thickness units, Z is the atomic number of the absorber element, E is the particle energy in MeV, and M is the mass number of the particle (*i.e.*, 1 for protons, 2 for deuterons, and 4 for alpha particles). For example, if we use the empirical formula provided above (Eq. 1.169) to calculate the range of 5.5 MeV alpha particles ($M = 4$) in aluminum ($Z = 13$) and a value of $R_{air} = 5.01 \times 10^{-3}$ g/cm², we obtain the value of $R_Z = 6.3 \times 10^{-3}$ g/cm², which is in close agreement to the mass thickness range calculated previously with Eqs. (1.167) and (1.168). In this example, Eq. (1.169) requires the value of R_{air} for 5.5 MeV alpha particles, which is determined according to Eq. (1.168) as the product of the 5.5 MeV alpha-particle linear range in air (previously calculated) and the density of air at STP ($\rho = 1.205$ mg/cm³), that is, $R_{air} = (4.15 \text{ cm})(1.205 \text{ mg/cm}^3) = 5.01 \text{ mg/cm}^2$ or $5.01 \times 10^{-3} \text{ g/cm}^2$. The value of $R_{air} = 5.01 \times 10^{-3} \text{ g/cm}^2$ is also available from the online ASTAR program (<https://physics.nist.gov/PhysRefData/Star/Text/programs.html>). The formula provided by Eq. (1.169) is applicable to charged particles over a wide range of energies (approximately over the range 0.001–1000 MeV) and for absorber elements of $Z > 10$. For lighter absorber elements, the term $0.90 + 0.0275Z$ is replaced by the value 1.00 with the exception of hydrogen and helium, where the value of 0.30 and 0.82 are used, respectively (Friedlander et al., 1964). Empirical equations, such as Eq. (1.169), should be used with caution and calculated results compared to the ASTAR computer program.

Where alpha particles alone are concerned, the range in mass thickness units can be calculated according to the following equation described by Ehman and Vance (1991), as follows

$$R_{\text{mg/cm}^2} = 0.173E^{3/2}A^{1/3} \quad (1.170)$$

where E is the energy of the alpha particle in MeV, and A is the atomic weight of the absorber. If we continue to use the 5.5 MeV alpha particles emitted from ²⁴¹Am as an example, we can calculate their range in mass thickness units in aluminum according to Eq. (1.170) as follows

$$R_{\text{mg/cm}^2} = 0.173(5.5)^{3/2}(27)^{1/3} = 6.6 \text{ mg/cm}^2$$

Ranges reported in mass thickness units (mg/cm²) of absorber can be converted to linear range (cm) in that same absorber material from the absorber density (ρ) from the relationship described in Eq. (1.168) or

$$R_{\text{cm}} = R_{\text{mg/cm}^2} / \rho \quad (1.171)$$

For example, the linear range of the 5.5 MeV alpha particles in aluminum ($\rho = 2.69 \text{ g/cm}^3$) is calculated as

$$R_{\text{cm}} = \frac{6.6 \text{ mg/cm}^2}{2690 \text{ mg/cm}^3} = 0.0024 \text{ cm} = 24 \text{ } \mu\text{m}$$

When the absorber material is not a pure element, but a molecular compound (*e.g.*, water, paper, polyethylene, etc) or mixture of elements, such as an alloy, the ranges of alpha particles in the absorber are calculated according to Eq. (1.172) on the basis of the atomic weights of the elements and their percent composition in the absorber material or, in other words, the weight fraction of each element in the complex material. Thus, the range in mass-thickness units for alpha particles in absorbers consisting of compounds or mixtures of elements is calculated according to the equation

$$\frac{1}{R_{\text{mg/cm}^2}} = \frac{w_1}{R_1} + \frac{w_2}{R_2} + \frac{w_3}{R_3} + \dots + \frac{w_n}{R_n} \quad (1.172)$$

where $R_{\text{mg/cm}^2}$ is the range of the alpha-particles in mass-thickness of the complex absorber material, and $w_1, w_2, w_3 \dots w_n$ are the weight fractions of each element in the absorber, and $R_1, R_2, R_3 \dots R_n$ are the ranges in mg/cm² of the alpha particle of defined energy in each element of the absorber. For example, the range of 5.5 MeV alpha particles in Mylar (polyethylene terephthalate) in units of mass thickness is calculated as follows:

$$\frac{1}{R_{\text{mg/cm}^2}} = \frac{w_C}{R_C} + \frac{w_H}{R_H} + \frac{w_O}{R_O}$$

where w_C, w_H , and w_O are the weight fractions of carbon, hydrogen, and oxygen, respectively, in Mylar and R_C, R_H , and R_O are the mass thickness ranges of the alpha particles in pure carbon, hydrogen, and oxygen, respectively. The ranges of 5.5 MeV alpha particles in carbon, hydrogen, and oxygen are calculated according to Eq. (1.170) as

$$R_C = 0.173(5.5)^{3/2}(12)^{1/3} = 5.10 \text{ mg/cm}^2$$

$$R_H = 0.173(5.5)^{3/2}(1)^{1/3} = 2.23 \text{ mg/cm}^2$$

$$R_O = 0.173(5.5)^{3/2}(16)^{1/3} = 5.62 \text{ mg/cm}^2$$

The weight fractions of the carbon, hydrogen, and oxygen in Mylar $[-(\text{C}_{10}\text{H}_8\text{O}_4)_n-]$ are calculated as

$$w_C = (12 \times 10)/192 = 0.625$$

$$w_H = (1 \times 8)/192 = 0.042$$

$$w_O = (16 \times 4)/192 = 0.333$$

The calculated ranges of the 5.5 MeV alpha particles in each element and the values of the weight fractions of each element in Mylar can now be used to calculate the alpha particle range in Mylar in mass-thickness units according to Eq. (1.172) as

$$\frac{1}{R_{\text{Mylar}}} = \frac{0.625}{5.10} + \frac{0.042}{2.23} + \frac{0.333}{5.62} = 0.201$$

$$R_{\text{Mylar}} = 4.9 \text{ mg/cm}^2$$

The more accurate online ASTAR program (<https://physics.nist.gov/PhysRefData/Star/Text/ASTAR.html>) provides a value of 4.7 mg/cm^2 for the alpha particle range in mass thickness units for Mylar (polyethylene terephthalate), which is close to that calculated above by the empirical formula. The linear range of these alpha particles in Mylar are obtained from the range in mass thickness units and the density of Mylar ($\rho = 1.38 \text{ g/cm}^3$) as

$$R_{\text{cm}} = \frac{4.9 \text{ mg/cm}^2}{1380 \text{ mg/cm}^3} = 0.0036 \text{ cm} = 36 \mu\text{m}$$

To provide illustrative examples, the values of the ranges of 5.5 MeV alpha particles in units of mass thickness of various absorber materials are provided in Table 1.9. The data in this table was calculated by means of the empirical equations described earlier in this chapter and

by the online ASTAR computer program. The empirical equations can provide good estimates of the alpha particle range; however, they may fall short for absorbers of high atomic number. These values in Table 1.9 represent the milligrams of absorber per square centimeter in the alpha particle absorption path. It can be difficult to envisage alpha particle distance of travel from the values of range when expressed in units of mass thickness. However, it is intuitively obvious that, the greater the charge on the nucleus of the absorber (*i.e.*, absorber atomic number, Z), the greater the atomic weight of the absorber (A), and the greater the absorber density (ρ), the shorter will be the path length of travel of the alpha particle through the absorber. This is more evident from the calculated values of linear range of 5.5 MeV alpha particles in various gaseous, liquid, and solid absorbers provided in Table 1.10. From the linear ranges, we can see that 5.5-MeV alpha particles could not pass through fine commercial aluminum foils 0.0025 cm thick. Also, the alpha particles of the same energy would not pass through a layer of Mylar only 0.0036 cm thick. Mylar is a polymer sometimes used as a window for gas ionization detectors. From our previous calculations in this chapter, we can see that a Mylar window of mass thickness 4.9 mg/cm^2 would not allow 5.5-MeV alpha particles to pass into the gas ionization chamber. A sample emitting such alpha particles would have to be placed directly into the chamber in a windowless fashion to be detected and counted.

From the above treatment, it is clear that the range of alpha particle travel depends on several variables including (1) the energy of the alpha particle, (2) the atomic number and atomic weight of the absorber, and (3) the density of the absorber. The higher the alpha particle energy, the greater will be its penetration power into or through a given substance as more coulombic interactions of the alpha particle with the electrons of the absorber will be required to dissipate its energy before coming to rest. Also, if we consider an alpha particle of given energy, its range will be shorter in absorbers of higher atomic number or atomic

^aCalculated by the online ASTAR computer program <https://physics.nist.gov/PhysRefData/Star/Text/programs.html>, which calculates the projected range of an alpha particle in an absorber in units of g/cm^2 . The value of the projected range is then divided by the density of the absorber in units of g/cm^3 to yield the range in units of cm. The projected range is defined by NIST as the average value of the depth to which a charged particle will penetrate in the course of slowing down to rest. The depth is measured along the initial direction of the particle.

^bThe absorbers are of increasing density from left to right. The densities of the absorbers are the following: Air (dry air at near sea level), $\rho = 1.205 \times 10^{-3} \text{ g}/\text{cm}^3$; Water, liquid $\rho = 1.00 \text{ g}/\text{cm}^3$; Mylar (polyethylene terephthalate), $\rho = 1.40 \text{ g}/\text{cm}^3$; Carbon (graphite), $\rho = 1.70 \text{ g}/\text{cm}^3$; Aluminum, $\rho = 2.69 \text{ g}/\text{cm}^3$; Copper, $\rho = 8.96 \text{ g}/\text{cm}^3$; Gold, $\rho = 19.32 \text{ g}/\text{cm}^3$.

weight and density, as the absorber atoms will contain a higher number of atomic electrons, which would consequently increase the number of columbic interactions of the alpha particle per path length of travel.

As the alpha particle travels through air and undergoes energy loss via numerous collisions, the velocity of the particle obviously diminishes. At reduced velocity and consequently reduced momentum, an alpha particle is more affected by columbic attraction within the vicinity of a given atom. Progressive reduction in the velocity of travel of the alpha particle therefore results in an increase in the number of ion pairs produced per millimeter of path length of travel. The increase in ionization per path length of travel of an alpha particle is illustrated in Fig. 1.44. The highest specific ionization (number of ion pairs formed per millimeter of path) occurs shortly before termination of the alpha particle's travel, some 2 or 3 mm before the end of its range.

B. Beta decay

A nuclear decay process, referred to as beta decay, results in some circumstances in the emission of beta radiation. Beta decay may be defined as any nuclear decay process whereby the mass number (A) of the nucleus remains the

**FIGURE 1.44** Specific ionization of an alpha particle in air along its range of travel.

same and the atomic number (Z) changes. There are three main types of beta decay. These are

- Negatron (β^-) emission, which involves the emission of a negative beta particle (i.e., negative electron) from the nucleus,
- Positron (β^+) emission whereby a positive beta particle (i.e., positively charged electron) is emitted from the nucleus, and
- EC, which does not result in the emission of any beta particle.

Each of the above beta decay processes will be treated in detail in the following sections of this chapter.

1. Negatron (β^-) emission

Negatron emission can be described by the general equation

where A_ZP is the parent nuclide of atomic number Z and mass number A , ${}^A_{Z+1}D$ is the daughter nuclide of atomic number $Z + 1$ and same mass number as the parent, β^- is the negatron or negative beta particle, $\bar{\nu}$ is the antineutrino, and K_T is the total kinetic energy released in the beta-decay process. The total kinetic energy released, also referred to as the decay energy (Q_β), is shared between the negatron, antineutrino, recoil daughter nucleus, and any gamma radiation that may be emitted by the daughter nucleus. Gamma ray emission can occur when the daughter nuclide is left in an excited energy state and decays to a lower energy state or ground (stable) state with the emission of energy as gamma ray photons. Gamma ray emission does not occur in all cases of negatron emission. There are some nuclides described further on in this section that decay with the emission of negatrons directly to the stable ground state without the emission of gamma radiation. The decay energy, Q_{β^-} , may be defined as

$$Q_{\beta^-} = K_T = E_{\beta^-} + E_{\bar{\nu}} + E_\gamma + E_{\text{recoil}} \quad (1.174)$$

where E_{β^-} is the kinetic energy of the negatron, $E_{\bar{\nu}}$ is the kinetic energy of the antineutrino, E_{γ} is the gamma-ray energy, which is emitted when the daughter nucleus is at an elevated energy state and drops to a more stable or ground state, and E_{recoil} is the kinetic energy of the recoil daughter nucleus. The recoil energy may be ignored in most calculations of beta decay energy, because it may be only a few electron volts (eV) compared to the fractional or multiple magnitudes of megaelectron volts (MeV) energy possessed by the beta particle, antineutrino, and gamma radiation (see the Section on Nuclear Recoil in this chapter). We should keep in mind that there is a maximum energy shared by the beta particle and antineutrino ($E_{\beta^-} + E_{\bar{\nu}}$), which is often referred to as the E_{max} of the beta particle.

a. Basic principles

A negatron or negative beta particle (β^-) is an electron emitted from the nucleus of a decaying radionuclide that possesses an excess of neutrons or, in other words, a neutron/proton (n/p) imbalance. The nuclear instability, caused by the n/p imbalance, results in the conversion of a neutron to a proton within the nucleus. The balance of charge is conserved by the simultaneous formation of an electron (negatron) according to the equation

A neutrino, which is a particle of zero charge, accompanies beta-particle emission. The neutrino can be identified further as two types with opposite spin, namely, the antineutrino ($\bar{\nu}$), which accompanies negative beta particle (negatron) emission and the neutrino (ν), which accompanies positive beta particle (positron) emission. The explanation for the neutrino and its properties, also emitted from the decaying nucleus, is given further on in this section. The electron formed cannot remain within the nucleus, and it is thus ejected as a negatron or negative beta particle, β^- , with an energy equivalent to the mass difference between the parent and daughter atoms, less the energy of the antineutrino or neutrino in the case of positron emission, and any gamma ray energy that may be emitted by the daughter nucleus, if the nucleus is left in an excited energy state, and recoil energy of the daughter nucleus as described by Eq. (1.174). Tritium (^3H), for example, decays with β^- emission according to the following:

The ^3H nucleus decays directly to the ground state of ^3He . Thus, there is no gamma ray energy emission in this case. The value of 0.0186 MeV (megaelectron volts) is the maximum energy the beta particle may possess. The unstable tritium nucleus contains two neutrons and one proton. The transformation of a neutron to a proton within the tritium nucleus results in a charge transfer on the nucleus

from +1 to +2 without any change in the mass number. Although there is no change in the mass number, the mass of the stable helium isotope produced is slightly less than that of its parent tritium atom. Eqs. (1.177) to (1.182) illustrate other examples of β^- decay, which decay to stable daughter nuclides whereby no gamma-ray emission occurs.

The energies of beta particle decay processes are usually reported as the maximum energy, E_{max} , that the emitted beta particle or antineutrino may possess. The maximum energy is reported because beta particles are emitted from radionuclides with a broad spectrum of energies. A typical spectrum is illustrated in Fig. 1.45. The shape of the beta particle energy spectra will vary among the beta-emitting radionuclides, but all beta-emitting radionuclides will display a wide spectrum of energies between zero and E_{max} . Unlike alpha particles, which have a discrete energy, beta particles are emitted with a wide spectrum of energies ranging from zero to E_{max} .

The majority of the beta particles emitted have energies of approximately $\frac{1}{3}E_{\text{max}}$. Only a very small portion of the beta particles is emitted with the maximum possible energy from any radionuclide sample. In 1930 Wolfgang Pauli was the first to postulate why beta particles were not emitted with fixed quanta of energy, quite the contrary to what is observed in alpha particle emission. He proposed the

FIGURE 1.45 General beta particle energy spectrum.

existence of an elusive, neutral particle of near zero rest mass in a letter to the participants of a Regional Meeting on Radioactivity at Tübingen, Germany. The neutrino was considered elusive because if it existed, its zero charge and near zero rest mass would make the neutrino undetectable by conventional means and allow a neutrino to penetrate matter easily and even pass through the entire earth without causing a single interaction. The neutrino would be emitted simultaneously with the beta particle from the decaying nucleus and share the energy of decay with the beta particle. For example, if a beta particle was emitted from tritium (decay energy = 0.0186 MeV) with an energy of 0.0086 MeV, the accompanying neutrino would possess the remaining energy of 0.01 MeV, that is, the decay energy less the beta particle energy (0.0186 – 0.0086 MeV). Consequently, if we observe any number of beta particles emitted from a tritium sample or other beta-emitting nuclide sample (e.g., ^{14}C , ^{32}P , ^{90}Sr), they would possess different energies and display an energy spectrum from zero to E_{max} as illustrated in Fig. 1.45.

b. Inverse beta decay

With Pauli's postulation of the neutral particle, Enrico Fermi elaborated the beta-decay theory in 1934 and coined the neutrino from the Italian language meaning "little neutral one". The particle remained elusive until the observation of the neutrino was demonstrated by Reines and Cowan in 1956 (see Reines and Cowan, 1956, 1957;

Cowan et al., 1956; Reines, 1960, 1979, 1994). They confirmed the existence of the neutrino by demonstrating inverse beta decay where an antineutrino interacts with a proton to yield a neutron and positron

They used a tank of water containing a solution of $^{113}\text{CdCl}_2$ illustrated schematically in Fig. 1.46. Antineutrinos interacted with the protons of the water to produce neutrons and positrons. Some of the neutrons produced would be absorbed by the ^{113}Cd with the concomitant emission of characteristic gamma radiation. In coincidence, they observed two 511 keV gamma rays, which originate when a positron comes to rest in the vicinity of an electron, its antiparticle, which results in the annihilation of two electrons into two gamma ray photons of energy equivalent to the electron masses, 0.511 MeV. In the same year, Lee and Yang (1956) proposed that neutrinos and antineutrinos possessed left-handed and right-handed spins, respectively. Inverse beta decay remains an important nuclear process utilized in the measurement of solar neutrinos today (Zuber, 2003; Ianni et al., 2005; Fukuda et al., 2010; Ianni, 2017; Vannucci, 2017).

An inverse beta decay, first proposed by Raghaven (1976), which involves the interaction of a neutrino with a neutron of ^{115}In is the following:

which can be written in general terms illustrating only the nucleons as

The superscript asterisk in Eq. (1.184) represents an excited state of ^{115}Sn , which decays into the ground state with a lifetime of 4.76 μs and emits two gamma ray photons of 116 and 497 keV. This provides a triple coincidence signal, namely the emitted electron together with the two gamma ray photons, that can be detected among huge backgrounds (Fukuda et al., 2010). Also, the neutrino energy may be calculated from the energy of the prompt electron according to the equation

$$E_{\text{e}^-} = E_{\nu} - (E_f - E_i) \quad (1.186)$$

where E_{e^-} is the energy of the electron produced, E_{ν} is the neutrino energy, and E_f and E_i are the final and initial energies of the nuclear state involved in the transition (Zuber, 2003). In the case of neutrino interactions with ^{115}In , Eq. (1.186) may be written, according to Fukuda et al. (2010) as

$$E_{\text{e}^-} = E_{\nu} - 118 \text{ keV} \quad (1.187)$$

Thus, neutrino spectroscopy is possible.

FIGURE 1.46 Detection scheme used by Reines and Cowan for the antineutrino signature signal. An antineutrino is illustrated entering the tank of aqueous CdCl₂ solution and striking a target proton. The proton converts to a neutron and positron. The positron annihilates on an electron with the emission of two 0.511 MeV gamma rays in opposite direction detected by the liquid scintillator in tanks above and below the water target tank. The neutron produced by the antineutrino interaction slows down in the water and is captured by a cadmium nucleus, and the resulting gamma rays are detected by the liquid scintillator in the adjacent tanks approximately 10 μs after the positron annihilation. From Reines (1995) Nobel Lecture with permission © The Nobel Foundation 1995.

In general, the detection principle of solar neutrinos involving the inverse beta decay reaction of Eq. (1.185), as described by Zuber (2003), may involve one of the following two reactions:

or

The reaction described in Eq. (1.188) involves the interaction of a neutrino with a neutron of nuclide ${}^A_Z\text{A}$ of atomic number Z and mass number A producing a nuclide ${}^A_{Z+1}\text{B}_{\text{g.s.}}$ at its ground state and a beta particle (e^-). The nuclide ${}^A_{Z+1}\text{B}_{\text{g.s.}}$ undergoes beta decay to nuclide ${}^A_{Z+2}\text{C}$ with the emission of a beta particle (e^-) and antineutrino ($\bar{\nu}$). This reaction has an $e-e$ tag whereby a coincidence signal between the two electron emissions provides the signature for the neutrino detection. The following reaction described by Eq. (1.189) depicts a neutrino interacting with a neutron of nuclide ${}^A_Z\text{X}$ producing nuclide ${}^A_{Z+1}\text{Y}^*$ at an excited energy state indicated by the superscript asterisk plus an electron or beta particle (e^-). The nuclide ${}^A_{Z+1}\text{Y}^*$ then undergoes deexcitation to its ground state ${}^A_{Z+1}\text{Y}_{\text{g.s.}}$ with the emission of a gamma ray photon. This reaction has an $e-\gamma$ tag whereby a coincidence signal between the electron and one or more gamma ray photon emissions provides the signature for the neutrino detection. The neutrino energies are determined by Eq. (1.186). Zuber (2003) provides a review of these two approaches to neutrino detection and spectroscopy. The interaction of a neutrino with ${}^{115}\text{In}$ previously discussed (Eq. 1.184), utilized by Fukuda et al. (2010), is an example of the generic reaction yielding an $e-\gamma$ tag depicted by Eq. (1.189), which is specifically

An example of the generic reaction depicted in Eq. (1.188) is the following:

This reaction was utilized by Ianni et al. (2005) for the detection of neutrinos. The reaction provides an $e-e$ tag as the beta particle (e^-) produced in the reverse beta decay yields one signal while the positron (e^+) produced in the subsequent decay of ${}^{13}\text{N}$ provides a time and space coincidence signal and signature for the neutrino detection.

c. Neutrino mass

Since its inception by Pauli in 1930 up to recent years, the neutrino or antineutrino had been thought to have no rest mass or to possess a near-zero rest mass. It was not until June 5, 1998 was it announced by the Super-Kamiokande

Collaboration, including scientists from 23 institutions in Japan and the United States, at the “Neutrino 98” International Physics Conference in Takayama, Japan, that neutrinos possessed a definite mass (Gibbs, 1998; Kesterbaum, 1998; Kearns et al., 1999; Nakahata, 2000). The mass was not reported, but evidence was provided that the neutrino did possess mass although it was considered to be “very small”, at least 0.07 eV, which would be less than a millionth of the electron mass. Evidence for the neutrino mass was provided by demonstrating that neutrinos can “oscillate” from one type into another (*i.e.*, electron-, muon-, and tau-neutrinos) as they travel through space and matter. Oscillation is the changing of neutrino types back and forth from one type to another, and this could occur only if the neutrino possessed mass. Experimental research on neutrino oscillation is reviewed by Messier (2006), and the Nobel prize in Physics 2015) was awarded jointly to Takaaki Kajita of the University of Tokyo, Kashiwa, Japan and Arthur B. McDonald of Queen’s University, Kingston, Canada for, in the words of the Nobel Committee “the discovery of neutrino oscillations, which show that neutrinos have mass”.

At the “Neutrino 2000” Conference held at Sudbury, Canada June 16–21, 2000, groups from the University of Mainz, Germany (Bonn et al., 2001) and Institute for Nuclear Research, Moscow (Lobashev et al., 2000) reported the mass of the neutrino to be between 2.2 and 2.5 eV/ c^2 , respectively, at 95% confidence levels. It is common to express subatomic particle mass in units of energy based on equivalence of mass and energy ($E = mc^2$), so that the particle mass m is measured in units of E/c^2 , and with energy expressed in units of electron volts, eV/ c^2 . Neutrino mass experiments are reviewed by Kraus et al. (2005), Otten and Weinheimer (2008), Beck (2010), and Kristiansen et al. (2010), and Ferri (2016). Beck (2010) underscores that results from previous research reported by the Triosk (Russia) and Mainz (Germany) neutrino mass experiments (see Lobashev et al., 1999a,b,c, 2000; Kraus et al., 2005) have set the best upper limits of 2.3 eV/ c^2 with a 95% confidence limit on the neutrino mass. Beck (2010) also reports that the KATRIN experiment (KARlsruhe TRItium Neutrino experiment) is under preparation to search for the mass of the electron neutrino with a sensitivity of 0.2 eV/ c^2 . With this objective the KATRIN experiment will perform a precision measurement of the endpoint region of the β -decay spectrum of tritium, the shape of which depends highly on the neutrino mass. A windowless gaseous tritium source is used in a transport system that guides the beta particles of tritium without energy loss to PIN diode detectors described by Wüstling et al. (2006). A prespectrometer rejects all beta particles with energy <200 eV below the β -spectrum endpoint, and the beta particle energies can be measured with a resolution of 0.93 eV. Ferri (2016) reports that the KATRIN spectrometer will operate with the aim of reaching a sensitivity of 0.2 eV/ c^2 in the determination of the neutrino mass during the next 5 years.

To put the mass of the neutrino in perspective, we can take the experimental value of the upper limit to the

neutrino rest mass, $m_\nu = 2.3 \text{ eV}/c^2$, and convert this to kilograms as follows:

By definition $1 \text{ eV} = 1.60 \times 10^{-19} \text{ J}$ and, from equation $E = mc^2$, we can calculate the neutrino rest mass in kilograms as

$$\begin{aligned} m_\nu &= E/c^2 \\ &= (2.3 \text{ eV})(1.6 \times 10^{-19} \text{ J/eV})/(3.0 \times 10^8 \text{ m/s})^2 \\ &= 4.1 \times 10^{-36} \text{ kg} \end{aligned} \quad (1.192)$$

If we compare the rest mass of the neutrino, m_ν , to that of the miniscule electron, m_e , we see that the neutrino rest mass is approximately 4 millionths that of the electron or

$$m_\nu/m_e = 4.1 \times 10^{-36} \text{ kg}/9.1 \times 10^{-31} \text{ kg} = 4.5 \times 10^{-6}$$

d. Negatron decay energy

The general reaction for negatron emission was described previously by Eq. (1.173). It is provided here again for a treatment on negatron decay energy calculations, and it is the following:

where ${}^A_Z P$ is the parent nuclide of atomic number Z and mass number A , ${}^A_{Z+1} D$ is the daughter nuclide of atomic number $Z + 1$ and same mass number as the parent, β^- is the negatron or negative beta particle, $\bar{\nu}$ is the antineutrino, and K_T is the total kinetic energy released in the beta decay process.

In terms of nuclear masses, we may write Eq. (1.193) as

$${}_Z M_P = {}_{Z+1} M_D + m_e + K_T \quad (1.194)$$

where ${}_Z M_P$ and ${}_{Z+1} M_D$ are the masses of the parent and daughter nuclei of atomic numbers Z and $Z + 1$, respectively, and m_e is the mass of the beta particle (*i.e.*, one electron mass). We may use atomic mass units (u) to calculate the mass difference of the parent and daughter nuclei by

adding firstly Z atomic electron masses to each side of Eq. (1.194) to give

$${}_Z M_P + Z m_e = {}_{Z+1} M_D + (Z + 1) m_e + K_T \quad (1.195)$$

The mass difference of the parent and daughter nuclei is equivalent to the decay energy (Q_{β^-}). We can now calculate the decay energy Q_{β^-} by the difference of the parent and daughter nuclide atomic masses, after adding Z atomic electrons to each side of the equation, ignoring the small difference in the binding energies of the electrons in the two nuclides as

$$Q_{\beta^-} = ({}_Z M_P - {}_{Z+1} M_D) c^2 = K_T = E_{\beta^-} + E_{\bar{\nu}} + E_\gamma + E_{\text{recoil}} \quad (1.196)$$

where c is the velocity of light in a vacuum and the product Mc^2 yields the energy equivalence of the mass, E_{β^-} is the kinetic energy of the negatron, $E_{\bar{\nu}}$ is the kinetic energy of the antineutrino, E_γ is the gamma ray energy, which only appears with the decay of a daughter nucleus when left at an excited energy state, and E_{recoil} is the kinetic energy of the daughter recoil nucleus. As previously described, the recoil energy, E_{recoil} , is generally relatively very small (a few electron volts) and will be ignored here. Also, if there is no gamma radiation emitted by the daughter nucleus, we can exclude the term E_γ . The remaining decay energy ($E_{\beta^-} + E_{\bar{\nu}}$) is shared as kinetic energy between the beta particle and antineutrino, most often referred to as the E_{max} .

A simple example would be that of the radionuclide ${}^{14}\text{C}$, which decays by negatron emission without the emission of gamma radiation to the stable daughter nuclide ${}^{14}\text{N}$ according to the following:

The decay scheme is illustrated in Fig. 1.47.

The decay energy of ${}^{14}\text{C}$ can be calculated according to Eq. (1.196) using atomic mass units (u) of the parent and daughter atoms as follows:

FIGURE 1.47 Negatron beta decay scheme of ${}^{14}\text{C}$. The radionuclide ${}^{14}\text{C}$ decays to stable ${}^{14}\text{N}$ by negatron emission. Nuclear decay occurs entirely (100%) by emission of a negatron (β^-) and antineutrino ($\bar{\nu}$) with an energy maximum of 0.156 MeV, which is shared by the negatron and antineutrino.

$$\begin{aligned}
 Q_{\beta^-} &= (M_{^{14}\text{C}} - M_{^{14}\text{N}})c^2 \\
 &= (14.00324199 \text{ u} - 14.00307401 \text{ u})(931.494 \text{ MeV/u}) \\
 &= 0.156 \text{ MeV}
 \end{aligned}
 \tag{1.198}$$

where 931.494 is the energy equivalence of 1 atomic mass unit as derived previously in this chapter. The energy of 0.156 MeV, calculated above, is shared between the beta particle and antineutrino. Thus, the maximum energy that the beta particle or antineutrino may possess is 0.156 MeV. The calculated decay energy may be found in Appendix A, which lists the decay energies of many radioactive nuclides. Also, one may utilize the online computer calculation (<http://www.nndc.bnl.gov/qcalc>), which agrees with the above beta-decay energy to be 156 keV or 0.156 MeV.

We may now look at yet a more complex example of ^{137}Cs decay where negatron β^- emission occurs with more than one energy maxima, or via what is referred to as a branching decay mode, and which decays with the emission of gamma radiation from the nucleus of the daughter nuclide ^{137}Ba . The decay equation is the following:

The decay scheme of ^{137}Cs to stable ^{137}Ba is illustrated in Fig. 1.48.

The decay energy of ^{137}Cs is calculated as follows.

$$\begin{aligned}
 Q_{\beta^-} &= (M_{^{137}\text{Cs}} - M_{^{137}\text{Ba}})c^2 = E_{\beta^-} + E_{\bar{\nu}} + E_{\gamma} + E_{\text{recoil}} \\
 &= (136.9070895 \text{ u} - 136.9058274 \text{ u})(931.494 \text{ MeV/u}) \\
 &= 1.1756 \text{ MeV}
 \end{aligned}
 \tag{1.200}$$

The 1.176 MeV decay energy is the energy liberated from ^{137}Cs decay to the ground state of stable ^{137}Ba . One

branch of this decay occurs at a 94% intensity (abundance) via the emission of a negatron and antineutrino with an E_{max} of 0.514 MeV followed by the emission of gamma radiation of 0.662 MeV from the daughter nuclide $^{137\text{m}}\text{Ba}$, which is metastable decaying to the stable ^{137}Ba (see Fig. 1.48). The remaining 6% of the negatron emissions (*i.e.*, 100% – 94%) arise from the decay of ^{137}Cs directly to the ground state of stable ^{137}Ba with the entire 1.176 MeV of decay energy shared by the negatron (β^-) and antineutrino ($\bar{\nu}$). The “QCalc” online (<https://www.nndc.bnl.gov/qcalc/>) computer-calculated decay energy is found to be 1175.6 keV or 1.1756 MeV as calculated above, which confirms the above calculated decay energy. The atomic mass units used in the above calculation are obtained from the Atomic Mass Data Center (AMDC) online via <http://amdc.impcas.ac.cn/web/masseval.html>. The recoil energy (E_{recoil}) in beta decay is relatively small (only several eV) and can be ignored in this case (see Part XIII of this chapter).

More complex negative beta decay schemes occur such as that of the radionuclide ^{131}I to stable ^{131}Xe , which is illustrated in Fig. 1.49.

The decay energy of ^{131}I to stable ^{131}Xe is calculated as.

$$\begin{aligned}
 Q_{\beta^-} &= (M_{^{131}\text{I}} - M_{^{131}\text{Xe}})c^2 = E_{\beta^-} + E_{\bar{\nu}} + E_{\gamma} + E_{\text{recoil}} \\
 &= (130.9061264 \text{ u} - 130.9050841 \text{ u})(931.494 \text{ MeV/u}) \\
 &= 0.9708 \text{ MeV}
 \end{aligned}
 \tag{1.201}$$

The online computer-calculated decay energy (<https://www.nndc.bnl.gov/qcalc/>) is determined to be 970.8 keV or 0.9708 MeV as calculated above. The atomic mass units used in the above calculation are obtained from the Atomic Mass Data Center (AMDC) online via <http://amdc.impcas.ac.cn/web/masseval.html>.

FIGURE 1.48 Negatron beta decay scheme of ^{137}Cs . The radionuclide ^{137}Cs decays to stable ^{137}Ba via two branching negatron emissions with energy maxima of 1.176 MeV at a relative intensity of 6% and 0.514 MeV at an intensity of 94%. Negatrons with energy maxima of 0.514 MeV produce metastable $^{137\text{m}}\text{Ba}$ daughter, which decays to stable ^{137}Ba with the emission of a gamma-ray photon of 0.662 MeV at an 85% intensity.

FIGURE 1.49 Negatron decay scheme of ^{131}I . The radionuclide ^{131}I decays to stable ^{131}Xe with three branching negatron emissions with energy maxima at 0.336 MeV, 0.607 MeV, and 0.806 MeV producing metastable $^{131\text{m}}\text{Xe}$ at three energy levels yielding several gamma ray lines of emissions, namely, $\gamma_1 = 0.635$ MeV, $\gamma_2 = 0.364$ MeV, $\gamma_3 = 0.284$ MeV, $\gamma_4 = 0.165$ MeV, and $\gamma_5 = 0.080$ MeV.

In summary, if we ignore the relatively very small nuclear recoil energy, we will find that the β^- energy maxima and the gamma-ray emission energies for the three beta decay branches of ^{131}I decay, illustrated in Fig. 1.49, yield the total decay energy of 0.971 MeV as follows:

β^- Branch 1 of 13% Intensity:

$$E_{\beta_1^-} + E_{\bar{\nu}} + \gamma_1 = E_{\max} \text{ of } 0.336 \text{ MeV} + \gamma_1 \text{ of } 0.635 \text{ MeV} = 0.971 \text{ MeV}$$

β^- Branch 2 of 86% Intensity:

$$E_{\beta_2^-} + E_{\bar{\nu}} + \gamma_2 = E_{\max} \text{ of } 0.607 \text{ MeV} + \gamma_2 \text{ of } 0.364 \text{ MeV} = 0.971 \text{ MeV}$$

β^- Branch 3 of 1% Intensity:

$$E_{\beta_3^-} + E_{\bar{\nu}} + \gamma_4 = E_{\max} \text{ of } 0.806 \text{ MeV} + \gamma_4 \text{ of } 0.165 \text{ MeV} = 0.971 \text{ MeV}$$

2. Positron (β^+) emission

Positron emission can be described by the general equation

where ${}^A_Z\text{P}$ is the parent nuclide of atomic number Z and mass number A , ${}^A_{Z-1}\text{D}$ is the daughter nuclide of atomic number $Z - 1$ and same mass number as the parent, β^+ is the positron or positive beta particle, ν is the neutrino, and K_T is the total kinetic energy released in the beta decay process.

a. Basic principles

In contrast to negatron emission from nuclei having neutron/proton (n/p) ratios too large for stability, positrons, which consist of positively charged electrons (positive beta

particles), are emitted from nuclei having n/p ratios too small for stability, that is, those which have an excess of protons.

To attain nuclear stability, the n/p ratio is increased. This is realized by a transformation of a proton to a neutron within the nucleus. The previously discussed alteration of a neutron to a proton in a negatron-emitting nuclide (Eq. 1.175) may now be considered in reverse for the emission of positrons. Eq. (1.203) illustrates such a transformation

The decay of the radionuclide ^{11}C may be cited as an example of a nuclide that decays by positron emission:

Note that the mass number does not change, but the charge on the nucleus (Z number) decreases by 1. A neutrino, ν , is emitted simultaneously with the positron (beta particle) and shares the decay energy with the positron. Thus, positrons, like negatrons emitted from a given radionuclide sample, may possess a broad spectrum of energies from near zero to E_{\max} , as illustrated in Fig. 1.45.

Decay by positron emission can occur only when the decay energy is significantly above 1.02 MeV. This is because two electrons of opposite charge are produced (e^+ , e^-) within the nucleus, and the energy equivalence of the electron mass is 0.51 MeV (see Section XII.C of this chapter.). The positive electron, e^+ , is ejected from the nucleus (i.e., β^+) and the negative electron, e^- , combines with a proton to form a neutron:

From the Chart of the Nuclides, it is possible to cite specific examples of the n/p imbalance in relation to negatron and positron emission. Fig. 1.50 illustrates a segment of

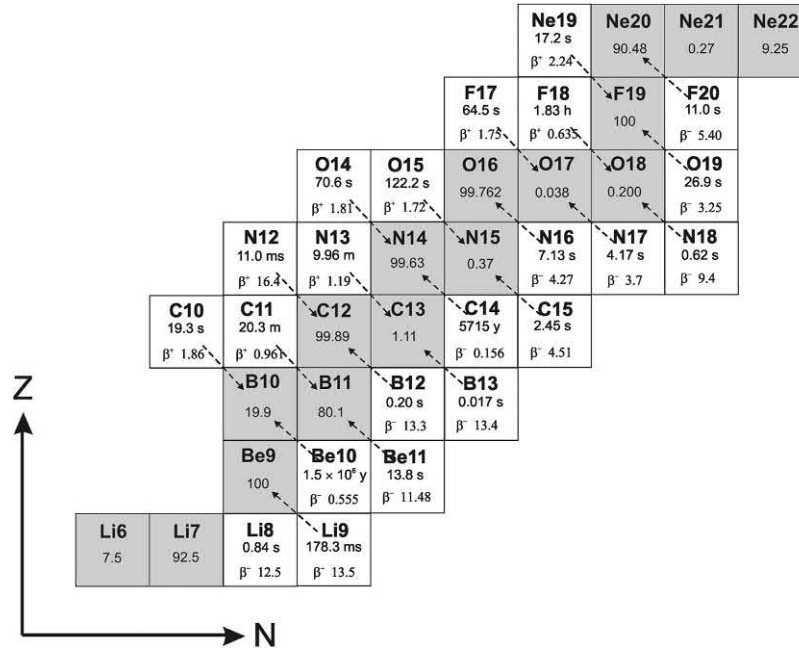

FIGURE 1.50 A Segment of the Chart of the Nuclides showing the relative positions of some stable (shaded) and unstable nuclides. The ordinate Z and abscissa N represent the number of protons (atomic number) and the number of neutrons (neutron number) within the nucleus, respectively. The mass number (number of protons + neutrons) in the nucleus of an isotope is provided alongside the abbreviation of the element. For example, the isotope ^{14}C (carbon-14) is written in the Chart as C14. Radionuclides that undergo positron emission (β^+) are illustrated with arrows pointing downward to stable nuclide products of lower atomic number, and radionuclides undergoing negatron (β^-) emission are illustrated with arrows pointing upward to stable nuclide products of higher atomic number. The maximum beta-particle energy in units of MeV is provided alongside the positron or negatron symbol. Numbers in shaded areas are the percent natural abundances of the stable isotopes, which for each element should add up to 100%. For example, the element lithium (Li) exists in nature as a combination of two stable isotopes, namely, ^6Li and ^7Li with abundances of 7.5% and 92.5%, respectively. When only one stable isotope of an element exists, its natural abundance will be expressed as 100%, such as is the case for ^9Be and ^{19}F illustrated above. The half-lives of the unstable nuclides are given in units of seconds (s), milliseconds (ms), minutes (m), hours (h) and years (y).

the Chart of the Nuclides and the relative positions of the stable nuclides (shaded areas) and of their neighboring radionuclides. The nuclides are positioned as a function of the number of protons, Z , and the number of neutrons, N , in their respective nuclei. Dashed arrows are placed through the blocks that segregate radionuclides interrelated with common daughter nuclides resulting from β^- or β^+ decay processes. For example, the stable nuclide ^{12}C of atomic number 6 has a nucleus with an n/p ratio of 6/6. However, the nuclide ^{12}N of atomic number 7 has an unstable n/p ratio of 5/7, an excess of protons. Thus, this radionuclide ^{12}N decays to ^{12}C via positron emission according to the equation

as indicated by a dashed arrow of Fig. 1.50.

The nuclide ^{12}B of atomic number 5 has the unstable n/p ratio of 7/5, an excess of neutrons. This nuclide thus decays to ^{12}C by negatron emission according to the equation

Similar reasoning may be used to explain positron and negatron decay of the unstable nuclides shown in Fig. 1.50

to the stable products ^{13}C , ^{14}N , and ^{15}N , etc. The interrelationship between β^- and β^+ decay leading to the formation of stable nuclides is to be found throughout the Chart of the Nuclides. Nuclear stability with n/p ratios close to unity only exists with nuclides of low atomic number ($Z \leq 20$), as discussed in Section VI.D.1 and in the following section of this chapter.

b. N/Z ratios and beta decay

Negatron and positron emission were discussed previously as processes whereby unstable nuclei may achieve stability via neutron or proton transformations, respectively. These processes in the nucleus of the radionuclide result in a change in the neutron/proton or N/Z ratio of the nucleus.

If we look throughout The Chart of The Nuclides, we will notice that the stable nuclides of low atomic number will have an N/Z ratio of approximately 1. However, as the atomic number increases ($Z > 20$), the N/Z ratio of the stable nuclides increases gradually and reaches as high as approximately 1.5 (e.g., $^{209}_{83}\text{Bi}$, $Z = 83$, $N/Z = 1.518$). This was illustrated previously in Fig. 1.20. Furthermore, there are no stable nuclides of atomic number greater than 83.

The nature of nuclear forces and the relationship of N/Z ratio to nuclear stability are discussed in detail in Part VI.D.1 of this chapter, and by Serway et al. (2005) and Sundaresan (2001). In brief, the importance of N/Z ratio to nuclear stability is explained by the fact that there exists a short-range attractive nuclear force, which extends to a distance of ≈ 2 fm (2 fermi or 2×10^{-15} m). This attractive force has charge independence and is a consequence of the relative spins of the protons and neutrons and their relative positions in the nucleus. These binding exchange forces exist therefore, regardless of charge on the particles, between two protons, two neutrons, and a proton and neutron. While the attractive nuclear forces will tend to hold the nucleus together there exists, at the same time, repelling columbic forces between the positively charged protons that act to force them apart. For nuclides of low Z , the attractive nuclear forces exceed the repelling columbic forces when $N \approx Z$. However, increasing the number of protons (e.g., $Z > 20$) further increases the strength of the repelling columbic forces over a larger nucleus, which will tend to force the nucleus apart. Therefore, additional neutrons, $N > Z$, provide additional attractive nuclear forces needed to overcome the repelling forces of the larger proton population. As the atomic number increases further, $Z > 83$, all nuclides are unstable. Even though N/Z ratios reach 1.5, nuclear stability is not achieved when the number of protons in the nucleus exceeds 83.

c. Positron decay energy

The general reaction for positron emission was described previously by Eq. (1.202). It is provided here again for a treatment on positron decay energy, and it is the following:

where A_ZP is the parent nuclide of atomic number Z and mass number A , ${}^A_{Z-1}D$ is the daughter nuclide of atomic number $Z-1$ and same mass number as the parent, β^+ is the positron or positive beta particle, ν is the neutrino, and K_T is the total kinetic energy released in the beta decay process.

In terms of nuclear masses, Eq. (1.208) may be written as

$${}_Z M_P = {}_{Z-1} M_D + m_e + K_T \quad (1.209)$$

where ${}_Z M_P$ and ${}_{Z-1} M_D$ are the masses of the parent and daughter nuclei of atomic number Z and $Z-1$, respectively, and m_e is the mass of the positron (*i.e.*, one electron mass). Atomic mass units (u) may be used to calculate conveniently the mass difference of the parent and daughter, if we add Z atomic electron masses to each side of Eq. (1.209) and ignore the negligible difference in electron binding energies of the parent and daughter atoms. Adding Z atomic electrons to each side of Eq. (1.209) gives

$${}_Z M_P + Z m_e = {}_{Z-1} M_D + (Z+1) m_e + K_T \quad (1.210)$$

and

$${}_Z M_P = {}_{Z-1} M_D + 2 m_e + K_T \quad (1.211)$$

The term $2m_e$ of Eq. (1.211) arises from the creation of two electrons of opposite charge (e^+ , e^-) within the nucleus. The positive electron, e^+ , is ejected from the nucleus as the positron; and the negative electron, e^- , combines with a proton to form a neutron. The mass difference of the parent and daughter nuclei is equivalent to the decay energy, Q_{β^+} . The decay energy, Q_{β^+} , may be calculated now using atomic mass units and taking the product of mass and c^2 to determine the energy equivalence of mass using Eq. (1.211) to give

$$Q_{\beta^+} = ({}_Z M_P - {}_{Z-1} M_D) c^2 = 2 m_e c^2 + K_T \quad (1.212)$$

or

$$Q_{\beta^+} = ({}_Z M_P - {}_{Z-1} M_D) c^2 = 2 m_e c^2 + E_{\beta^+} + E_\nu + E_\gamma + E_{\text{recoil}} \quad (1.213)$$

where ${}_Z M_P - {}_{Z-1} M_D$ is the mass difference of the parent and daughter nuclides, c is the speed of light in a vacuum, and $2m_e c^2$ is the energy equivalence of two electron masses or 1.022 MeV, which is the energy required for the creation of the $e^+ e^-$ pair in the positron decay process described previously in this section. The terms $E_{\beta^+} + E_\nu$ are the shared positron and neutrino kinetic energies, which combined is referred often to as the E_{max} of the beta decay. The term E_γ is gamma-ray energy that may be emitted by the daughter nucleus, and E_{recoil} is the nuclear recoil energy, which is relatively small (measured in eV) and can be ignored as negligible when calculating the overall decay energy (measured in MeV).

We may take an example of a simple case of positron emission in the decay of ${}^{13}\text{N}$ where there is no gamma radiation from the daughter nucleus, that is, the ${}^{13}\text{N}$ nucleus decays directly to ${}^{13}\text{C}$ at its stable ground state with the emission of a positron and neutrino with maximum energy 1.198 MeV. The scheme for the decay of ${}^{13}\text{N}$ is illustrated in Fig. 1.51.

The E_{max} is the combined energy of the positron and neutrino ($E_{\beta^+} + E_\nu$), that is, the energy shared by the positron and neutrino. In other words, the E_{max} is the maximum energy of the positron when the neutrino is at its minimum energy or vice versa.

The decay energy, Q_{β^+} , for ${}^{13}\text{N}$ decay is calculated as

$$\begin{aligned} Q_{\beta^+} &= (M_{13\text{N}} - M_{13\text{C}}) c^2 \\ &= (13.0057386 \text{ u} - 13.0033548 \text{ u})(931.494 \text{ MeV/u}) \\ &= 2.2204 \text{ MeV} \end{aligned} \quad (1.214)$$

which is the magnitude of the Q value for ${}^{13}\text{N}$ listed in standard reference tables (*e.g.*, Table of the Isotopes in Rumble, 2017) and the National Nuclear Data Center online data base NuDat 2.7 (<https://www.nndc.bnl.gov/>)

FIGURE 1.51 Beta decay of ^{13}N to stable ^{13}C by positron (β^+) emission. The scheme illustrates the energy equivalence (1.022 MeV) of two electron masses (e^+e^-) required for positron emission. The remaining 1.198 MeV energy is shared by the β^+ and ν .

[nudat2/chartNuc.jsp](https://www.nndc.bnl.gov/nudat2/chartNuc.jsp)). The maximum energy of the β^+ or neutrino in this case may be calculated easily according to Eq. (1.213) by ignoring the nuclear recoil energy (E_{recoil}), because of its small value and ignoring the gamma-ray energy (E_γ), because, in this example, no gamma-ray energy arises from the daughter nucleus following beta decay. Thus, the maximum energy of the β^+ or neutrino is

$$\begin{aligned} E_{\text{max}} &= E_{\beta^+} + E_\nu = Q_{\beta^+} - 2m_e c^2 \\ &= 2.220 \text{ MeV} - 1.022 \text{ MeV} \\ &= 1.198 \text{ MeV} \end{aligned} \quad (1.215)$$

The above value of 1198 keV or 1.198 MeV calculated above agrees with the maximum positron energy (End-point energy) provided the National Nuclear Data Center online database NuDat 2.7 (<https://www.nndc.bnl.gov/nudat2/chartNuc.jsp>).

A more complex example would be that of the decay of ^{22}Na , which decays by positron (β^+) emission and EC decay with the emission of gamma radiation according to the decay Eqs. (1.216) and (1.217) and the decay scheme illustrated in Fig. 1.52.

Positron emission (90.06%):

Electron capture (9.94%):

As illustrated in Fig. 1.52, the radionuclide ^{22}Na may decay by EC or positron emission. EC is a decay mode that competes with positron emission as discussed in the following section of this chapter. In this case, 90.06% of

FIGURE 1.52 Beta decay scheme of ^{22}Na by competing positron (β^+) and electron capture (EC) decay. Positron emission occurs in 90.06% of the nuclear decays and EC in the remaining 9.94%. Decay by EC involves the emission of a mono-energetic neutrino of 1.567 MeV (i.e., $E_\nu = 2.842 - 1.275 \text{ MeV}$) to metastable ^{22}Ne . Positron emission occurs with the consumption of the energy equivalence of two electron masses (i.e., $2m_e c^2$) followed by two branching positron emissions with intensities of 90% and 0.06%.

the ^{22}Na radionuclides decay via positron emission and the remaining 9.94% decay via EC. When the decay energy, Q_{β^+} , is well above 1.022 MeV (the minimum energy required for e^+e^- pair production) positron emission will predominate over EC decay.

The decay energy for ^{22}Na may be calculated according to Eq. (1.213) as

$$\begin{aligned} Q_{\beta^+} &= (M_{^{22}\text{Na}} - M_{^{22}\text{Ne}})c^2 \\ &= (21.994437 \text{ u} - 21.9913855 \text{ u})(931.494 \text{ MeV/u}) \\ &= 2.842 \text{ MeV} \end{aligned} \quad (1.218)$$

which is in agreement with the magnitude of the Q value for ^{22}Na provided by the National Nuclear Data Center online database NuDat 2.7 (<https://www.nndc.bnl.gov/nudat2/chartNuc.jsp>). The calculated decay energy corresponds to the theoretical value described by Eq. (1.213), that is,

$$Q_{\beta^+} = 2m_e c^2 + E_{\beta^+} + E_\nu + E_\gamma + E_{\text{recoil}} \quad (1.219)$$

where $E_{\beta^+} + E_\nu = \beta_{\text{max}}^+$ and, if we ignore the relatively very small value of E_{recoil} , we calculate

$$\begin{aligned} Q_{\beta_1^+} &= 2m_e c^2 + \beta_{\text{max}}^+ + E_\gamma \\ &= 1.022 \text{ MeV} + 0.540 \text{ MeV} + 1.275 \text{ MeV} \\ &= 2.84 \text{ MeV} \end{aligned} \quad (1.220)$$

which is in accord the β_1^+ transition illustrated in Fig. 1.52, and

$$\begin{aligned} Q_{\beta_2^+} &= 2m_e c^2 + \beta_{\text{max}}^+ \\ &= 1.022 \text{ MeV} + 1.820 \text{ MeV} \\ &= 2.84 \text{ MeV} \end{aligned} \quad (1.221)$$

which is in agreement with the β_2^+ transition illustrated in Fig. 1.52 whereby ^{22}Na decays directly to the stable ground state of ^{22}Ne without gamma emission in 0.06% of the nuclear decays.

3. Electron capture

The electron capture (EC) decay process is described by the following general equation.

where ${}^A_Z P$ is the parent nuclide of atomic number Z and mass number A , e^- is an orbital electron captured by the nucleus of the parent nuclide, ${}^A_{Z-1} D$ is the daughter nuclide of atomic number $Z-1$ and same mass number as the parent, ν is the neutrino, and K_T is the total kinetic energy released in the beta decay process.

a. Basic principles

EC is another form of beta decay. The change in atomic number is the same as occurs with positron (β^+) emission. EC competes with positron emission and most radionuclides that decay by positron emission also decay by EC to the same daughter nuclide.

The mechanism by which an unstable nucleus can increase its n/p ratio is via the capture by the nucleus of a proximate atomic electron (*e.g.*, *K*- or *L*-shell electron). The absorbed electron combines with a proton to yield a neutron within the nucleus as follows:

The decay process is known as EC, or sometimes referred to as *K* capture, because most of the electrons are captured from the *K* shell, which is closest to the nucleus. A neutrino ν , is emitted and this is accompanied by the emission of internal bremsstrahlung, which is a continuous spectrum of electromagnetic radiation that originates from the atomic electron as it undergoes acceleration toward the nucleus. Unlike the beta decay process, which results in the emission of a neutrino from the nucleus with a broad spectrum of energies, the neutrino emitted from the EC decay process does not share the transition energy with another particle and, therefore, it is emitted with a single quantum of energy equal to the transition energy less the atomic electron binding energy. The capture of an atomic electron by the nucleus leaves a vacancy in an electron shell, and this is filled usually by an electron from an outer shell, resulting in the production of X-radiation (see Sections XI.D.2.c). The electron that fills the vacancy leaves yet another vacancy at a more distant shell. A cascade of electron vacancies and subsequent filling of vacancies from outer electron shells occurs with the production of X-rays characteristic of the daughter atom. The X-rays will either travel out of the atom or the energy emitted by the electron transition will be transferred to an outer orbital electron causing the electron to be ejected as an Auger electron. Gamma radiation is illustrated in the above Eq. (1.223) because it is emitted only when the daughter nuclide is left at an unstable elevated energy state (see Figs. 1.52–1.54).

The EC decay process may compete with β^+ emission. That is, some radionuclides may decay by either EC or, β^+ -emission. As discussed previously, positron emission requires a transition energy of at least 1.022 MeV, the minimum energy required for pair production in the nucleus (*i.e.*, two electron rest mass energies or $2 \times 0.511 \text{ MeV}$). Positron emission, therefore, will not compete with EC for decay transitions less than 1.022 MeV. In general, positron emission will predominate when the transition energy is high (well above 1.022 MeV) and for nuclides of low atomic number, while the EC decay

FIGURE 1.53 Beta decay scheme of ^{44}Sc by competing EC decay and positron (β^+) emission. The high decay energy of 3.653 MeV favors β^+ emission, as it is well above the minimum 1.022 MeV or $2m_0c^2$ required for positron emission. EC decay occurs in only 5% of the nuclear decays and β^+ emission in the remaining 95%. Both EC and β^+ decay yield metastable $^{44\text{m}}\text{Ca}$, which decays to stable ^{44}Ca with gamma ray emission of 1.159 MeV.

FIGURE 1.54 Decay scheme of ^7Be . The decay occurs exclusively by branching electron capture (EC). In 10.4% of the transitions, ^7Be emits a monoenergetic neutrino of 0.384 MeV (i.e., $0.862 - 0.478$ MeV) followed by the emission of a 0.478 MeV gamma-ray photon. The remaining EC decay events occur with the emission of a monoenergetic neutrino of 0.862 MeV directly to the ground state of stable ^7Li in 89.6% of the decay transitions.

process will predominate for low transition energies and nuclides of higher atomic number. The decay transitions of ^{22}Na and ^{65}Zn serve as examples. In the case of ^{22}Na , decay by β^+ emission predominates (90.06%) as compared with decay via EC (9.94%)

and

The transition energy of ^{22}Na is 2.842 MeV (Holden, 1997a and calculated previously, see Eq. 1.218), well above the 1.022 MeV minimum required for positron emission. Thus, positron emission predominates. On the

other hand, taking the following example of the nuclide ^{65}Zn , we see that EC predominates over β^+ emission:

and

In the case of ^{65}Zn , the transition energy is only 1.35 MeV (Holden, 1997a), which is not much above the minimum energy of 1.02 MeV required for positron emission. Consequently, EC decay predominates.

b. EC decay energy

The general decay equation for EC was described previously by Eq. (1.222). It is provided here again for

a treatment on EC decay calculations, and it is the following:

$${}_Z^AP + e^- \xrightarrow{\text{EC}} {}_{Z-1}^AD + \nu + K_T \quad (1.228)$$

where ${}_Z^AP$ is the parent nuclide of atomic number Z and mass number A , e^- is an orbital electron captured by the nucleus of the parent nuclide, ${}_{Z-1}^AD$ is the daughter nuclide of atomic number $Z-1$ and same mass number as the parent, ν is the neutrino, and K_T is the total kinetic energy released in the beta decay process.

In mass and energy terms, Eq. (1.228) can be written as

$${}_Z M_P + m_e = {}_{Z-1} M_D + K_T \quad (1.229)$$

where ${}_Z M_P$ is the mass of the parent nuclide of atomic number Z , m_e is the mass of the atomic electron captured by the nucleus, and ${}_{Z-1} M_D$ is the mass of the daughter nucleus of atomic number $Z-1$. We may use atomic mass units (u) to calculate conveniently the mass difference of the parent and daughter nuclei and arrive at the decay energy by firstly adding $Z-1$ atomic electrons to each side of Eq. (1.229), which yields

$${}_Z M_P = {}_{Z-1} M_D + K_T \quad (1.230)$$

The mass difference of the parent and daughter nuclei is equivalent to the decay energy (Q_{EC}). We can now calculate the decay energy Q_{EC} by the difference of the parent and daughter nuclide atomic masses ignoring the small difference in the binding energies of the electrons in the two nuclides as

$$Q_{\text{EC}} = ({}_Z M_P - {}_{Z-1} M_D) c^2 = K_T = E_\nu + E_\gamma + E_{\text{recoil}} \quad (1.231)$$

where c is the velocity of light in a vacuum and the product Mc^2 yields the energy equivalence of the mass, E_ν is the kinetic energy of the neutrino, E_γ is the gamma ray photon energy, which only appears with the decay of the daughter nucleus when it is left at a metastable or excited energy state, and E_{recoil} is the kinetic energy of the daughter recoil nucleus. As in previously described beta decay processes, we will ignore the relatively very small recoil energy when calculating the overall decay energy.

As an example, let us look at the decay scheme of ${}^{44}\text{Sc}$, which decays by EC and positron emission. The decay equations are the following

and

The decay scheme is illustrated in Fig. 1.53.

The scheme in Fig. 1.53 illustrates that 5% of the ${}^{44}\text{Sc}$ nuclides decay by EC and the remaining 95% of the nuclides decay with positron emission with a positron E_{max} of

1.472 MeV. The ${}^{44}\text{Ca}$ product nuclides then decay to a stable ground state with the emission of gamma radiation of 1.159 MeV energy.

The decay energy for either mode of decay (EC or β^+ emission) is calculated according to Eqs. (1.231) and (1.218), respectively, as follows:

For electron capture

$$\begin{aligned} Q_{\text{EC}} &= ({}_Z M_P - {}_{Z-1} M_D) c^2 = E_\nu + E_\gamma + E_{\text{recoil}} \\ &= (M_{44\text{Sc}} - M_{44\text{Ca}}) c^2 \\ &= (43.9594029 \text{ u} - 43.9554815 \text{ u})(931.494 \text{ MeV/u}) \\ &= 3.6527 \text{ MeV} \end{aligned} \quad (1.234)$$

which is in agreement with the decay energy of 3652.7 keV provided in the standard reference tables (e.g., Holden, 1997a) and the online QCalc computation (<https://www.nndc.bnl.gov/qcalc/>). As we know, that the gamma ray energy $E_\gamma = 1.159$ MeV (see Fig. 1.53) and, if we disregard the very small magnitude of the recoil energy, we can calculate the neutrino energy in this case as

$$\begin{aligned} E_\nu &= Q_{\text{EC}} - E_\gamma = 3.653 \text{ MeV} - 1.159 \text{ MeV} \\ &= 2.494 \text{ MeV} \end{aligned} \quad (1.235)$$

The neutrino energies are monoenergetic in the case of the EC decay mode.

For positron emission

$$\begin{aligned} Q_{\beta^+} &= ({}_Z M_P - {}_{Z-1} M_D) c^2 \\ &= 2m_e c^2 + E_{\beta^+} + E_\nu + E_\gamma + E_{\text{recoil}} \\ &= (M_{44\text{Sc}} - M_{44\text{Ca}}) c^2 = 3.653 \text{ MeV} \end{aligned} \quad (1.236)$$

If we again ignore the very small recoil energy of the daughter nucleus and combine the positron and neutrino energies as $E_{\text{max}} = E_{\beta^+} + E_\nu$, we can arrive at the decay energy taking the values from Fig. 1.53 as

$$\begin{aligned} Q_{\beta^+} &= 2m_e c^2 + E_{\text{max}} + E_\gamma \\ &= 1.022 \text{ MeV} + 1.472 \text{ MeV} + 1.159 \text{ MeV} \\ &= 3.653 \text{ MeV} \end{aligned} \quad (1.237)$$

The decay energy of 3.653 MeV is well above the minimum energy for e^+e^- pair production ($2m_e c^2$ or 1.022 MeV) required for positron emission. Thus, the EC decay does not compete well against positron emission in the case of ${}^{44}\text{Sc}$, which decays via positron emission in 95% of the disintegrations and by EC decay in the remaining 5%.

Let us take another example, which is that of ${}^7\text{Be}$ decaying exclusively by EC according to the following equation:

The decay energy is calculated as

$$\begin{aligned} Q_{\text{EC}} &= (M_{{}^7\text{Be}} - M_{{}^7\text{Li}})c^2 \\ &= (7.0169287 \text{ u} - 7.0160034 \text{ u})(931.494 \text{ MeV/u}) \\ &= 0.8619 \text{ MeV} \end{aligned} \quad (1.239)$$

which is in agreement with the magnitude of the decay energy reported in standard reference tables (*e.g.*, [Holden, 1997a](#)) and the online QCalc computation (<https://www.nndc.bnl.gov/qcalc/>). The decay energy is not sufficient to satisfy the minimum energy requirement of 1.022 MeV for positron emission in this case. Thus, there is no competition here between EC and β^+ decay modes, and the ${}^7\text{Be}$ nuclides decay exclusively by EC according to the decay scheme illustrated in [Fig. 1.54](#).

The daughter nuclide, ${}^7\text{Li}$, emits a gamma ray of 0.478 MeV in 10.4% of the transitions. The neutrino energy from the EC decay of ${}^7\text{Be}$ in these transitions would be derived from the difference of the decay energy and gamma ray energy while ignoring the relatively very small recoil energy or

$$\begin{aligned} E_\nu &= Q_{\text{EC}} - E_\gamma \\ &= 0.862 \text{ MeV} - 0.478 \text{ MeV} \\ &= 0.384 \text{ MeV} \end{aligned} \quad (1.240)$$

The remaining 89.6% of the transitions are due to a neutrino emission of 0.862 MeV directly to the stable ground state of the daughter nuclide without any gamma ray emission. Neutrinos emitted in the EC decay process are monoenergetic. They do not possess any broad spectrum of energies, contrary to the neutrinos emitted during β^+ or β^- emission, because the neutrinos emitted from the nucleus in EC decay do not share the decay energy with any other particle.

There is nuclear recoil of the parent nucleus during EC decay resulting from the emission of the neutrino. The nuclear recoils in EC decay have been measured by researchers confirming the mono-energetic character of the emitted neutrino. The calculation of nuclear recoil energies is discussed in detail in [Section XIII](#) of this chapter.

The ${}^7\text{Li}$ ion will recoil at two energy maxima corresponding to the neutrino emissions of 0.862 and 0.384 MeV calculated above. The maximum recoil energy corresponding to the neutrino emission of 0.862 MeV is calculated according to [Eq. \(1.487\)](#) of this chapter to be 56.84 eV. The calculation agrees with the experimental measurement of the

${}^7\text{Li}$ recoil energy reported by 2002 Nobel Laureate Raymond Davis Jr. ([1952](#)) to be 56 ± 1 eV. The recoil energy in this case is relatively high (>10 eV) because of the relatively low mass of the ${}^7\text{Li}$ nucleus. Nevertheless, the recoil energy here may be ignored as negligible when calculating the decay energy, which has units of MeV.

c. Chemical and pressure effects on EC decay rates

In general, the chemical and physical environment of radionuclides do not control nuclear decay processes. However, because the electron-capture decay process involves the capture of an orbital electron by the nucleus, atomic or molecular binding effects, which vary with chemical structure, can influence the electron-capture decay process. Also, external pressure that may alter electron densities in the vicinity of the nucleus could also have an altering effect on the EC decay rate.

[Segré \(1947\)](#) at the Los Alamos Laboratories in the US and [Daudel \(1947\)](#) at the Curie Laboratories of the Radium Institute in Paris, France, were the first to independently suggest that the rate of disintegration of nuclei decaying by EC or internal conversion (IC) would be subject to extra-nuclear environments. Numerous works were published from 1948 to the 1970s confirming the effect of chemical environment on the decay rate of ${}^7\text{Be}$, and these are reviewed by [Huh \(1999\)](#). The effect of pressure on the decay constant of ${}^{99}\text{Tc}$ was first confirmed by [Bainbridge \(1952\)](#), and the mathematical expression for the shift in the binding energy of the atomic electron under pressure, that would affect EC decay rates, was derived by [Mukoyama and Shimizu \(1974\)](#).

During the last 2 decades or so much attention has been given to experimentation related to chemical and pressure effects on radionuclide EC decay rates due to the technological advances in detector instrumentation with improved detection efficiencies and energy resolution of semiconductor detectors that can now yield more precise decay-rate measurements. Utilizing a 100% efficiency high-purity germanium detector, [Huh \(1999\)](#) was able to determine the decay constant of ${}^7\text{Be}$ in three chemical environments, namely, $\text{Be}^{2+}(\text{OH}_2)_4$, $\text{Be}(\text{OH})_2$, and BeO with a precision of 0.01% resulting in a $\sim 1.5\%$ difference in the decay rates of ${}^7\text{Be}$ in $\text{Be}(\text{OH})_2$ and BeO . Also, [Ray et al. \(1999\)](#) found the decay rate of ${}^7\text{Be}$ implanted in Au was $0.72 \pm 0.07\%$ lower than ${}^7\text{Be}$ implanted in Al_2O_3 . The variation in decay rates of the ${}^7\text{Be}$ was considered a result of the change in the electron density around the nucleus of ${}^7\text{Be}$ due to its association with different anions, and atomic electron affinity and geometry of the lattice within which the ${}^7\text{Be}$ was implanted. EC occurs mostly with electrons in closest proximity to the nucleus, such as electrons from the K shell, and any chemical bond or environment that would force atomic electrons closer to the nucleus or reduce the electron binding energy would increase the EC decay rate.

The combination of chemical environment and pressure can affect electron-capture decay rates. Liu and Huh (2000) found a steady increase in the decay constant of ^7Be in $\text{Be}(\text{OH})_2$ as a function of pressure over the range of 1 atm–441 kbar. The decay constant increased by 1% at 441 kbar compared to the decay constant at 1 atm, which corresponded to a change in half-life from 53.414 ± 0.003 days at 1 atm to 52.884 ± 0.022 days at 441 kbar pressure. These results were consistent with calculations made by Tossell (2002) on the effects of Be–O bond compression in $\text{Be}(\text{OH})_4^{2-}$ on the energy and the electron density at the nucleus of ^7Be , which indicates that several hundred kbar pressure could increase the electron density by 1% or more. This would expectedly facilitate the capture of an orbital electron by the nucleus and increase the decay rate. Lee and Steinle-Neumann (2008) demonstrated a 0.1–0.2% increase in the decay constant of ^7Be as a metal, chloride, or oxide under a pressure of 25 GPa. Ohtsuki et al. (2004) studied the half-life of ^7Be , which was found to be up to 1.1% shorter when the ^7Be was encapsulated in fullerene (C_{60}) molecules as compared to ^7Be embedded in metal at room temperature. The ^7Be half-life is reduced by close to 1.5%, when the ^7Be embedded in the C_{60} molecules is kept at a very low temperature of $\sim 5\text{K}$ with liquid helium (Ohtsuki et al., 2007). A thorough study of the chemical environment of the ^7Be encapsulated in the C_{60} molecules by Ono et al. (2013) demonstrates the electron density at the Be nucleus to be proportional to the magnitude of the ^7Be decay rate.

The radionuclides ^{22}Na and ^{40}K in metallic form showed an increase of 0.06% and 0.025% in their decay constants, respectively, at 25 GPa pressure. Ray et al. (2009) also observed an increase in the orbital EC rates of ^{109}In and ^{110}Sn by $1.00 \pm 0.17\%$ and $0.48 \pm 0.25\%$, respectively, when implanted in the smaller Au lattice compared to implantation in a larger Pb lattice. They interpret the increased decay rates as due to an increase in the eigenstate energies of an atom under spatial confinement. This effect would increase the electron density of the orbital electrons at the nucleus and thus increase the decay rate of an electron capturing radioactive nucleus.

While the fluctuations in the observed EC decay rates may appear small, Zito and Schiferl (1987) indicate that the affects may be significant in terms of stellar energetics. They note that pressure-dependent decay may be an important source of heat generation in Jovian planets where central pressures may reach megabars. They give the example of Jupiter's rock-ice core, which contains as much potassium as Earth's continental crust, and that ^{40}K decay accounts for about 11.5% of the total excess energy output of Jupiter. This energy divided into two parts gives 9.3% due to normal (zero-pressure) beta and EC decay, and the remaining 2.2% would be due to pressure effects alone on the EC decay rate. Also, they surmise that pressure effects on the EC decay rate of $^{90\text{m}}\text{Nb}$ could account for 14% of the total energy output of Jupiter's

core. The high pressures in Saturn, Uranus, and Neptune could have a role in pressure-accelerated EC decay as an important heat source in these planets. Zito and Schiferl (1987) also provide convincing arguments in support of the role of ^{50}V , ^{123}Te , ^{138}La , ^{40}K , ^{26}Al , and ^{36}Cl , which undergo EC decay, in stellar energetics. They note that peculiar A stars are enriched in La isotopes by a factor of 600 over normal stars; and other stars breed significant amounts of ^{26}Al and ^{36}Cl . They point out that sudden pressure changes in the interior of these stars could result in EC outbursts.

4. Branching β^- , β^+ and EC decay

It is a common practice to characterize radionuclide beta decay according to (1) negatron (β^-) emission, (2) positron (β^+) emission and/or EC. However, there exists also several radionuclides of odd atomic number Z and even mass number A that decay via all beta decay modes, namely β^- , β^+ and EC decay to varying degrees yielding two daughter nuclides that differ by two units of atomic number. Their decay may be described by the branching pathways illustrated in Fig. 1.55 where the parent nuclide ^A_ZP decays in two directions, namely, by β^- emission to a daughter nuclide $^{A}_{Z+1}\text{D}$ of atomic number $Z + 1$ and by β^+ emission and by EC decay to a daughter nuclide $^{A}_{Z-1}\text{D}$ of atomic number $Z - 1$. This decay phenomenon is also referred to as “dual beta decay”; however, it should not be confused with “double beta decay”, which is an altogether different and more elusive decay process described in a subsequent section of this chapter.

Radionuclides that decay by means of this branching β^- , β^+ and EC decay are listed in Table 1.11 together with the relative intensity (%) to which these three beta decay modes occur, along with the decay energies of each mode, and their daughter nuclides. These radionuclides can be found in the Chart of the Nuclides together with their neighboring isobars that are stable. A segment of the Chart of the Nuclides illustrating the positions of ^{36}Cl and ^{40}K , which decay by the

FIGURE 1.55 Branching β^- , β^+ and EC decay illustrated by (A) the general decay reaction of a parent nuclide ^A_ZP to daughter nuclides $^{A}_{Z+1}\text{D}$ and $^{A}_{Z-1}\text{D}$, and (B) the decay of $^{64}_{29}\text{Cu}$ to the daughter nuclide $^{64}_{30}\text{Zn}$ by negatron (β^-) emission and to the daughter nuclide $^{64}_{28}\text{Ni}$ by positron (β^+) emission or electron-capture (EC) decay. The intensities of the three modes of decay, that is, their branching ratios are $\sim 40\%$ for negatron emission, $\sim 19\%$ for positron emission and $\sim 41\%$ for EC decay.

TABLE 1.11 Radionuclides that decay via branching β^- , β^+ , and EC.^a

Radionuclide	Decay modes (%)	Decay energies (MeV)	Product nuclides
³⁶ ₁₇ Cl	β^- (98%)	Q_{β^-} , 0.708	³⁶ ₁₈ Ar (β^-)
	β^+ (0.002%)	$Q_{\beta^+, EC}$, 1.421	³⁶ ₁₆ S (β^+ , EC)
	EC (1.9%)		
⁴⁰ ₁₉ K	β^- (89%)	Q_{β^-} , 1.311	⁴⁰ ₂₀ Ca (β^-)
	β^+ (0.3%)	$Q_{\beta^+, EC}$, 1.505	⁴⁰ ₁₈ Ar (β^+ , EC)
	EC (10.7%)		
⁶⁴ ₂₉ Cu	β^- (40%)	Q_{β^-} , 0.579	⁶⁴ ₃₀ Zn (β^-)
	β^+ (19%)	$Q_{\beta^+, EC}$, 1.675	⁶⁴ ₂₈ Ni (β^+ , EC)
	EC (41%)		
⁷⁴ ₃₃ As	β^- (32%)	Q_{β^-} , 1.353	⁷⁴ ₃₄ Se (β^-)
	β^+ (31%)	$Q_{\beta^+, EC}$, 2.562	⁷⁴ ₃₂ Ge (β^+ , EC)

	β^+ (43.6%)	$Q_{\beta^+, EC}$, 2.979	¹³⁰ ₅₄ Xe (β^+ , EC)
	EC (54.8%)		

^aData from Lide (2010), Firestone et al. (1996), and National Data Center, Brookhaven National Laboratory: <https://www.nndc.bnl.gov/nudat2/>.

three β^- , β^+ and EC modes, and their neighboring stable daughter isobars is provided in Fig. 1.56.

The decay schemes of ³⁶Cl and ⁴⁰K exhibit very low relative occurrences of their β^+ decay modes, namely 0.002% and 0.3%, respectively (see Table 1.11), which may be due to their relatively low decay energies of (Q_{EC, β^+}) of 1.142 and 1.505 MeV, respectively (see Table 1.11). Positron decay will compete and predominate

over the EC decay mode when the decay energy is well above 1.022 MeV, which is the energy required for the production of an e^+e^- pair needed for the positron decay mode. The following two nuclides listed in Table 1.11, namely ⁶⁴Cu and ⁷⁴As, have higher decay energies (Q_{EC, β^+}) of 1.675 and 2.562 MeV, respectively, yielding more significant intensities of 19% and 31%, respectively, for their β^+ decay modes as listed in Table 1.11.

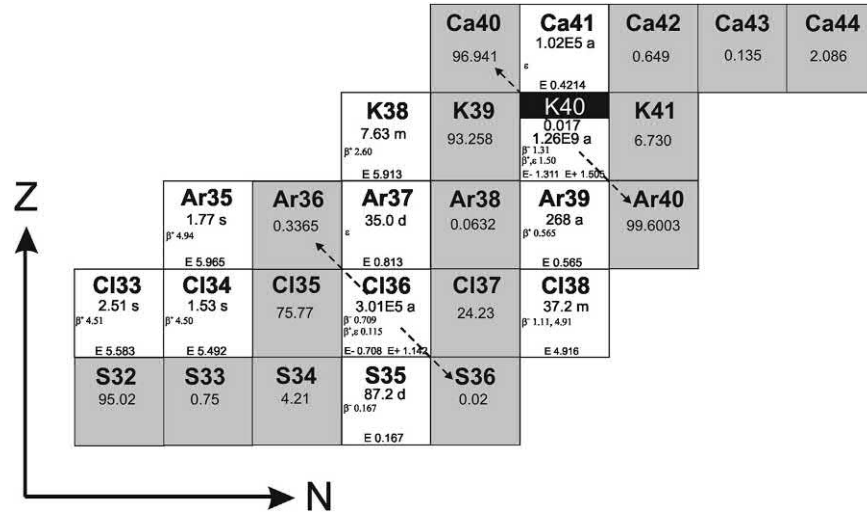

FIGURE 1.56 A segment of the Chart of the Nuclides illustrating the location of $^{36}_{17}\text{Cl}$ and $^{40}_{19}\text{K}$, which decay to neighboring stable isobars (indicated by arrows via negatron (β^-) emission with increasing Z and via positron (β^+) emission and EC with decreasing Z). The stable and naturally occurring nuclides are shaded blocks, and the percent natural abundance of the isotope is included in the center of the shaded block. ^{40}K is a naturally occurring, but radioactive isotope of potassium, and it is thus displayed differently with a black bar over the symbol of the element and the mass number of the isotope. Units of half-life are abbreviated as “s”, “m”, “d”, or “a” for seconds, minutes, days, or anni (years). Beta decay modes are abbreviated as β^- , β^+ , and ϵ for negatron, positron, and EC, respectively, with decay energies in MeV. The decay energy of a radionuclide is in MeV at the bottom of each block alongside the letter E. Two decay energies are given for the radionuclides, ^{36}Cl and ^{40}K , because of their branching beta decay modes. The value after the negative sign (E^-) is the decay energy for the negatron decay mode and the other with a positive sign (E^+) is the decay energy for the positron and EC decay modes.

There are an additional 25 radionuclides that decay by branching negatron (β^-) and EC decay modes, whereas positron (β^+) emission does not occur. These radionuclides decay according to the general scheme provided in Fig. 1.55 with the exception that the positron (β^+) decay mode does not occur. The properties of these radionuclides, their decay modes, and product nuclides are included in the Table of Radioactive Isotopes listed in Appendix A. They can be easily identified by the fact that both β^- and EC decay modes are listed and there are two product nuclides rather than the customary one nuclide product. Although positron emission does not occur in these cases, the parent nuclide of atomic number Z decays to two daughter nuclides of atomic numbers $Z - 1$ and $Z + 1$. These nuclides, which do not decay by positron emission, have mostly low decay energies ($Q_{\text{EC}} < 1.0$ MeV). The decay energies are below the minimum decay energy equivalent to two electron masses (1.022 MeV) for the production of an e^+e^- pair required in the positron decay mode.

5. Double beta ($\beta\beta$) decay

Double-beta ($\beta\beta$) decay is the rarest of all radioactive decay processes ever observed. Among these rare double beta decay events, the mode of decay that is the most common may be described by the following general equation:

which involves the simultaneous emission of two negatrons and two antineutrinos. This mode of double beta decay is abbreviated as $\beta\beta$ decay or $2\nu\beta\beta$ decay to read two-neutrino double beta decay. The parent nucleus transforms to a daughter nucleus of the same mass number A , but with an increase in atomic number Z by two. In accord with the beta-decay scheme, within the nucleus of the parent nuclide, two neutrons decay to two protons with the simultaneous emission of two negative beta particles (negatrons) and two antineutrinos, or

The National Nuclear Data Center (NNDC, 2018a,b) of the Brookhaven National Laboratory (<https://www.nndc.bnl.gov/bbdecay/list2013.html>) currently lists 11 nuclides that are known to undergo double-beta ($\beta\beta$) decay according to the double negatron emission described above. These nuclides are the following: $^{48}_{20}\text{Ca}$, $^{76}_{32}\text{Ge}$, $^{82}_{34}\text{Se}$, $^{96}_{40}\text{Zr}$, $^{100}_{42}\text{Mo}$, $^{116}_{48}\text{Cd}$, $^{128}_{52}\text{Te}$, $^{130}_{52}\text{Te}$, $^{136}_{54}\text{Xe}$, $^{150}_{60}\text{Nd}$, and $^{238}_{92}\text{U}$. The NNDC lists an additional nuclide, $^{130}_{56}\text{Ba}$, that decays by double electron capture (ECEC), which is another mode of double beta decay. These nuclides all have very long half-lives with orders of magnitude that range from 10^{19} to 10^{24} years.

As discussed previously, beta decay by definition includes nuclear decay processes where the mass number (A) of the nucleus remains constant and the atomic number (Z) changes. Thus, we must include EC decay, as a beta decay process, which does not result in the emission of any beta

particle. Double beta decay, which involves exclusively EC, has been observed to this date to occur in the case of the decay of ^{130}Ba to ^{130}Xe (Meshik et al., 2001; Pujol et al., 2009). Double beta decay involving exclusively EC can be described by the following general equation:

The parent nucleus captures two orbital electrons and transforms to a daughter nucleus of the same mass number A , but with a decrease in atomic number Z by two with the simultaneous emission of two neutrinos. In accord with the EC beta decay scheme, within the nucleus of the parent nuclide, two protons capture two orbital electrons converting the protons into two neutrons with the simultaneous emission of two neutrinos, or

This form of double beta decay is often abbreviated ECEC or 2 EC signifying the decay mechanism involving the simultaneous capture of two orbital electrons. It is in short referred to as two neutrino double EC.

Other possible modes of double beta decay whereby two nuclear protons transform to two neutrons resulting in the parent nuclide of atomic number Z transforming into a daughter nuclide of atomic number $Z - 2$ may occur via (1) the simultaneous emission of two positrons ($\beta^+\beta^+$) and two neutrinos, (2) combined positron emission and electron capture ($\beta^+\text{EC}$) with the emission of two neutrinos, or the simultaneous double electron capture (ECEC) with the emission of two neutrinos. For example, the decay of ^{130}Ba to ^{130}Xe could occur by either of the three modes of decay, $^{130}\text{Ba}(\beta^+\beta^+)^{130}\text{Xe}$, $^{130}\text{Ba}(\beta^+\text{EC})^{130}\text{Xe}$, or $^{130}\text{Ba}(\text{ECEC})^{130}\text{Xe}$. Among the three possible modes of double beta decay, the latter mode $^{130}\text{Ba}(\text{ECEC})^{130}\text{Xe}$ was calculated to have the shortest half-life by a magnitude of 10^2 , and thus ECEC decay of ^{130}Ba would be the mode of decay in this case (Pujol et al., 2009). The measurement of double ECEC beta decay of ^{130}Ba cannot be accomplished by direct measurement of the radiation emissions, because the only emissions in this double EC decay process are the simultaneous emission of two neutrinos, which would be a technically impossible task for a rare decay event. Double ECEC decay of ^{130}Ba was measured by geochemical methods. These methods required the mass spectroscopic measurement of a strong isotope excess of the daughter nuclide ^{130}Xe that could be identified in mineral deposits close to a depth of ~ 90 m where the mineral deposits are shielded from cosmic radiation, and the observation of a Xe isotope spectrum was distinct from ancient or modern atmospheric Xe (Pujol et al., 2009).

a. Discovery and current research

Double-beta decay was first predicted by Nobel Laureate Maria Goeppert-Mayer (1935) at Johns Hopkins University, who calculated a predicted half-life of over 10^{17} years for this decay phenomenon. It was not until 1987 did Steven R.

Elliott, Alan A. Hahn, and Michael K. Moe at the University of California, Irvine report the first observation of double-beta decay in a sample of ^{82}Se enriched from its natural abundance of 8.7% to an isotope abundance of 97% to provide more source material for the double beta decay as well as reduce contamination in the sample from other sources (Elliott et al., 1986, 1987; Moe, 1986; Moe and Rosen, 1989).

The rarity of this decay process is manifested by the very large half-lives (from 10^{18} to 10^{24} years) of the nuclides that decay by this process. Because of the rarity of double-beta decay, its observation in the laboratory is extremely difficult requiring highly enriched radionuclide sources and sophisticated coincidence (double-beta) counting instrumentation capable of extreme suppression or vetoing of background radiation (Elliott et al., 2006; Gómez et al., 2007; Campbell et al., 2008; Gehman et al., 2010; McGrath et al., 2010; Poda et al., 2013; Arnold et al., 2014; Belli et al., 2014; Barabash, 2015; Asakura et al., 2016). Thus, double-beta decay is difficult to detect and not measured routinely. The phenomenon is discussed briefly here, because our knowledge of its existence helps us understand more fully the beta decay process. More detailed treatments of double-beta decay are provided in various chapters of this book.

b. $2\nu\beta\beta$ decay energy

The double-beta decay of ^{82}Se , as observed by Elliott et al. (1987), can be written as follows:

The decay equation illustrated above would only be possible if the daughter nucleus, ^{82}Kr , is lower in mass than the nucleus of its parent ^{82}Se . As explained by Moe and Rosen (1989), the mass of the daughter nucleus is diminished by the mass equivalent to its binding energy, the energy needed to pull the nucleus apart. Thus, a more tightly bound nucleus is lighter than a more loosely bound nucleus containing the same number of nucleons. The number of nucleons or mass number (82) in the above equation remain the same; however, the mass of the nucleus of ^{82}Kr is less than that of its parent ^{82}Se , and the difference in mass of the two nuclei would yield the mass equivalent to the decay energy, $Q_{\beta\beta}$. In mass terms Eq. (1.245) may be written as

$${}_Z M_P = {}_{Z+2} M_D + 2m_e \quad (1.246)$$

where ${}_Z M_P$ and ${}_{Z+2} M_D$ are the masses of the parent and daughter nuclei of atomic numbers Z and $Z+2$, respectively, and $2m_e$ is the mass of two beta particles (*i.e.*, two electron masses). We may use atomic mass units (*u*) to calculate the mass difference of the parent and daughter nuclei by adding firstly Z atomic electron masses to each side of Eq. (1.246) to give

$${}_Z M_P + Zm_e = {}_{Z+2} M_D + (Z+2)m_e \quad (1.247)$$

The decay energy, $Q_{\beta\beta}$, may then be calculated by the difference in parent and daughter nuclide atomic mass units ignoring the small difference in the binding energies of the electrons in the two nuclides or

$$\begin{aligned}
 Q_{\beta\beta} &= (M_{^{82}\text{Se}} - M_{^{82}\text{Kr}})c^2 \\
 &= (81.916699 \text{ u} - 81.913482 \text{ u})(931.494 \text{ MeV/u}) \\
 &= 2.99662 \text{ MeV} \\
 &= 2.997 \text{ MeV}
 \end{aligned}
 \tag{1.248}$$

The above calculated value is in agreement with the decay energy reported by the National Nuclear Data Center of the Brookhaven National Laboratory, which is 2.997 MeV (<https://www.nndc.bnl.gov/qcalc/>). The decay scheme of ^{82}Se is illustrated in Fig. 1.57. The scheme illustrates the decay of ^{82}Se of higher mass to ^{82}Kr of lower mass, and the mass difference of the two is equivalent to the decay energy, $Q_{\beta\beta}$. The decay energy is shared as energy of four particles, namely, two beta particles and two antineutrinos. Single beta decay of ^{82}Se to ^{82}Br , a nuclide of higher mass is energetically forbidden as depicted in Fig. 1.57.

All of the nuclides that undergo double beta ($\beta\beta$) decay have an even number of protons and even number of neutrons. They exhibit a significant stability to beta decay with half-lives that vary over the range of 10^{19} – 10^{24} years. The stability of these nuclei, as described by Moe and Rosen (1989), may be due to their “even–even” characteristic, that is, their nuclei consist of an even number of protons and neutrons versus a neighboring “odd–odd” nucleus in the Chart of the Nuclides with the same number of nucleons consisting of an odd number of protons and neutrons. The strong nuclear force that holds the nucleus together binds

pairs of like particles more tightly than unlike particles. Thus, a nucleus with even number of protons and even number of neutrons can pair and be bound more tightly than a nucleus with the same mass number but with an odd number of protons and odd number of neutrons. For example, the nucleus of $^{82}_{34}\text{Se}$ contains 34 protons and 48 neutrons, whereas, its neighboring isobar, $^{82}_{35}\text{Br}$ contains the odd numbers of 35 protons and 47 neutrons. The mass of the ^{82}Br nucleus is slightly higher than that of ^{82}Se , as illustrated in Fig. 1.57. The diminished mass of the ^{82}Se is due to its higher binding energy. Thus, the ^{82}Se is a more tightly bound nucleus than the ^{82}Br , and the transition by beta decay from ^{82}Se to ^{82}Br is forbidden energetically, as illustrated in Fig. 1.57.

As discussed in previous parts of this chapter, beta decay is not confined to negatron emission. There also exist positron and EC decay processes, which are other forms of beta decay. Thus, there may exist double $\beta^+\beta^+$ and double electron capture (ECEC) as well as $\beta^+\text{EC}$ double beta decay processes, and research is underway to observe these alternative double beta decay processes (Barabash et al., 2007, 2008; Kolhinen et al., 2010). The ECEC decay of ^{130}Ba to ^{130}Xe was confirmed by Pujol et al. (2009). In single positron emission a minimum decay energy of 1.022 MeV was discussed previously (see Section X.B.2). Double $\beta^+\beta^+$ would then require a minimum of 2.044 MeV decay energy.

c. Neutrinoless $\beta\beta$ decay

There is much research currently underway on double-beta decay particularly with respect to the search for neutrinoless double-beta decay by research groups around the world, and only a few of the research papers are cited here (Šimkovic et al., 2011; Giuliani, 2011; Pocar, 2012; Cremonesi, 2013; Delf’Oro, 2015; Maneschg, 2015; Henning, 2016). In accord with the Standard Model, which explains the continuous spectrum of beta energies emitted from decaying nuclei, the neutrino always accompanies beta emission, that is,

FIGURE 1.57 Double-beta decay of $^{82}_{34}\text{Se}$ to $^{82}_{36}\text{Kr}$. The decay energy, $Q_{\beta\beta}$, of 2.99662 MeV (equivalent to the mass difference between the ^{82}Se and ^{82}Kr) is shared by the two beta particles and two antineutrinos created in the process. Transition via beta decay of ^{82}Se to ^{82}Br is forbidden energetically, as the mass of ^{82}Br is greater than that of ^{82}Se . The double-beta decay occurs with the simultaneous emission of two beta particles and two antineutrinos.

specifically the antineutrino accompanies negatron (β^-) emission and the neutrino accompanies positron (β^+) emission, and accordingly two antineutrinos would accompany double $\beta^-\beta^-$ decay and two neutrinos would accompany $\beta^+\beta^+$ emission or the ECEC decay mode. However, beyond this Standard Model there exists the possibility that the neutrino could be its own antiparticle referred to as a Majorana neutrino in honor of the exceptionally gifted Italian mathematician and theoretical physicist Ettore Majorana (1906—presumed year of death 1938), who first postulated the possibility. According to this theory, if the neutrino possesses a mass (now estimated to have a mass upper limit of $2.3 \text{ eV}/c^2$) and is its own antiparticle, a neutrino emitted in one beta decay could be reabsorbed in the second beta decay resulting in a double-beta decay in which no neutrinos are emitted, *i.e.*, a neutrinoless double-beta decay often abbreviated as $0\nu\beta\beta$. The search for the neutrinoless double-beta decay is important, because it would reaffirm the mass of the neutrino, as only a particle with a definite rest mass can oscillate from one form into another. Earlier in the chapter it was noted that the Nobel Prize in Physics 2015 was awarded jointly to Takaaki Kajita and Arthur B. McDonald for the discovery of neutrino oscillations, which show that neutrinos have mass. The current search and measurement of neutrinoless double beta decay would allow the measurement of the effective neutrino mass and define the absolute neutrino mass scale as described by Maneschg (2015).

Diagrams illustrating the double-beta decay processes that would occur in a decaying nucleus for the two neutrino double beta-decay ($2\nu\beta\beta$) and the, yet to be observed, neutrinoless double-beta decay ($0\nu\beta\beta$) are illustrated in Fig. 1.58. In both cases, two neutrons (n) transform into two protons (p) in the nucleus when two down quarks (d) in the two neutrons change into two up quarks (u) with the emission of $2 W^-$ bosons. The W^\pm bosons were discovered at the Super Proton Synchrotron (SPS) proton-antiproton collider at CERN in 1983 by the UA1 and UA2 collaborations (Arnison et al., 1983a,b, Banner et al., 1983 and Bagnaia et al., 1983). These particles are the carriers of the weak interactions between elementary particles and are responsible for the weak decays of the particles (Sundaresan, 2001; L'Annunziata, 2016). As illustrated in Fig. 1.58, the $2 W^-$ bosons transform

into two high-energy electrons (beta particles) and two antineutrinos. In the case of neutrinoless double-beta decay (yet to be confirmed) the Majorana neutrino emitted in one stage of the decay is reabsorbed in the second stage and two high-energy electrons are emitted without neutrinos.

In the $2\nu\beta\beta$ process, the two beta particles that are emitted simultaneously share the total decay energy, $Q_{\beta\beta}$, with the two neutrinos. Thus, the decay energy is shared between four particles, namely, the two neutrinos and two beta particles. In the $0\nu\beta\beta$ process, the two beta particles emitted share the entire decay energy, as there would be no neutrinos emitted with which to share the decay energy. The beta-particle energy spectra for $2\nu\beta\beta$ and $0\nu\beta\beta$ decay are illustrated in Fig. 1.59. The two beta-particle spectra are very distinct. In the $2\nu\beta\beta$ decay process, the numbers of beta particles (N) vary over a wide range of energy plotted as the sum of the two beta-particle energies divided by the decay energy, *i.e.*, $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta}$. The beta-particle energy spectrum for the $2\nu\beta\beta$ decay would encompass the continuous energy range with a spectral shape similar to that of the single beta-particle emission, because the beta particles share the decay energy with neutrinos. Notice in Fig. 1.59, that the endpoint of the continuous beta-particle spectrum of the $2\nu\beta\beta$ decay does not reach the value of 1.0. This is due to the fact that the two beta particles emitted in the $2\nu\beta\beta$ decay process must share decay energy with two neutrinos, and thus the sum of the two beta particle energies can never equal the decay energy, $Q_{\beta\beta}$. However, the beta-particle energy spectrum for the $0\nu\beta\beta$ decay, where neutrinos do not escape with any of the decay energy, would display a single energy line for the sum of the two beta particle energies, and this line would occur at $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta} = 1$. Current research is underway in the search for the sum of the two beta particles to equal the decay energy, $Q_{\beta\beta}$, or where $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta} = 1$, which would confirm $0\nu\beta\beta$ decay.

6. Parity violation in beta decay

Spatial parity involves the behavior of a physical system under the inversion of special coordinates (Sundaresan, 2001). This is equivalent to changing or transforming the coordinates (*e.g.*, x to $-x$ and vice versa) of a physical

FIGURE 1.58 Feynman diagrams illustrating double-beta decay via (1) two antineutrino double-beta decay ($2\bar{\nu}\beta\beta^-$), and (B) neutrinoless double beta decay ($0\bar{\nu}\beta\beta^-$). From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.

FIGURE 1.59 Beta-particle energy spectra for (A) two-neutrino double-beta decay ($2\nu\beta\beta$), and (B) neutrinoless double-beta decay ($0\nu\beta\beta$). In the $2\nu\beta\beta$ decay process, the sum of the two beta particle energies divided by the decay energy, $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta}$, displays a continuous spectrum, and the maximum will never reach 1.0. However, the spectrum for $0\nu\beta\beta$ would display a single line at $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta} = 1$.

system, as illustrated in Fig. 1.60. As described by Sundaresan (2001), the parity operation is equivalent to going from a right-handed system of coordinates to one that is left-handed, and parity is conserved if the system has “left-right symmetry”. In Fig. 1.60, the clock and its mirror image represent a change in the sign of coordinates. Both clocks function equally and tell the same time. They are identical and they display symmetry and parity is conserved. In natural systems, we can find molecules in biological systems, which are mirror images of each other. Both molecules display the same physical and chemical properties, and thus display left-right symmetry.

Elementary particles possess the quantum number, parity (P), which may be either +1 or -1, which are referred to as even parity or odd parity, respectively. Particles with even parity (+1) have states which possess an even angular momentum (ℓ), and those with odd parity (-1) have states possessing an odd value for the angular

FIGURE 1.60 The inversion of the coordinates along the x axis ($-x$ to $+x$ and vice versa) resulting in a spatial parity transformation of a clock yielding the mirror image of each. Both clocks run identically and display symmetry, and parity is conserved. From L’Annunziata (2016); reprinted with permission from Elsevier © 2016.

momentum. The parity quantum number (P) is determined according to $P = (-1)^\ell$ where the angular momentum (ℓ) is an exponent. Parity is one of many quantum numbers that a particle may possess. A particle may have several quantum numbers, which will define the quantum state of the particle. For example, the quantum state of an atomic electron is defined by its principal number n , orbital quantum number ℓ , magnetic quantum number m_ℓ , and the spin quantum number m_s , which all together define the energy state and orbital of an atomic electron.

The principle of symmetry in nature was examined by Chen-Ning Yang in his Nobel Lecture given on 11 December 1957. He used the example of a person, who’s heart is on the left side looking into a mirror, and the image in the mirror is that of a person with a heart on the right side. (Although the base of the human heart is really located along the midline of the body, the heart points to the left and about two-thirds of the mass of the heart are found on the left side of the body and the other one-third is on the right side of the body. Thus, it is common to refer to the heart being on the left side of the body). Chen-Ning Yang (1957) provided the following example in his Nobel Lecture [with the writer’s comment in brackets] with:

One of the symmetry principles, the symmetry between the left and the right, is as old as human civilization ... Of course, in daily life, left and right are quite distinct from each other. Our hearts, for example, are on our left sides ... the laws of physics have always shown complete symmetry between the left and the right ... To illustrate the point, we mention that if there existed a mirror image man [from another world] with his heart on his right side, his internal organs reversed compared to ours, and in fact his body molecules, for example sugar molecules, the mirror image of ours, and if he ate the mirror image of the food that we eat, then according to the laws of physics, he should function as well as we do ... The law of right-left symmetry then leads also to a conservation law: the conservation of parity.

Prior to the work of Nobel Laureates Lee and Yang (1956), and Chien-Shiung Wu and her collaborators (Wu et al., 1957), it was always assumed that right-left symmetry was conserved throughout all physical processes involving elementary particles and their reactions. This was explained clearly by Professor O. B. Klein, member of the Nobel Committee for Physics during his Award Ceremony Speech on the presentation of the Nobel Prize in Physics on 11 December 1957 when he stated the following:

But what has the question of right and left to do with elementary particle physics?... it was assumed almost tacitly, that elementary particle reactions are symmetric with respect to right and left ... That this assumption was made was very natural,... it looked as if the electrons, the best known elementary particles, possessed no feature which would permit

a distinction between right and left ... In fact, most of us were inclined to regard the symmetry of elementary particles with respect to right and left as a necessary consequence of the general principle of right-left symmetry of Nature. Thanks to Lee and Yang and the experimental discoveries inspired by them we now know that this was a mistake. The starting-point of Lee and Yang in their revision of the whole question of right-left symmetry in elementary particle reactions were certain strange observations concerning a kind of new particles called K mesons, which looked as if they were in contrast with the assumption mentioned.

After a thorough study of the various forces in nature, Lee and Yang (1956) began to question if right-left symmetry is conserved in all interactions. They researched for evidence of the symmetry and the conservation of parity among the forces that act between subatomic particles, namely the nuclear forces, electromagnetic forces and the weak forces. They found that there was considerable evidence that parity was conserved in the strong nuclear and the electromagnetic forces between particles; however, it was only assumed by the scientific community that right-left symmetry and parity conservation was consistent in the weak forces that govern decay interactions, such as beta decay and the decay of subatomic particles. In his Nobel Lecture Yang (1957) explained these forces as follows [with the writer's comments in brackets]:³

We list the four classes of interactions below. The [relative] strength of these interactions is indicated in the column on the right.

1. Nuclear Forces	1
2. Electromagnetic Forces	10^{-2}
3. Weak Forces (Decay Interactions) ³	10^{-13}
4. Gravitational Forces	10^{-38}

The strongest interactions are the nuclear interactions which include the forces that bind nuclei together and the interaction between the nuclei and the π mesons ... The second class of interactions are the electromagnetic interactions of which physicists know a great deal. In fact, the crowning achievement of the physicists of the 19th century was a detailed understanding of the electromagnetic forces. [The electromagnetic forces hold electrons in orbitals about the nucleus of an atom; and these are the forces involved in the collision and scattering between charged particles via the exchange of photons between them.] ... The third class of forces, the weak interactions, was first discovered around the beginning of this century in the β -radioactivity of nuclei,... About the last class of forces, the gravitational forces, we need only mention that in atomic and nuclear interactions they are so weak as to be completely negligible in all the observations with existing techniques

The fact that parity conservation was assumed by the scientific community and never demonstrated was

emphasized by Lee and Yang (1956), and they proposed some experiments that might demonstrate right-left symmetry in the weak interactions including beta decay. The basic principles of these experiments, as described by Yang (1957) are the following:

One constructs two sets of experimental arrangements which are mirror images of each other, and which contain weak interactions. One then examines whether the two arrangements always give the same results in terms of the readings of their meters (or counters).

When applying such an experiment to β decay, the readings of the meters or counters described above refer to the counting of β -particles emitted by the decaying nuclei. If the results of two readings are the same for nuclei arranged as mirror images, then one can demonstrate right-left symmetry in the beta decay and the conservation of parity. Yang (1957) illustrated such an experiment in which Cobalt-60, which decays by the emission of β -particles, are polarized in a magnetic field so that the radioactive ^{60}Co nuclei spin in a given direction. The magnetic field can then be reversed so that the ^{60}Co nuclei spin in the opposite direction (the nuclei become a mirror image of those that spin in the opposite direction). If the radioactivity counters, that detect and count the emitted β -particles, yield the same count rate when the nuclei are spinning in either direction, then right-left symmetry and parity would be demonstrated. This is illustrated in Fig. 1.61.

Chien-Shiung Wu would become the physicist who would demonstrate whether or not there is conservation of parity in the weak interactions, such as in β -decay. As related in the biographical memoir of Chien-Shiung Wu by Benczer-Koller (2009), Nobel Laureate Tsung-Dao Lee consulted with Chien-Shiung Wu, because she was the leading experimentalist in β -decay. They confirmed that there was no evidence in the scientific literature for parity conservation or nonconservation in the weak interaction, and that an experiment would be necessary to find an answer. Benczer-Koller (2009) notes that Chien-Shiung Wu knew that the ^{60}Co , which undergoes β -decay, would be the isotope of choice for the experiment, because the spin of the ^{60}Co nucleus could be polarized in a certain direction with respect to emission of β -particles.

The design of the experiment to ultimately test the parity symmetry in the weak interaction (i.e., β -decay) was left to Chien-Shiung Wu (Benczer-Kolle, 2009). She would design an arrangement whereby an external magnetic field could polarize ^{60}Co nuclei so that their nuclear spins would be directed uniformly according to the external magnetic field. This required embedding the radioactive ^{60}Co in a cerium magnesium (cobalt) nitrate crystal at the extremely low temperature of about 0.003K (Wu et al., 1957), which is very close to absolute zero. The very low temperature essentially eliminates thermal agitation and movement of the atomic nuclei, and thereby essentially freezing the polarized ^{60}Co nuclei in the orientation controlled by the external

FIGURE 1.61 Experimental arrangement to test right-left symmetry and parity in β -decay of ^{60}Co . In the first experiment (on the left) nuclei of ^{60}Co are aligned in a magnetic field so that the nuclei exhibit spin in a fixed direction. The number of β -particles emitted by the nuclei is counted over a fixed period of time (count rate) by a radiation detector fixed at a given location relative to the ^{60}Co source. In the second experiment (on the right) the magnetic field is reversed so that the radioactive ^{60}Co nuclei spin in the opposite direction thereby creating the mirror image of the ^{60}Co nuclei of the first experiment. If the radiation detector yields the same count rate as in the first experiment than the β -decay will exhibit right-left symmetry and conservation of parity. If the count rates are significantly different in the two cases, the β -decay of ^{60}Co would demonstrate that parity is not conserved in the decay process. Figure is from Yang (1957); printed with permission © The Nobel Foundation 1957.

magnetic field. Such as experiment required expertise that was available at the low temperature laboratory of the National Bureau of Standards (NBS) in Washington, D.C., which is now the National Institute of Standards and Technology (NIST). The low temperature laboratory at the NBS had previous experience in the low-temperature alignment of atomic nuclei. Thus, the experiment that would demonstrate parity conservation would be a collaboration between Chien-Shiung Wu of Columbia University and Ernest Ambler, Raymond W. Hayward, Dale D. Hoppes, and Ralph P. Hudson of the low temperature laboratory of the NBS (Forman, 1982; <http://physics.nist.gov/GenInt/Parity/parity.html>). The specific experimental arrangement that they designed is illustrated in Fig. 1.62.

The apparatus used by Chien-Shiung Wu and collaborators to test parity symmetry in β -decay in ^{60}Co , illustrated in Fig. 1.62, consists of a cryostat housing the radioactive ^{60}Co (labeled as Specimen in the figure) as a thin source (0.005 cm thick) embedded in CeMg nitrate to facilitate the

FIGURE 1.62 Schematic drawing of the ^{60}Co source, detector and lower part of the cryostat used by Chien-Shiung Wu and collaborators at NIST to test parity conservation in beta decay. From Wu et al. (1957) © 1957 by the American Physical Society, <https://doi.org/10.1103/PhysRev.105.1413>.

polarization of the ^{60}Co nuclei with the cryostat housing in a magnetic field at near absolute zero temperature. The anthracene crystal located about 1 cm above the ^{60}Co source is a scintillation detector sensitive to the β -particles emitted by the ^{60}Co . The anthracene scintillator emits a flash of light following the interaction of each β -particle with the crystal. The individual flashes of light are transmitted by the Lucite Rod, illustrated in Fig. 1.62, to an external photomultiplier tube (PMT), which will convert the light to voltage pulses. Each voltage pulse is then counted over a fixed period of time providing a counting rate (e.g., counts per minute) of the β -particles emitted by the ^{60}Co . Beta-decay of ^{60}Co yields ^{60}Ni according to the following:

The antineutrino emitted in the β -decay escapes without detection. The gamma radiation is emitted by the ^{60}Ni product nuclide, which is produced at an excited energy state resulting in the immediate emission of γ -rays before reaching a stable state. The γ -rays are detected by NaI solid

FIGURE 1.63 Beta particle asymmetry for polarizing fields pointing up and pointing down. From Wu et al. (1957) © 1957 by the American Physical Society, <https://doi.org/10.1103/PhysRev.105.1413>.

scintillation detectors located over 40 cm away from the apparatus at the equatorial and near the polar position of the ^{60}Co (see Fig. 1.62). The NaI detectors were used by Wu and collaborators to measure the γ -ray anisotropy to provide a measure of the ^{60}Co nuclear polarization.

Before cooling and before the application of an external magnetic field, the ^{60}Co nuclei exhibit thermal agitation and they are not polarized. Thus, the β -particles that they emit under these conditions would be isotropic, that is, they would be emitted in all directions. Under these warm (i.e., room temperature) conditions, Wu and her collaborators would determine the count rate of the β -particles and label this count rate as “ $\langle \text{COUNTING RATE} \rangle_{\text{warm}}$ ” (see Fig. 1.63). When the ^{60}Co specimen is cooled and the magnetic field applied, the ^{60}Co nuclei become polarized and remain rigid in their polarized state. The number of β -particles detected by the anthracene crystal over a fixed period of time under these conditions were determined and labeled as the COUNTING RATE (see Fig. 1.63). The ratio $\text{COUNTING RATE} / \langle \text{COUNTING RATE} \rangle_{\text{warm}}$ was then used by Wu and co-workers to determine if the counting rate of the β -particles emitted by the ^{60}Co was higher or lower than the counting rate under warm conditions and in the absence of a magnetic field.

They discovered that when the magnetic field is applied in one direction (see $H \downarrow$ in Fig. 1.63) with the ^{60}Co nuclei at near absolute zero temperature and the ^{60}Co nuclei polarized in one direction, the β -particle counting rate was at its highest, higher than when the sample is at room temperature and in the absence of a magnetic field. Reversing the direction of the magnetic field (see $H \uparrow$ in Fig. 1.63) and thereby reversing the direction of the polarization of the ^{60}Co nuclei resulted in a reduction of the β -particle counting rate to magnitudes below that determined when the sample was at room temperature and in the absence of a magnetic field. When the ^{60}Co is warmed slowly to room temperature, the ^{60}Co nuclei would return to normal thermal agitation and lose their polarization after about 7 minutes of warming, as illustrated in Fig. 1.63.

FIGURE 1.64 Parity violation in the decay of cobalt-60. The large spheres in the center represent groups of ^{60}Co nuclei. The β -particle emissions from the ^{60}Co nuclei are illustrated as smaller spheres, which are emitted predominantly in the direction opposed to that of the nuclear spin (curving arrow). The two orientations of the ^{60}Co nuclei in the “Mirror World” were created in the laboratory by Wu and coworkers, by polarization of the ^{60}Co nuclei in a magnetic field at near absolute zero temperature to fix the nuclei in one orientation and then flipping the nuclei by polarization in an opposite direction. The beta emissions of the two ^{60}Co nuclei are not identical in their mirror images and thus parity conservation is violated in the beta decay of ^{60}Co . Figure is from Atkinson (2006); reprinted with permission from Elsevier © 2006.

As described above, the findings of Wu and her collaborators demonstrated that the β -particle emissions were not the same for the two spin directions of the ^{60}Co nuclei; that is, the β -particle emissions differed for the two mirror images of the ^{60}Co nuclei. Thus, the β -decay process in ^{60}Co nuclei does not exhibit right-left symmetry or, in other words, this β -decay violates parity. This is illustrated in Fig. 1.64.

The experiment of Wu and her collaborators at the National Bureau of Standards (i.e., National Institute of Standards and Technology) demonstrated that the β -particle emissions from decaying ^{60}Co nuclei is greatest in the direction of the south pole of the nucleus, which would be the pole that would point toward the north pole of an external magnetic field (Forman, 1982). This is illustrated in Fig. 1.64 labeled “Our World”. Once the significance of Chien-Shiung Wu’s work was ascertained, other researchers including Richard Garwin, Leon Lederman and Marcel Weinrich at the Nevis Cyclotron Laboratories at Columbia University, detected asymmetry in muon decay, which broadened the acceptance of parity violation in weak interactions other than β -decay (Garwin et al., 1957).

7. Beta-particle interactions with matter

Owing to the very low mass of the beta particle (i.e., electron) compared with the alpha particle, it travels at a much higher velocity than an alpha particle of equivalent energy. Because of its greater velocity, lower mass, and lower charge, the specific ionization produced in air by the traveling beta particle is much lower (by a factor of a 1000) than that of an alpha particle of equivalent energy.

Like the alpha particle, the beta particle interacts with matter via (1) ionization and (2) electron orbital excitation as it dissipates its kinetic energy. A third mechanism of interaction with matter, which distinguishes the beta particle, is radiative energy dissipation via Bremsstrahlung production (see Section XI.D.2). Thus, as described by Turner (1995) the stopping power for beta particles (β^- or β^+) is the sum of the collisional and radiative contributions or

$$\left(-\frac{dE}{dx}\right)_{tot}^{\pm} = \left(-\frac{dE}{dx}\right)_{col}^{\pm} + \left(-\frac{dE}{dx}\right)_{rad}^{\pm} \quad (1.250)$$

where the superscript \pm refers to positively or negatively charged electrons. The radiative contribution, that is, the absorption of beta particle energy with the concomitant emission of Bremsstrahlung radiation is significant with high-energy beta particles (e.g., ^{32}P and ^{90}Y beta-particle emissions) in absorbers of high atomic number (e.g., Pb-glass). Bremsstrahlung radiation is discussed in Section XI.D.2 of this chapter.

Collisional interactions of beta particles are somewhat different from those that occur with alpha particles. A beta particle may collide with an orbital electron or come into close proximity to it and cause the electron to be ejected, resulting in the formation of an ion pair. Considerable scattering of beta particles occurs in such collisions, because the mass of the beta particle is equivalent to that of an atomic electron. This is in direct contrast to the alpha particle, which, for the most part, retains a relatively undeviating path while passing through matter and interacting with atomic electrons. The mass equivalence of beta particles and electrons is an important factor that gives bombarding beta particles the power to impart a major portion of their kinetic energy to atomic electrons in a single collision. The atomic electrons ejected upon beta particle collisions themselves cause ionization in a similar fashion. This is referred to as secondary ionization, and the ionization caused by initial beta particle-electron collisions is classified as primary ionization. Because the major portion of beta particle energy may be imparted to an atomic electron upon collision, secondary ionization may account for as much as 80% of the total ionization produced in a given material bombarded by beta particles.

The probability of beta particle interactions with atomic electrons increases with the density of the absorbing material. Beta particle absorption is consequently proportional to the density and thickness of an absorber. Figs. B.2 and B.3 of Appendix B provide graphs from which the range of negatrons (β^-) in units of surface density or mass thickness (g/cm^2) in air or water, respectively, can be estimated

for particles of energies from 0.01 to 10 MeV. More precise ranges and graphs are available from the online computer program ESTAR “Electron Stopping Power and Range” (Berger et al., 2017a) available from the National Institute of Standards and Technology (NIST) at <https://physics.nist.gov/PhysRefData/Star/Text/method.html>. The range of negatrons expressed in terms of surface density or mass thickness (g/cm^2) of absorber can be converted to absorber thickness (cm) when the absorber density (g/cm^3) is known.

Several empirical equations exist for calculating negatron ranges based on the E_{max} of the beta particle and on experimental data collected by several researchers during the early years of research with nuclear radiation. These empirical equations may be used to obtain estimates of beta particle range, and should be used with caution. More accurate data is currently available from the online computer program ESTAR “Electron Stopping Power and Range” (Berger et al., 2017a) available from the National Institute of Standards and Technology (NIST) at <https://physics.nist.gov/PhysRefData/Star/Text/method.html>. The ESTAR computer program will provide Stopping Power and Ranges for electrons in 98 elements and in 200 compounds or materials. The data provided by ESTAR include collisional stopping power, radiative stopping power, and total stopping power and ranges for electrons over the electron energy range of 10^{-2} to 10^3 MeV. Empirical equations reported by Glendenin (1948) are

$$R = 0.542E - 0.133 \quad \text{for } E > 0.8 \text{ MeV} \quad (1.251)$$

and

$$R = 0.407E^{1.38} \quad \text{for } 0.15 \text{ MeV} < E < 0.8 \text{ MeV} \quad (1.252)$$

where R is the beta particle range in g/cm^2 and E is the energy of the beta particle (i.e., E_{max}) in MeV. In addition, the following is an empirical equation of Flammersfield (1946) described by Paul and Steinwedel (1955):

$$R = 0.11 \left(\sqrt{1 + 22.4E^2} - 1 \right) \quad \text{for } 0 < E < 3 \text{ MeV} \quad (1.253)$$

This equation provides calculated ranges in units of g/cm^2 in close agreement to those obtained from Eqs. (1.251) and (1.252).

For negatrons or electrons exceeding 2.5 MeV up to ~ 20 MeV, the following are empirical equations reported by Katz and Penfold (1952), the U.S. Public Health Service (1970) and Evans (1955):

$$R = 530E - 106 \quad \text{for } 2.5 \text{ MeV} < E < \sim 20 \text{ MeV} \quad (1.254)$$

and

$$R = 412E^{1.265 - 0.0954 \ln E} \quad \text{for } 0.01 \text{ MeV to } \sim 3 \text{ MeV} \quad (1.255)$$

where R is the negatron or electron range in mg/cm^2 . The above empirical equations have been used for low atomic number absorbers such as aluminum ($Z = 13$). Semi-

empirical equations developed by Tabata et al. (1972) and described in detail by Tsoulfanidis (1995) yield beta-particle or electron ranges in absorber elements and compounds of a wide range of atomic number. Empirical equations are helpful in providing an estimate of the beta particle or electron ranges.

More accurate values and graphs on the ranges of beta particles or electrons with energies of 0.01–1000 MeV in 98 elements from hydrogen to californium and a wide range of media including air and natural and synthetic compounds are available from the NIST Electron Stopping Power and Range (ESTAR) data online via <https://physics.nist.gov/PhysRefData/Star/Text/method.html>. Beta particle energies general do not exceed 5.0 MeV. Using data from NIST, the ranges of beta particles with energies from 0.01 to 5.0 MeV in dry air, water, and aluminum are provided in Table 1.12 to provide a comparison of beta particle ranges in material of varying density and effective atomic number.

Table 1.12 illustrates that 1 cm of dry air has about the same stopping power as 0.001 cm of water or 0.0005 cm of aluminum.

The range of beta particles in matter is considerably greater than that of alpha particles of the same energy. Again,

this is due to the lower mass, lower charge, and higher velocity of travel of the beta particle in comparison with an alpha particle of equivalent energy. The significance of this difference may be appreciated by reference to Table 1.13, in which the alpha particle and beta particle and/or electron ranges in air as a function of particle energy are compared.

To put the data of Table 1.13 into historical perspective, it is interesting to recall the origin of the names “alpha and beta radiation”. Before alpha and beta particles were characterized fully, Rutherford (1899) carried out experiments that demonstrated two types of radiation existed; one radiation that was most easily absorbed by matter and another that possessed a greater penetrating power. Out of convenience, he named these radiations as “alpha” and “beta”. Not much later, Villard (1900b,c) in France discovered a yet more penetrating radiation. In harmony with the nomenclature assigned to the “alpha” and “beta” radiation, Rutherford (1903) coined the term “gamma rays” to the yet more penetrating radiation. In the *Philosophical Magazine* Rutherford (1903) named and characterized the three types of nuclear radiation on the basis of their penetration power in matter as follows:

TABLE 1.12 CSDA^a ranges of beta particles^b or electrons of various energies in air, water, and aluminum.

^aDefined by NIST (<https://physics.nist.gov/PhysRefData/Star/Text/appendix.html>), the CSDA range is a very close approximation of the average path length traveled by a charged particle as it slows down to rest, calculated in the continuous-slowing-down approximation. In this approximation, the rate of energy loss at every point along the track is assumed to be equal to the total stopping power. Energy loss fluctuations are neglected. The CSDA range is obtained by integrating the reciprocal of the total stopping power with respect to energy.

^bBeta particles are emitted with a broad range of energies from 0 to E_{\max} . When calculating the maximum range of beta particles emitted by a given radionuclide, the energy of the emissions at E_{\max} is used.

^cThe values are for dry air at near sea level.

^dThe values of range in units of surface density or mass thickness (g/cm²) are obtained from the NIST online ESTAR (Electron Stopping Power and Range) data (<https://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html>) (Berger et al. (2017a)).

^eThe values of range in units of path length (cm) are obtained by dividing the range in surface density (g/cm²) by the density (σ) of the absorber. The densities used are the following: $\sigma = 1.205 \times 10^{-3}$ g/cm³ for dry air at near seal level, $\sigma = 1.00$ g/cm³ for water and $\sigma = 2.69$ g/cm³ for aluminum.

TABLE 1.13 CSDA^a ranges of alpha and beta particles (or electrons) of various energies in air.

8.0	9.10	4246	7.5	3524

^aDefined by NIST (<https://physics.nist.gov/PhysRefData/Star/Text/appendix.html>), the CSDA range is a very close approximation of the average path length traveled by a charged particle as it slows down to rest, calculated in the continuous-slowing-down approximation. In this approximation, the rate of energy loss at every point along the track is assumed to be equal to the total stopping power. Energy loss fluctuations are neglected. The CSDA range is obtained by integrating the reciprocal of the total stopping power with respect to energy.

^bData is from the National Institute of Standards and Technology (NIST) Database ASTAR (Berger et al., 2017a) for CSDA (continuous slowing down approximation) ranges: <http://www.nist.gov/pml/data/star/index.cfm>.

^cData is from the National Institute of Standards and Technology (NIST) Database ESTAR (Berger et al., 2017a) for CSDA (continuous slowing down approximation) ranges: <http://www.nist.gov/pml/data/star/index.cfm>.

^dCalculated from the range in mass thickness units (mg/cm²) and the density of dry air at STP, $\rho_{\text{air}} = 1.205 \text{ mg/cm}^3$.

Radium gives out three distinct types of radiation:

- (1) The α -rays, which are very easily absorbed by thin layers of matter, and which give rise to the greater portion of the ionization of the gas observed under the usual experimental conditions.
- (2) The β rays, which consist of negatively charged particles projected with high velocity, and which are similar in all respects to cathode rays produced in a vacuum tube.
- (3) The γ -rays, which are nondeviable by a magnetic field, and which are of a very penetrating character.

These rays differ very widely in their power of penetrating matter. The following approximate numbers, which show the thickness of aluminum traversed before the intensity is reduced to one-half, illustrate this difference:

Radiation	Thickness of aluminum (cm)
α -rays	.0005
β -rays	.05
γ -rays	8

It is important to emphasize that, although all beta particles can be completely absorbed by matter, the shields we select can be of great consequence. Hazardous bremsstrahlung radiation can be significant when high-energy

beta particles interact with shields of high atomic number. The phenomenon of bremsstrahlung production is discussed further in Section XI.D.2 of this chapter.

Positrons dissipate their energy in matter via the same mechanisms as previously described for negatrons, which is understandable, as both are electrons. When charged particles travel through matter they interact with the target atoms along their trajectory and dissipate energy in the absorber by two mechanisms, namely, (1) they may interact with the target nuclei by the transfer of momentum and (2) interact with the orbital electrons of the target/absorber material dissipating energy by means of electron excitation and ionization. The energy dissipated by positrons and electrons in the media with which they travel (i.e., stopping power) and their ranges in matter will differ and, as described in the following paragraphs, this difference is dependent on the positron and electron energy. The scattering of positrons by atomic nuclei (i.e., elastic scattering) is less than that for negatrons of the same energy when traveling through matter of a given atomic number Z as demonstrated by Fowler and Oppenheimer (1938), Lipkin and White (1950) and Feshbach (1952). However, the positive charge on positrons would be expected to create Coulombic forces of attraction between the positron and orbital electrons of the medium through which the

^aData from [Berger and Seltzer \(1982\)](#), US Dept. of Commerce, National Bureau of Standards NBSIR 82-2550.

^bMost beta particle emissions have an $E_{\text{max}} < 5$ MeV. Electrons (e^+ , e^-) can be accelerated to very high energies; and data on electron and positron stopping powers and ranges in various materials for electron and positron energies up to 1000 MeV are available from [Berger and Seltzer \(1982\)](#) and online from NIST at <https://www.nist.gov/publications/nist-7-nist-electron-and-positron-stopping-powers-materials>. The work by [Berger and Seltzer \(1982\)](#) is available online via the NIST publications cite (<https://nvlpubs.nist.gov/nistpubs/Legacy/IR/nbsir82-2550.pdf>).

positron travels. Negatrons, which carry a negative charge would not possess any attractive forces with atomic electrons of the target material.

In the early 1950s, Walter H. Barkas studied the tracks produced by high-energy pions in nuclear emulsions, as related in historical and technical accounts by [Lindhard \(1976\)](#) and [Andersen \(1985\)](#). Barkas and his coworkers discovered that the negatively charged pions (π^-) produced tracks that were recognizably longer in the emulsion than its antiparticle, the positively charged pions (π^+), of the same energy. Ten years later, Barkas and coworkers ([Barkas et al., 1963](#)) observed the same effect when measuring the tracks produced by the sigma hyperons, Σ^- and Σ^+ . In this case, the difference in range was more definitive; whereby, the range of the negatively charged Σ^- hyperon was 3.6% longer than that of its antiparticle, positively charged Σ^+ , which possessed the same energy or velocity. From then on, this effect was named “the Barkas effect” or the “Barkas-Andersen effect” after its original investigator Walther H. Barkas and Hans Hendrik Andersen, who undertook research into the effect ([Andersen et al., 1966, 1967, 1969a,b](#)). The Barkas effect may be defined as the difference in the stopping force on a charged particle compared to that of its antiparticle as it penetrates through matter ([Sigmund and Schinner, 2003](#)).

A few years following Barkas’s confirmed observation, [Heckman and Lindstrom \(1969\)](#) made stopping power measurements of the π^- and π^+ at identical velocities in hydrogen, and they found that the differences in range between the π^- and π^+ would decrease with increasing energy. In other words, there was an energy level above which the particles would not exhibit a difference in their range. This observation agrees with electron and positron

collision stopping powers and ranges in target matter or absorber media evidenced by data provided in [Table 1.14](#), as an example. Similar examples of the Barkas effect of electrons and positrons in other absorber media (e.g., H₂O, C, Al, Cu, Ag, Pb, etc.) are available from data provided by [Berger and Seltzer \(1982\)](#) of the former National Bureau of Standards. [Table 1.14](#) compares the negatron (β^-) and positron (β^+) (i.e., electron and positron) collision stopping powers and CSDA ranges.

[Eq. \(1.250\)](#) noted previously defines the total stopping power of beta particles or electrons in absorber media as the sum of collisional and radiative losses of energy by the beta particles as they travel through matter. Differences in radiative losses between negatrons and positrons are not included in [Table 1.14](#), [Berger and Seltzer \(1982\)](#) assumed radiative losses to be the same for negatrons and positrons in their tabulations. Collision losses of energy, which are charge dependent, are higher for positrons at lower energies (~ 0.01 – 1.0 MeV), as illustrated in [Table 1.14](#). From the data of [Table 1.14](#), we can see that the atoms of the absorber have a higher stopping power for positrons of low energy (<1 MeV) than the negatrons of the same energy, which results in a shorter range for the positrons and longer range for the negatrons. As defined in part XVI.A of this chapter, stopping power is the average energy dissipated by ionizing radiation in a medium per unit path length of travel of the radiation in the medium. Taking into account the definition of stopping power, we can visualize in the case of positrons of low energy (<1 MeV), how a positron traveling through matter can interact with the Columbic field of the negatively charged electrons bound in their atomic orbitals. The attraction between the low-energy positron and atomic orbital electrons can create a drag on the positron as it travels

through the atoms of the medium. This drag would cause the positron to dissipate more energy than a negatron of the same energy and consequently reduce the range of the low-energy positron compared to a negatron of the same energy. However, at higher energies (>1 MeV) and consequently higher speeds, the positrons would be more resistant to the negative charges of the atomic orbital electrons of the medium through which it travels and consequently dissipate less energy per path length of travel in the medium. As a result, the high-energy positrons (>1 MeV) would have ranges more similar to those of negatrons of the same energy.

Two equations (Eqs. 1.524 and Eq. 1.525) are cited in Section XVI.A of this chapter for calculating the ionization-excitation stopping powers for negatrons and positrons due to collision interactions with absorbers. Their difference, as noted by Tsoufanadis (1995), is due only to the second term in the brackets of these two equations, which is much smaller than the logarithmic term, and consequently the differences between negatron and positron stopping powers are small as evidenced from the data in Table 1.14.

For further reading on the Barkas effect, the reader may peruse papers by Lindhard (1976), Mikkelsen (1992), Sigmund and Schinner (2003), Lodi Rizzini et al. (2004), Nersisyan and Das (2005), Sigmund et al. (2005), Fettouhi et al. (2006), and Archubi et al. (2013).

8. Beta particle absorption and transmission

Early research work on measuring the range of beta particles involved placing absorbers of increasing thickness between the radioactive source and the detector. The detector would measure the beta particles transmitted through the absorber. Increasing the absorber thickness would increasingly diminish the number of beta particles transmitted on to the detector. The transmission of beta particles was then plotted against absorber thickness in an attempt to determine the thickness of absorber required to stop all of the beta particles. Unfortunately, the plots could not be used directly to determine accurately beta particle ranges; rather they had to be compared to an absorption curve of a beta emitter of known range by what became known as Feather analysis (Feather, 1938; Glendenin, 1948). An auspicious outcome of this work was the observation that the plots of beta particle absorption had more or less an exponential character. When plotted logarithmically against absorber thickness the beta particle absorption and/or transmission through the absorber was linear or near linear at certain levels of transmission, as illustrated in Fig. 1.65 and described by Eq. (1.256). The linearity is a fortuitous outcome of the continuous energy spectrum of beta particles emitted from any given source. These findings are quite the contrast to the absorption curve of alpha particles discussed previously (Fig. 1.43), where the alpha particle is emitted from a radionuclide at a unique level of energy and comes to an almost abrupt stop at the end of its range in an absorber.

FIGURE 1.65 A typical beta transmission curve and its exponential approximation in an arbitrarily selected point at a low transmission value. From Švec (2015), reprinted with permission from Elsevier © 2015.

The curve illustrated in Fig. 1.65 is characteristic of beta particles. The linear segment of the semi-logarithmic plot of activity transmitted versus absorber thickness levels off horizontally (not illustrated in Fig. 1.65) due to a background of Bremsstrahlung radiation. Negatrons and positrons both display a linear semi-logarithmic plot with the exception that, in the case of positrons, the plot has an added background due to annihilation radiation (Glendenin, 1948). Because beta particles have a definite range in matter, beta particle transmission is not a purely logarithmic one as is the case for gamma radiation (see Section XII.D of this chapter.). The curves may not display a purely exponential character and the plots may have a degree of concavity to them depending on the distance of the source and detector to the absorber and on the shape of the beta particle continuous energy spectrum. The greater the atomic number of the beta particle emitter, and the more the beta spectrum is displaced toward the lower energies, the more nearly exponential (linear) will be the absorption curve (Glendenin, 1948). Studies by Thontadarya (1985) indicate that attenuation coefficient values of Eq. (1.256) or 1.257 depend on the part of the transmission curve selected and best fit (i.e., greatest linearity) is achieved at low transmission (i.e., low I/I_0) of $<20\%$. This is explained by Švec (2015), who provides the following logic: (a) the beta spectra of various radionuclides differ in shape; however, their beta spectra resemble each other at the descending parts of their spectra close the maximum beta particle energies, (b) at a transmission of $<20\%$, the absorber has removed 80% or more of the beta particles from the radiation field, and the remaining high-energy beta particles are partly collimated by passing the shortest paths (i.e., particles that have undergone less scattering) in the absorber representing a radiative “arrow head”, and (c) high energy particles at the end of the beta spectrum encompass only a narrow band of energies providing them with an “almost monoenergetic” character.

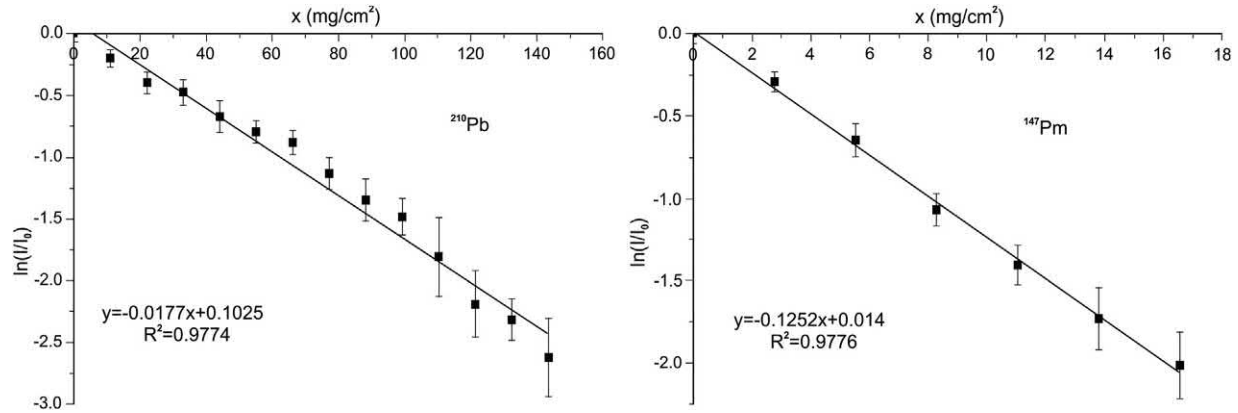

FIGURE 1.66 Beta transmission curves of $\ln(I/I_0)$ versus the thickness of Al absorber for beta emitters ^{210}Pb and ^{147}Pm . From Şen et al. (2014), reprinted with permission from Elsevier © 2014.

Based on the exponential character of beta-particle absorption we can describe the transmission of beta particles through the absorber as

$$I = I_0 e^{-\mu x} \quad (1.256)$$

where I is intensity of the beta-particles transmitted through the absorber (e.g., measured as disintegrations per minute, DPM, by a detector), I_0 is the initial intensity of the beta particles (DPM) incident on the absorber, μ is the linear absorption coefficient in units of cm^{-1} and x is the absorber thickness in cm. It is common to express the amount of absorber in mass thickness units, that is, mass per unit area (e.g., g/cm^2), which is the product of absorber thickness and density, as it is easier to measure accurately very thin absorbers simply from their weight. If we express absorber thickness in mass thickness units (e.g., g/cm^2 or mg/cm^2) we can rewrite Eq. (1.256) as

$$I = I_0 e^{-(\mu/\rho)(\rho x)} \quad (1.257)$$

or

$$\frac{I}{I_0} = e^{-(\mu/\rho)(\rho x)} \quad (1.258)$$

and

$$\ln \frac{I}{I_0} = -(\mu/\rho)(\rho x) \quad (1.259)$$

where μ/ρ is the mass absorption coefficient (also referred to as mass attenuation coefficient) in units of cm^2/g , that is, the linear absorption coefficient μ , with units of cm^{-1} , divided by the absorber density ρ with units of g/cm^3 ; and ρx is the absorber thickness in mass thickness units g/cm^2 , that is, the product of the absorber density and absorber thickness. The μ/ρ value for each radionuclide source is determined by the least squares fit method for the linear portion of the beta transmission curve (Thontadarya, 1985).

Eq. (1.258) can be used to determine experimentally the unknown thickness of absorber materials. A standard curve is plotted with the ratio I/I_0 on a logarithmic scale versus

mass thickness (ρx with units of mg/cm^2) of the absorber on a linear scale as illustrated in Fig. 1.66. A value for I in units of DPM are determined with a detector by measuring the beta-particle intensity transmitted through a given absorber thickness. This is repeated with absorbers of different thickness. The magnitude of the incident beta particle intensity, I_0 , is a constant value and determined with the detector in the absence of absorber. The linear portion of the plot has a negative slope, such as that illustrated in Fig. 1.66, and from least squares analysis the mass attenuation coefficient μ/ρ is determined (Singh and Batra, 1987; Yi et al., 1999). Consequently, the thickness of an unknown similar material can be determined from the measured intensity, I , of the transmitted beta particle radiation after placing the material between the beta particle source and detector without altering the counting geometry. The sample thickness is calculated or determined directly from the aforementioned curve (Tumul'kan, 1991; Clapp et al., 1995).

The radionuclide utilized for a thickness gauge will depend on the maximum energy of the beta emissions and the thickness and atomic number of the absorber. Şen et al. (2014) demonstrate excellent beta transmission curves for the determination of Al absorber thickness, and two examples are provided in Fig. 1.66. Linear beta transmission curves are reported by Şen et al. (2014) with the following beta emitters and Al absorber thicknesses: ^{99}Tc (1–35 mg/cm^2), ^{36}Cl (10–120 mg/cm^2), ^{14}C (1–14 mg/cm^2), ^{210}Pb (10–150 mg/cm^2), and ^{147}Pm (1–17 mg/cm^2).

Jaklevic et al. (1983) describe the detailed schematic arrangement of a plastic scintillator detector, photo-multiplier and electronics for a beta gauge system that can be easily set up in any laboratory. Timing measurements may also be used for the determination of linear (μ) or mass attenuation coefficients (μ/ρ) in beta transmission measurements. Ermis and Celiktaş (2012) demonstrated timing measurements that focus on the determination of the time that the beta particle crosses the detector, which can be successfully used to measure the attenuation coefficients whereby the beta particle energy has a less significant importance or can even be disregarded.

Beta particle transmission has many practical applications today in industrial manufacturing. Beta particle sources and detectors are placed on the production line to test for thickness, uniformity, and defects in the manufacture of paper, metal, and plastic films (Yoshiyuki and Hiroshi, 1999; Gardner et al., 2004) as well as online inspection of sewn seams or fabric density in the textile industry (Ogando, 1993; Clapp et al., 1995; Mapleston, 1997; Titus et al., 1997; Kim et al., 2009) and in agronomic research to measure leaf water content (Mederski, 1961; Mederski and Alles, 1968; Nakayama and Ehrler, 1964; Jones, 1973; Obregewitsch et al., 1975; Barthakur, 1983) or to measure the biomass of a prairie (Knapp et al., 1985). These are commonly referred to as beta transmission thickness gauges. The beta particle sources used depend on the absorber thickness to be measured and the E_{\max} of the beta particles. Three sources commonly used are ^{14}C ($E_{\max} = 0.156$ MeV), ^{147}Pm ($E_{\max} = 0.224$ MeV), ^{85}Kr ($E_{\max} = 0.672$ MeV), ^{36}Cl ($E_{\max} = 0.714$ MeV), ^{204}Tl ($E_{\max} = 0.763$ MeV), and ^{90}Sr (^{90}Y) in secular equilibrium (E_{\max} of ^{90}Sr and $^{90}\text{Y} = 0.546$ and 2.280 MeV, respectively). A source of low beta particle E_{\max} (e.g., ^{14}C or ^{147}Pr) is used to measure the finest thickness of material (Jaklevic et al., 1983. Balasubramanian, 1997, 1998), and the sources are changed according to beta particle energy and material density and thickness to be tested. A practical reference for radioisotope thickness gauge measurements is provided by Johansen and Jackson (2004) and Wagner et al. (2014).

C. Internal conversion electrons

Decay by internal conversion (IC) results in the emission of an atomic electron. This electron, called the IC electron, is emitted from an atom after absorbing the excited energy of a nucleus. In this decay process, an unstable nucleus decaying to a lower more stable state transmits its decay energy to an atomic electron, which is emitted from the atom with an energy corresponding to the nuclear decay energy less the binding energy of the atomic electron. This mode of decay accompanies and even competes with gamma ray emission as a deexcitation process of unstable nuclei.

The kinetic energy of the electron emitted is equivalent to the energy lost by the nucleus (energy of transition of the excited nucleus to its ground or lower energy state) less the binding energy of the electron. This is illustrated by the following equation:

$$E_e = (E_i - E_f) - E_b \quad (1.260)$$

where E_e is the kinetic energy of the IC electron, ($E_i - E_f$) is the energy of transition between the initial, E_i , and the final, E_f , nuclear energies normally associated with gamma ray emission, and E_b is the binding energy of the atomic electron. Lise Meitner and Otto Hahn in Germany (Meitner, 1924; Hahn and Mettner, 1924) were the

first to interpret the origin of this mono-energetic electron energy as derived from the IC of the gamma decay energy. Nobel Laureate Luis W. Alvarez at the University of California, Berkeley was the first to provide experimental evidence of IC of artificially produced radioactive atoms (Alvarez, 1938).

An example of radionuclide decay by IC is found in Fig. 1.67, which illustrates the decay of the parent–daughter nuclides ^{109}Cd ($^{109\text{m}}\text{Ag}$). Note that the $^{109\text{m}}\text{Ag}$ daughter decays by IC with a 96% probability (i.e., 45% for IC from the K shell + 48% from the L shell + 3% from higher electron shells – the latter is not illustrated in Fig. 1.67) and decay occurs also via gamma emission with the remaining 4% probability (Rachinhas et al., 2000).

Because the emission of internal conversion electrons competes with gamma ray emission as an alternative mode of nuclear deexcitation, many radioactive nuclei that emit gamma radiation will also emit IC electrons. The degree to which this competition occurs is expressed as the total internal conversion coefficient (α), which is the ratio of the

FIGURE 1.67 Decay scheme of ^{109}Cd ($^{109\text{m}}\text{Ag}$). The numbers in parenthesis indicate energy values in keV. The electron capture (EC) process occurs from K, L and outer shells with probabilities of 79%, 17% and 4%, respectively, but only K-capture is represented above. The $^{109\text{m}}\text{Ag}$ daughter decays by emission of 88.0 keV gamma rays with a 4% probability or by internal conversion (IC) with the probabilities of 45% and 48% for K and L shells. IC from shells higher than L contributes the remaining 3% (not illustrated). The K and L IC decay illustrated involve the ejection of a conversion electron with energy $e_K = 62.5$ keV or $e_L = 84.6$ keV, accompanied by the emission of an Ag K- or L-fluorescence X-ray photon ($K_\alpha = 22.1$, $K_\beta = 25.0$ keV, or $L_\alpha = 3.0$, $L_\beta = 3.3$ keV) or by the emission of Auger electrons (not represented) and X-ray photons following Auger electron emissions. From Rachinhas et al. (2000), reprinted with permission from Elsevier Science.

rate of emission of IC electrons to the rate of emission of gamma rays of equivalent energy or

$$\alpha = e/\gamma = N_e/N_\gamma \quad (1.261)$$

where N_e and N_γ are the number of electrons and number of gamma ray photons, respectively, emitted by a radionuclide sample in a given time interval for a given decay energy transition. In other words, the internal conversion coefficient is a quantitative measure of the number of internal conversion electrons divided by the number of gamma ray photons emitted from a radionuclide sample for a given radionuclide energy transition.

Internal conversion electrons may be emitted from specific electron shells of atoms and may be expressed in terms of internal conversion electrons and gamma rays of the same energy less the energy difference resulting from the binding energy of the electron as described by Eq. (1.260). When expressed in terms of electrons emitted from specific shells, the shell-conversion coefficients are written with a subscript denoting the electron shell of origin, for example, α_K or e_K/γ , α_L or e_L/γ , and α_i or e_i/γ , where $i = K, L, M \dots$ electron shells, where the total internal conversion coefficient would be the sum of the shell-conversion coefficients or

$$\alpha = \alpha_K + \alpha_L + \alpha_M + \dots \alpha_i \quad (1.262)$$

where $\alpha_K, \alpha_L, \alpha_M$ and α_i are the shell-conversion coefficients for the L, K, M electrons, etc.

As described by Evans (1955), theoretical values of the IC coefficient depend on the energy of the transition, the atomic number of the transforming nucleus, the atomic shell ($K, L_1, L_2, \dots M_1, M_2, \dots$) in which conversion takes place, and the electric or multipole order of the transition. Values of internal conversion coefficients are provided in reference tables on isotope decay, such as those found in Lederer and Shirley (1978) and total theoretical IC coefficients based on gamma-ray energy lines are available from the online Nuclear Data Sheets via ScienceDirect (<http://www.sciencedirect.com/science/journal/00903752/145?sdc=2>). To utilize the data sheets, it is only necessary to specify a title and the mass number of the radionuclide of interest, such as Nuclear Data Sheets for A = (insert mass number) whereby it is necessary to specify a mass number. The Nuclear Data Sheets will provide the nuclear data including values of α of the total theoretical IC coefficients and corresponding gamma ray lines for all isobars of mass number A. For example, inserting the title Nuclear Data Sheets for A = 99 will provide the nuclear data for isobars of A = 99 compiled by Browne and Tuli (2017).

In general, internal conversion coefficients are small for gamma ray-emitting nuclides of low Z and high-energy transitions and larger for nuclides of high Z and low-energy transitions. This relationship is illustrated in Table 1.15, which lists a few radionuclides selected at

random as examples in order of increasing Z . As can be seen, large internal conversion coefficients occur when internal conversion electrons are emitted with low-energy nuclear transitions as indicated by the large values of α associated with low gamma ray energies and high Z . Also, the internal conversion electron (e^-) energies listed are slightly lower than the gamma ray energies. This is because the energy of the IC electron is equal to the energy absorbed from the decaying nucleus (transition energy) less the binding energy of the atomic electron described previously in Eq. (1.260). On the other hand, gamma ray energies serve as a measure of the exact quanta of energies lost by a nucleus.

The loss of atomic electrons through the emission of internal conversion electrons leaves vacancies in atomic electron shells. The vacancies are filled by electrons from outer higher-energy shells, whereby there is a concomitant loss of electron energy as X-radiation. Emission of X-radiation resulting from electron filling of vacancies in electron shells ($K, L, M \dots$) is also listed in Table 1.15. This is a process that occurs in the daughter atoms; the X-rays are a characteristic of the daughter rather than of the parent.

Internal conversion electrons are identical in their properties to beta particles. They differ, however, in their origin. Beta particles originate from the nucleus of an atom as a result of beta decay, whereas internal conversion electrons originate from atomic electron shells. A characteristic difference between these two types of electron is their energy spectra. Beta particles, as discussed previously, are emitted from nuclei with a broad spectrum or smear of energies ranging from near zero to E_{\max} . However, internal conversion electrons are emitted from the atoms of decaying nuclei with discrete lines of energy of a magnitude equivalent to that of the energy lost by the nucleus less the electron binding energy. The energy of an internal conversion electron can be used to estimate the energy lost by a nucleus.

Like beta particles, internal conversion electrons dissipate their energy by ionization they cause in matter. The abundance of internal conversion electrons emitted from some nuclide samples can be significant and should not be ignored. In certain cases IC can play a significant role in radionuclide detection and measurement. Internal conversion electron energies are slightly lower than the true gamma decay energy because of the energy consumed in the ejection of the bound atomic electron (E_b in Eq. 1.260).

D. Auger and Coster-Kronig electrons

An Auger (pronounced OH-ZHAY) electron can be considered as the atomic analogue of the IC electron. Auger electrons are defined as atomic electrons that are emitted from atoms after acquiring energy from an atomic electron transition within the atom. For example, in the electron

capture (EC) decay processes, vacancies are left in electron shells (K , L , ...) that can be filled by atomic electrons from higher energy levels. In the process of falling to a lower energy shell to fill a vacancy, electron energy is lost as a photon of X-radiation (see Section XI.D of this chapter). Alternatively the energy liberated in the shift of an electron from its higher energy state to a lower one can be transferred to an electron in an outer shell resulting in the emission of the electron as an Auger electron.

At the young age of 24 years Pierre Victor Auger at the Ecole Normale Supérieure de Paris discovered the emission of electrons from atoms excited by X-rays (Auger, 1923, 1925a,b). Pierre Auger irradiated krypton and argon gas with X-rays and discovered the emission of electrons. He reasoned that an X-ray photon causes the ejection of an atomic electron from a given shell or quantum level leaving a vacancy behind. He further reasoned that an electron from the next outer shell could fill the vacancy causing the emission of electromagnetic radiation that would correspond to the difference in the energy levels of the electrons in the outer and inner shells. For example, Auger noted that, if an electron in the K -shell was ejected by an artificially produced X-ray photon, an electron from the next outer L -shell could fill the vacancy resulting in the emission

of energy, E , as electromagnetic radiation, which he described by the following equation:

$$E_{\text{x-ray}} = h\nu = E_L - E_K \quad (1.263)$$

where h is Planck's constant ($h = 4.14 \times 10^{-15} \text{ eV s} = 6.626 \times 10^{-34} \text{ J s}$), ν is the photon frequency in units of s^{-1} , and E_L and E_K are the energy levels of the electrons in the L and K shells, respectively. The transition energy $h\nu$ may be emitted as an X-ray photon characteristic of the atom or, alternatively, the transition energy may be absorbed by an atomic electron resulting in its emission from the atom. The electron emitted in this fashion is identified as an Auger electron in the name of Pierre Auger for his discovery and interpretation of this phenomenon. Lise Meitner (1923) also independently discovered Auger electrons the same year as Pierre Auger; however, the Auger electrons and the phenomenon that gives rise to these electrons, the Auger Effect, are named after Pierre Auger.

Electron transitions, that may result in the emission of Auger electrons, will occur when an atom becomes ionized by the loss of an electron from an inner shell. For example, an atom may become ionized by the ejection of an electron from an inner shell by one of several mechanisms such as (1) irradiation with artificial external X-rays or irradiation

with particle beams, (2) the emission of an IC electron such as K -shell IC, or (3) by EC also known as K -capture. The vacancy left in the K -shell can be filled by an electron from an outer L -shell. In turn, the vacancy left in the L -shell could be filled by another electron from the outer M -shell, etc. The process of nonradiative rearrangement of atomic electrons as a result of the ionization of the atom in one of its inner shells is defined as the Auger effect (Borisenko and Ossicini, 2004). In the process of falling to a lower energy shell to fill a vacancy, electron energy may be lost as a photon of X-radiation. The energy of the photon radiation is equivalent to the differences in the energy levels of the electrons in the outer and inner shells as described by the above Eq. (1.263). The X-ray photon may be emitted from the atom, or alternatively the energy released in the electron transition will be transferred to an electron of an outer shell and cause its emission from the atom as an Auger electron. The energy of the Auger electron would be that defined by the above Eq. (1.263) less the binding energy, E_b , of the electron or

$$E_{\text{Auger}} = (E_L - E_K) - E_b \quad (1.264)$$

The energy of the Auger electron is thus equivalent to the energy of the X-ray photon less the binding energy of the electron or

$$E_{\text{Auger}} = E_{\text{x-ray}} - E_b \quad (1.265)$$

Values of the binding energies of electrons in various shells (K , L , M , ...) are found in references texts such as Rumble (2017). Either of two processes, the emission of an X-ray photon or the emission of an Auger electron, can occur as a result of electron energy-level transitions from higher to lower energies. Auger electron emission competes with X-ray emission. An example of the Auger effect and the resultant emission of an Auger electron as compared to X-ray emission are illustrated in Fig. 1.68. The emission of an Auger electron from an atom will occur as a consequence of the following transitions: (1) an atom losses an atomic electron from an inner shell leaving a hole or vacancy in that shell, (2) an electron from a higher energy level fills the vacancy, and (3) the energy emitted in the transition of the electron from the higher to lower energy levels is transferred to an outer atomic electron causing the electron to be emitted from the atom.

Whenever an X-ray photon causes the ejection of an atomic electron, another electron falls from an outer shell to a lower one to fill the vacancy, and there is a cascading effect of electrons falling from yet more distant shells to fill vacancies left behind until the atom reaches the ground or stable state. The downward transitions of electrons in this fashion produce additional X-ray photons of lower energy than the initial X-ray photon. The production of X-ray photons in this fashion is referred to as X-ray fluorescence.

FIGURE 1.68 Decay of the radionuclide ^{139}Ce by electron capture (EC) resulting in (A) X-ray emission or (B) Auger electron emission. An electron vacancy in a shell is illustrated as an empty circle and an electron as a filled circle. Specific binding energies for Cerium atomic electrons in K , L and M shells were obtained from Lide (2010) and are provided along the right-hand side of lines illustrating the various electron energy levels. The Auger effect or process by which an Auger electron is emitted from an atom occurs according to the following sequence as noted in the figure: (a) an atom losses an atomic electron from an inner shell leaving a hole or vacancy, (b) an electron from a higher energy level fills the vacancy, and (c) the energy emitted in the electron transition in step (b) is transferred to an outer atomic electron causing the electron to be emitted from the atom. The energy of the K X-ray illustrated above is equal to the electron transition ($E_{\text{x-ray}} = h\nu = E_L - E_K = -0.0057 - (-0.0404) = 0.0347 \text{ MeV}$). The energy of the Auger Electron is equal to the electron transition energy ($E_L - E_K$) less the binding energy of the electron (E_b) or, in other words, the X-ray energy less the binding energy of the electron ($E_{\text{Auger}} = 0.0347 - 0.0011 = 0.0336 \text{ MeV}$). The daughter nucleus of the ^{139}Ce remains in an excited state after EC and emits a gamma-ray (not illustrated). Also the loss of an Auger electron will leave an electron vacancy, which can be filled by an electron of an outer shell. This will produce another X-ray, which is not illustrated here. The electron filling the vacancy will, in itself leave another vacancy, which could be filled by yet another electron in an outer shell. The production of X-rays by this cascading effect of electron transitions from outer to inner shells is known as X-ray fluorescence.

Auger electron emission competes with X-ray emission, and it can accompany any nuclear decay process that results in the production of X-rays, such as a consequence of EC decay or nuclides that have IC in their decay. Like internal-conversion electron emission described previously, the electron-capture decay process also results in the emission of appreciable quantities of X radiation. Auger electron emission can reduce appreciably the abundance of X-ray emission normally expected to accompany radionuclide decay processes. The two competing processes of Auger-electron emission and X-ray emission are important to consider in the detection and measurement of nuclides that decay by EC. This is measured by both the fluorescence yield and Auger yield. The fluorescence yield is the fraction of vacancies in a given electron shell that is filled with accompanying X-ray emission, and Auger yield is the fraction of vacancies that is filled resulting in the emission of Auger electrons (Friedlander et al., 1964). For example, as described by Burhop and Asaad (1972), an initial vacancy in the *K*-shell may be filled either by the emission of *K* series X-radiation (fluorescence yield ω_K) or *K* Auger electrons (Auger yield a_K) where

$$\omega_K + a_K = 1 \quad (1.266)$$

Fig. 1.69 illustrates the *K*-shell fluorescence yield as a function of nuclide atomic number. The *L*-shell, which consists of subshells, such as *L*₁, *L*₂, and *L*₃, can exhibit fluorescence yields characteristic of the subshells. The *L*-shell fluorescence yield also varies similarly with atomic number as the *K*-shell fluorescence yield, but it is several times lower in magnitude (Friedlander et al., 1964). When an Auger electron is emitted as a result of an electron transition from a higher subshell to a lower subshell of the same shell, it is referred to as a Coster–Kronig transition, which is a special type of Auger effect named in honor of Dirk Coster and Ralph Kronig from the Netherlands (Coster and

FIGURE 1.69 Fluorescence *K*-shell yields, ω_K , as a function of atomic number, *Z*: (A) according to Kostroun et al. (1971); (B) a best fit to selected experimental data; and (C) critically evaluated experimental results. From Bambynek et al. (1972), <https://doi.org/10.1103/RevModPhys.44.716>, reprinted with permission ©1972 The American Physical Society.

Kronig, 1935). The ejected electrons in Coster–Kronig transitions are of very low energy (≤ 1 keV), and in X-ray spectroscopy, they cause the broadening and lowering of intensities of corresponding X-ray lines.

Auger electron emission energies and intensities, including those arising from Coster–Kronig transitions are measured and accounted for in radionuclide standardization (Grau Carles and Grau Malonda, 2006; Grau Malonda et al., 2006; Bé et al., 2006; Kossert and Grau Carles, 2008, 2010; Grau Carles and Kossert, 2009; Tarancón Sanz and Kossert, 2011; Yunoki et al., 2014; García-Toraño et al., 2017). As described previously both Auger and IC electron emissions possess discrete energies, and these energy lines can be envisaged by the electron emission spectra illustrated in Fig. 1.70. The emission spectra illustrated in Fig. 1.70 provide an excellent picture of the energy magnitudes and monoenergetic character of Auger and IC electrons. Certain radionuclides, such as ^{123}I , ^{125}I , ^{111}In , and ^{119}Sb , which decay by EC with significant intensities of Auger electrons emissions, have received much attention for their applications in cancer therapy (Behr et al., 2000; Janson et al., 2000; Bodei et al., 2003; Capello et al., 2003; Michel et al., 2003; Chen et al., 2006; Constantini et al.,

FIGURE 1.70 Simulation of the electron emission spectrum (Auger and IC) of ^{125}I . The 36-keV γ -transition of ^{125}I is highly converted with a probability of 93.3%. As described by Grau Carles and Kossert (2009), three regions characterize the spectrum. The first region below 20 keV comprises about 57% of the spectral events. The peaks are created by the emission of *K*-IC electrons with about 3.7 keV, which may occur in coincidence with one or two *L*-Auger electrons stemming from the subsequent rearrangement processes of the preceding EC decay. Thus, the region shows three sharp peaks. The second region at about 40 keV contains about 37.6% of the counts. It corresponds to the coincident interaction of *K*-IC and *K*-Auger electrons or the interaction of *L*-IC electrons. *K*-Auger electrons may have energies between ~ 21.8 and 31.8 keV. The energy of *L*-IC electrons is about 31 keV. Again, the emissions can be in coincidence with one or two *L*-Auger electrons yielding the subdivision into three peaks. The third region above 60 keV contains coincidences of *L*-IC and *K*-Auger electron emissions and encompasses $\sim 5.4\%$ of the total spectral events. From Grau Carles and Kossert (2009) reprinted with permission from Elsevier © 2009.

2007; Thisgaard and Jensen, 2009; Sedlacek et al., 2014; Zhang et al., 2014; Panosa et al., 2015; Cai et al., 2016; Aghevlian et al., 2017). The low energies of the Auger electrons emitted by these radionuclides, and consequently their short range in the human body, can increase the highly localized radiation-induced kill of cancer cells.

Another auspicious outcome of the discovery of the Auger Effect is the development of Auger electron spectroscopy (AES). The technique of AES involves irradiating the surface of a sample with an electron beam of energy sufficient to ionize the inner orbitals of atoms thereby inducing the concomitant emission of Auger electrons. The Auger-electron energy spectra drawn from the induced emissions serve as fingerprints of different atoms to enable their identification and quantitative analysis (Chourasia and Chopra, 1997; Melhorn, 1998; Vandendael, 2010; Ilyin, 2017).

E. Neutron radiation

The neutron is a neutral particle, which is stable only in the confines of the nucleus of the atom. Outside of the nucleus the neutron decays with a mean lifetime of about 15 minutes. Its mass, like that of the proton, is equivalent to 1 u (atomic mass unit). Unlike the particulate alpha and beta nuclear radiation previously discussed, neutron radiation is not emitted in any significant quantities from radionuclides that undergo the traditional nuclear decay processes with the exception of a few radionuclides such as ^{252}Cf and ^{248}Cm , which decay to a significant extent by spontaneous fission (see Section X.E.3.b). Significant quantities of neutron radiation occur when neutrons are ejected from the nuclei of atoms following reactions between the nuclei and particulate radiation. Due to its lack of charge, the neutron cannot produce directly any ionization in matter, again unlike alpha and beta radiation. The various sources, properties, and mechanisms of interaction of neutrons with matter are described subsequently.

1. Discovery of the neutron

The discovery of the neutron had eluded us until as late as 1932. The particle's neutral charge and high penetrating power when traveling through matter made its discovery more difficult during the early years of research on radioactivity. In 1932, James Chadwick provided evidence for the existence of the neutron (see Chadwick, 1932a,b). He placed a source of alpha particle radiation in close proximity to beryllium. It was known that bombarding beryllium with alpha radiation would produce another source of radiation, which had a penetration power through matter even greater than that of known gamma radiation. Chadwick observed that, when a sheet of paraffin (wax) was placed in the path of travel of this unknown radiation, he could detect a high degree of ionization in a gas ionization chamber caused by

protons emitted from the paraffin. This phenomenon would not occur when other materials such as metals and even lead were placed in the path of this unknown radiation. Based on further measurements of the proton velocities and scattering intensities, it was concluded that the unknown radiation had a mass similar to that of the proton, but with a neutral charge. Only a particle with neutral charge would have a high penetration power through matter. A very detailed account of the experimental technique and calculations that Chadwick used to prove the existence of the neutron is given in a previous text by the writer (L'Annunziata, 2016). As noted in the previous discussion of beta particle decay, the neutron possesses a mass similar to that of the proton and, within the nucleus of an atom, the particle is a close union between a proton and an electron.

2. Neutron classification

Neutrons are generally classified according to their kinetic energies. There is no sharp division or energy line of demarcation between the various classes of neutrons; however, the following is an approximate categorization according to neutron energy:

*	Cold neutrons	<0.003 eV
*	Slow (thermal) neutrons	0.003–0.4 eV
*	Slow (epithermal) neutrons	0.4–100 eV
*	Intermediate neutrons	100 eV–200 keV
*	Fast neutrons	200 keV –10 MeV
*	High-energy (relativistic) neutrons	>10 MeV

The slow (thermal) neutrons are classified above within the encompassing energy range of 0.003–0.4 eV; however, many reference tables may provide the thermal neutron cross sections of the elements and their isotopes at the specific thermal neutron energy of 0.0253 eV and a neutron velocity of 2200 m per second, which are neutrons in thermal equilibrium with matter at room temperature (20.43°C) (Holden, 1997b).

The energies of neutrons are also expressed in terms of velocity (meters per second) as depicted in the terminology used to classify neutrons. A neutron of specific energy and velocity is also described in terms of wavelength, because particles in motion also have wave properties. It is the wavelength of the neutron that becomes important in studies of neutron diffraction. The values of energy, velocity, and wavelength of the neutron, as with all particles in motion, are interrelated. The velocity of neutrons increases according to the square root of the energy, and the wavelength of the neutron is inversely proportional to its velocity. Knowing only one of the properties, either the energy, velocity, or wavelength of a neutron, we can

calculate the other two. We can relate the neutron energy and velocity using the kinetic energy equation

$$K = \frac{1}{2}mv^2 \quad \text{or} \quad v = \sqrt{2K/m} \quad (1.267)$$

where K is the particle kinetic energy in joules ($1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$), m is the mass of the neutron ($1.674 \times 10^{-27} \text{ kg}$), and v is the particle velocity in meters per second. The wavelength is obtained from the particle mass and velocity according to

$$\lambda = \frac{h}{p} = \frac{h}{mv}, \quad (1.268)$$

where λ is the particle wavelength in meters, h is Planck's constant ($6.626 \times 10^{-34} \text{ J s}$), p is the particle momentum, and m and v are the particle mass and velocity as previously

defined. The correlation between neutron energy, velocity, and wavelength is provided in Fig. 1.71, which is constructed from the classical Eqs. (1.267) and (1.268) relating particle mass, energy, velocity, and wavelength. However, calculations involving high-energy particles that approach the speed of light will contain a certain degree of error unless relativistic calculations are used, as the mass of the particle will increase according to the particle speed. In Section XII.C of this chapter we used the Einstein equation $E = mc^2$ to convert the rest mass of the positron or negatron to its rest energy (0.51 MeV). When gauging particles in motion, the *total energy* of the particle is the sum of its kinetic (K) and rest energies (mc^2) or

$$E = K + mc^2 = \gamma mc^2 \quad (1.269)$$

FIGURE 1.71 Correlation between neutron energy in electron volts (eV), velocity (m/sec), and wavelength (nm). From the energy of the neutron in eV on the abscissa, a line is drawn vertically to cross the wavelength and velocity curves. The values of neutron wavelength and velocity are obtained directly from the ordinate. For example, to determine the wavelength and velocity of 0.025 eV thermal neutrons, the value of 0.025 eV is found on the abscissa. A line is then drawn vertically from the point of 0.025 eV to cross the values of 0.18 nm wavelength and 2200 m/sec velocity.

And thus, the kinetic energy of the particle would be the difference between the total energy of the particle and its rest energy or

$$K = \gamma mc^2 - mc^2 \quad (1.270)$$

where

$$\gamma = \frac{1}{\sqrt{1 - (u^2/c^2)}}, \quad (1.271)$$

u is the particle speed, and $u < c$, which was derived by Einstein (1916a,b). The complete derivation of Einstein is provided in the Appendix of a former book by the writer (L'Annunziata, 2016). If we call the particle rest mass m_0 , then the relativistic mass, m_r , which is the speed-dependent mass of the particle is calculated as

$$m_r = \frac{m_0}{\sqrt{1 - (u^2/c^2)}} \quad (1.272)$$

and from Eq. (1.269) the kinetic energy of the particle can be written as

$$K = \frac{m_0}{\sqrt{1 - (u^2/c^2)}} c^2 - m_0 c^2 \quad (1.273)$$

Eq. (1.273) can be transformed to read

$$K + m_0 c^2 = \frac{m_0 c^2}{\sqrt{1 - (u^2/c^2)}} \quad (1.274)$$

and

$$\frac{K + m_0 c^2}{m_0 c^2} = \frac{1}{\sqrt{1 - (u^2/c^2)}} \quad (1.275)$$

and

$$\left(\frac{K}{m_0 c^2} + 1 \right)^2 = \frac{1}{1 - (u^2/c^2)} \quad (1.276)$$

which can be transformed to read

$$\frac{u^2}{c^2} = 1 - \frac{1}{(K/m_0 c^2 + 1)^2} \quad (1.277)$$

From Eq. (1.277) the relativistic speed of the particle can be defined as

$$u_r = c \sqrt{1 - (K/m_0 c^2 + 1)^{-2}} \quad (1.278)$$

where K is the kinetic energy, and the particle speed u is always less than c (Serway et al., 2005). The nonrelativistic speed is that described by Eq. (1.267) or $u_{nr} = \sqrt{2K/m_0}$.

As particles increase in energy and approach the speed of light, the relativistic calculation of the particle speed should be used. To compare the use of nonrelativistic calculations of particle speed for the construction of Fig. 1.71,

let us use Eqs. (1.267) and (1.278) to calculate the differences between the nonrelativistic and relativistic speeds of a neutron of 10 MeV kinetic energy. This energy was selected, because it is the highest neutron energy included in Fig. 1.71, and differences between nonrelativistic and relativistic calculations increase with particle energy. The difference between the two calculated speeds is defined by the ratio of the two or

$$\frac{u_{nr}}{u_r} = \frac{\sqrt{2K/m_0}}{c \sqrt{1 - (K/m_0 c^2 + 1)^{-2}}} \quad (1.279)$$

The rest energy of the neutron, mc^2 , is first calculated as

$$\begin{aligned} mc^2 &= (1.6749 \times 10^{-27} \text{ kg}) (2.9979 \times 10^8 \text{ m/s})^2 \\ &= 1.505 \times 10^{-10} \text{ J} \end{aligned}$$

and

$$\frac{1.505 \times 10^{-10} \text{ J}}{1.602 \times 10^{-19} \text{ J/eV}} = 939.5 \text{ MeV}$$

since by definition, $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$. From Eq. (1.279) the ratio of the nonrelativistic and relativistic speeds are calculated as

$$\begin{aligned} \frac{u_{nr}}{u_r} &= \frac{\sqrt{2(10 \text{ MeV})(1.602 \times 10^{-13} \text{ J/MeV})/1.6749 \times 10^{-27} \text{ kg}}}{c \sqrt{1 - ((10 \text{ MeV}/939.5 \text{ MeV}) + 1)^{-2}}} \\ &= \frac{4.3737 \times 10^7 \text{ m/s}}{0.1447751c} = \frac{4.3737 \times 10^7 \text{ m/s}}{(0.1447751)(2.9979 \times 10^8 \text{ m/s})} \\ &= \frac{4.3737 \times 10^7 \text{ m/s}}{4.340 \times 10^7 \text{ m/s}} = 1.0079 = 0.79\% \text{ error} \end{aligned}$$

The error between the nonrelativistic and relativistic calculations is small at the 10 MeV neutron energy. However, if we consider higher neutron energies in excess of 10 MeV, the error of making nonrelativistic calculations increases.

As we observed above in the case of particle speed, we will also see that particle wavelength will also differ for nonrelativistic and relativistic calculations. In 1923 Louis Victor de Broglie first postulated that all particles or matter in motion should have wave characteristics just as photons display both a wave and particle character. We therefore attribute the wavelength of particles in motion as de Broglie wavelengths. Let us then compare calculated nonrelativistic and relativistic wavelengths. From Eq. (1.268), we can describe the nonrelativistic wavelength, λ_{nr} , as

$$\lambda_{nr} = \frac{h}{p} = \frac{hc}{pc} = \frac{hc}{cmv} = \frac{hc}{cm \sqrt{2K/m}} = \frac{hc}{\sqrt{2mc^2 K}} \quad (1.280)$$

where $p = mv = m\sqrt{2K/m}$. For relativistic calculations the value of pc is calculated according to the following equation described by Halpern (1988):

$$pc = \left[2m_0c^2K \left(1 + \frac{K}{2m_0c^2} \right) \right]^{1/2} \quad (1.281)$$

The above Eq. (1.281) is derived as follows:

From Eq. (1.374) of Part XI.A Dual Nature: Wave and Particle, the following expression was derived that defines the relationship between the total energy ($E = mc^2$) and rest energy ($E = m_0c^2$) of a particle:

$$\begin{aligned} \frac{\lambda_{nr}}{\lambda_r} &= \frac{hc/\sqrt{2m_0c^2K}}{hc/[2m_0c^2K(1 + (K/2m_0c^2))]^{1/2}} \\ &= \frac{\{[(6.626 \times 10^{-34} \text{ J s})(2.9979 \times 10^8 \text{ m/s})/1.602 \times 10^{-13} \text{ J/MeV}]/\sqrt{2(939.5 \text{ MeV})(10 \text{ MeV})}\}}{\{[(6.626 \times 10^{-34} \text{ J s})(2.9979 \times 10^8 \text{ m/s})/1.602 \times 10^{-13} \text{ J/MeV}]/\sqrt{2(939.5 \text{ MeV})(10 \text{ MeV})[1 + (10 \text{ MeV}/2(939.5 \text{ MeV})]}\}} \\ &= \frac{12.3958 \times 10^{-4} \text{ MeV nm}/\sqrt{18790 \text{ MeV}^2}}{12.3958 \times 10^{-4} \text{ MeV nm}/\sqrt{18890 \text{ MeV}^2}} \\ &= \frac{9.0430 \times 10^{-6} \text{ nm}}{9.0190 \times 10^{-6} \text{ nm}} = 1.0026 = 0.26\% \text{ error} \end{aligned} \quad (1.290)$$

$$E^2 = p^2c^2 + E_0^2 \quad (1.282)$$

where $p = \gamma mu$ is the relativistic momentum and $\gamma = 1/\sqrt{1 - (u^2/c^2)}$, u is the particle speed and $u < c$ as described previously by Eq. (1.271). Because the total energy (E) of a particle is the sum of its kinetic (K) and rest energy (E_0), we can transform Eq. (1.282) to read

$$p^2c^2 = (K + m_0c^2)^2 - (m_0c^2)^2 \quad (1.283)$$

which is transposed to read

$$(pc)^2 = K^2 + 2Km_0c^2 + (m_0c^2)^2 - (m_0c^2)^2 \quad (1.284)$$

and

$$(pc)^2 = K^2 + 2m_0c^2K \quad (1.285)$$

and

$$(pc)^2 = 2m_0c^2K \left(1 + \frac{K}{2m_0c^2} \right) \quad (1.286)$$

Finally Eq. (1.286) can be expressed as

$$pc = \left[2m_0c^2K \left(1 + \frac{K}{2m_0c^2} \right) \right]^{1/2} \quad (1.287)$$

And, according to Eq. (1.280), the expression for the relativistic de Broglie wavelength, λ_r , then becomes

$$\lambda_r = \frac{hc}{pc} = \frac{hc}{[2m_0c^2K(1 + (K/2m_0c^2))]^{1/2}} \quad (1.288)$$

With Eqs. (1.280) and (1.288) we can compare the difference between the calculated nonrelativistic and relativistic wavelengths for the 10 MeV neutron as follows:

From the above comparison of nonrelativistic and relativistic calculations of neutron wavelength and velocity, we see that the data provided in Fig. 1.71 based on nonrelativistic calculations are valid with less than 1% error for the highest energy neutron included in that figure. However, if we consider higher energies beyond 10 MeV, where we classify the neutron as relativistic, the errors in making nonrelativistic calculations will increase with neutron energy. It will be clearly obvious to the reader that factors in Eq. (1.290) can be canceled out readily and the equation simplified to the following, which provides a quick evaluation of the effect of particle energy on the error in nonrelativistic calculation of the de Broglie wavelength:

$$\frac{\lambda_{nr}}{\lambda_r} = \sqrt{1 + \frac{K}{2m_0c^2}} \quad (1.291)$$

where K is the particle kinetic energy in MeV and m_0c^2 is the rest energy of the particle (e.g., 939.5 MeV for the neutron and 0.511 MeV for the beta particle). For example, a nonrelativistic calculation of the wavelength of a 50-MeV neutron would have the following error:

FIGURE 1.72 A graph comparing particle speeds derived from (a) nonrelativistic and (b) relativistic interpretations of the particle speed as a function of the particle kinetic energy. The particle speeds in units of the speed of light ($c = 2.9979 \times 10^8$ m/s) are plotted versus particle energy expressed as a ratio of its kinetic energy (K) over its rest energy (mc^2). In the nonrelativistic case, the particle kinetic energy is defined as $K = 1/2mv^2$ and its speed is calculated according to $v = \sqrt{2K/m}$; whereas in the relativistic case, the particle kinetic energy is the difference between the total energy of the particle and its rest energy ($K = \gamma mc^2 - mc^2$), where $\gamma = 1/\sqrt{1 - (u^2/c^2)}$ and its speed $u = c\sqrt{1 - (K/mc^2 + 1)^{-2}}$ is always less than c . From *L'Annunziata (2016)*; reprinted with permission from Elsevier © 2016.

$$\frac{\lambda_{nr}}{\lambda_r} = \sqrt{1 + \frac{50 \text{ MeV}}{2(939.5 \text{ MeV})}} = 1.0132 = 1.32\% \text{ error.}$$

Note that the above-computed errors in nonrelativistic calculations of the de Broglie wavelength increased from 0.26% for a 10-MeV neutron to 1.32% for a 50-MeV neutron, and the error will increase with particle energy. Errors in nonrelativistic calculations are yet greater for particles of smaller mass (*e.g.*, beta particles or electrons) of a given energy compared to neutrons of the same energy. This is due obviously to the fact that particles of lower mass and a given energy will travel at higher speeds than particles of the same energy but

higher mass. This is illustrated in Fig. 1.72 where the particle speed, u , is a function of the particle kinetic energy, K , and its mass or rest energy, mc^2 . The particle energy in Fig. 1.72 is expressed as K/mc^2 to permit the reader to apply the curves for nonrelativistic and relativistic calculations to particles of different mass. For example, from the abscissa of Fig. 1.72, the values of K/mc^2 for a 2-MeV beta particle is $2 \text{ MeV} / 0.51 \text{ MeV} = 3.9$ and that for a 2-MeV neutron is $2 \text{ MeV} / 939.5 \text{ MeV} = 0.0021$. From Fig. 1.72 we see that the nonrelativistic calculation of the speed of a 2-MeV beta particle would be erroneously extreme (well beyond the speed of light), while there would be only a small error in the relativistic calculation of the speed of the massive neutron of the same energy.

TABLE 1.16 Processes for production of neutrons and short description of corresponding spectral fluence.

Process	Example	Neutron fluence energy distribution
Spontaneous fission	$^{252}\text{Cf} \rightarrow n + \text{FP}$	Maxwellian, $E_{\text{mean}} \sim 2 \text{ MeV}$
Neutron-induced fission	$^{235}\text{U}(n, f)$	
Radioisotope (α, n) sources	$\alpha + {}^9\text{Be} \rightarrow {}^{12}\text{C} + n$	Mono ^a or polyenergetic neutrons
Photon reaction	${}^A\text{X}(\gamma, n){}^{A-1}\text{X}$	Mono ^a or polyenergetic
	$\gamma + {}^9\text{Be} \rightarrow {}^8\text{Be} + n$	neutrons (short half-life of γ -ray emitters)
Charged particle direct reaction	${}^2\text{H}(d, n){}^3\text{He}$	Monoenergetic ^a neutrons
Charged particle breakup reaction	${}^2\text{H}(d, np){}^2\text{H}$	Broad energy distribution $E_{\text{mean}} \sim 0.5 E_d$

^aDefinition of monoenergetic neutron source from ICRU Report 63 (2000): "A neutron source can be consider 'monoenergetic' if the energy spectrum consists of a single peak, which has an energy spread which is much less than the energy of the peak. The ideal source has a small energy spread and negligible neutron intensity at lower and higher energies."

3. Neutron sources

Neutron sources are vital to our development and well being. They serve to produce the energy we need and for the production of many of the radionuclides vital to our well-being, such as radioactive sources used in medical diagnosis and treatment of many forms of cancer as well as numerous applications in industry including nondestructive testing and analysis. A review of current practical applications of neutrons and nuclear radiation is provided by the writer in a previous text (L'Annunziata, 2016). There are several sources of neutrons, including (1) alpha particle induced (α, n) nuclear reactions (2) radionuclides that decay by spontaneous fission, (3) neutron-induced fission, (4) photoneutron (γ, n) sources, (5) charged-particle accelerator sources, and (6) nuclear fusion. A basic list of these sources is provided in Table 1.16, and a more detailed description of the sources of neutrons will be provided subsequently. Also, the reader may peruse a review on neutron sources by Furrer (2016).

a. Alpha particle—induced nuclear reactions

It is interesting to note that the method used by Chadwick in 1932 in his discovery of the neutron, namely by an alpha particle—induced reaction, described in Section X.E.1, remains an important method of producing a neutron source, particularly when a relatively small or easily transportable neutron source is required. The source may be prepared by compressing an alpha particle—emitting radioisotope substance with beryllium metal. The nuclear reaction, which occurs between the alpha particle and the beryllium nucleus, terminates with the emission of a neutron and the production of stable carbon as follows

where 5.702 MeV is the energy released in the reaction. The kinetic energy released in the reaction is determined by calculating the Q value of the reaction according to Eq. (1.137), namely:

$$Q = (m_{\text{reactants}})c^2 - (m_{\text{products}})c^2 \quad (1.293)$$

which for the above reaction is written as

$$\begin{aligned} Q &= (M_{{}^9\text{Be}} + M_{{}^4\text{He}})c^2 - (M_{{}^{12}\text{C}} + M_{{}^1\text{n}})c^2 \\ &= \left[(9.01218306 \text{ u} + 4.00260325 \text{ u})931.494 \text{ MeV/u} - \right. \\ &\quad \left. (12.000000 \text{ u} + 1.00866492 \text{ u})931.494 \text{ MeV/u} \right] \\ &= 5.702 \text{ MeV} \end{aligned} \quad (1.294)$$

The calculated value agrees with the Q -value Calculator (QCalc) of the National Nuclear Data Center, Brookhaven National Laboratory (NNDC, 2010a,b: [http://www.nndc.](http://www.nndc.bnl.gov/qcalc/)

<http://www.nndc.bnl.gov/qcalc/>), which provides a computer-calculated value of 5702 keV. The neutrons emitted from the reaction will have an average energy of ~ 5.5 MeV, as the kinetic energy released in the reaction is shared between the neutron and ${}^{12}\text{C}$ nucleus, and the neutron may possess varying energies and velocities as a consequence of the various directions of emission of neutrons from the nucleus.

Several alpha particle sources are used to produce neutrons via the preceding (α, n) reaction. Among these are the alpha emitters ${}^{241}\text{Am}$, ${}^{242}\text{Cm}$, ${}^{210}\text{Po}$, ${}^{239}\text{Pu}$, and ${}^{226}\text{Ra}$. The alpha radiation source selected may depend on its half-life as well as its gamma ray emissions. As noted previously in this chapter, gamma radiation often accompanies alpha decay. The use of an alpha source, which also emits abundant gamma radiation, requires additional protection for the user against penetrating gamma rays. For example, Am—Be sources may be preferred over the Ra—Be sources of neutrons used in soil moisture probes (Nielsen and Cassel, 1984; O'Leary and Incerti, 1993; Dwevedi et al., 2017), because the latter have a higher output of gamma radiation and require more shielding for operator protection.

The energies of the neutrons emitted from these sources will vary over the broad spectrum of 0–10 MeV. The neutrons produced by these sources vary in energy as a consequence of several factors, including the sharing of the liberated energy between the neutron and the daughter nucleus, the varying directions of emission of neutrons from the nucleus with consequent varying energies and velocities, and the variations in kinetic energies of the bombarding alpha particles.

The neutron activities available from these sources increase up to a maximum as a function of the amounts of alpha emitter and beryllium target material used (Didi, 2017). For example, as explained by Bacon (1969), the Ra—Be source, prepared by mixing and compressing radium bromide with beryllium powder, increases steadily in neutron activity (neutrons per second) for each gram of radium used as the amount of beryllium is increased to about 10 g; but no significant increase in neutron output is achieved if more beryllium is used. The maximum neutron output achieved is approximately 2×10^7 neutrons per second per gram of radium. Because alpha decay from any alpha particle—emitting source occurs by means of random events, the production of neutrons by (α, n) reactions is also a random event. Therefore, these reactions can be referred to as “not time correlated.” This is contrary to the case of neutron sources provided through fission, discussed subsequently.

Beryllium is not the exclusive element that may be used for the alpha particle—induced neutron source. Other low Z elements may be packed with an alpha emitter (*e.g.*, boron or carbon); however, their neutron yields are about six times lower than Be (Lacoste, 2010). For example, Skidmore et al. (2009) tested oxygen enriched with ${}^{18}\text{O}$ packed

TABLE 1.17 The total flux emitted by the neutron sources per second integrated over energy.

Neutron source	Integrated flux ($\text{s}^{-1}\text{g}^{-1}$)	Approximate source Mass required for 100 W thermal power generation (g)
^{252}Cf	2.3×10^{12}	0.05
Am–Be	1.4×10^6	2000
Enriched AmO ₂	3.7×10^5	2000
Pu–Be	7.2×10^6	2000

From Skidmore et al. (2009) reprinted with permission of Elsevier © 2009.

with ^{241}Am as a possible neutron energy source for planetary research. The neutron flux and energy yield from this source is compared to conventional sources of alpha emitters with Be as well as the ^{252}Cf spontaneous fission neutron source in Table 1.17.

Switchable neutron generators, that is generators that may be turned on or off, of the (α, n) type are possible when the alpha emitter and target are not packed intimately. The alpha emitter need not be packed intimately with the target material, but both must be close enough to allow the alpha particles to be absorbed by the target. Hertz et al. (2003) studied many combinations of alpha-emitter and target materials for switchable neutron sources, and they found the $^9\text{Be}(\alpha, n)$ generator with an ^{241}Am alpha emitting source the most suitable as a switchable neutron source. In the “off” position a mechanical device is used to prevent the alpha particles from reaching the Be target. These switchable neutron sources are classified as micromachines because they can be constructed to have the dimensions of the same order of magnitude as the alpha particle range.

b. Spontaneous fission

About 100 radioisotopes are known to decay by spontaneous fission (SF) with the emission of neutrons (Karelin et al., 1997; Santhosh and Priyanka, 2015) as an alternative to another decay mode, such as alpha decay. SF involves the spontaneous noninduced splitting of the nucleus into two nuclides or fission fragments and the simultaneous emission of more than one neutron on the average. This phenomenon occurs with radionuclides of high mass number, $A \geq 230$. The radionuclide ^{252}Cf is a good example of a commercially available SF neutron source. It decays with a half-life of 2.65 years primarily by alpha emission (96.91% probability), and the remaining of the ^{252}Cf nuclides decay by SF with a probability of 3.09% (Martin et al., 2000, see also Appendix A). Decay of ^{252}Cf by SF produces an average number of 3.7 neutrons per fission. Because the sizes of the two fragments resulting from fission are not predictable, average sizes of the two fragments are determined. Consequently, the numbers of neutrons emitted from individual fissions are not the same, and an average number of neutrons produced per fission is

determined. The fission rate of ^{252}Cf is 6.2×10^5 SF/s/ μg (Isotope Products Laboratories, 1995). The neutron emission from ^{252}Cf in units of neutrons per second per unit mass is reported to be 2.314×10^6 neutrons/s/ μg with a specific activity of 0.536 mCi/ μg (Martin et al., 2000; Skidmore et al., 2009). Thus, 1 milligram of ^{252}Cf would emit 2.314×10^9 neutrons per second. If we know the radionuclide specific activity and the % probability of decay by SF, we can calculate the fission rate. For example, taking the specific activity and % probability of SF reported above for ^{252}Cf , we can calculate the fission rate as the product of decay rate and probability of SF per decay or

$$\begin{aligned} & (0.536 \text{ mCi} / \mu\text{g})(3.7 \times 10^7 \text{ dps} / \text{mCi})(0.0309) \\ & = 6.13 \times 10^5 \text{ SF/s}/\mu\text{g} \end{aligned} \quad (1.295)$$

which is in close agreement with the value cited above. See Section XVIII.A for a discussion of radioactivity units and calculations.

The variations in fission fragment sizes and number of neutrons emitted per fission provide variable neutron energies over the range 0–5.5 MeV with an average neutron energy from ^{252}Cf of approximately 2.3 MeV. Small sources of ^{252}Cf are commercially available for a wide range of applications such as prompt-gamma neutron activation analysis of coal, cement, minerals, interplanetary analysis, petroleum contamination analysis in soil (Mercer et al., 2007; Skidmore et al., 2009; Hadad et al., 2016), moisture distribution analysis in porous media (El Abd et al., 2013), detection of explosives and land mines (Elsheikh et al., 2012), and neutron radiography (Meshkian, 2016). There is an increasing interest in the use of ^{252}Cf neutron sources in radiation therapy or specifically neutron brachytherapy treatment of various types of cancer (Melhus and Rivard, 2006; Wang et al., 2008; Ghassoun et al., 2010; Lei, 2010; Samerdokiene et al., 2015; Ulinskas et al., 2016). Small commercial sources are described by Martin et al. (1997, 2000) among which include 50-mg sources of ^{252}Cf providing a neutron intensity $> 10^{11}/\text{s}$ and measuring only 5 cm in length \times 1 cm diameter. They report also larger sources of mass > 100 mg of ^{252}Cf that approach reactor capabilities for neutrons.

Another standard nuclide source of neutrons is ^{248}Cm , which provides a SF intensity of only $4.12 \times 10^4/\text{s/mg}$ and decays with a half-life of 3.6×10^5 years (Radchenko et al., 2000; Tudora, 2010). The lower neutron flux intensity of this source limits its application, although it has the advantage of a very long half-life providing invariability of sample intensity with time.

Some radionuclides of interest in nuclear energy and nuclear safeguards also decay by SF. The isotopes of plutonium of even mass number, namely ^{238}Pu , ^{240}Pu , and ^{242}Pu , decay principally by alpha particle emission but can also undergo SF to a lesser extent at rates of 1100, 471, and 800 SF/s/g, respectively (Esaka et al., 2017; Redd et al., 2017). The average number of neutrons emitted per fission is between 2.16 and 2.26 of broad energy spectrum (Cannberra Nuclear, 1996). Because the neutrons produced with each fission occurrence are emitted simultaneously, we can refer to these emissions as “time correlated.” Other isotopes of uranium and plutonium also undergo SF, but at a much lower rate.

c. Neutron-induced fission

When the naturally occurring isotope of uranium, ^{235}U , is exposed to slow neutrons, it can absorb the neutron to form the unstable nuclide ^{236}U . The newly formed nucleus may decay by alpha-particle and gamma ray emission with the long half-life of 2.4×10^7 years. This occurs in approximately 14% of the cases when ^{235}U absorbs a slow neutron. However, in the remaining 86% of the cases, the absorption of a slow neutron by ^{235}U results in the production of the unstable ^{236}U nuclide, which takes on the characteristics of an unstable oscillating droplet (see Fig. 1.18 of Section VI.D.1 of this chapter). This oscillating nuclear droplet with the opposing forces of two positively charged nuclides splits into two fragments, not necessarily of equal size, with the liberation of an average energy of 193.6 MeV. The general ^{235}U fission reaction may be written as

which represents the reaction of one atom of $^{235}_{92}\text{U}$ with one thermal neutron ${}^1_0\text{n}$ to yield the release of fission products fp of varying masses plus an average yield of $\nu = 2.42$ neutrons and an overall average release of energy $E = 193.6$ MeV (Koch, 1995). The intermediate nuclide ^{236}U is shown in brackets in the above reaction. Most of this energy (over 160 MeV) appears in the form of kinetic energy of the two fission fragments. The remaining energy is shared among the neutrons emitted, with prompt gamma radiation accompanying fission and also beta particles and gamma radiation from decaying fission fragments and neutrinos accompanying beta decay. When a sample of ^{235}U is bombarded with slow neutrons, the fission fragments produced are rarely of equal mass. The ^{236}U

intermediate nuclide breaks into fragments in as many as 30 different possible ways, producing, therefore, 60 different nuclide fission fragments. In a review, Koch (1995) provides a list of the fission fragments and their relative abundances as produced in a typical PWR. The most common fission fragments have a mass difference in the ratio 3:2 (Bacon, 1969). Neutrons emitted from this fission process vary in energy over the range 0–10 MeV with an average neutron energy of 2 MeV, which are classified as fast neutrons.

Let us take one of many possible examples of ^{236}U fission to calculate the magnitude of energy liberated. One example of many possible fission reactions, that may be written conserving mass and charge of the ^{236}U nucleus with the emission of three neutrons, is the following:

The energy liberated in the above fission reaction can be determined from its Q value, which is calculated from Eqs. (1.136) and (1.137) of Section IX.C. as follows:

$$Q = E_{0, \text{reactants}} - E_{0, \text{products}} \quad (1.298)$$

where $E_{0, \text{reactants}}$ and $E_{0, \text{products}}$ are the rest energies of the nuclear reactants and products, respectively. Eq. (1.298) may be written as

$$Q = (M_{\text{reactants}})c^2 - (M_{\text{products}})c^2 \quad (1.299)$$

where $M_{\text{reactants}}$ and M_{products} are the combined masses of the nuclear reactants and products, respectively, and c is the velocity of light in a vacuum. For the fission reaction 1.297 we can calculate its Q value as

$$\begin{aligned} Q &= (M_{^{235}\text{U}} + M_{\text{n}})c^2 - (M_{^{90}\text{Sr}} + M_{^{143}\text{Xe}} + 3M_{\text{n}})c^2 \\ &= \left[(235.0439282 \text{ u} + 1.0086649158 \text{ u}) - \right. \\ &\quad \left. (89.9077309 \text{ u} + 142.935370 \text{ u} + 3(1.0086649158 \text{ u})) \right] \\ &\quad \times 931.494013 \text{ MeV/u} = 170.927 \text{ MeV}, \end{aligned} \quad (1.300)$$

which is in agreement with the computer calculated Q value of 170927 keV determined with QCalc provided by the National Nuclear Data Center, Brookhaven National Laboratory (NNDC, 2018a,b: <https://www.nndc.bnl.gov/qcalc/>) with atomic mass units obtained from the Atomic Mass Data Center (<http://amdc.impcas.ac.cn/web/masseval.html>). As noted previously, most of the energy released appears as kinetic energy of the fission fragments (~ 165 MeV). The neutrons carry off about 2 MeV each on the average. Additional energy is released from fission via gamma radiation and beta decay of the fission products and the neutrino radiation that accompanies beta decay. The total energy released by the neutron-induced fission of ^{235}U , in the example given by Eq. (1.297), to the ultimate decay of the fission products ^{90}Sr and ^{143}Xe to their stable ground states is calculated by determining

firstly the decay schemes of the two fission products as follows:

Decay of ^{90}Sr :

Decay of ^{143}Xe :

Thus, the final reaction to the stable nuclides can be written as

If we use atomic mass units to calculate the Q value of the above reaction, the eight additional atomic electrons of the ${}^{90}_{40}\text{Zr} + {}^{143}_{60}\text{Nd}$ (100 atomic electrons) over the ${}^{235}_{92}\text{U}$ (92 atomic electrons) force the eight electrons represented by the eight beta particles ($8\beta^-$) to drop out of the equation. Thus, we can calculate the Q value as

$$\begin{aligned} Q &= (M_{235\text{U}} + M_{1\text{n}})c^2 - (M_{90\text{Zr}} + M_{143\text{Nd}} + 3M_{1\text{n}})c^2 \\ &= \left[(235.0439282 \text{ u} + 1.0086649158 \text{ u}) - \right. \\ &\quad \left. (89.90469876 \text{ u} + 142.9098199 \text{ u} + 3 \times 1.0086649158 \text{ u}) \right] \\ &\quad \times 931.494013 \text{ MeV/u} = 197.55 \text{ MeV} \end{aligned} \quad (1.304)$$

The calculated Q value of 197.55 MeV represents the total energy released in the example of the neutron-induced fission of ${}^{235}\text{U}$ to the unstable ${}^{90}\text{Sr}$ and ${}^{143}\text{Xe}$ fission products, followed by the decay of these fission products, to the stable ${}^{90}\text{Zr}$ and ${}^{143}\text{Nd}$ nuclides. This calculated value is close to the estimated value of ~ 202 MeV using average binding energies of the parent and daughter nuclides found in Section VI.C of this chapter.

Let us take another example of many possible fission possibilities of the neutron-induced fission of ${}^{235}\text{U}$. This

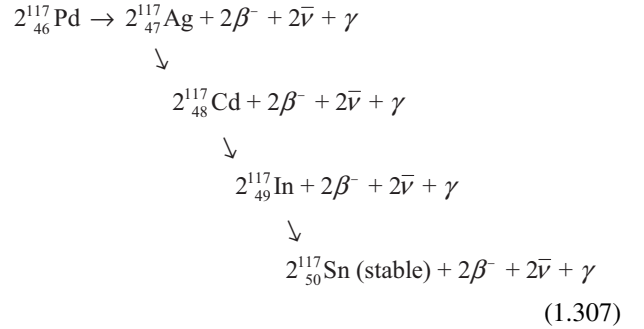

example is one where the two fission products are of the same mass number, which is the following:

The fission products in this case are two nuclides of ${}^{117}\text{Pd}$ and two neutrons. The energy released by the neutron-induced fission is calculated as

$$\begin{aligned} Q &= (M_{235\text{U}} + M_{1\text{n}})c^2 - (2M_{117\text{Pd}} + 2M_{1\text{n}})c^2 \\ &= \left[(235.0439282 \text{ u} + 1.0086649158 \text{ u}) \right. \\ &\quad \left. - (2 \times 116.917955 \text{ u} + 2 \times 1.0086649158 \text{ u}) \right] \\ &\quad \times 931.494013 \text{ MeV/u} = 185.696 \text{ MeV}, \end{aligned} \quad (1.306)$$

which agrees with the value of 185696 keV calculated by the online QCalc provided by the National Nuclear Data Center, Brookhaven National Laboratory (NNDC, 2018a,b: <https://www.nndc.bnl.gov/qcalc/>) with atomic mass units obtained from the Atomic Mass Data Center (<http://amdc.impcas.ac.cn/web/masseval.html>). The total energy yield, that includes the decay of the radioactive ${}^{117}\text{Pd}$, can be calculated after firstly determining the decay scheme of two nuclides of ${}^{117}\text{Pd}$ to final stable daughter nuclides. The decay scheme is the following:

From the above reaction schemes, the total reaction of the neutron-induced fission of ${}^{235}\text{U}$ to two nuclides of ${}^{117}\text{Sn}$ can be written as follows:

The total energy released from this example of neutron-induced fission of ${}^{235}\text{U}$ is calculated as

$$\begin{aligned} Q &= (M_{235\text{U}} + M_{1\text{n}})c^2 - (2M_{117\text{Sn}} + 2M_{1\text{n}})c^2 \\ &= \left[(235.0439282 \text{ u} + 1.0086649158 \text{ u}) \right. \\ &\quad \left. - (2 \times 116.9029540 \text{ u} + 2 \times 1.0086649158 \text{ u}) \right] \\ &\quad \times 931.494013 \text{ MeV/u} = 213.6 \text{ MeV} \end{aligned} \quad (1.309)$$

with atomic mass units obtained from the Atomic Mass Data Center (<http://amdc.impcas.ac.cn/web/masseval.html>).

TABLE 1.18 Approximate energy released from neutron-induced ^{235}U fission.

Type	Energy released (MeV)
Prompt energy	
Fission product kinetic energy	165
Neutrons (2.5 n/fission on average, ~ 2 MeV/n on average)	5
Gamma-ray emissions	7
Energy from fission product decay	
Gamma ray emissions	7
Beta radiation	6
Neutrinos	10
Total	200 MeV

Thus, from the two examples of possible fission reactions taken above (Eqs. 1.303 and 1.308), which include the decay of the fission products to stable nuclides, we calculated the energy released by the two fission processes as 197.5 MeV (Eq. 1.304) and 213.6 MeV (Eq. 1.309). We can see that approximately 200 MeV is the amount of energy released from the two examples taken of the neutron-induced fission of ^{235}U . The magnitude of the energy released from neutron-induced fission of ^{235}U would be an average figure, because the actual amount of energy released would depend on the fission reaction, and there are many possible ways that the ^{236}U could break into two nuclides. Some of the energy arises from fission product radioactivity including gamma ray emission as fission product nuclides decay to lower energy states, beta particle emission from fission product decay, and the emission of neutrinos that accompany beta decay. The energy released can be itemized into the various energy categories listed in Table 1.18, which are tallied to provide an approximate average figure for the energy released in neutron-induced fission of ^{235}U .

Because more than one neutron is released per fission, a self-sustaining chain reaction is possible with the liberation of considerable energy, forming the basis for the nuclear reactor as a principal source of neutrons and energy. In the case of ^{235}U , neutron capture and fission will occur with more efficiency when the neutrons are moderated to reduce their speed to slow neutrons. The nuclear reactor, therefore, will be equipped with a moderator such as heavy water (D_2O) or graphite, which can reduce the energies of the fast neutrons via elastic scattering of the neutrons with atoms of low atomic weight. The protons of water also serve as a good moderator of fast neutrons, provided the neutrons lost via the capture process $^1\text{H}(\text{n},\gamma)^2\text{H}$ can be compensated by the use of a suitable enrichment of the ^{235}U in the nuclear reactor fuel (Bryne, 1994).

The previously described fission of ^{235}U represents the one and only fission of a naturally occurring radionuclide that can be induced by slow neutrons. The radionuclides ^{239}Pu and ^{233}U also undergo slow neutron-induced fission; however, these nuclides are man-made via the neutron irradiation and neutron capture of ^{238}U and ^{232}Th , as illustrated in the following equations (Murray, 2009). The preparation of ^{239}Pu occurs by means of neutron capture by ^{238}U followed by beta decay as follows:

The preparation of ^{233}U is carried out via neutron capture of ^{232}Th followed by beta decay according to the following:

Nuclides that undergo slow neutron-induced fission are referred to as fissile materials. Although ^{235}U is the only naturally occurring fissile radionuclide, it stands to reason that, if an excess of neutrons is produced in a thermal reactor, it would be possible to produce fissile ^{239}Pu or ^{233}U fuel in a reactor in excess of the fuel actually consumed in the reactor. This is referred to as “breeding” fissile material, and it forms the basis for the new generation of breeder reactors (Murray, 2009).

Other heavy isotopes, such as ^{232}Th , ^{238}U , and ^{237}Np , undergo fission but require capture by fast neutrons of at least 1 MeV energy to provide sufficient energy to the nucleus for fission to occur. These radionuclides are referred to as fissionable isotopes.

d. Photoneutron (γ, n) sources

Many nuclides emit neutrons upon irradiation with gamma or X-radiation; however, most elements require high-energy electromagnetic radiation in the range of 10–19 MeV. The gamma or X-ray energy threshold for the production of neutrons varies with target element. Deuterium and beryllium metal are two exceptions, as they can yield appreciable levels of neutron radiation when bombarded by gamma radiation in the energy range of only 1.7–2.7 MeV. The target material of D_2O or beryllium metal is used to enclose a β^- -emitting radionuclide, which also emits gamma rays. The gamma radiation bombards the targets deuterium or beryllium to produce neutrons according to the photonuclear reactions $^2\text{H}(\gamma, n)^1\text{H}$ and $^9\text{Be}(\gamma, n)^8\text{Be}$, respectively. The photoneutron source $^{124}\text{Sb} + \text{Be}$ serves as a good example of a relatively high-yielding combination of gamma emitter with beryllium target. The ^{124}Sb gamma radiation of relevance in photoneutron production is emitted with an energy of 1.69 MeV at 50% abundance (*i.e.*, one-half of the ^{124}Sb radionuclides emit the 1.69-MeV gamma radiation following beta decay). A yield of 5.1 neutrons per 106 beta disintegrations per gram of target material has been reported (Bryne, 1994). The half-life ($t_{1/2}$) of ^{124}Sb is only 60.2 days, which limits the lifetime of the photoneutron generator; nevertheless, this isotope of antimony is easily prepared in the nuclear reactor by neutron irradiation of natural stable ^{123}Sb . An excellent example is that reported by Fantidis et al. (2009), whereby a SbBe neutron source was demonstrated to be very useful as a transportable neutron source applicable to a neutron radiography system. Also, Golshanian et al. (2016) demonstrate the use of an ^{124}Sb –Be source for Boron Neutron Capture Therapy (BNCT) for the therapeutic treatment of brain tumors. They demonstrate the use of 150 kCi of ^{124}Sb could yield an epithermal neutron flux of $0.23 \times 10^9 \text{ n/cm}^2 \text{ s}$, which would permit a treatment time of only 40 minutes for a patient with brain cancer. There is increasing research into the development of photoneutron sources for the treatment of cancer by Boron Neutron Capture Therapy such as the use of tungsten and D_2O as the photon converter and photoneutron target, respectively (Rahmani et al., 2015). The particular advantage of such a neutron source is the ability to effectively have an on/off switching capability because the production of neutrons can be stopped by simply removing the beryllium or deuterium target from the antimony gamma ray source. A unique application of the

FIGURE 1.73 A photoneutron assembly consisting of (1) a disc of tungsten (W) target embedded within (2) a photoneutron converter consisting of Be or BeD_2 . Typical dimensions are $2 \times 8 \text{ cm}$ (thickness \times radius W target) and $10 \times 12 \text{ cm}$ or $60 \times 60 \text{ cm}$ Be or BeD_2 target. From Rahmani and Shahriari (2010). Reprinted with permission from Elsevier © 2010.

$^9\text{Be}(\gamma, n)^8\text{Be}$ reaction is reported by Moussavi-Zarandi (2008), who used the gamma emissions from an ^{124}Sb source to survey for the Be content of minerals in the exploration of potential beryllium mines. The neutrons emitted from the Be nucleus via the (γ, n) reaction are detected by a BF_3 neutron counter providing a survey meter for Be exploration.

An alternative to a gamma source for the (γ, n) reaction is the use of electrostatic and linear accelerators (LINAC). Commercially available linear accelerators are capable of accelerating electrons against a high Z element, such as tungsten, to produce bremsstrahlung radiation. The bremsstrahlung photons interact with a converter material such as Be or BeD_2 , which converts the photon beam to a neutron beam via the reactions $^9\text{Be}(\gamma, n)^8\text{Be}$ and $^2\text{H}(\gamma, n)^1\text{H}$. The symbol γ is used here to denote the nuclear reaction projectile although bremsstrahlung photons (X-rays), rather than gamma rays, are the projectiles. This is done out of convenience, as bremsstrahlung and gamma rays are photons which differ only in their origins. The target and converter materials are arranged with respect to the electron beam in a fashion such as illustrated in Fig. 1.73. Alternatively the electron beam may be directed to impinge immediately onto a Be or BeD_2 target material, whereby the bremsstrahlung photons, that are produced, interact directly with the Be or BeD_2 target to yield neutrons (Auditore et al., 2005).

In such an arrangement, as illustrated in Fig. 1.73, neutrons are produced by means of the electron accelerator. The process, as described by Eshwarappa et al. (2007), entails the acceleration of electrons to impinge on a high Z target (*e.g.*, tungsten, W), which generates a cascade shower of bremsstrahlung photons with an energy spectrum having an end-point equal to the electron beam energy. The photons, produced in this fashion, travel through a suitable photoneutron target (*e.g.*, Be or BeD_2), producing excited compound nuclei of energy equal to the sum of the binding energy of the last neutron and the energy of the

bremsstrahlung X-rays. When the excitation energy is larger than the binding energy of the last neutron in the compound nucleus, a neutron is emitted. Any excess energy is shared as kinetic energy of the neutron and the residual nucleus (Eshwarappa et al., 2007). Essentially the energy conversion follows the path of $e-\gamma-n$, that is, the accelerated electron energy is converted to bremsstrahlung photons, which subsequently yields neutrons.

LINACs producing high-energy (15–25 MeV) photon beams are becoming widespread (Yücel et al., 2016; Zolfaghari and Sedaghatizadeh, 2016; Gracanic et al., 2017). Low-energy LINACs (<10 MeV) are found useful for neutron radiography and radiation Boron Neutron Capture Therapy (BNCT) in radiation oncology. A 5 MeV electron LINAC with Be and BeD₂ targets can lead to thermal neutron beams of 8.48×10^7 n/cm²/s/mA and 1.23×10^8 n/cm²/s/mA, respectively (Auditore et al., 2005; Hodges et al., 2017).

The use of LINACs for $e-\gamma-n$ conversions as neutron sources in cancer therapy using Boron Neutron Capture Therapy (BNCT) is under development (Martínez et al., 2010; Rahmani and Shahriari, 2010; Farhad Masoudi and Rasouli, 2015; Alikaniotis et al., 2016; Ghal-Eh et al., 2017). BNCT entails the use of thermal neutrons to kill individual cancer cells (e.g., brain tumors) with minimal damage to cancer-free cells. The principle and technique of BNCT is firstly the administration of a ¹⁰B-loaded pharmaceutical to a cancer patient followed by the irradiation of the tumor with thermal neutrons, produced as previously described with the LINAC $e-\gamma-n$ conversion. The ¹⁰B-loaded pharmaceutical concentrates in the cancer cells, and the neutrons react with the ¹⁰B to yield ⁷Li and alpha-particles within the cancer cell according to ¹⁰B(n,α)⁷Li, that is,

The ⁷Li and alpha particles share the kinetic energy liberated in the reaction. Their high mass attributes a high linear energy transfer (LET), high relative biological effectiveness (RBE) and short range of travel of 4.1 and 7.7 μm for the ⁷Li and alpha particles, respectively (Eskandari and Kashian, 2009; Tanaka et al., 2009a; Rahmani and Shahriari, 2010). The total range of 11.8 μm is equivalent to the dimensions of a cell in the human body, thus providing BNCT with the advantage of cell selectivity over other methods of radiotherapy.

Accelerated electron-generated neutrons via the (γ,n) reactions have been reported to yield in a uranium target as many as 10⁻² neutrons per accelerated electron at an electron energy of 30 MeV with a total yield of 2×10^{13} neutrons per second (Bryne, 1994). The use of a uranium target with a 20 MeV linear accelerator as a photoneutron source was

demonstrated by Rahmani and Shahriari (2010) and Rahmani et al. (2010, 2015) yielding an epithermal neutron flux of 2.7×10^9 n/cm²/s/mA for Boron Neutron Capture Therapy. The accelerator is a good neutron source for the potential generation of nuclear fuels. Some other applications of photoneutrons produced by X-rays from electron accelerators are the detection of explosives by the measurement of photoneutron-induced gamma rays (Yang et al., 2007; McFee et al., 2013), photoneutron assay of highly enriched uranium via neutron-induced fission (Lakosi and Nguyen, 2008; Lakosi et al., 2011), and the elemental analysis of short-lived activation products (Patil et al., 2010a,b).

e. Charged-particle accelerator sources

The accelerator utilizes electric and magnetic fields to accelerate beams of charged particles such as protons, electrons, and deuterons into target materials. Nuclear reactions are made possible when the charged particles have sufficient kinetic energy to react with target nuclei. Some of the reactions between the accelerated charged particles and target material can be used to generate neutrons.

When electrons are accelerated, they gain kinetic energy as a function of the particle velocity. This kinetic energy is lost as Bremsstrahlung electromagnetic radiation when the accelerated electrons strike the target material. Bremsstrahlung radiation is described in Section XI.D.2 of this chapter. It is the Bremsstrahlung photons that interact with nuclei to produce neutrons according to the mechanisms described in the previous section under photoneutron (γ,n) sources.

Accelerated deuterons can be used to produce high neutron yields when deuterium and tritium are used as target materials according to the reactions ²H(d,n)³He and ³H(d,n)⁴He, respectively. In the deuterium energy range of 100–400 keV, it is possible to obtain neutron yields of the order of 10¹¹ neutrons per second from these (d,n) reactions with relatively small electrostatic laboratory accelerators (Bryne, 1994; Kim et al., 2008; Eskandari and Kashian, 2009; Park et al., 2009; Zheng et al., 2016; Liu et al., 2016, 2018). The ²H(d,n)³He and ³H(d,n)⁴He reactions are referred to as the D-D and D-T neutron sources. When low-energy deuterons are used as projectiles, the D-D and D-T reactions yield 2.4 and 14.1 MeV fast monoenergetic neutrons, respectively (Eskandari and Kashian, 2009; Tracz et al., 2009; Sharma et al., 2010; Liu et al., 2016). The Q values for the D-D and D-T reactions are 3.27 and 17.58 MeV, respectively, which explains the energy of the neutrons liberated in these reactions. The remaining energy not carried away by the neutrons remains with the residual ³He and ⁴He nuclei of the D-D and D-T reactions. The two (d,n) reactions are the same as the fusion reactions discussed in the subsequent section of this chapter. The low energies of the deuteron projectiles required for the D-D and D-T reactions are advantageous when small

accelerators are used in facilities that utilize neutrons for radiation therapy such as BNCT described in the previous sections of this chapter. Neutrons of higher energy (14–30 MeV) may be obtained from the D-T reactions by increasing the deuteron projectile energy, as the neutron energy is a function of the deuteron energy (Eskandari and Kashian, 2009). By means of a low-energy (350 keV) deuteron beam and a tritium target of 0.37 TBq of ^3H , Ochiai et al. (2007) report the D-T reaction yielding a neutron fluence of 1.5×10^{11} n/s, which was determined by counting the 3.5 MeV alpha-particles. The neutron flux from this generator could be increased 10-fold by increasing the thickness of the ^3H target (Csikai, 1987; Eskandari and Kashian, 2009).

By accelerating deuterons and protons to energies between 1.8 and 4 MeV, neutron generation using beryllium and lithium targets via the following reactions: $^9\text{Be}(d,n)^{10}\text{B}$, $^7\text{Li}(p,n)^7\text{Be}$, and $^9\text{Be}(p,n)^9\text{B}$ are routine (Bayanov et al., 2009a,b, 2010; Eskandari and Kashian, 2009; Feinberg et al., 2009; Iwashita et al., 2011). A higher energy 30 MeV proton beam against a beryllium target was used by Tanaka et al. (2009b), and the fast neutrons were moderated for boron-neutron capture therapy.

The acceleration of protons in the energy range of ~ 0.5 –5 GeV against targets of high atomic number will result in nuclear spallation with the emission of typically 20–30 high-energy neutrons per incoming proton, depending on the energy of the proton beam and the nature of the target material (Samec et al., 2009; Krása et al., 2010). Even higher yields of 40–50 neutrons emitted per proton projectile are possible at the very high proton energies of 4 and 5 GeV (Krása et al., 2010). Nuclear spallation is the process that occurs when a nucleus of high atomic number emits a large number of neutrons following impact by a high-energy projectile. Such reactions are abbreviated often with the notation (p,xn) which signifies a proton projectile with the emission of an x number of neutrons (see Table 1.16). Such high-power neutron sources can yield a neutron flux of up to 10^{14} n/cm² s at the surface of the source. Some typical targets of high mass number, which have favorable spallation-neutron production characteristics, are Hg, W, ^{238}U , Pb, and Th (Aydin et al., 2008; Fomin et al., 2015; Aguilar et al., 2017; Nowicki et al., 2017). The potential of utilizing neutron sources for the generation of nuclear fuels were noted previously in Section X.E.3.c. and research in this field is described by Kulikov et al. (2016).

When protons are accelerated at lower energies of 20–60 MeV against targets of intermediate mass number (e.g., Cr and Cu), the spallation-neutron production characteristics are less favorable, that is, the yield of number of neutrons emitted per proton projectile is lower. Aydin et al. (2008) measured the spallation reaction cross sections for protons in the energy range of up to 100 MeV against target nuclei consisting of isotopes of Cr and Cu. The neutrons

emitted per proton projectile ranged from (p,n) at the low 20–30 MeV proton energies to (p,4n) at the higher 50–60 MeV proton energies. Thus, a cyclotron capable of accelerating protons to 20–60 MeV was found suitable for the production of neutrons from these target materials.

f. Thermonuclear fusion

The fusion of two atomic nuclei into one nucleus is not possible under standard temperature and pressure. The repulsing coulombic forces between the positive charges of atomic nuclei prevent them from coming into the required close proximity of 10^{-15} m before they can coalesce into one. However, as described by Kudo (1995) in a review on nuclear fusion, if temperatures are raised to 100 million degrees, nuclei can become plasmas in which nuclei and electrons move independently at a speed of 1000 km/s, thereby overcoming the repulsing forces between nuclei. Nuclear fusion reactors or controlled thermonuclear reactors (CTRs) are under development to achieve nuclear fusion as a practical energy source. The reactors are based on maintaining plasmas through magnetic confinement as described previously in this chapter (Part VI.C.2). Some fusion reactions also produce neutrons.

The energy liberated during nuclear fusion is derived from the fact that the mass of any nucleus is less than the sum of its component protons and neutrons. This is because protons and neutrons in a nucleus are bound together by strong attractive nuclear forces discussed previously in Section VI.C. of this chapter. As described by Eq. (1.36), earlier in this chapter, the total energy of the nucleus with its bound nucleus is always less than the total energy of the separate protons and neutrons, and this difference is the binding energy of the nucleus. The binding energy is equivalent to the energy required to pull a bound system apart, such as a bound nucleus, leaving its component protons and neutrons free of attractive forces. From Eq. (1.36) we can see that, if it is possible to overcome the repulsive forces of protons in nuclei and fuse the nuclei into a new nucleus of lower mass, energy will be liberated.

Nuclear fusion reactions of two types emit neutrons, and these are of prime interest in man-made CTRs. The first type is fusion between deuterium and tritium nuclei according to

and the other type involves fusion between two deuterium nuclei according to either of the following equations, which have approximately equal probabilities of occurring (Kudo, 1995):

and

FIGURE 1.74 A schematic diagram of a spherical IECF device and its geometrical and electrical parameters, namely, r_a = anode radius (17.10 cm), r_c = cathode radius (3 cm), P = gas pressure (0.07–0.2 Pa), V = discharge voltage (60–120 kV), I_{IEC} = discharge current (2 mA–4 A), and I_{assist} = injected ion current (2–200 mA). The central inner cathode, illustrated as a dashed circle, consists as a spherical wire grid. From *Noborio et al. (2006)* reprinted with permission of Elsevier © 2006.

The fusion reaction between deuterium and tritium or D-T reaction (Eq. 1.317) gives rise to a 14.06-MeV neutron and a 3.52-MeV alpha particle. The D-D fusion reaction of Eq. (1.318) gives rise to a 0.82 MeV ^3He nucleus and a 2.45 MeV neutron; while the D-D fusion reaction of Eq. (1.319) gives rise to a 1.01 MeV ^3H nucleus and 3.03 MeV proton (^1H).

g. Inertial electrostatic confinement fusion

Under development are compact neutron sources, which utilize either D-D or D-T fusion reactions as well as D- ^3He fusion. One instrument described by Miley and Sved (1997) is the inertial electrostatic confinement (IECF) device, which accelerates deuteron ions producing fusion reactions as the ions react with a pure deuterium or deuterium-tritium plasma target. The device is compact measuring 12 cm in diameter and provides a neutron flux of 10^6 – 10^7 2.5-MeV D-D n/s or 10^8 – 10^9 14-MeV D-T n/s.

Advances in the development of IECF devices yield higher neutron fluxes greater than 10^{10} n/s range, and they present no or only a minimal safety concerns when turned off (Sztejnberg Gonçalves-Carralves and Miller, 2015; Ohnishi et al., 2016; Lang et al., 2018). Many designs have been developed for various practical applications as on/off neutron sources. Some of the basic designs will be described briefly in the following paragraphs.

As described by Noborio et al. (2006) IECF involves a basically simple device, which can cause the fusion reaction, and it can be used as a compact neutron-beam generator. A basic IECF device is illustrated in Fig. 1.74. The device consists of a spherical grounded anode that surrounds a much smaller inner spherical grid cathode. Ions are generated by glow discharge in low pressure deuterium gas ($< \sim 2$ Pa), and the ions are accelerated toward the center region by a high electric field. Within the center cathode, concentrated energetic ions collide with each other or with background neutral gases resulting in the D–D fusion reaction or D–T fusion when tritium is also included as a fuel.

As described by Tomiyasu et al. (2010), ions are accelerated to fusion-relevant energies by the electric field between concentric electrodes and circulate inside the outer anode through the inner gridded cathode. The inner cathode consists of a spherical wire grid, which is highly transparent to ions, as illustrated in Fig. 1.75. The objective, as described by Khachan and Samarian (2007) is to create a deep potential well in order to trap ions and confine them for a long enough time, for which reason the concept was called inertial electrostatic confinement (IEC). The inner cathode spherical wire grid may be of many designs including a wire grid design such as that illustrated in Fig. 1.75 and even buckyball-shaped spherical cathodes that resemble the geometry of the C-60 “buckyball” fullerene (Wulfkühler and Tajmar (2016).

FIGURE 1.75 Basic design of a spherical IECF chamber. (Left) A cut-away view of a spherical outer chamber consisting of an anode sphere of 50 cm radius with an inner spherical cathode grid of 3.0 cm radius suspended in the center by a 7-mm-thick dielectric holder with inner cathode rod. The dielectric holder has a total length (h) of 50 cm, and the outer sphere has a skin depth (d) 5 mm. (Right) The mesh structure of the inner cathode sphere with six vertical ring structures. The grid radius G_0 is 3 cm and the skin depth of the wire grid (t) is 5 mm. For the color version of the figure, the reader is referred to the online or electronic version of the book. From *Kurt and Arslan (2012)*; reprinted with permission from Elsevier © 2012.

The first effective IECF device of the spherical design was reported by Hirsh (1967), who obtained a neutron output of $\sim 10^8$ D–D n/s and 10^{10} D–T n/s from a gridded IECF device driven by six ion guns. In addition to the D–D and D–T fusion reactions as neutron sources described by Eqs. (1.317) to (1.319), the IECF device is also a portable proton source yielding 10^8 protons/s utilizing the D– ^3He fusion reaction as described by Ashley et al. (2000), Masuda et al. (2006) and Buzarbaruah et al. (2015). In summary, the fusion reactions that may yield neutrons and/or protons are the following:

D – D fusion:

$$\begin{cases} {}^2_1\text{H} + {}^2_1\text{H} \rightarrow {}^3_2\text{He}(0.82 \text{ MeV}) + {}^1_0\text{n}(2.45 \text{ MeV}) 50\% Q = 3.27 \text{ MeV} \\ {}^2_1\text{H} + {}^2_1\text{H} \rightarrow {}^3_1\text{H}(1.01 \text{ MeV}) + {}^1_1\text{H}(3.03 \text{ MeV}) 50\% Q = 4.04 \text{ MeV} \end{cases} \quad (1.320)$$

$$\begin{aligned} \text{D – T fusion : } & {}^2_1\text{H} + {}^3_1\text{H} \rightarrow {}^4_2\text{He}(3.52 \text{ MeV}) \\ & + {}^1_0\text{n}(14.06 \text{ MeV}) \quad Q = 17.58 \text{ MeV} \end{aligned} \quad (1.321)$$

$$\begin{aligned} \text{D – } ^3\text{He} \text{ fusion : } & {}^2_1\text{H} + {}^3_2\text{He} \rightarrow {}^4_2\text{He}(3.7 \text{ MeV}) \\ & + {}^1_1\text{H}(14.7 \text{ MeV}) \quad Q = 18.4 \text{ MeV} \end{aligned} \quad (1.322)$$

The D–D fusion, as illustrated in Eq. (1.320), may occur via two possible reactions that have equal probabilities of occurrence yielding either 2.45 MeV neutrons or 3.03 MeV protons (Lang et al., 2018). The D–T and D– ^3He fusion reactions yield high-energy (14 MeV) neutrons or protons respectively, according to Eqs. (1.321) and (1.322).

Although the concept of inertial electrostatic confinement fusion had an early beginning, only in the last several years has intense research been devoted to making this a compact portable neutron and proton source. In a review by

Tomiyasu et al. (2010) two approaches have been taken to improve the IECF reaction rates, namely, (1) to increase the ion density by increasing the input current (Yamauchi et al., 2006; Ohnishi et al., 2007; Radel et al., 2007) and (2) to increase the ion energy by reducing the background gas pressure, which reduces the energy loss due to collisions with background neutral ions (Higashi et al., 2003; Piefer et al., 2005; Miley et al., 2005; Takamatsu et al., 2006; Buzarbaruah et al., 2015).

Tomiyasu et al. (2010), Dursun and Kurt (2016) and Dursun et al. (2017) proposed cylindrical chambers with inner cathode and outer anode with magnetic-assisted electrostatic confinement whereby the ion motion can be controlled, as illustrated in Fig. 1.76. With the application of an appropriate magnetic field, the ions are forced to an azimuthal direction by Lorentz force as they are accelerated toward the center of the electric field. Gridless cathode designs in IECF chambers are under research, as gridded cathodes lead to heating, thermionic electron emission, power loss and even ultimate grid melting and these are reviewed by Knapp (2015).

In addition to efforts to increase the reaction rates achieved with the IECF device, research is conducted toward the practical applications of the device as a portable neutron or proton source in light of its simple configuration and compact size. Applications of such a portable neutron and proton source include the detection and measurement of highly enriched uranium (Radel et al., 2007), the detection of explosives including landmine detection (Yoshikawa et al., 2007a,b and Takahashi et al., 2010), isotope production (Cipiti and Kulcinski, 2005; Ohnishi et al., 2016), and medical applications including neutron irradiation facilities for Boron Neutron Capture Therapy in

the treatment of various cancers (Sztejnberg Gonçalves-Carralves and Miller, 2015). Because of the simplicity and compact size of the IECF device, Yoshikawa et al. (2007a) list numerous applications subject to the expected improvements in reactions rates achieved by this neutron/proton source. These applications are listed in Fig. 1.77.

4. Interactions of neutrons with matter

If a neutron possesses kinetic energy, it will travel through matter much more easily than other nuclear particles of similar energy, namely, alpha particles, negatrons, positrons, protons, or electrons. In great contrast to other nuclear particles, which carry charge, the neutron, because it lacks charge, can pass freely through the Coulombic barrier of the atomic electrons and actually collide with nuclei of atoms and be scattered in the process or be captured by the nucleus of an atom. Collision of neutrons with nuclei can result in scattering of the neutrons and recoil nuclei with conservation of momentum (elastic scattering) or loss of kinetic energy of the neutron as gamma radiation (inelastic scattering). The capture of a neutron by a nucleus of an atom may result in the emission of other nuclear particles from the nucleus (nonelastic reactions) or the fragmentation of the nucleus into two (nuclear fission). A brief treatment of the various types of neutron interactions, which are based on their scattering or capture by atomic nuclei, is provided next.

a. Elastic scattering

The elastic scattering of a neutron by collision with an atomic nucleus is similar to that of billiard-ball collisions. A portion of the kinetic energy of one particle is transferred to the other without loss of kinetic energy in the process. In other words, part of the kinetic energy of the neutron can be transferred to a nucleus via collision with the nucleus, and the sum of the kinetic energies of the scattered neutron and recoil nucleus will be equal to the original kinetic energy of the colliding neutron. This

FIGURE 1.78 Elastic scattering of a neutron by collision of the neutron with an atomic nucleus. The neutron is scattered at an angle α and the nucleus recoils at an angle β to the direction of travel of the incident neutron.

process of interaction of neutrons with matter results only in scattering of the neutron and recoil nucleus. It does not leave the recoil nucleus in an excited energy state. Elastic scattering is a common mechanism by which fast neutrons lose their energy when they interact with atomic nuclei of low atomic number, such as hydrogen (^1H) in light water or paraffin, deuterium (^2H) in heavy water, and ^{12}C in graphite, which may be encountered in nuclear reactor moderators. It is easy to conceptualize what would occur when particles of equal or similar mass collide; the event would result in energy transfer and scattering without any other secondary effects, similar to what occurs in billiard-ball collisions.

Neutron scattering is the principal mechanism for the slowing of fast neutrons, particularly in media with low atomic number. Let us consider what occurs when a neutron collides with a nucleus and undergoes elastic scattering. Fig. 1.78 illustrates the direction of travel of an incident neutron with given kinetic energy (dashed line). The neutron collides with the nucleus. The nucleus is illustrated as undergoing recoil at an angle β , while the neutron is scattered at an angle α to the direction of travel of the incident neutron. The kinetic energy (E_k) lost by the neutron in this collision is defined by the equation

$$E_k = \frac{4Mm_n}{(M + m_n)^2} \cos^2 \beta \quad (1.323)$$

where M is the mass of the nucleus, m_n is the mass of the neutron, and β is the recoil angle of the nucleus. A derivation of Eq. (1.323) is provided by Bacon (1969). Let us look at two extreme examples of elastic collisions between a neutron and a nucleus. In the first example, it is intuitively obvious from Eq. (1.323), that for a recoil angle $\beta = 90$

TABLE 1.19 The maximum fraction of the kinetic energy (E_k) that a neutron can lose upon collision with the nucleus of various atoms listed in increasing mass in atomic mass units (u).

Nuclide	Nuclide mass, M	Neutron mass, m_n	$E_k = \left(\frac{4Mm_n}{(M+m_n)^2} \right) \cos^2 \beta$
^1H	1.007825	1.008665	$4.065566/4.066232 = 0.999$ or 99.9%
^2H	2.014102	1.008665	$8.126217/9.137120 = 0.89$ or 89%
^9Be	9.012182	1.008665	$36.36109/100.41737 = 0.362$ or 36.2%
^{12}C	12.000000	1.008665	$48.41592/169.22536 = 0.286$ or 28.6%
^{16}O	15.994915	1.008665	$64.53404/289.12173 = 0.223$ or 22.3%
^{28}Si	27.976927	1.008665	$112.87570/840.16454 = 0.134$ or 13.4%
^{55}Mn	54.938047	1.008665	$221.65633/3130.0329 = 0.071$ or 7.1%
^{197}Au	196.96654	1.008665	$787.86616/39194.175 = 0.020$ or 2.0%

degrees, $\cos^2 \beta = 0$, and consequently $E_k = 0$. Under such a circumstance, the neutron is undeflected by the nucleus and there is no energy transfer to the nucleus. The neutron continues along its path undeflected until it encounters another nucleus. For the second case, however, let us consider the other extreme in which the recoil angle, $\beta = 0^\circ$, where we have a head-on collision of the neutron with the nucleus of an atom. In this case, the maximum possible energy of the neutron is imparted to the nucleus, where $\cos^2 \beta = 1$. For example, Table 1.19 provides the maximum fraction of the kinetic energy, calculated according to Eq. (1.323), that a neutron can lose upon collision with various atomic nuclei. As illustrated in Table 1.19, the neutron can transfer more energy to the nuclei of atoms, which have a low mass, and the highest fraction of its energy can be transferred to the nucleus of the proton, which is almost equal in mass to the neutron. Nuclides of low mass number are, therefore, good moderators for the slowing down of fast neutrons. The substances often used are light water (H_2O), heavy water (D_2O), paraffin ($\text{C}_n\text{H}_{2n+2}$), and graphite (C).

b. Inelastic scattering

We may picture a fast neutron colliding with a nucleus. The neutron is scattered in another direction as described in the previous paragraph; however, part of the neutron's kinetic energy is lost to the recoil nucleus, leaving it in an excited metastable state. Inelastic scattering can occur when fast neutrons collide with nuclei of large atomic number. The recoil nucleus may lose this energy immediately as gamma radiation or remain for a period of time in the excited metastable state. Inelastic scattering occurs mainly with fast neutron collisions with nuclei of large atomic number.

Neutron scattering is a common mechanism by which fast and intermediate neutrons are slowed down to the thermal neutron energy levels. Thermal neutrons have an

energy level at which they are in thermal equilibrium with the surrounding atoms at room temperature. There is an energy range for thermal neutrons, as described earlier in this chapter; however, the properties of thermal neutrons are often cited at an energy calculated to be the most probable thermal neutron energy of 0.0253 eV at 20.43°C corresponding to a velocity of 2200 m/s (Gibson and Piesch, 1985 and Holden, 1997a,b). Fig. 1.71, illustrated earlier in this chapter, may be used to find the velocity of the neutron at energy levels over the range 0.001 eV–10 MeV. For example, if we select the position 0.025 eV on the X axis and follow up the graph with a straight line to the upper curve, we find the value 2200 m/s. At the thermal energy state, the mechanisms of interaction of neutrons with matter change drastically as discussed in the following section.

c. Neutron capture

Because of the neutral charge on the neutron, it is relatively easy for slow neutrons, regardless of their low kinetic energy, to “find themselves” in the vicinity of the nucleus without having to hurdle the Columbic forces of the atom. Once in close proximity to nuclei, it is easy for slow neutrons to enter into and be captured by nuclei to cause nuclear reactions. The capture of thermal neutrons, therefore, is possible with most radionuclides, and neutron capture is the main reaction of slow neutrons with matter. The power of a nucleus to capture a neutron depends on the type of nucleus as well as the neutron energy. The neutron absorption cross section, σ , with units of 10^{-24} cm^2 or “barns,” is used to measure the power of nuclides to absorb neutrons. A more detailed treatment of reaction cross section and its units and application was given earlier in Section IX.D, and this is provided further on in Section X.E.5 of this chapter. Because the capture of thermal neutrons is possible with most radionuclides, references

TABLE 1.20 Cross Sections σ in barns for thermal neutron capture reactions of selected nuclides in order of increasing magnitude.

Nuclide	σ (barns)
^3_1H	<0.000006
$^{16}_8\text{O}$	0.00019
^2_1H	0.00052
$^{12}_6\text{C}$	0.0035
^1_1H	0.332
$^{14}_7\text{N}$	1.8
$^{238}_{92}\text{U}$	2.7
$^{232}_{90}\text{Th}$	7.4
$^{55}_{25}\text{Mn}$	13.3
$^{233}_{92}\text{U}$	530
$^{235}_{92}\text{U}$	586
$^{239}_{94}\text{Pu}$	752
^6_3Li	940
$^{10}_5\text{B}$	3840
^3_2He	5330
^7_4Be	39,000
$^{155}_{64}\text{Gd}$	61,000
$^{157}_{64}\text{Gd}$	254,000

Data from [Holden \(1997a,b\)](#) and [Lide \(2010\)](#).

will cite the neutron capture cross sections of the nuclides for comparative purposes at the thermal neutron energy of 0.0253 eV equivalent to a neutron velocity of 2200 m/s. This is also the energy of the neutron, which is in thermal equilibrium with the surrounding atoms at room temperature. For comparative purposes, therefore, [Table 1.20](#) lists the cross sections for thermal neutron capture reactions in barns (10^{-24} cm^2) for several nuclides. The nuclides selected for [Table 1.20](#) show a broad range of power for thermal neutron capture. Some of the nuclides listed have practical applications, which are referred to in various sections of this book.

The capture of a slow neutron by a nucleus results in a compound nucleus, which finds itself in an excited energy state corresponding to an energy slightly higher than the binding energy of the neutron in the new compound nucleus. This energy of excitation is generally emitted as gamma radiation. Neutron capture reactions of this type are denoted as (n, γ) reactions. Two practical examples of (n, γ) neutron capture reactions were provided earlier in this chapter in the neutron irradiation of ^{238}U and ^{232}Th for the preparation of fissile ^{239}Pu and ^{233}U ([Eqs. 1.310](#)

to [1.315](#)), respectively. Another interesting example of a (n, γ) reaction is the neutron capture by ^{235}U according to the following:

This neutron capture reaction is interesting because the ^{236}U product nuclide decays by alpha emission with a very long half-life ($2.4 \times 10^7 \text{ y}$) in $\sim 14\%$ of the cases and decays by nuclear fission with emission of neutrons in the remaining 86% of the cases, as discussed previously in [Section X.E.3.c](#). The subject of neutron capture is treated in more detail in [Section X.E.5](#), which concerns the neutron cross section and neutron attenuation in matter.

d. Nonelastic reactions

Neutron capture can occur in nuclei resulting in nuclear reactions that entail the emission of nuclear particles such as protons (n,p), deuterons (n,d), alpha particles (n, α), and even neutrons (n,2n). These reactions may not occur in any specific energy range but may be prevalent at specific resonances, which are energy states of the excited compound nuclei that are specific to relatively narrow energies of the incident neutron. The effect of resonance in neutron capture by nuclei is discussed in more detail subsequently in [Section X.E.5](#). The (n,2n) reactions occur at very high incident neutron energies, $>10 \text{ MeV}$ ([Gibson and Piesch, 1985](#)). The (n,p) and (n, α) reactions can occur in the slow neutron capture and reaction with nuclides of low atomic number (low Z), where the Coulomb forces of the electron shells are limited and present less a hurdle for the escape of charged particles from the confines of the atom. Some practical examples of these reactions are the (n,p) reaction used in the synthesis of ^{14}C by slow (thermal) neutron capture by ^{14}N

and the (n,p) and (n, α) reactions used to detect neutrons by the interaction of slow neutrons with ^3He and ^{10}B , respectively, according to [Eqs. \(1.326\)](#) and [\(1.327\)](#).

Either of these reactions is used to detect neutrons by using gas proportional detectors containing helium-3 gas or a gaseous form of boron (e.g., boron trifluoride). Slow neutrons that penetrate these detectors produce either radioactive tritium ([Eq. 1.326](#)) or alpha particles ([Eq. 1.327](#)), which produce ionization in the gas. The ionization events or ion pairs formed can be collected and counted to determine a neutron count rate.

e. Nuclear fission

The reaction of neutron-induced fission occurs when a neutron interacts with a fissile or fissionable nucleus and the nucleus becomes unstable, taking on the characteristics of an oscillating liquid droplet, which then fragments into two nuclides (fission fragments). At the same time, there is the release of neutrons (2.4 neutrons on the average for neutron-induced ^{235}U fission) and a relatively high amount of energy (~ 194 MeV for neutron-induced ^{235}U fission). Neutron-induced fission of natural ^{235}U and man-made ^{233}U and ^{239}Pu is optimal at thermal incident neutron energies; whereas, neutron-induced fission in ^{232}Th , ^{238}U and ^{237}Np requires neutron energies of at least 1 MeV. A more detailed treatment of nuclear fission was provided previously in Sections VI.C, VI.D, and X.E.3.c of this chapter.

5. Neutron attenuation

The neutron, because of its neutral charge, has a relatively high penetration power in matter. Unlike charged particles, neutrons will not be impeded by the atomic electrons of the material through which the neutrons travel, and the neutron will consequently not lose energy via ionization. However, neutrons will interact with the nuclei of matter. As discussed previously in this chapter, there are several possible interactions of neutrons with nuclei. Among these are elastic scattering, inelastic scattering, neutron capture, nonelastic reactions, and neutron-induced nuclear fission. As we have seen in several examples, probabilities exist for any of these interactions to occur depending on the energy of the incident neutron and the mass of the nuclide with which the neutron interacts. Atoms of low mass (e.g., ^1H , ^2H , ^9Be , ^{12}C) have a higher probability of slowing-down neutrons than atoms of high mass, as seen previously

FIGURE 1.79 Attenuation of a neutron flux I_0 incident on a sample of thickness x . The neutron flux, after passing through the sample is reduced in intensity (I) as a result of interactions with atomic nuclei of the sample. Several interactions of neutrons with atomic nuclei are possible (e.g., elastic and inelastic scattering, neutron capture, and nonelastic reactions including (n, γ) , (n, p) , (n, α) , and (n, d) , among others. The reactions of neutrons with the nuclei will depend on the incident neutron energy, the magnitude of the cross section of a particular interaction of the nuclide with which the neutron interacts, and the density of the nuclide in the sample (nuclei/cm³).

from the data of Table 1.19. We can define this probability of interaction of neutrons with specific nuclei by the magnitude of the cross section of the interaction, which is a measure of the power of interaction of a particular nucleus for neutrons of a specific energy.

The transmission of neutrons in matter is a function of the neutron energy and the cross section or interaction power of the atoms of the material through which the neutrons travel. The cross section then is a measure of the probability that a particular neutron interaction will occur, as described previously in Part IX.D of this chapter. Fig. 1.79 illustrates various types of interaction of neutrons with atomic nuclei as the neutrons travel through a target material. We can consider an incident beam of neutrons of given intensity or flux (I_0), which is defined in units of neutrons/cm²·s). The incident neutrons impinge on a material of unit area (e.g., cm²) and thickness x , as illustrated in Fig. 1.79.

Earlier in Part IX.D of this chapter, Eqs. (1.148) and (1.149) were described whereby the rate of reaction of the particles of an incident particle beam with respect to the incident particle beam intensity is proportional to the effective target area (cm²) and total target area that the nuclei present to the incident particles, which is expressed as

$$\frac{\text{Rate of reaction (particles/s)}}{\text{Beam intensity (particles/s)}} = \frac{\text{Effective target area (cm}^2\text{)}}{\text{Total target area (cm}^2\text{)}} \quad (1.328)$$

In accord with the Eq. (1.328) and the previously described Eq. (1.149) (Part IX.D of this chapter), we can express the rate of reaction as the change in the intensity of incident particles (dI) with respect to the incident particle intensity (I) to be proportional to the effective target area. i.e., effective nuclei and its numbers in the target area ($N\sigma A dx$) and the total target area (A) and or

$$-\frac{dI}{I} = \frac{N\sigma A dx}{A} = N\sigma dx \quad (1.329)$$

where the negative sign signifies the diminishing particle beam intensity. Thus, the rate of change of the neutron flux or intensity (dI) with respect to the incident neutron flux or intensity (I) will be proportional to the number of effective nuclei (N) per unit volume in the material (# of nuclei/cm³) and the “area of obstruction” (e.g., cm²) or nuclei cross section of obstruction that the nuclei present to the incident neutron flux. Eq. (1.329) can be integrated over the limits of beam intensity from I_0 to I and absorber thickness from 0 to x as follows:

$$\int_{I_0}^I \frac{dI}{I} = -N\sigma \int_0^x dx \quad (1.330)$$

to give the equation

$$\ln(I/I_0) = -N\sigma x \quad (1.331)$$

or

$$I = I_0 e^{-N\sigma x} \quad (1.332)$$

Eq. (1.332) is generally written as

$$I = I_0 e^{-\Sigma x} \quad (1.333)$$

where, as described in an early research paper by Vandecasteele et al. (1973), I is the neutron flux ($\text{n/cm}^2 \text{ s}$) after passing through a sample of thickness x (cm), I_0 is the incident neutron flux (i.e., the neutron flux without the sample in its path), and Σ is the macroscopic cross section (cm^{-1}) for neutrons at a given neutron energy. The macroscopic cross section (Σ) embodies the effective target area of all of the nuclei in the target volume; whereas, the microscopic cross section (σ) embodies the effective target area of a single target nucleus. Because target areas generally contain different nuclides, Eq. (1.333) is written as

$$I = I_0 e^{-\Sigma_t x} \quad (1.334)$$

where $\Sigma_t = N\sigma_t$ is the total macroscopic cross section, as described by Tellili et al. (2014), with units of cm^{-1} , where N is the number of nuclei per unit volume (e.g., # of nuclei/ cm^3) of target material, and σ_t is the total microscopic cross section with units in barns where $1 \text{ barn} = 10^{-24} \text{ cm}^2$. The macroscopic cross section, Σ_t , has units of cm^{-1} , and it is calculated from the following

$$\Sigma_t = N\sigma_t = \left(\frac{\delta N_A}{A} \right) \sigma_t \quad (1.335)$$

where δ is the density of the target material (g/cm^3), N_A is Avogadro's number (6.022×10^{23} molecules or nuclei/mol), A is the molar mass (g/mol), that is the nuclide mass in units of g/mol or gram molecular weight (g/mol) of a molecular compound, and σ_t is the total microscopic cross section of a nucleus in the target material at a particular neutron energy. The term

$$\frac{\delta N_A}{A} = N \quad (1.336)$$

is the number of nuclei of a given nuclide per unit volume (# of nuclei/ cm^3), as described by Vandecasteele et al. (1973). The magnitude of σ_t is a measure of the probability that a neutron of a given energy interacts with the atoms of the material through which the neutrons travel, and it is defined as the sum of the microscopic cross section for neutron scattering (σ_s) and the microscopic cross section for neutron absorption (σ_a),

$$\sigma_t = \sigma_s + \sigma_a \quad (1.337)$$

as described by Tellili et al. (2014). In the case of a mixture of nuclides in the target material, the total macroscopic cross section, Σ_t , is the sum of the macroscopic cross sections of all of the different nuclides or

$$\Sigma_t = N_a \sigma_a + N_b \sigma_b + N_c \sigma_c + \dots \quad (1.338)$$

where N_a , N_b , and N_c are the number of nuclei of each element per unit volume (# of nuclei/ cm^3), σ_a , σ_b , and σ_c are the total microscopic cross sections of each of the different nuclides in the sample, as described in reviews by Tellili et al. (2014) and Elmahroug et al. (2015).

Microscopic cross sections (σ) in units of barns, where $1 \text{ barn} = 10^{-24} \text{ cm}^2$, for specific nuclides as a function of neutron energy are available from tables or plots of cross section versus neutron energy online from the Brookhaven National Laboratory, National Nuclear Data Center (NNDC) (<http://www.nndc.bnl.gov/sigma/index.jsp?as=1&lib=endfb7.1&nsup=10>). The tables of microscopic cross sections for specific nuclides (e.g., ^1H , ^2H , ^{10}B , ^{12}C , etc.) and specific neutron energies in eV are separated into various types such as the total cross section or cross sections for specific neutron interactions or reactions with a nuclide such as elastic interactions, inelastic interactions, nonelastic reactions and specific reactions such as (n, γ), (n,p), (n,d), and (n, α), among others.

To take an example of a calculation of neutron attenuation, we can consider a case where the absorber material consists of only one pure nuclide, and calculate the attenuation of an incident neutron flux by pure aluminum. Elemental aluminum consists of 100 atom % of the nuclide ^{27}Al , and we will calculate the attenuation of thermal neutrons (0.0253 eV) by aluminum and determine the

FIGURE 1.80 Cross section plots for neutron interactions in Aluminum-27 over the neutron energy range 10^{-5} to 10^8 eV. Three plots are illustrated from top to bottom, namely, total cross section (n, total), elastic interaction cross section (n, elastic), and neutron capture cross section (n, gamma). From the Brookhaven National Laboratory (BNL), National Nuclear Data Center (NNDC) online data <http://www.nndc.bnl.gov/sigma/index.jsp?as=Elemental&lib=endfb7.1&nsup=10>.

thickness (x) of aluminum required to attenuate an incident neutron flux by one-half or 50%. The total microscopic cross section in units of barns where 1 barn = $1 \times 10^{-24} \text{ cm}^2$ for the most common nuclides and a wide range of neutron energies from 10^{-5} – 10^8 eV can be obtained from the Internet online tables of the Brookhaven National Laboratory (BNL) National Nuclear Data Center (NNDC) Website: <http://www.nndc.bnl.gov/sigma/index.jsp?as=1&lib=endfb7.1&nsb=10>). In the case of ^{27}Al , the total microscopic cross section (σ_t), identified as “n, total” on the BNL website, is 1.69 barns, which is equivalent to $1.69 \times 10^{-24} \text{ cm}^2$. See also Fig. 1.80, which pro-

Eq. (1.339) can be transposed to read

$$\ln \frac{I_0}{I} = \left(\frac{\delta N_A \sigma_t}{A} \right) x \quad (1.340)$$

If we assign to the incident unattenuated neutron flux I_0 , the value of unity (i.e., $I_0 = 1$), we should assign the value of the attenuated neutron flux intensity $I = 0.5$ to determine the value of the thickness of the medium x when the incident neutron flux intensity is reduced by one-half. In this case, the ratio of $I_0/I = 1/0.5 = 2$, and we can then solve for the value of the thickness of aluminum required to attenuate the neutron flux by 50% according to Eq. (1.340) as

$$\begin{aligned} \ln \frac{I_0}{I} &= \left(\frac{\delta N_A \sigma_t}{A} \right) x \\ \ln 2 &= \left[\frac{(2.70 \text{ g/cm}^3)(6.022 \times 10^{23} \text{ }^{27}\text{Al atoms/mol})(1.69 \times 10^{-24} \text{ cm}^2/\text{ }^{27}\text{Al atom})}{26.98 \text{ g/mol}} \right] x \\ 0.693 &= [(6.026 \times 10^{22} \text{ }^{27}\text{Al atoms/cm}^3)(1.69 \times 10^{-24} \text{ cm}^2/\text{ }^{27}\text{Al atom})] x \\ 0.693 &= (0.1018 \text{ cm}^{-1}) x \\ x &= 6.81 \text{ cm} \end{aligned}$$

vides plots of the microscopic cross sections for neutron elastic scattering (n, elastic), neutron capture (n, gamma), and the total microscopic cross section (n, total). If we have an incident neutron flux of 5×10^{14} neutrons/cm²·s, we can calculate the thickness, x , of aluminum necessary to attenuate the neutron flux as follows:

From Eq. (1.334) we can write

$$I = I_0 e^{-\Sigma_t x} = I_0 \exp - (N \sigma_t) x = I_0 \exp - \left(\frac{\delta N_A \sigma_t}{A} \right) x \quad (1.339)$$

If we, in turn want to determine the magnitude of the attenuation of a certain incident neutron flux with respect to the thickness of the material through which the neutrons must travel, we can use Eq. (1.339). Taking the above calculated aluminum thickness of $x = 6.81 \text{ cm}$, we can calculate the attenuation of an incident neutron flux $I_0 = 5 \times 10^{14}$ neutrons/cm²·s as follows

$$\begin{aligned} I &= I_0 \exp - \left(\frac{\delta N_A \sigma_t}{A} \right) x \\ I &= (5 \times 10^{14} \text{ n/cm}^2 \cdot \text{s}) \exp - \left[\frac{(2.70 \text{ g/cm}^3)(6.022 \times 10^{23} \text{ }^{27}\text{Al atoms/mol})(1.69 \times 10^{-24} \text{ cm}^2/\text{ }^{27}\text{Al atom})}{26.98 \text{ g/mol}} \right] 6.81 \text{ cm} \\ I &= (5 \times 10^{14} \text{ n/cm}^2 \cdot \text{s})(0.50) \\ I &= 2.5 \times 10^{14} \text{ n/cm}^2 \cdot \text{s} \end{aligned}$$

FIGURE 1.81 Neutron capture cross sections of some nuclides important for neutron detection as a function of neutron energy. The lowest curve shows a typical moderated neutron spectrum of a nuclear reactor (right y-axis).

If we were to consider other natural or synthetic materials that contain a mixture of different nuclides, each nuclide would possess a different total cross section (σ_t) and different concentration per unit volume in the material. This would require the calculation of the total macroscopic cross section (Σ_t), which is the sum of the macroscopic cross sections of all of the different nuclides in the material as described by Eq. (1.338).

In the above example, the total cross section was chosen to calculate the neutron attenuation, because the total cross section represents all types of interaction that can result from the collision of a neutron with an atom within the material it travels (Anders and Briden, 1964; Vandecasteele et al., 1973). However, certain reaction cross sections are more relevant when it is our interest to optimize the detection efficiency of neutron radiation rather than the total neutron attenuation of neutron flux. For example, neutron capture cross sections for reactions of neutrons with nuclides that result in the production of easily detectable products or particles such as ^3H or protons from ^6Li , fission products from ^{235}U , alpha particles from ^6Li and ^{10}B , protons from ^6Li , conversion electrons and gamma radiation from ^{155}Gd , ^{157}Gd and ^{113}Cd would be more relevant than neutron scattering cross section interactions. The neutron capture cross sections of several nuclides used in the detection of neutrons are plotted as a function of neutron energy in Fig. 1.81.

The above treatment dealt with the attenuation of slow neutron energies where neutron absorption reactions can be relevant in the total neutron cross section σ_t used in the calculation of the macroscopic cross section Σ_t . During early research into neutron attenuation (Anders and Briden, 1964; Vandecasteele et al., 1973) it

was recognized that at slow neutron energies the total neutron cross section would be the most appropriate, because σ_t “represents all interaction processes that may result from the collision of a neutron with an atom”. However, early researchers also noted that for fast neutrons (2–12 MeV) elastic scattering with heavy nuclei would be significant, because the elastic scattering would change the direction of neutrons away from the beam of penetrating uncollided neutrons (Blizard and Abbot, 1962; Nargowalla et al., 1968, 1970; Adams et al., 1971; Vandecasteele et al., 1973). Thus, they concluded that another macroscopic cross section called the removal cross section, Σ_R with units of cm^{-1} , would provide the best measure of neutrons removed via scattering from the main penetrating neutron flux.

Treatments on the theory of fast neutron attenuation and the calculation of the macroscopic removal cross sections Σ_R of many natural and synthetic materials are provided by El-Khayatt (2010, 2011), El-Khayatt and El-Sayed Abdo (2009), El-Khayatt and Akkurt (2013), Kurudirek et al. (2014), Tellili et al. (2014) and Elmahroug et al. (2015). Excellent descriptions of fast neutron attenuation is provided by Tellili et al. (2014) and Elmahroug et al. (2015) and a brief summary of their explanation will be provided here. In the case of fast neutrons, which are in the MeV energy range (e.g., 2–12 MeV), the most probable mechanism of removal of fast neutrons from the penetrating neutron beam is via elastic scattering, and all other known mechanisms of neutron interaction with atomic nuclei are negligible. An exception would be the case of fast neutrons penetrating water or other compound high in hydrogen atoms due to the similarity of mass between neutrons and protons resulting in efficient neutron attenuation via

neutron-proton collision; however, for the heavy elements, elastic scattering of fast neutrons is the main mechanism for the removal of neutrons from the fast group of penetrating neutron flux. Tellini et al. (2014) and Elmahroug et al. (2015) note that fast neutron attenuation is described by the macroscopic removal cross section, Σ_R (cm^{-1}), which is different from the total macroscopic cross section, and it is a fraction of it. The Σ_R is approximately 2/3 of the total Σ_t between neutron energies of 6–8 MeV except for materials containing a lot of hydrogen for which the $\Sigma_R \cong \Sigma_t$. The removal cross section is a measure of the probability that a fast neutron will undergo a first elastic collision with an atomic nucleus, which removes the neutron of penetrating uncollided neutrons (Tellini et al., 2014). The neutrons that are removed by this initial elastic collision lose some of their initial kinetic energy and are then able to undergo additional elastic collisions with nuclei in the medium and until they fall into the thermal neutron energy range. At this low energy range, the neutrons will undergo neutron capture as described previously in this chapter.

Computer programs for the calculation of the macroscopic removal cross sections of natural and synthetic material are provided by El-Khayatt (2010, 2011), El-Khayatt and El-Sayed Abdo (2009), El-Khayatt and Akkurt (2013) and Elmahroug et al. (2015). The following empirical equations, which relate the macroscopic removal cross section to the atomic weight of an element have been developed based on experimental and calculated data based on measurements at 8 MeV neutron energies (Kurudirek et al., 2014):

$$\Sigma_R = 0.21A^{-m} \text{ cm}^{-1} \quad (1.341)$$

where A is the atomic weight in g/mol and m is a constant. A value of $m = 0.56$ was found by Kurudirek et al. (2014) to provide the best agreement with experimental and calculated data. When more than one element is found in the material, Eq. (1.341) is modified with an effective atomic weight, A_{eff} , or

$$\Sigma_R = 0.21A_{\text{eff}}^{-m} \text{ cm}^{-1} \quad (1.342)$$

and the effective atomic weight for a multielement material is obtained from the following:

$$A_{\text{eff}} = \left(\sum_i w_i A_i^{-m} \right)^{-1/m} \quad (1.343)$$

where w_i is the weight fraction and A_i is the atomic weight of the i th constituent element (Kurudirek et al. (2014)).

As the examples illustrate in Figs. 1.80 and 1.81, the neutron cross section of nuclei decreases as the energy or velocity of the neutron increases. That is, the neutron reactions with nuclei obey the general rule of having some proportionality to $1/v$, where v is the velocity of the

neutron. This inverse proportionality of cross section and neutron velocity is particularly pronounced in certain regions of energy as illustrated in the total neutron cross section curves illustrated in Figs. 1.80 and 1.81, respectively. However, this is not always the case with many nuclides at certain neutron energies where there exists a resonance between the neutron energy and the nucleus. At some specific or very narrow neutron energy ranges, certain nuclei have a high capacity for interaction with neutrons. The elevated neutron cross sections at specific neutron energies appear as sharp peaks in plots of neutron cross section versus energy, such as some of the cross section plots illustrated in Figs. 1.80 and 1.81. These peaks are called resonances and often occur with (n,γ) reactions. The high cross sections occur when the energy of the incident neutron corresponds exactly to the quantum state of the excited compound nucleus, which is the newly formed nucleus consisting of a compound between the incident neutron and the nucleus. Most nuclides display both the $1/v$ dependence on neutron cross section and the resonance effects over the entire possible neutron energy spectrum.

We should keep in mind that neutron cross sections can be specific and differ in value for certain reactions, such as proton (σ_p)- and alpha particle (σ_α)-producing reactions, fission reactions (σ_f), or neutron capture cross sections (σ_c). The total neutron cross section (σ_{tot}) would be the cross section representing the sum of all possible neutron reactions at that specific neutron energy. For example, the thermal neutron cross section for ^{235}U , which is the neutron cross section at 0.0253 eV neutron energy corresponding to a neutron velocity of 2200 m/s at room temperature, can be given as $\sigma_c = 95$ barns for the neutron capture cross section, $\sigma_f = 586$ barns for the fission cross section, and $\sigma_\alpha = 0.0001$ barns for the neutron cross section for the alpha particle-producing reaction. These neutron cross section values indicate that neutron fission would predominate at the thermal neutron energy of 0.0253 eV, although some neutron capture would also occur. The total neutron cross section, σ_{tot} , would be the total of the three possible reactions or $\sigma_{\text{tot}} = 95 \text{ barns} + 586 \text{ barns} + 0.0001 \text{ barns} = 681 \text{ barns}$. In our treatment of slow neutron capture by ^{235}U in Section X.E.4.c, illustrated by Eq. (1.324), we noted that about 14% of the slow neutron captures by ^{235}U nuclei result in the formation of a long-lived ^{236}U and gamma radiation, and the remaining 86% of the slow neutron captures result in nuclear fission. This is exactly what is predicted by the thermal neutron cross section values just provided; that is, for ^{235}U

$$\sigma_c/\sigma_{\text{tot}} = 95\text{barns}/681\text{barns} = 14\% \text{ neutron capture}$$

and

$$\sigma_f/\sigma_{\text{tot}} = 586 \text{ barns}/681 \text{ barns} = 86\% \text{ fission}$$

6. Neutron decay

We have seen that fast neutrons may lose their energy through elastic and inelastic collisions with other nuclei, and if these neutrons do not undergo other reactions with nuclei, they may lose sufficient energy to reach thermal equilibrium with surrounding atoms and possibly be captured by atomic nuclei. The question remains of what would happen to a free neutron that is not absorbed by any atomic nucleus.

Earlier in this chapter (Section X.B.1) we discussed the transformation of the neutron within nuclei of radioactive atoms, which have a neutron/proton ratio too high for stability. In these unstable nuclides the neutron breaks up into a proton, negatron (negative electron), and antineutrino (see Eq. 1.175). If the neutron can transform itself in unstable nuclei, it stands to reason that the neutron might be unstable outside the protective boundaries of the stable nucleus. This is just the case, which A. H. Snell and L. C. Miller demonstrated in 1948. This work was followed with further studies by Robson (1950a,b) and Snell et al. (1950), that demonstrated neutrons in free flight in a vacuum would indeed decay with a lifetime in the range of 9–25 minutes with a release of 0.782 MeV of energy. Later more accurate measurements of neutron decay by researchers including Andreev et al. (2017), Arzumanov (2015), Arzumanov, et al. (2000a,b), Pichlmaier et al. (2000, 2010) and Serebrov et al. (2008, 2013) among others, determined the neutron lifetime to be 878.5 ± 0.8 s, which is close to 15 minutes. Much research has been carried out over the past several years to obtain the most accurate measurement of the neutron lifetime (Andreev et al., 2017; Coakley, 2007; Wilkinson, 2007; Serebrov et al., 2008, 2013; Arzumanov, 2009, 2015; Dewey et al., 2009; Ezhov et al., 2009; Leung and Zimmer, 2009; Materne et al., 2009; Müller et al., 2009; O'Shaughnessy et al., 2009; Walstrom et al., 2009; Pichlmaier et al., 2010), which is an important physical parameter. The most accurate measurement of the neutron lifetime will help answer questions in particle and astrophysics. In particle physics, the neutron lifetime will help us address the weak interaction parameters within baryons, such as the transformation of a “d” quark into a “u” quark described in Section VI.B of this chapter (Walstrom et al., 2009). In astrophysics the neutron lifetime is a key process in establishing the model for the Big-Bang primordial nucleosynthesis whereby there was an equilibrium of neutrons and protons a few minutes after the Big-Bang described by Paul (2009). A detailed treatment of the Big-Bang primordial nucleosynthesis is given in previous books by the writer (L'Annunziata, 2007, 2016).

Various methods are used to measure the neutron lifetime including the trapping and magnetic storage of neutrons followed by the counting of decay products. Paul (2009) provides a very thorough review of the methods used worldwide to determine most accurately the lifetime of the

neutron. The present world average of the neutron lifetime of $\tau_n = 878.5 \pm 0.8$ s was reported by the Petersburg Nuclear Physics Group Andreev (2017), Serebrov et al. (2008, 2013); however, research to achieve the measurement of the lifetime of the neutron to a precision of ± 0.1 s is currently under intensive research. The decay of elementary particles is characterized in terms of lifetime. The lifetime, usually symbolized as τ , is related to the term half-life, $t_{1/2}$, the mean time it takes for one-half of the particles to decay (Sundaresan, 2001) according to the relationship

$$t_{1/2} = (\ln 2)\tau = 0.693\tau \quad (1.344)$$

The free neutron decays according to the scheme

The 0.7823 MeV of energy released in the neutron decay corresponds to the difference in mass of the neutron and the sum of the masses of the products of the neutron decay, the proton plus the electron, or

$$\begin{aligned} Q &= m_n - (m_p + m_e) \\ &= [1.00866491588 \text{ u} - (1.007276466879 \text{ u} \\ &\quad + 0.000548579909 \text{ u})] (931.494013 \text{ MeV/u}) \\ &= 0.7823 \text{ MeV} \end{aligned} \quad (1.345)$$

The neutron, therefore, outside the protective confines of the stable nucleus, has a very short lifetime.

F. Proton and neutron radioactivity

In the previous sections of this chapter various radionuclide decay modes were described as mechanisms whereby unstable nuclei emit particles and energy in their transitions from an elevated energy state to a lower or stable state (ground state). Some of these transitions to lower energy states involve the transformation of a proton to a neutron or a neutron to a proton in the nucleus, as in beta decay, whereby a nucleus arrives at a more stable ratio of protons/neutrons in the nucleus. Some artificially produced radionuclides, that is, radionuclides that are not encountered naturally, but those produced through nuclear reactions such as reactions facilitated with an accelerator, may possess an excess number of protons or neutrons. Such nuclei that are unstable due to an excess number of protons or neutrons are said to have exceeded their nucleon “drip line”. The nucleon drip, be it a proton drip line or neutron drip line, refers to the ratio of protons-to-neutrons in a nucleus (*i.e.*, the numbers of protons or neutrons in a nucleus) of a given element beyond which the isotopes of that element are unstable. Many isotopes produced by nuclear reactions via the bombardment of target nuclei with accelerated nuclei possess proton or neutron numbers beyond their drip lines

and are unstable with very short half-lives, and these are referred to as exotic isotopes. Such isotopes may undergo nuclear decay to a more stable state by emitting a proton or a neutron directly from the unstable nucleus. The nucleus literally “spits out” a proton or a neutron to achieve a more stable or optimum proton/neutron ratio. The direct emission of a proton or neutron from the nucleus is a decay process referred to as “proton radioactivity” or “neutron radioactivity”, respectively. The process is also referred to as “proton emission” or “neutron emission”. Nuclides that decay by proton or neutron radioactivity generally have very short half-lives, which is measured most often in fractional seconds. As these radionuclides are produced artificially with very short half-lives, they are often referred to as “exotic nuclei”. The decay process of direct “proton or neutron emission” may also be considered as exotic; however, much research is underway currently in this field, because it helps us understand the shell structure of the nucleus and its magic numbers of protons and neutrons in the stable nucleus.

1. Proton radioactivity

The phenomenon of proton radioactivity is eloquently introduced by Blank et al. (2003), and this introduction applies also to the phenomenon of neutron radioactivity. Their introduction is the following:

The atomic nucleus is made up of positively-charged protons and neutral neutrons, the nucleons. To form a stable atomic species, a balance between the number of neutrons and of protons has to be respected. For light nuclei, this requires an equal number of both nucleons. Beyond mass or nucleon number $A = 40$, stable atomic nuclei accommodate more neutrons than protons to outbalance the repulsion of the charged protons. The number of neutrons with respect to the number of protons increases until reaching a neutron number of $N = 126$ and a proton number $Z = 82$ for lead.

Nuclei which do not respect this balance are unstable and decay by radioactive processes. For a minor disequilibrium, β decay occurs: an excess neutron is transformed into a proton and vice versa by emitting an electron/positron and an anti-neutrino/neutrino. If the imbalance between proton and neutron numbers is too large, the nuclear forces can no longer bind all nucleons and the atomic nucleus becomes particle-unstable. Thus the limits of nuclear stability are reached and the unstable nucleus will emit single excess nucleons or clusters of nucleons. The emission of clusters of two protons and two neutrons, a ${}^4\text{He}$ nucleus was the first radioactivity observed and was called α radioactivity. It occurs mainly for very heavy nuclei in the lead to uranium region ($Z = 82-92$), but also for very proton-rich lighter nuclei. For the heaviest nuclear species,

fission may occur, where the heavy nucleus splits into two medium-heavy pieces.

Theoretical investigations [Goldansky, 1960, 1961] in the 1960s predicted that for medium-mass ($A = 50-100$) nuclei, other new radioactive decays might occur. For very proton-rich odd- Z nuclei, one-proton radioactivity, i.e., the emission of one single excess proton, should be observable, whereas for even- Z nuclei with a large proton excess, two-proton radioactivity, the emission of a pair of protons, should occur. Although these one-proton or two-proton emitting nuclei are particle-unbound, they may exhibit a measurable half-life due to the Coulomb barrier the protons have to tunnel through.

a. Beta-delayed proton emission

The first observation of proton radioactivity was a proton emission from an excited state (elevated energy state) of a nucleus following beta decay (Barton et al., 1963), which is referred to as “beta-delayed proton emission”. This process is abbreviated as $\beta^+(p)$ or $\beta^+(2p)$ to signify the emission of one proton or two protons from a nucleus that was the product of positron emission. Silicon-25 was the radionuclide from which the beta-delayed proton emission was observed for the first time by Barton et al. (1963). The radionuclide was produced by bombarding aluminum with 97-MeV protons. The researchers also produced other radionuclides, namely ${}^{21}\text{Mg}$, ${}^{17}\text{Ne}$, and ${}^{13}\text{O}$, that decayed by the same process, after bombarding various elements with accelerated protons. They observed that all of the beta-delayed proton emissions, where a parent nuclide with a proton and neutron number (Z, N) is of the form $(2k + 2, 2k - 1)$, exhibited the following decay sequence:

$$(2k + 2, 2k - 1) \xrightarrow{\beta^+} (2k + 1, 2k)^* \xrightarrow{p} (2k, 2k) \quad (1.347)$$

In the above reaction sequence, the notation above each arrow signifies the decay process (i.e., β^+ for beta decay with positron emission and p for proton emission). The asterisk in Eq. (1.347) signifies an excited or elevated energy state of the daughter nuclide of the beta decay.

The beta-delayed proton emissions observed by Barton et al. (1963) in the decay of ${}^{25}\text{Si}$, ${}^{21}\text{Mg}$, ${}^{17}\text{Ne}$, and ${}^{13}\text{O}$, exhibited decay sequences in accord with Eq. (1.347), which are written as

FIGURE 1.82 The scheme for beta-delayed proton emission in the decay of ^{48}Fe . The positron (β^+) and proton (p) emission intensities are from Audi et al. (2003). As illustrated, 14.6% of the elevated ^{48}Mn daughter nuclides undergo proton emission to ^{47}Cr . The remaining 85.4% decay by gamma-ray emission to the ground state of ^{48}Mn . From Dossat et al. (2007); reprinted with permission from Elsevier © 2007..

The decay process, beta decay with positron emission (β^+), is written above each arrow and the half-life of the radionuclide below an arrow.

A typical decay scheme of the beta-delayed proton emission, as an example, is illustrated in Fig. 1.82. The decay scheme illustrates ^{48}Fe , which decays with a half-life of 43.3 milliseconds by beta-decay with positron emission to a daughter nuclide ^{48}Mn . At an elevated energy state, 14.6% of the ^{48}Mn daughter nuclides decay by proton emission to the granddaughter nuclide ^{47}Cr . Gamma-ray emission accompanies daughter nuclide de-excitation. The decay equation is written as follows:

Beta-delayed proton emission may involve the sequential emission of two protons following beta decay, as in the decay of ^{26}P , described by Honkanen et al. (1983).

FIGURE 1.83 The scheme for the beta-delayed two-proton emission decay of ^{26}P according to the reaction sequence described by Eq. (1.353). Adapted from Honkanen et al. (1983); © 1983 with permission from Elsevier.

The decay of ^{26}P occurs according to the following sequence:

Such a decay scheme is abbreviated as $\beta^+(2p)$, and its simplified decay scheme is illustrated in Fig. 1.83. As described by Honkanen et al. (1983), the two protons are not emitted simultaneously but in a sequential two-step process. As they explain and as illustrated in the decay scheme of Fig. 1.83, one proton is emitted to an energy level of an intermediate nucleus, which then becomes unbound to a subsequent emission of a second proton.

b. Direct proton emission

Proton emission from exotic nuclei may also occur directly from an unstable nucleus that possesses an excess number of protons without the initial beta decay. Direct proton radioactivity occurs by the following sequence:

where a radionuclide X of atomic number Z, mass number A, and neutron number N emits a proton p to transform into an isotope of element Y of atomic number $Z - 1$, mass number $A - 1$, and neutron number N.

The first direct proton emission as a radioactive decay process was observed by Jackson et al. (1970) and Cerny et al. (1970) in the decay of $^{53\text{m}}\text{Co}$ following the production of this exotic isotope of cobalt by the cyclotron bombardment of ^{40}Ca target with 81 MeV ^{16}O ions or the bombardment of an ^{54}Fe target with 32 MeV protons according to the reactions $^{40}\text{Ca}(^{16}\text{O}, 2np)^{53\text{m}}\text{Co}$ and $^{54}\text{Fe}(p, 2n)^{53\text{m}}\text{Co}$, respectively. These abbreviated reaction notations with parenthesis read as follows: “target

FIGURE 1.84 Direct proton emission decay scheme and decay equation of $^{53\text{m}}\text{Co}$.

nucleus(projectile, emitted particles)product nucleus". The $^{53\text{m}}\text{Co}$ was observed by Jackson et al. (1970) to decay with the direct emission of a 1.53 MeV proton, and the decay scheme is illustrated in Fig. 1.84.

The direct emission of a proton as a disintegration mode of a nuclear ground-state was first observed by Hofmann et al. (1982) in the direct proton decay of ^{151}Lu and by Klepper et al. (1982) in the proton decay of ^{147}Tm . As noted by Klepper et al. (1982), this work demonstrated for the first time that the direct proton decay is a possible disintegration mode of nuclear ground-states similar to disintegration process that occur with alpha- and beta-decay as well as nuclear fission. The decay sequence, half-lives, and proton emission energies of the direct proton emission decay modes of the two radionuclides are the following:

Two-proton radioactivity, that is, the direct emission of two protons from an atomic nucleus that has an excess number of protons, *i.e.* beyond their proton drip line, is also possible. The two-proton emission from such a nucleus

could occur in a sequential process, described by Blank et al. (2003) as follows:

... one-proton emission populates a well-defined quantal state in the one-proton daughter, before a second one-proton emission occurs to a two-proton daughter state.

This sequential emission of two protons in nuclear decay is illustrated in the left-hand portion of Fig. 1.85. The term "mass excess" in the figure is a measure of the energy levels of each nuclear state, which is determined by the energy equivalence to mass of the nuclides. The mass excess, as defined by Audi et al. (2003), is the difference between the atomic mass (in mass units) and the mass number for each nuclear state. Thus, the mass excess is a measure of the energy levels, and the mass excess is expressed usually in units of keV or MeV. The simultaneous emission of two protons from the nucleus could occur when the one-proton daughter state is energetically not possible (*i.e.*, a forbidden transition) as illustrated in the right-hand portion of Fig. 1.85. The simultaneous emission of two protons is explained by Blank et al. (2003) as follows:

... "the nuclear pairing force, which couples two nucleons of the same type to gain energy, is responsible for the fact that the masses of even- Z nuclei (in our case those of the two-proton emitter and the two-proton daughter) are smaller than the one of the one-proton daughter, thus rendering one-proton emission impossible (see Fig. 1.85). In such a case, the two protons have to be emitted simultaneously for energy conservation."

An example of the simultaneous emission of two protons in a direct two-proton emission according to the sequence illustrated in the right-hand part of Fig. 1.85 is taken from the work of Mukha and Schneider (2001). They predicted the decay of ^{19}Mg to proceed by a simultaneous two-proton emission to ^{17}Ne , due to the higher energy state of the one-proton daughter, as illustrated in Fig. 1.86. The predicted two-proton daughter nuclide ^{17}Ne was found to decay by simultaneous two-proton emission by Chromik et al. (1998). It is

FIGURE 1.85 Schematic representation of sequential (left) and simultaneous two-proton emission (right). If the one-proton daughter state is energetically not accessible, the emission has to be simultaneous. Reproduced from Blank et al. (2003), with permission © 2003 Elsevier Masson SAS. All rights reserved.

FIGURE 1.86 The predicted decay scheme of ^{19}Mg by the simultaneous emission of two protons.

interesting to note here that the decay sequence from ^{17}Ne would stop at the production of stable ^{15}N , which contains the magic number of eight neutrons according to the following:

c. Detection and measurement of proton radioactivity

The detection and measurement of protons emitted simultaneously during radionuclide decay is accomplished with position-sensitive detectors, such as the Si semiconductor microstrip detector arrangement illustrated in Fig. 1.87.

A gas electron multiplier (GEM) detector is used often to detect and measure particles in nuclear reactions and decay. This is an advanced ionization detector, which can provide images of particle tracks with X- and Y-direction readout strips. GEM detectors were introduced by Sauli (1997), and the current state-of-the-art in the operation and applications of these detectors in particle physics is

FIGURE 1.87 Experimental arrangement for the simultaneous detection of the emission of protons and the ^{17}Ne daughter nuclide from ^{19}Mg disintegration. A beam of ^{20}Mg ions are accelerated to bombard against a target resulting in a nuclear reaction causing a neutron “knock out” from the ^{20}Mg nucleus yielding ^{19}Mg . The ^{19}Mg disintegrates in flight by the emission of two protons producing the daughter nuclide ^{17}Ne . The directions of flight are determined by alignments of signals from the microstrip detectors, and the particle energies can be measured by scintillation detectors.

provided by Sauli (2014). An example of a two- and three-dimensional image of a 2-proton radioactivity event is illustrated in Fig. 1.88. This figure provides an image and the intensities of the two protons emitted simultaneously in the radioactive decay of ^{45}Fe . The radionuclide, ^{45}Fe , decays by beta-delayed proton emission; that is, the ^{45}Fe decays by positron emission to an elevated energy state of ^{45}Mn , which then emits simultaneously two protons to ^{43}V as described by the following decay sequence:

The two protons that are emitted simultaneously share 1.1 MeV (Pfützner et al., 2002; Giovino et al., 2002), which is written into the decay sequence of Eq. (1.358). The relatively equal sharing of the 1.1 MeV energy by the two protons is evidenced in the three-dimensional Fig. 1.88 by the relatively equal length of travel of the two protons in the gas ionization detector.

Another experimental arrangement used for the measurement of proton radioactivity is the optical time-projection chamber (OTPC) developed by Miernik et al. (2007a,b) and utilized by Pomorski et al. (2011) for the beta-delayed emission of one, two, and three protons in the nuclear decay of ^{43}Cr . The OTPC, described by Pomorski et al. (2011), consists of an ionization counting chamber measuring $20 \times 20 \times 42 \text{ cm}^3$ filled with a mixture of He, Ar, N_2 , and methane gas. Charged particles (*e.g.*, protons) produce ionization (*i.e.*, ion pairs) in the gas, and the primary electrons drift in a uniform electric field toward a double-stage amplification structure formed by parallel-mesh flat electrodes. In this multiplication stage UV photons are emitted and the UV wavelengths are converted to the visual range by a thin luminescent foil providing an image of particle tracks, which are recorded by a CCD camera and photomultiplier tube. CCD camera images of the simultaneous emission of one, two, and three protons from the beta-delayed proton emission decay of ^{43}Cr are illustrated in Fig. 1.89. The decay schemes are the following:

The branching ratios for the emission of one, two, and three protons were determined by Pomorski et al. (2011) to be 81%, 7.1%, and 0.1%, respectively.

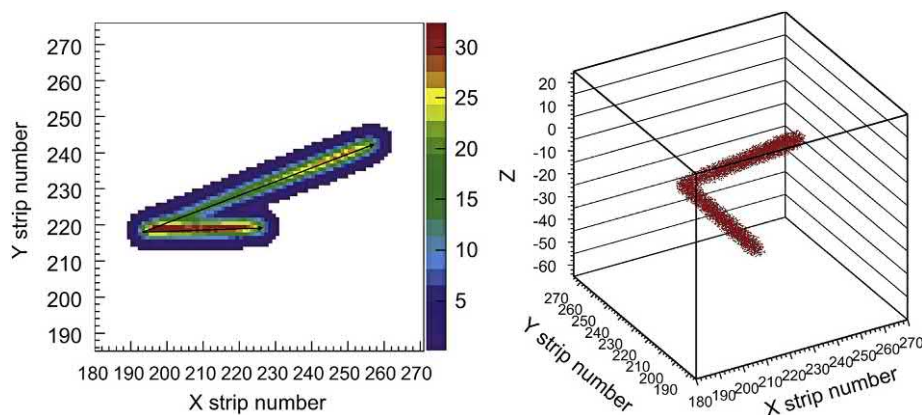

FIGURE 1.88 Two-dimensional (left) and three-dimensional (right) view of ^{45}Fe events as reconstructed from the strip information in X and Y. The color/gray code is indicative of the energy loss detected by the strips. For the color version of this figure, the reader is referred to the electronic version of the book.

FIGURE 1.89 Example CCD images of ^{43}Cr decays by β -delayed proton emissions, recorded in the synchronous mode of an OTPC detector in which the track of an incoming ion is not seen. The cases of emission of (A) a single proton, (B) two protons, and (C) three protons are shown. The ionizing power of the positron is too small to see its trace. In the synchronous mode of the OTPC detector, the CCD camera image is started by a trigger, which avoids the image of the incoming heavy ions. For the color version of this figure, the reader is referred to the electronic version of the book. From Pomorski et al. (2011); reprinted with permission © 2011 by the American Physical Society, <https://doi.org/10.1103/PhysRevC.83.014306>.

Over 40 exotic nuclei have been identified that exhibit proton radioactivity. These are artificially produced via nuclear reactions, and they have short half-lives of the order of seconds or milliseconds. Their study has provided much insight into nuclear structure in terms of proton and neutron shells, nuclear stability, and proton and neutron drip lines. For further reading, reviews on proton radioactivity are available from Pfützner et al. (2012), Pfützner (2013), and Roeckl and Mukha (2013), Gonçalves et al. (2017), and Saxena et al. (2017).

2. Neutron radioactivity

The term “neutron radioactivity” should not be confused with the emission of neutrons from heavy nuclei following nuclear fission reactions or neutron emission as the result of the decay of nuclei by spontaneous fission. Somewhat analogous to proton radioactivity, which was described previously in this chapter, neutron radioactivity refers to the direct emission of neutrons from light nuclei that possess an excess number of neutrons, that is, a number of neutrons beyond their neutron drip line.

a. Beta-delayed neutron emission

Neutron radioactivity most commonly occurs as a beta-delayed process, that is, neutron emission from the atomic nucleus occurs following beta (β^-) decay. Beta-delayed neutron emission by fission products is an important source of neutrons that contributes to the total number of neutrons responsible for the continuity of nuclear fission chain reactions in nuclear power reactors.

Beta-delayed neutron emission involves the emission of one or more neutrons from a neutron-rich nucleus when the neutrons exist in neutron-unbound states in a daughter nucleus at an elevated energy following beta decay (Birch et al., 2014). This decay process is abbreviated as $\beta^- n$, $\beta^- 2n$, or $\beta^- 3n$, for the emission of one, two, or three neutrons following beta decay. The emission of four neutrons from a beta-decay daughter nucleus at an excited state is possible; but not yet confirmed. The half-lives of nuclei that exhibit neutron radioactivity are considerably shorter than those that undergo proton radioactivity, because a neutron, due to its lack of charge, does not encounter any Coulomb barrier to hinder its emission from a nucleus. When half-lives are

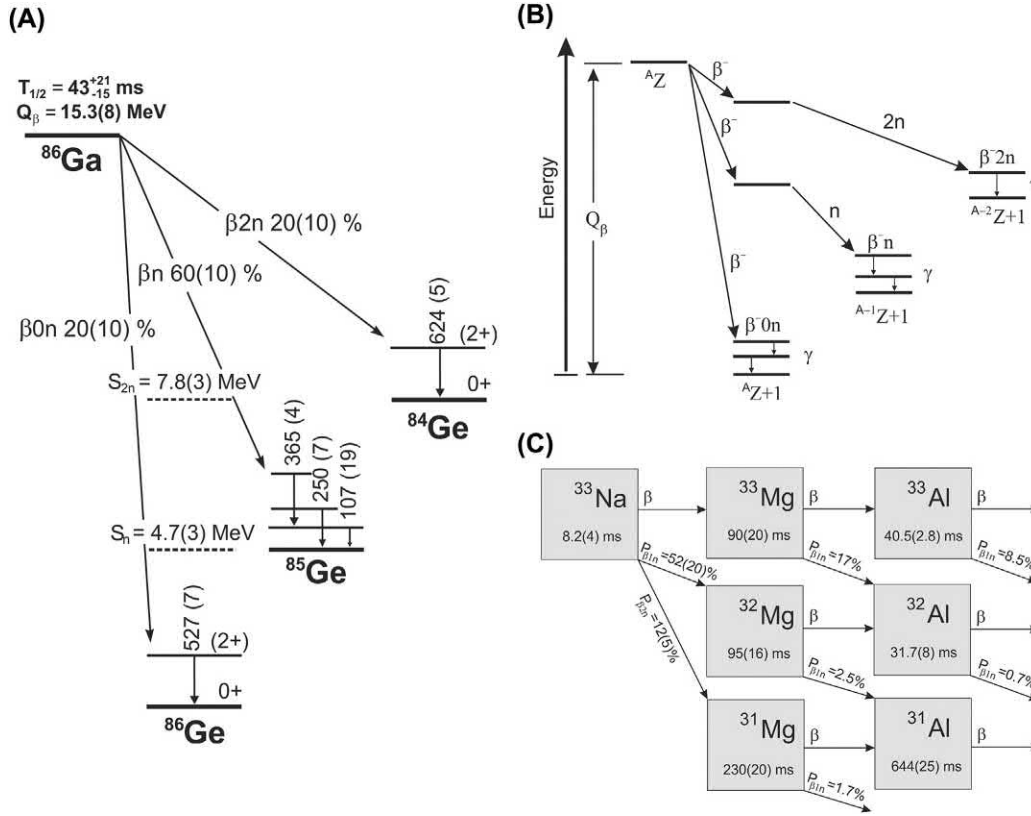

FIGURE 1.90 (A) The beta-delayed neutron emission decay scheme of neutron-rich ^{86}Ga (reprinted with permission from Miernik et al. (2013), <https://doi.org/10.1103/PhysRevLett.111.132502> © 2013 American Physical Society; (B) basic beta-delayed neutron emission transitions of a neutron-rich radionuclide; and (C) beta-delayed neutron emission in the decay of neutron-rich ^{33}Na and its daughters and granddaughters. From Radivojevic et al. (2002); reprinted with permission from Elsevier © 2002.

very short ($<10^{-12}$ s), the process may be referred to as neutron emission, rather than neutron radioactivity, as described by Thoennessen et al. (2013).

The basic pathways of negatron emission of a neutron-rich radionuclide are illustrated in Fig. 1.90A. The figure illustrates the decay of a radionuclide of atomic number Z and mass number A by negatron emission to a nuclide of atomic number $Z + 1$ with the same mass number A with no neutron emission ($\beta^- 0n$). Other possibilities are the delayed-emission of one or two neutrons following beta decay to nuclides of atomic number $Z + 1$ and mass numbers of $A - 1$ and $A - 2$ resulting from the emission of one neutron ($\beta^- 1n$) or two neutrons ($\beta^- 2n$), respectively. An example can be taken from a thorough study of the beta-delayed neutron emission in the decay of neutron-rich ^{86}Ga by Miernik et al. (2013). They measured the half-life and beta branching ratios of the three possible beta-decay modes (expressed in %) as follows:

The element gallium has an atomic number $Z = 31$, whereby the isotope ^{86}Ga with a neutron number of 55 ($N = 86 - 31 = 55$) is very rich in neutrons. The beta-decay of ^{86}Ga leaves neutrons of the germanium daughter nuclei ^{86}Ge at elevated unbound energy states permitting their emission from the ^{86}Ge nucleus to form ^{85}Ge or ^{84}Ge , respectively. Either one or two neutrons are emitted simultaneously from the ^{86}Ge nucleus according to the neutron-emission decay sequences described in the decay sequences 1.363 and 1.364. The beta-delayed neutron emission of neutron-rich ^{86}Ga , illustrated in Fig. 1.90A, can occur with branching ratios of $\sim 60\%$ and $\sim 20\%$ for the delayed emission of 1 neutron (βn) to ^{85}Ge or 2 neutrons ($\beta 2n$) to ^{84}Ge , as illustrated in Fig. 1.90A. The remaining

$\sim 20\%$ of the transitions occur without the emission of neutrons ($\beta 0n$) to ^{86}Ge . All of the transitions yield daughter nuclides at excited states with the emission of gamma radiation at energy lines depicted in Fig. 1.90A.

The decay of neutron-rich nuclides by beta-delayed neutron emission are generally described by decay diagrams, as illustrated in Fig. 1.90B, where the atomic number Z increases by 1 ($Z + 1$) in negatron emission and the mass number (A) decreases by 1 (i.e., $A - 1$) and 2 (i.e., $A - 2$) in single neutron emission ($\beta^- n$) and double neutron emission ($\beta^- 2n$), respectively, followed by gamma photon emission from daughter nuclides at excited energy states. Chains of beta-delayed neutron emission occur among neutron-rich parent, daughter, and granddaughter nuclides, as illustrated in the decay of neutron-rich ^{33}Na illustrated in Fig. 1.90C.

Among the light nuclei ($Z \leq 28$), there are numerous isotopes for which the beta-delayed neutron emission probabilities have been measured. By the year 2014, a total of 203 nuclei have been identified as potential precursors to beta-delayed neutron emission, and among these the probabilities of $\beta^- n$ emission have been measured experimentally for over 109 nuclei; whereas, probabilities of $\beta^- 2n$ emission have been measured experimentally for only 19; and the probabilities of $\beta^- 3n$ emission measured in four nuclei (Birch et al., 2014). The beta-delayed emission of four neutrons (i.e., $\beta^- 4n$) is yet to be measured. The

nuclides that exhibit neutron radioactivity are found in the neutron-rich region of the Chart of the Nuclides, which is a Z versus N plot of the nuclides. These are illustrated in Fig. 1.91 for nuclides in the region of $Z \leq 28$. The radio-nuclides that decay by beta-delayed $1n$ emission ($\beta^- n$) are marked in red color. Nuclides decaying by $\beta^- 2n$ and $\beta^- 3n$ are fewer in number as mentioned previously. Also, as noted by Birch et al. (2014), all nuclides that decay by $\beta^- 2n$ also decay by $\beta^- 1n$ precursors, and all $\beta^- 3n$ precursors are also $\beta^- 2n$ and $\beta^- 1n$. Nuclides that exhibit negatron emission and neutron radioactivity reside in the neutron-rich side of the Chart of the Nuclides, i.e., the region to the right of the black stable line of nuclides; whereas, nuclides that decay by positron emission and exhibit proton radioactivity are found in the region to the left of the black stable line of nuclides. Nuclides that decay by proton emission are not identified in Fig. 1.91; however, they reside among the yellow boxes of proton-rich nuclides to the left of the black boxes of stable nuclides.

b. Direct neutron emission

The direct emission of neutrons from neutron-rich nuclei can occur, and in such cases the half-life is generally much shorter than proton emission, because neutrons will not encounter any Coulombic barrier to their escape from the atomic nucleus. An example is the dineutron decay of

FIGURE 1.91 Chart of nuclides for $Z \leq 28$ nuclei. The coloring of the boxes indicates the measurement status of single neutron decay emission probability, P_{1n} . Small white boxes indicate the existence of an isomer for that isotope. This figure was adapted from the NUCLEUS display software (http://amdc.in2p3.fr/web/nubdisp_en.html) of the Atomic Mass Data Center. For the color version of the figure, the reader is referred to the online version of the book. From Birch et al. (2014); reprinted with permission from Elsevier © 2014.

neutron-rich ^{16}Be measured by [Spyrou et al. \(2012\)](#), which decays with a 200 ns half-life according to the following decay sequence:

The emission of only one neutron or the sequential emission of two neutrons from ^{16}Be is not possible energetically, because the ground state of ^{15}Be is at a significantly higher energy than the parent ^{16}Be nuclide [Spyrou et al. \(2012\)](#).

c. Detection and measurement of neutron radioactivity

The detection and measurement of neutron radioactivity requires instrumental techniques that are different to the gas ionization detection and measurement techniques described previously for proton radioactivity. The neutral charge on the neutron will not permit its detection by gas ionization. However, certain inorganic and organic plastic scintillators are sensitive to neutron interactions such as proton recoil following elastic scattering in organic and plastic scintillators. The detection and measurement of neutrons is described in Chapters 6 and 9 of this volume.

A method proposed by [Caesar et al. \(2013\)](#) for the detection and measurement of neutron radioactivity and the very short half-lives involved is described in detail by [Thoennessen et al. \(2013\)](#). A diagram of the instrumental arrangement is illustrated in [Fig. 1.92](#) with the decay scheme of ^{16}B as an example. The neutron-rich nucleus of ^{16}B emits a neutron with a half-life of <190 ps according to the decay sequence

The very short half-life requires the measurement of the neutron emissions from the onset of the production of the

^{16}B . A method of half-life measurement, illustrated in [Fig. 1.92](#), is the measurement of the neutron distribution along position-sensitive scintillation detectors referred to as the Decay in a Magnetic Field (DiMF) method. As described by [Thoennessen et al. \(2013\)](#), the ^{16}B is produced by accelerating a beam of ^{17}C against a target material that knocks out a proton from the ^{17}C producing ^{16}B . The reaction $^{17}\text{C}(-p)^{16}\text{B}$ occurs at the location identified by a red dot in [Fig. 1.92](#). The decay sequence $^{16}\text{B} \rightarrow ^{15}\text{B} + n$ at various times in flight, which is illustrated by three blue dots along the flight path of the ^{16}B , bent by a deflecting magnetic field with a bend radius r and a deflecting angle θ after a possible drift distance d . The deflecting magnetic field will bend the path of the charged particles away from the paths of the emitted neutrons permitting the detection and counting of ^{15}B . The distribution of the neutrons measured along the distance x of the position-sensitive scintillation detectors (see [Fig. 1.92](#)) will provide a measure of the half-life of the nuclear decay. Decay times as short as 10 picoseconds (10 ps) will show a concentration of neutrons detected near the zero degree line (little deflection) at a distance l from the target. The longer the half-life of the order of 500 ps to 1 nanosecond (1 ns) will exhibit a distribution of neutrons further away from the zero degree line along the distance x . Longer decay times of up to 100 microseconds (100 μs) will exhibit a spread further away from the zero degree line.

For additional reading on neutron radioactivity the reader may peruse the papers by [Spyrou et al. \(2012\)](#), [Thoennessen et al. \(2013\)](#), [Birch et al. \(2014\)](#), [Kahlbow et al. \(2017\)](#), and [Li et al. \(2017\)](#).

G. Neutrino interactions with matter

Because neutrinos do not carry charge, they do not produce the Cherenkov Effect. However, neutrino interactions

FIGURE 1.92 Schematics of the DiMF technique. The incoming ^{17}C beam produces ^{16}B in the target (red dot) which enters a magnetic field (bend radius r and deflection angle θ) after a drift distance d . The ^{16}B then can decay at different positions along the flight path (blue dots) into ^{15}B and a neutron. The ^{15}B fragments and neutrons are detected and identified in a set of charged-particle detectors and position sensitive scintillation detectors (at a distance l of 1500 cm from the target), respectively. For the color version of the figure, the reader is referred to the online or electronic version of the book. [Thoennessen et al. \(2013\)](#); reprinted with permission from Elsevier © 2013.

within very large bodies of transparent material can produce high-energy charged particles, which in turn produce Cherenkov photons. Photon detectors, namely photomultiplier tubes, are used to measure the Cherenkov photon intensity produced by the charged particles, which provides a measure of the neutrino flux.

The very large volumes of transparent material currently used for the detection of Cherenkov photons from neutrino interactions contain water or ice, and these have been designed to detect neutrinos from various sources such as solar neutrinos, atmospheric neutrinos of the cosmic ray showers, geo-neutrinos, artificially produced neutrinos arising from nuclear reactors and accelerators, and ultra-high energy (UHE) astrophysical neutrinos. The following large bodies of water or ice are utilized:

1. Heavy water (D₂O) weighing > 1 kiloton in an underground vessel, such as that utilized by the Sudbury Neutrino Observatory (SNO) near Sudbury, Canada (Boudjemline et al., 2010; Bellerive et al., 2016) or light water (H₂O) weighing > 50 kilotons contained in a large vessel underground, such as that utilized by the Super-Kamiokande and Hyper-Kamiokande Cherenkov detector under Mt. Ikenoyama, Japan (Fukuda et al., 2003; Abe et al., 2016 and F. Li et al., 2017). Both vessels are surrounded by photomultiplier detectors for the detection of the Cherenkov photons.
2. Lake or ocean waters with Cherenkov photon detectors (photomultiplier tubes) located deep within lake or ocean waters. In ocean waters, photon detectors have been placed at depths of up to 2.5 km. There are currently two large-scale neutrino telescopes in operation in lake or ocean waters, namely, the NT200 in Lake Baikal in Siberia (Aynutdinov et al., 2006, 2011; Avrorin et al., 2015, 2016), and the ANTARES (Astronomy with a Neutrino Telescope and Abyss Environmental RESearch) in the Mediterranean Sea (Carr, 2008; Aguilar et al., 2011; Brunner, 2011; De Bonis, 2016; Spurio et al., 2017).
3. Polar ice with Cherenkov photon detectors placed deep within holes drilled into the polar ice cap. The current large-scale neutrino telescope of this type is the Ice-Cube/AMANDA (Antartic Muon and Neutrino Detector Array) at the South Pole (Achterberg et al., 2006; Berghaus, 2009; Montaruli, 2009; Abbasi et al., 2010, 2011; Hultqvist, 2011; Desiati et al., 2014; Tosi et al., 2017; Xu, 2017 and Xu et al., 2017).

The very large bodies of water or ice are required to detect the neutrino interactions, because of the high penetrating power of neutrinos due to their lack of charge and very low mass.

The Cherenkov photons, that are detected, are those produced by charged particles resulting from neutrino interactions such as (i) elastic scattering (ES) of electrons by

neutrinos in the detector medium, (ii) neutrino charged current (CC) interactions with deuterium nuclei in heavy water, and (iii) neutral current (NC) interactions of neutrinos with atomic nuclei of water or ice.

Electron Scattering. The elastic scattering (ES) of electrons by neutrinos, described by the following:

$$\nu_x + e^- \rightarrow \nu_x + e^- \quad (1.367)$$

is sensitive to all neutrino flavors (where $x = e, \mu, \text{ or } \tau$), but with a reduced sensitivity to the muon neutrino (ν_μ) and the tau neutrino (ν_τ). In the ES interaction described by Eq. (1.367), neutrino energy is transferred to an atomic electron, and the electron will, in turn, travel as a scattered electron in light water, heavy water, or ice at relativistic speeds and produce Cherenkov photons as illustrated in Fig. 1.93. From this interaction and the anisotropic property of the Cherenkov radiation, the directional information of the neutrino can be determined.

Charged Current Interactions. The charged current (CC) interaction with a deuterium nucleus or deuteron (d) is described as follows:

$$\nu_e + d \rightarrow p + p + e^- \quad (1.368)$$

where the resultant energy of the electron (e^-) is well correlated with the energy of the electron neutrino (ν_e). The high-energy scattered electron produced from interactions 1.367 and the high-energy negatron from reaction 1.368 produce Cherenkov photons in transparent media. The electron neutrino ν_e is the only neutrino flavor that is able to convert the deuterium nucleus (*i.e.*, deuteron) into two protons and a negatron. The interaction of a neutrino with the deuteron described by Eq. (1.368) can be illustrated further whereby a neutron of the deuterium nucleus is transformed into a proton and a negatron as illustrated in Fig. 1.94.

The interaction described by Eq. (1.368) and Fig. 1.94 is called a charged current (CC) interaction, because a charged W boson, which can carry either a positive or negative charge (W^\pm), acts as an intermediate vector in the transformation process of a neutron in the nucleus of deuterium (d) into a proton (p). The charged W bosons act as exchange particles involved in the transformation of

FIGURE 1.93 An electron with energy in excess of 262 keV traveling in H₂O, D₂O, or ice producing a Cherenkov photon ring, and the direction of travel of the Cherenkov photons are determined by the photon detectors (*e.g.*, photomultiplier tubes). The anisotropic property of Cherenkov photons permits the design and orientation of photon detectors to register only Cherenkov photons traveling in a certain direction. Thus, the directional information of the neutrino can be determined.

FIGURE 1.94 Charged current interaction of an electron neutrino with a deuterium nucleus resulting in the transformation of a neutron (n) into a proton (p) and negatron (e^-). The negatron or negative electron travels in the heavy water to produce Cherenkov photons illustrated with a Cherenkov photon ring. From L'Annunziata (2016): reprinted with permission from Elsevier © 2016.

quark flavor, which in this interaction, involves the transformation of a down quark (d) of the neutron into an up quark (u) transforming the neutron into a proton. This is illustrated by the Feynman diagram of Fig. 1.95.

Another **charged current** interaction that is currently employed to detect atmospheric neutrinos involves the creation of secondary muons by atmospheric neutrinos in large bodies of water, such as lakes, ocean floors, and arctic ice. As described by Formaggio (2009), Katz (2009) and

FIGURE 1.95 Feynman diagram illustrating the charged current (CC) interaction of an electron neutrino (ν_e) with a neutron of a deuterium nucleus via the mediation of a W^+ boson resulting in the transformation of a down quark (d) of the neutron into an up quark (u) resulting in the transformation of the neutron into a proton. The diagram illustrates on the lower left, an incoming electron neutrino (ν_e) interacting with a down quark (d) of a neutron (lower right) via a W^+ boson (dashed line). The down quark (d) of the neutron is transformed into an up quark (u) (upper right), thereby changing the neutron into a proton (upper right) with the creation of a negatron (e^-) illustrated with the arrow upward on the upper left of the diagram. From L'Annunziata (2016): reprinted with permission from Elsevier © 2016.

Abbasi et al. (2010), the following charged current reaction results in the creation of high-energy muons, which travel at relativistic speeds ($0.8c$) and produce Cherenkov photons detected by photon detectors located deep within lakes, ocean floors or arctic ice:

$$\nu_\mu(\bar{\nu}_\mu) + N \rightarrow \mu^-(\mu^+) + X \quad (1.369)$$

where atmospheric muon neutrinos (ν_μ) or muon antineutrinos ($\bar{\nu}_\mu$) interact with nuclei N of elements that surround the Cherenkov photon detector to produce charge muons (μ^- or μ^+) and nuclei of element X . The nuclei change from N to X , because in the charge current reaction mediated by a W^+ boson, the quark flavor within a nucleon is changed as illustrated by the Feynman diagram of Fig. 1.96.

Neutral Current Interactions. The Cherenkov photon detection and measurement of neutrinos via neutral current interactions of neutrinos with deuterium nuclei in heavy water is described by the following:

$$\nu_x + d \rightarrow p + n + \nu_x \quad (1.370)$$

where ν_x is a neutrino of any flavor, that is $x = e, \mu$ or τ , to represent the electron, muon, or tau neutrino, d is the deuteron or nucleus of deuterium, and p and n are the proton and neutron, respectively, liberated when the deuterium nucleus breaks apart. The reaction is called a neutral current interaction, because a neutral Z boson (Z^0) acts as the intermediate exchange particle in this interaction of a neutrino

FIGURE 1.96 Feynman diagram describing the charge current interaction of a muon neutrino and a down quark of a nucleon in element N , mediated by a W^+ boson, converting the quark flavor from a down quark (d) to an up quark (u) with the production of a negative muon (μ^-). The conversion of the quark flavor from d to u results in the conversion of a neutron to a proton and consequently conversion of nuclide N to nuclide X . From L'Annunziata (2016): reprinted with permission from Elsevier © 2016.

with the deuterium nucleus. The Z^0 boson does not change the flavor of quarks in a nucleon; however, the energy transferred causes the nucleus to break up into its proton and neutron component nucleons. An illustration, by means of a Feynman diagram, of the neutral current interaction of a neutrino with a deuterium nucleus, is provided in Fig. 1.97.

All neutrino flavors react equally with deuterium in this neutral current reaction, which can provide a measure of the total neutrino flux for neutrino energies in excess of 2.2 MeV (Prior, 2009). The neutron produced in reaction 1.370 becomes quickly thermalized in the water, and the thermal neutron is subsequently captured by a deuterium (^2H) nucleus or by a nucleus of ^{35}Cl when the water is doped with a high concentration of NaCl. Neutron capture by ^2H or by ^{35}Cl results in the emission of gamma radiation. The gamma rays will interact with atomic electrons of the water to produce Compton electrons. All Compton electrons with energy in excess of the 262 keV threshold energy will produce Cherenkov photons in the water. The detection and measurement of the Cherenkov photons provide a measurement of the neutrino flux. The neutral current interaction in heavy water doped with NaCl is illustrated in Fig. 1.98.

An illustration of the layout of a neutral current detector, namely the SNO Cherenkov detector, which utilized heavy water (D_2O), described previously for the detection and measurement of neutrinos, is provided in Fig. 1.99. The

SNO (Sudbury Neutrino Observatory) is located 2100 m underground in Sudbury, Ontario, Canada. Fig. 1.99 illustrates a person standing above the detector, which provides a perspective of the magnitude of the heavy water detector.

The Nobel Prize in Physics 2015 was awarded in one part to Takaaki Kajita of the University of Tokyo, Kashiwa, Japan for his work with the Super-Kamiokande Collaboration and in another part to Arthur B. McDonald of Queens University, Kingston, Canada for his work with the Sudbury Neutrino Observatory (SNO) Collaboration, which resulted, in the words of the Nobel Committee, in “the discovery of neutrino oscillations, which shows that neutrinos have mass.” From the detection and analysis of neutrinos they were able to demonstrate that neutrinos can oscillate from one flavor to another, and this would be possible only if neutrinos have mass. The Super-Kamiokande detected atmospheric neutrinos. The muon neutrinos (ν_μ) that arrived at the Super-Kamiokande detector from the atmosphere above were more numerous than the muon neutrinos that traveled through the globe and collided with the detector from below. This demonstrated that the muon neutrinos that traveled longer (i.e., through the earth) had more time to change into a neutrino of another flavor (e.g., ν_e or ν_τ). In addition, the SNO measured the solar electron neutrino (ν_e) intensity, as only electron neutrinos are produced by the Sun. Neutrinos of all three flavors (i.e., ν_e , ν_μ , and ν_τ) could also be detected by

FIGURE 1.97 Feynman diagram describing a neutral current interaction of an electron, muon, or tau neutrino (where $x = e, \mu$, or τ) with a down quark (d) of a neutron in a nucleus of deuterium (deuteron) via the neutral Z boson (Z^0) as an intermediate exchange particle. The flavor of the quark does not change, that is, the down quark (d) of the neutron remains a down quark, and thus the neutron does not change into a proton. However, energy of the neutrino is transferred, and the neutron and proton of the deuterium nucleus (lower right, dashed circles overlapping) break apart (upper right, dashed circles separated). From *L'Annunziata* (2016); reprinted with permission from Elsevier © 2016.

FIGURE 1.98 A neutral current interaction of a neutrino utilized for the detection of neutrinos of any flavor (electron, muon or tau) where $x = e, \mu$, or τ , in heavy water (D_2O) doped with a high concentration of NaCl. The neutrino interacts with a deuterium nucleus causing the nucleus to break apart into its constituent proton and neutron. The neutron rapidly undergoes thermalization after several collisions (jagged path of arrow) with atomic nuclei, and the thermalized neutron (n_{th}) is captured by a ^{35}Cl nucleus. Gamma-ray emission from ^{36}Cl following neutron capture undergoes Compton scatter, and the Compton electrons, in excess of 262 keV energy, produce Cherenkov photons in the water. The Cherenkov photons are measured with suitable photon detectors (e.g., photomultiplier tubes). From *L'Annunziata* (2016); reprinted with permission from Elsevier © 2016.

FIGURE 1.99 Layout of the SNO Cherenkov detector. The D_2O (1000 tons) is contained within an acrylic vessel. This volume could be accessed via the neck. The Neutral Current Detectors (NCDs), illustrated as vertical lines in the acrylic vessel housing the D_2O , were employed in the third phase of the experiment. The acrylic vessel was surrounded by water for shielding the radioactivity from the rock (outer H_2O) and photomultiplier tubes (inner H_2O). The photomultiplier SUPport Structure (PSUP) holds the photomultiplier tubes and light concentrators. A figure of a person is illustrated in the upper right to provide a perspective of the magnitude of the underground Cherenkov detector. Reprinted from *Boudjemline et al. (2010)*, with permission from Elsevier © 2010.

the deuterium in the SNO. As described by the Nobel Committee, the electron neutrinos were smaller in number than expected, whereas the combined number of the three neutrino flavors corresponded to expectations, which indicated that the electron neutrinos had changed into a muon of another flavor (Rose, 2015).

The Sudbury Neutrino Observatory (SNO) is currently under modification to SNO+, which will involve reusing the SNO facility to investigate the Majorana nature of neutrinos (i.e., the ability of neutrinos to oscillate from one flavor to another via the search for neutrinoless double beta decay of ^{130}Te (Lozza et al., 2016). In the search for neutrinoless double beta decay the facility would be loaded with 0.3% natural tellurium in 780 tonnes of liquid scintillator (PPO fluor in linear alkyl benzene solvent), which would correspond to 800 kg of ^{130}Te . As described by Lozza et al. (2016) on behalf of the SNO+ Collaboration, the redesigned SNO+ will be equipped to measure reactor anti-neutrino oscillations, geo-antineutrinos, solar neutrinos, and supernova neutrinos. The solar neutrinos would be measured with the pure liquid scintillator (i.e., without the Te loading). Anti-neutrinos are detected by inverse beta decay as described previously in this chapter and via the basic reactions illustrated in Fig. 1.46 earlier in this chapter. The anti-neutrinos will be measured during the

double beta-decay research on ^{130}Te . The measurement of anti-neutrinos originating from the Earth's crust and mantle (i.e., geo anti-neutrinos) could provide information on heat production of the Earth. Supernova neutrinos will be detected via charged current interactions and neutral current interactions on ^{12}C of the organic liquid scintillator solvent and via proton scattering (Lozza et al., 2016). Charged current and neutral current interactions are described earlier in this chapter via Eqs. (1.369) and (1.370) and Figs. 1.96 and 1.97. Neutral current interactions, as illustrated in Fig. 1.97, are possible with all neutrino flavors (i.e., electron, muon, and tau neutrinos), and thus the neutral current interaction can provide data on the combined flux of all neutrino flavors.

Ultra-high energy (UHE) astrophysical neutrino interactions with atomic nuclei can produce particles yielding Cherenkov radio waves, which are detected with antennas. For additional reading on the detection of neutrinos by the Cherenkov Effect, the reader may peruse a detailed review by the writer in a previous book (L'Annunziata, 2016).

XI. Electromagnetic radiation – photons

A. Dual nature: wave and particle

In the latter part of the 19th century, Hertz (1887) carried out a series of experiments demonstrating that an oscillating electric current sends out electromagnetic waves similar to light waves, but of different wavelength. Hertz proved, thereby, the earlier theory of James Clerk Maxwell, that electric current oscillations would create alternating electric and magnetic fields, and radiated electromagnetic waves would have the same physical properties of light. A subsequent discovery by Nobel Laureate Zeeman (1897) further linked the properties of light with electricity and magnetism when he discovered that a magnetic field would alter the frequency of light emitted by a glowing gas, which we now refer to as the Zeeman Effect. The magnetic field would alter the spectral line corresponding to the frequency of the light into a triplet or even a more complex multiplet of lines. This discovery was significant, because it was the very first to link the properties of light with electricity and magnetism.

Not long after the discoveries of Hertz and Zeeman came the work of Max Planck, who in 1900 proposed a formula to explain that the vibrating particles in the heated walls of a kiln could radiate light only at certain energies. These energies would be defined by the product of a constant having the units of energy \times time and the radiation frequency. The constant, which Planck

calculated became known as the universal Planck constant, $h = 6.626 \times 10^{-34}$ J s. Therefore, radiation would be emitted at discrete energies, which were multiples of Planck's constant and the radiation frequency, ν . Planck named the discrete radiation energy as the quantum from the Latin *quantus* meaning “how great”.

In 1905 Einstein grasped the calculations of Planck to explain and provide evidence that light, not only traveled as waves, but also existed as discrete packets of energy or particles, which he named “energy quanta”. Today we refer to these energy quanta as photons. Einstein demonstrated the existence of the photon in his explanation of the photoelectric effect (see Section XII.A of this chapter.). He demonstrated that the energy of an electron (photoelectron) ejected from its atomic orbital after being struck by light was not dependent on the light intensity, but rather on the wavelength or frequency of the light. In other words, increasing the light intensity would increase the number of photoelectrons, but not their energy. Whereas, altering the frequency, thus energy, of the light would alter the energy of the photoelectron. In summary, Einstein demonstrated that the energy of the photoelectron depended on the energy of the photon that collided with the electron or, the product of Planck's constant times the light frequency according to the formula

$$E = h\nu = \frac{hc}{\lambda} \quad (1.371)$$

Eq. (1.371) is referred to as the Planck–Einstein relation (Woan, 2000). From this observation Einstein is credited with discovering the photon as an elementary particle. Also, we may notice from Eq. 1.371 that the product of the photon frequency, ν , and wavelength, λ , always yields the velocity, c , the speed of light. The photon always travels at the constant speed in a vacuum, $c = 2.9979 \times 10^8$ m/s; it cannot travel at a speed less than c in a vacuum.

From our previous treatment we see that the photon behaves as a particle, which could knock out an electron from its atomic orbital provided it possessed sufficient energy to do so, that is, an energy in excess of the electron binding energy. Therefore, the photon is considered as another elementary particle. In his explanation of the photoelectric effect, Einstein was the first to demonstrate the particulate nature of light, and it is for this work he won the Nobel Prize. Since these findings of Einstein, electromagnetic radiation is known to have a dual nature as energy that travels as a wave and as a particle.

Electromagnetic radiation may be classified according to its wavelength or origin. For example, gamma rays and X-rays are similar, but have different origins. Gamma rays arise from energy-state transitions of the nucleus of an atom

while X-rays come from energy-state transitions of extra-nuclear electrons. The classification of electromagnetic radiation according to wavelength and frequency is illustrated in Fig. 1.100.

Seeing as electromagnetic radiations or photons have properties of particles, they should also possess momentum. We calculate momentum as the product of mass and velocity. For relativistic conditions, the mass of a particle is a function of its speed according to Eq. (1.272) previously described or

$$m = \frac{m_0}{\sqrt{1 - (u^2/c^2)}} \quad (1.372)$$

where m and m_0 are the particle relativistic and rest masses, respectively, u is the particle speed and c , the speed of light. Gautreau and Savin (1999) transform Eq. (1.372) by squaring both sides and then multiplying each side by $c^4[1 - (u^2/c^2)]$ to yield the equation

$$m^2 c^4 - m^2 u^2 c^2 = m_0^2 c^4 \quad (1.373)$$

Using $E = mc^2$ and $E_0 = m_0 c^2$ to define the relativistic and rest energies and $p = mu$ to define the particle momentum together with the fact that the rest energy of the photon is always zero, i.e., $m_0 = 0$, Eq. (1.373) becomes

$$E^2 - p^2 c^2 = (m_0 c^2)^2 \quad (1.374)$$

$$E^2 - p^2 c^2 = 0 \quad (1.375)$$

and

$$p = \frac{E}{c} \quad (1.376)$$

From Eqs. (1.371), (1.375), and (1.376) we can further describe the photon momentum as

$$p = \frac{E}{c} = \frac{h\nu}{c} = \frac{h}{\lambda} \quad (1.377)$$

To illustrate the use of the above equations defining the relationships of photon properties, we can calculate the wavelength, frequency, and momentum of a 2-MeV gamma-ray photon. From Eq. (1.371) we can write the equation for calculating the wavelength as

$$\lambda = \frac{hc}{E} \quad (1.378)$$

Planck's constant, h , can be converted from units of J·s to eV·s as

$$\begin{aligned} h &= \frac{6.626 \times 10^{-34} \text{ J s}}{1.602 \times 10^{-19} \text{ J/eV}} \\ &= 4.136 \times 10^{-15} \text{ eV s} \end{aligned} \quad (1.379)$$

FIGURE 1.100 The electromagnetic radiation spectrum is illustrated above by classifying the types of radiation as a function (from left to right) of decreasing wavelength (λ) and increasing frequency (ν). As the wavelength of the radiation decreases, its frequency (ν) and its energy ($E = h\nu$) increase, where h is Planck's constant ($h = 6.626 \times 10^{-34}$ J s). There are no sharp lines of demarcation between the radiation types, as their wavelengths and frequencies can overlap between neighboring radiation types. Thus, the wavelengths and frequencies given above are only approximate. The uppermost wave in the figure is provided as an abstract illustration of how radiation frequency increases with decreasing wavelength. Radiation, visible to the human eye, is found in a very narrow region between the infrared (IR) and ultra violet radiation (UV) bands with decreasing wavelengths in the region of 740 to 380 nanometers (nm) yielding the colors of red, orange, yellow, green, blue, indigo, and violet. For the color version of this figure, the reader is referred to the electronic version of the book.

and hc is calculated as

$$\begin{aligned} hc &= (4.136 \times 10^{-15} \text{ eV s})(2.9979 \times 10^8 \text{ m/s}) \\ &= 12.4 \times 10^{-7} \text{ eV m} \\ &= 12.4 \text{ keV } \text{\AA} \end{aligned} \quad (1.380)$$

The wavelength of the 2.0 MeV gamma ray according to Eq. 1.378 becomes

$$\lambda = \frac{hc}{E} = \frac{12.4 \text{ keV } \text{\AA}}{2 \times 10^3 \text{ keV}} = 0.0062 \text{ } \text{\AA} \quad (1.381)$$

The frequency is calculated according to Eq. (1.371) as

$$\begin{aligned} \nu &= \frac{c}{\lambda} = \frac{2.9979 \times 10^8 \text{ m/s}}{0.0062 \times 10^{-10} \text{ m}} = 484 \times 10^{18} \text{ s}^{-1} \\ &= 4.84 \times 10^{20} \text{ Hz} \end{aligned} \quad (1.382)$$

The momentum is expressed according to Eq. (1.376) as

$$p = \frac{E}{c} = 2.0 \text{ MeV}/c \quad (1.383)$$

Notice that relativistic calculations of momentum have units of MeV/ c , while conventional units of momentum are derived from mass times velocity or kg m/s. Units of MeV/

c can be converted to the conventional units with the conversion factor $1 \text{ MeV}/c = 5.36 \times 10^{-22} \text{ kg m/s}$ (Fermi National lab: <https://quarknet.fnal.gov/toolkits/ati/whatgevs.html>).

B. Gamma radiation

Radionuclide decay processes often leave the product nuclide in an excited energy state. The product nuclide in such an excited state either falls directly to the ground state or descends in steps to lower energy states through the dissipation of energy as gamma radiation.

A nuclide in an excited energy state is referred to as a nuclear isomer, and the transition (or decay) from a higher to a lower energy state is referred to as isomeric transition. Gamma rays are emitted in discrete energies corresponding to the energy state transitions a nucleus may undergo when in an excited state. The energy, E_γ , of a gamma ray may be described as the difference in energy states of the nuclear isomers:

$$E_\gamma = h\nu = E_1 - E_2 \quad (1.384)$$

where $h\nu$ is the energy of the electromagnetic radiation described previously in Section XI.A, and E_1 and E_2 represent the energy levels of the nuclear isomers.

FIGURE 1.101 Decay scheme of $^{86}_{37}\text{Rb}$.

Let us consider the decay schemes of some radionuclides to illustrate the process in more detail.

Fig. 1.101 shows the decay scheme of $^{86}_{37}\text{Rb}$ with a half-life of 18.8 days. This nuclide decays by β^- emission with an increase in atomic number to $^{86}_{38}\text{Sr}$. Eighty-eight percent of the beta particles emitted have a maximum energy of 1.77 MeV; the remaining 11% have a maximum energy of 0.70 MeV. The percentages cited and illustrated in the figure are referred to as transition probabilities or intensities. Obviously, a greater quantum of energy is released by the 1.77-MeV, β^- -decay process. As a consequence, the ^{86}Sr product nuclides that result from beta decay energy of 0.70 MeV (11%) are at a higher energy state than those that result from beta decay energy of 1.77 MeV. The energy difference of the two ^{86}Sr product nuclide isomers, $E_1 - E_2$, is equivalent to the difference of the two beta-decay energies, $1.77 \text{ MeV} - 0.70 \text{ MeV} = 1.07 \text{ MeV}$. Consequently, the ^{86}Sr nuclide isomers, which are products of the 0.70-MeV β^- -decay process, can emit the remaining energy as 1.07-MeV gamma-ray photons.

As illustrated in Fig. 1.101, 11 % of the parent ^{86}Rb nuclides decay to a ^{86}Sr nuclear isomer at an elevated energy state. Not all of these isomers immediately decay to the ground state. Only 8.8% of the $^{86}\text{Rb} \rightarrow ^{86}\text{Sr}$ disintegrations result in the emission of a gamma-ray photon of 1.07 MeV in a given period of time. For example, a 37-kBq sample of ^{86}Rb by definition would emit 2.22×10^6 beta particles in 1 minute ($37,000 \text{ dps} \times 60 \text{ s/min}$). However, only $(2.22 \times 10^6)(0.088) = 1.95 \times 10^5$ gamma-ray photons of 1.07 MeV can be expected to be emitted in 1 minutes from this sample.

Fig. 1.102 shows the somewhat more complicated decay scheme of $^{144}_{58}\text{Ce}$, which has a half-life of 284.5 days. This nuclide decays by β^- emission with an increase in atomic number to $^{144}_{59}\text{Pr}$. In this case, three distinct β^- -decay processes produce three nuclear isomers of the daughter ^{144}Pr . Seventy-five percent of the beta particles emitted

FIGURE 1.102 Decay scheme of $^{144}_{58}\text{Ce}$.

have a maximum energy of 0.31 MeV, 20% have a maximum energy of 0.18 MeV, and the remaining 5% have a maximum energy of 0.23 MeV. Obviously, a greater amount of energy is released by the 0.31-MeV β^- -decay process. As a consequence, ^{144}Pr nuclides that result from beta-decay energy of 0.23 MeV can decay to the ground state with the emission of gamma-ray photons with an energy equivalent to 0.08 MeV, that is, $0.31 - 0.23 \text{ MeV}$. Likewise, ^{144}Pr isomers at an even higher energy state are products of the 0.18-MeV β^- -decay process. These can decay to the ground state with the emission of gamma-ray photons of energy 0.13 MeV, that is, $0.31 - 0.18 \text{ MeV}$. Not all of the product isomers decay with the immediate emission of gamma radiation, and the abundance of these transitions is given in Fig. 1.102.

It is also possible that essentially all of the product nuclides of a decay reaction will be at an excited or elevated energy state and subsequently fall to a lower energy state by the emission of gamma radiation.

The decay scheme of the nuclide $^{22}_{11}\text{Na}$ with a 2.6-year half-life serves as an example (see Fig. 1.103). The $^{22}_{11}\text{Na}$ nuclides decay by both electron capture (EC) and β^+ emission, at relative proportions of $\sim 10\%$ and $\sim 90\%$, respectively, to yield immediate $^{22}_{10}\text{Ne}$ product nuclides in an elevated energy state. Only a trace of the ^{22}Na nuclides (0.06%) decay directly to the ground state. All of the $^{22}_{10}\text{Ne}$ isomers in the excited energy state decay immediately with the emission of gamma-ray photons of 1.28 MeV energy, which is equivalent to the difference of the energy levels of the two $^{22}_{10}\text{Ne}$ isomers and also equivalent to the difference in energies released by the two β^+ -decay processes ($1.82 - 0.54 \text{ MeV}$).

Isomeric transition, as described earlier, is a decay process in which γ emission is the sole process of

FIGURE 1.103 Decay scheme of $^{22}_{11}\text{Na}$.

eliminating energy from an excited nucleus. This mode of decay is referred to as isomeric transition because neither the mass number, A , nor the atomic number, Z , of a nuclide (^A_ZX) changes in the decay process, and the nuclides are considered to be in isomeric energy states.

In the previous examples (Figs. 1.101–1.103) the isomeric energy state transitions are short-lived; that is, they occur virtually immediately after the other decay processes (*e.g.*, β^- , β^+ , and EC); and the half-life of the parent nuclide is dependent on these initial processes. If, however, the isomeric transitions are long-lived, the nuclide is considered to be in a metastable state. These nuclides are denoted by a superscript m beside the mass number of the nuclide. The radionuclide $^{119m}_{50}\text{Sn}$ with a 250-day half-life is an example. Its decay scheme, shown in Fig. 1.104, consists of the emission of two γ photons of 0.065 and 0.024 MeV energy falling from the 0.089-MeV excited state to the ground (stable) state.

Gamma radiation is not produced in all radionuclide decay processes. Instead, some radionuclides decay by emitting only particulate radiation to yield a product nuclide at an unexcited ground state. An example is the

FIGURE 1.104 Decay scheme of $^{119m}_{50}\text{Sn}$.FIGURE 1.105 Decay scheme of $^{32}_{15}\text{P}$.

radionuclide $^{32}_{15}\text{P}$, which decays by the scheme shown in Fig. 1.105.

C. Annihilation radiation

The negatron or negative beta particle, produced by β^- decay, will travel through matter until it has completely dissipated its kinetic energy via ionization, electron excitation, or bremsstrahlung. The negatron then at rest acts as an atomic or free electron in matter.

A positron or positive beta particle, however, is an “antiparticle” of an electron and consequently, in the electron environment of atoms, has a definite instability. A given positron (*i.e.*, positive electron) emitted by pair production or by β^+ decay will also dissipate its kinetic energy in matter via interactions described previously for the case of the negatron. However, as the positron loses its kinetic energy and comes to a near stop, it makes contact with an electron (Fig. 1.106) with nearly simultaneous annihilation of the positron and the electron masses and their conversion into energy. The annihilation involves the formation of positronium, which is a short-lived association of the

FIGURE 1.106 Annihilation. The interaction between a positron and an electron, and the conversion of their masses into two photons of 0.511 MeV energy.

positron and electron. Its lifetime is only approximately 10^{-10} or 10^{-7} seconds, depending on whether the spin states of the associated particles are parallel (ortho-positronium) or opposed (para-positronium). The para-positronium is the shorter-lived spin state. The energy released in this annihilation appears as two photons emitted in opposite directions. This transformation of mass into energy, considered as the reverse of pair production, is described as

$$e^+ + e^- = 2h\nu = 2E_\gamma \quad (1.385)$$

where a positron, e^+ , and negative electron, e^- , combine to form two gamma-ray photons of energy E_γ . To maintain the equivalence of mass and energy, the equivalent of two electron rest masses (0.511 MeV) must appear as photon energies. In agreement with Eq. (1.385), the annihilation results in the emission of two 0.511-MeV photons in opposite directions.

D. Line-spectra X-radiation and bremsstrahlung

X-radiation is electromagnetic radiation similar to gamma (γ) radiation. Both X-rays and γ -rays are identical in their properties. Both X-rays and γ -rays are photons that possess a quantum of energy defined by Eq. (1.371), namely, $E = h\nu$, which is the product of Planck's constant and the frequency of the radiation. X-rays and γ -rays differ only in their origin. X-rays originate from electron energy transitions, and γ -rays originate from the nucleus of an atom as a nucleus at an elevated energy state decays to a lower more stable energy state. There are two types of X-rays, which are the following:

- (i) Electromagnetic radiation characterized by discrete spectral lines of energy resulting from electron transitions in shells of the atoms (e.g., K , L , M ,... shells) from which they originate. These are X-ray emissions produced when an electron from a given shell is ejected from an atom and an electron from outer shell fills the vacancy left by the ejected electron. This is followed generally by a cascade of electron transitions from outer electron shells, since the filling of one electron vacancy by the transition of an electron from an outer to inner shell will leave another electron vacancy in the outer shell. For example, an electron vacancy in the K -shell created by the capture of an electron by the nucleus (e.g., EC or K -capture decay) is filled by an electron in the next outer L -shell creating an electron vacancy in that shell, which is followed by the filling of that electron vacancy by an electron in the next outer M -shell, etc. The spectra of these discrete energy lines of electromagnetic radiation are characteristic of the atoms from which they originate.

- (ii) Electromagnetic radiation characterized as a broad smear of continuous energies referred to as **bremsstrahlung**, which is produced by electrons or other charged particles, such as protons and alpha-particles, as they are accelerated toward an atomic nucleus and are deflected by the coulomb field of the nucleus. This was the type of X-ray discovered by Wilhelm Röntgen in 1895, who was the first to discover X-rays. Röntgen discovered the mysterious invisible rays on November 8, 1895, when he was studying cathode rays, i.e., the current that would flow through a partially evacuated glass tube (cathode-ray tube then referred to as a Crooke's tube). With such a tube covered in black paper and in a dark room, he noticed that a paper plate covered with the chemical barium platinocyanide would become fluorescent (give off light) even at a distance of 2 meters from the cathode ray tube. He was able to demonstrate that the invisible rays came from the collision of the cathode rays (electrons) with the glass surface of the cathode-ray tube or from the collision of the cathode rays with other materials such as aluminum inserted into the glass of the tube. Further studies by Röntgen demonstrated that these rays could travel through various materials to varying extents, when these were placed in the path of the invisible rays, and the transmitted rays could be measured with photographic plates. He gave these mysterious rays the name X-rays, because of their unknown nature and "for the sake of brevity", as he stated in his original papers (Roentgen (1895, 1896).

1. X-rays characterized by discrete spectral lines

In Section X.B.3 we discussed the electron-capture (EC) or K -capture decay process whereby an electron from one of the atomic shells (generally the innermost K shell) is absorbed by the nucleus, where it combines with a proton to form a neutron. The vacancy left by the electron from the K shell is filled by an electron from an outer shell (generally the adjacent L shell). Transitions produced in electron shell energy levels result in the emission of energy as X-radiation. This radiation consists of photons of electromagnetic radiation similar to gamma radiation. X-radiation and gamma radiation differ only in their origin. X-rays arise from atomic electron energy transitions and gamma rays from energy state transitions of an atomic nucleus. Another nuclear decay process that results in the loss of atomic electrons is decay by internal conversion (IC), which competes with gamma-ray emission, discussed in Section X.C of this chapter. Also, Auger electron emission, that may follow EC decay, will leave a vacancy in an electron shell that would cause electron transitions from outer shells during the filling of that vacancy and the emission of X-

FIGURE 1.107 Electron capture (EC) decay and the accompanying gamma ($h\nu$) and X-radiation.

FIGURE 1.108 Atomic electron energy levels or shells (K , L , M , etc.) and lines of transition corresponding to characteristic X-rays (K_α , K_β , K_γ , etc.).

rays. The production of X-radiation from atomic electron transitions is illustrated in Figs. 1.67, 1.68, 1.107, and 1.108.

When an electron transition occurs from the outer L shell to an inner K shell, the energy emitted is equivalent to the difference between the K and L electron binding energies. The electron transitions that ensue in the filling of vacancies result in energy lost by the atom as X-radiation, which is equivalent to the difference of the electron binding energies of the outer, E_{outer} , and its new inner state, E_{inner} , as described by

$$h\nu = E_{\text{outer}} - E_{\text{inner}} \quad (1.386)$$

The radiation emitted consists of a discrete line of energy characteristic of the electron shell and, consequently, of the atom from which it arises.

The production of X-rays in radionuclide decay is, however, more complex. The filling of one electron vacancy in an inner shell is followed by a series of electron transitions in an overall adjustment of electrons in outer shells. This gives rise to further X-rays with lines characteristic of outer shells. Such electron transitions, each resulting in the emission of discrete lines of characteristic X-rays, are illustrated in Fig. 1.108. The transitions are identified by a letter corresponding to the shell (K , L , M , etc.) with vacancy giving rise to the X-ray photon and a subscript (α , β , γ , etc.) to identify, from among a series of outer electron shells of the atom, the shell from which the electron vacancy is filled. For example, an X-ray arising from an electron transition from the L to the K shell is denoted as K_α and that arising from a transition from the M to the K shell as K_β . Transitions involving the filling of electron vacancies in the L shell from outer M , N , and O shells are denoted by L_α , L_β , and L_γ , etc.

The complexity of X-ray lines emitted and their abundances of emission are compounded by the existence of other mechanisms of X-ray production in unstable atoms. One of these mechanisms is the production of Auger electrons. An electron transition involving the filling of an electron vacancy in an inner shell from an outer shell of an atom may produce an Auger electron (see Section X.D), which results in the emission of an atomic electron from a shell farther away from the nucleus. The vacancy left by the Auger electron gives rise to X-rays characteristic of outer shells following the electron readjustments that ensue. Auger electrons can be emitted from a variety of electron shells, followed by an equal variety of characteristic X-rays from subsequent electron adjustments in outer shells.

Any process that would cause the ejection of an atomic electron of an inner shell can result in the production of X-radiation. Other processes, such as radiation-induced ionization within inner electron shells of atoms, will result in the filling of the missing electron from an outer shell and a cascade of electron rearrangements from outer to inner shells. Any radiation source that can produce ionization, even X-rays that impinge on a target material, will produce additional X-rays as a consequence of the ionization of internal electron shells of atoms, and these X-ray emissions will be characteristic of the elements that were ionized by the external radiation. Nobel Laureate Charles Glover Barkla (Barkla, 1917) made this observation in 1917 in his Nobel lecture where he stated

Each element when traversed by x-rays emits x-radiations characteristic of the element; each characteristic radiation is unaffected by changes in the physical condition or

state of chemical combination of the radiating element, and its quality is independent of that of the exciting primary radiation. But only primary radiations of shorter wavelength are able to excite the characteristic x-radiations ... all of the radiations hitherto definitely observed have fallen into three series, the K-, L-, and M-series.

Thus, each element can be characterized by its X-ray emission spectra. It was Henry Moseley who devised an apparatus whereby he could bombard individually all of the known and available elements with cathode rays and measure the wavelengths of the X-rays emitted by each element (Moseley, 1913, 1914). In his first report Moseley (1913) measured the X-ray emission spectra of 21 elements of increasing numbers of the Periodic Table of the Elements from aluminum to silver and determined the wavelengths of the α and lower intensity β lines that belong to Barkla's K series. In a subsequent paper Moseley (1914) measured the wavelengths of the L series of X-ray emissions of 24 elements of increasing numbers of the Periodic Table of the Elements from zirconium to gold. Of the L-series he measured the wavelengths of α , β , γ , and δ lines of decreasing wavelengths and decreasing intensities. Moseley then plotted the square root of the radiation frequencies against a characteristic integer (N) assigned to each element. Starting with aluminum, being the 13th element in the periodic table, he assigned it the number $N = 13$. The next element, silicon, was assigned the next highest integer $N = 14$, phosphorus $N = 15$, etc. A copy of his plots are illustrated in Fig. 1.109. The plots showed an incredibly straight line relationship between the assigned integer N and the X-radiation frequencies for each element. From this relationship he concluded the following with the writer's comments in brackets (Moseley, 1914):

Now if either the elements were not characterized by these integers or any mistake had been made in the order chosen, or in the number of places left for unknown elements [places for three unknown elements in the Periodic Table were found, See Fig. 1.109], these irregularities would at once disappear. We can therefore conclude from the evidence of the x-ray spectra alone, without using any theory of atomic structure, that these integers are really characteristic of the elements. Further, as it is improbable that two different stable elements should have the same integer, three, and only three, more elements are likely to exist between Al and Au. As the x-ray spectra of these elements can be confidently predicted, they should not be difficult to find ... There is ever reason to suppose that the integer which controls the x-ray spectrum is the same number of electrical units in the nucleus ...

In this work Moseley was able to demonstrate that the number of electrons in the atoms of each element are equivalent to what we now refer to as the atomic number Z (Moseley's N) and that the X-ray emission spectra is a characteristic of each element.

Nobel Laureate Karl Manne Siegbahn provided insight into the energy quanta emitted by the X-rays and consequently the energy states of the electrons in the K-, L-, M-, N- and other electron energy levels of the elements. The impact of Siegbahn's findings was underscored in the Nobel Prize Presentation Speech (Gullstrand, 1925) with the statement

In an element that can emit both K-and L-rays, the former radiation has much shorter wavelengths and consequently greater frequencies than the latter. As the energy quanta are proportional to the frequencies, therefore, the K radiation involves a larger change in the energy of the atom than the L radiation; and in the atomic theory this is as much as to say that an orbit into which an electron falls on emission of a K-line must lie nearer the nucleus than an orbit to which an electron falls on emission of an L-line. In this way it was inferred that there is a K-level nearest the nucleus, outside that a L-level, and after that a M-level and a N-level (and so on ...), all these four being experimentally determined [by Manne Siegbahn].

Because X-radiation is characteristic of the atom from which it arises, it is customary to identify the element along with the X-ray photon (e.g., Cr K X-rays, Hg L X-rays, etc., and many examples are listed in Appendix A). In these examples, the fine structure of the X-ray emissions is not given in the Appendix, and the lines are grouped together as K and L X-rays.

Whenever, a nuclide undergoes alpha- or beta-decay including EC decay, the daughter nucleus may be left at an excited energy state whereby the daughter nucleus then decays to the ground state with the emission of gamma radiation. The emission of IC electrons often competes with gamma emission, which leaves vacancies in electron shells and the concomitant emission of X-rays. In such cases, the X-ray emissions are characteristic of the daughter atom. See examples throughout Appendix A in the Table of Radioactive Isotopes where the X-ray emission intensities are listed as those of the daughter nuclide rather than the parent.

2. Bremsstrahlung

Bremsstrahlung is a type of X-radiation that is characterized by a broad smear of continuous energies of electromagnetic radiation anywhere in the range between zero and an energy maximum. In general, any charged particle that undergoes acceleration will emit electromagnetic radiation;

FIGURE 1.109 Artist's portrayal of Moseley's original 1914 graph of the frequencies and wavelengths of X-rays emitted by all of the then known elements plotted against each element and an integer N assigned to each element starting at aluminum (Al, assigned $N = 13$) to gold (Au, assigned $N = 79$). Three missing and yet unknown elements are listed with blank spaces adjacent to integers $N = 43, 61,$ and 75 . The two lines of the lower curves (elements $N = 13$ to 47) are X-rays resulting from α and β lines of the K series of electron transitions, and the four lines of the upper curves (elements $N = 40$ to 79) are X-rays resulting from $\alpha, \beta, \gamma,$ and δ lines of the L series of electron transitions. The original Moseley graph, drawn by his own hand, may be seen in the Moseley Room of the Cavendish Laboratory, University of Oxford). From *Moseley (1914)*.

thus, an accelerating charged particle will emit bremsstrahlung when it is made to decelerate upon deflection from its path of travel by collision or near encounter with an atomic nucleus. Charged particles undergoing acceleration, such as beta particles, electrons, protons, deuterons, and alpha particles, can emit bremsstrahlung as these particles decelerate in a series of collisions with atomic nuclei. This mechanism is illustrated in Fig. 1.110, where a beta particle traveling through matter approaches a nucleus and is deflected by it. This deflection causes a deceleration of the

beta particle and consequently a reduction in its kinetic energy with the emission of energy as a photon of bremsstrahlung, which is taken from the German language meaning "braking radiation." The phenomenon is described by

$$h\nu = E_i - E_f \quad (1.387)$$

where $h\nu$ is the energy of the photon of bremsstrahlung, E_i is the initial kinetic energy of the beta particle prior to collision or deflection, producing a final kinetic energy E_f of the electron.

FIGURE 1.110 Bremsstrahlung production. A beta particle is deflected by an atomic nucleus and loses kinetic energy with the emission of a photon of X-radiation.

As described by Evans (1955), the acceleration produced by a nucleus of charge Ze on a particle of charge ze and mass M is proportional to Zze^2/M , where Z is the atomic number of the nucleus, e is the elementary charge $= 4.803 \times 10^{-10}$ esu, and z is the particle atomic number or 1 for electrons and protons, 2 for alpha particles. Thus, the bremsstrahlung intensity, which is proportional to the square of the product of the amplitude and the charge ze , will vary according to $Z^2 z^4 e^6 / M^2$ (Evans, 1955). From this relation it is seen that the production of bremsstrahlung per atom of absorber is proportional to the square of the atomic number of the absorber material, and that the total bremsstrahlung is inversely proportional to the square of the mass M of the accelerating charged particle. It is intuitively obvious and it has been demonstrated through experiment, that an absorber material of higher atomic number will yield a greater production of bremsstrahlung per atom, because the size of the nucleus as well as its charge increases with atomic number, and thus the probabilities of interaction of the accelerating charged particle with a nucleus will be a function of the magnitude of the charge on the nucleus as well as the nuclear size. For example, a charged particle (*e.g.*, electron or beta particle) of given energy will yield more bremsstrahlung upon interaction with absorber material consisting of pure Pb than one of Cu or C (*e.g.*, graphite), that is, bremsstrahlung in Pb ($Z = 82$) $>$ Cu ($Z = 29$) $>$ C ($Z = 6$). The inverse proportionality of bremsstrahlung to the square of the mass M of the charged particle, yields as an outcome that bremsstrahlung production by electrons ($M = 0.0005485$ u) is the most significant among all other charged particles, which are of much higher mass, *e.g.*, the muon ($M = 0.1134$ u), proton ($M = 1.007$ u), deuteron ($M = 2.014$ u), or the alpha particle ($M = 4.001$ u). For example the muon, which has a mass equivalent to 206.7

times that of the electron, would yield less bremsstrahlung than an electron of equal energy in the same absorber medium by a factor of more than 42,000, *i.e.*, $M_\mu^2 / M_e^2 = 0.1134^2 / 0.0005485^2 = 42,700$. A proton of the same energy and in the same absorber material would yield yet less bremsstrahlung than that of the electron by a factor of $M_p^2 / M_e^2 = 1.007^2 / 0.0005485^2 = 3.37 \times 10^6$. Nevertheless, bremsstrahlung from accelerated charged particles, such as accelerated muons and protons, are significant (Mahjour-Shafiei et al., 2006; Cohen et al., 2008; Johansson and Wilkin, 2009; Pérez et al., 2014; Sandrock et al., 2018).

The tremendous difference between the magnitudes of bremsstrahlung production by protons and electrons of the same energy in a given absorber material described in the previous paragraph (*i.e.*, $M_p^2 / M_e^2 = 1.007^2 / 0.0005485^2 = 3.37 \times 10^6$) was utilized by Olzem et al. (2007) to measure cosmic-ray positron radiation through bremsstrahlung conversion. A major difficulty in the measurement of cosmic-ray positrons in the energy range of 50 GeV is the high background of cosmic-ray protons, which exceed the number of positrons by a factor of 10^4 (Aguilar et al., 2002; Beatty et al., 2004; L'Annunziata, 2007, 2016). By detecting the bremsstrahlung produced by the high-energy (1–50 GeV) cosmic-ray positrons, the proton background in this same energy range is suppressed by a factor of more than 3×10^6 with respect to the electron (*i.e.*, positrons), as described by Olzem et al. (2007). Bremsstrahlung by cosmic-ray pions are also significantly suppressed compared to electron bremsstrahlung by a factor of $M_\pi^2 / M_e^2 = (0.1485\text{u})^2 / (0.0005485\text{u})^2 = 7.3 \times 10^4$. A diagram illustrating the process of cosmic-ray positron bremsstrahlung conversion is illustrated in Fig. 1.111.

FIGURE 1.111 Signature of pair production by a bremsstrahlung photon. From Olzem et al. (2007). Reprinted with permission of Elsevier © 2007.

As illustrated in Fig. 1.111 a primary cosmic-ray positron enters into the detector material from above producing bremsstrahlung photons. The bremsstrahlung photon then converts into a positron–electron pair. Three particles are observed in the tracking detector, namely, the positron and negatron each of 0.511 MeV energy created in the pair production, which are highly deflected in a magnetic field, and the incident high-energy positron, which is only slightly deflected in the magnetic field. Olzem et al. (2007) report that additional background rejection of cosmic-ray mesons and protons are provided by the photon emission angles, which are essentially zero for high-energy positrons and significantly larger than zero for mesons and protons due to their higher mass.

a. Bremsstrahlung in beta-particle absorbers

When beta particles from a particular radionuclide source strike an absorber material, a wide spectrum of bremsstrahlung photon wavelengths (or energies) will be produced. The bremsstrahlung photon energies will range from zero to a maximum photon energy, $h\nu_{\max}$. The broad spectrum of bremsstrahlung is due to the broad possibilities of different interactions, *i.e.*, deflections or collisions, that the beta particles can have with atomic nuclei of the absorber and the broad spectrum of beta-particle energies emitted from any given radionuclide. In a given spectrum of bremsstrahlung the shortest wavelength, λ_{\min} , is observed when a beta particle or electron undergoes a direct collision with the nucleus of an atom and loses all of its kinetic energy, $h\nu_{\max}$, as bremsstrahlung or X-radiation according to the relation

$$h\nu_{\max} = \frac{hc}{\lambda_{\min}}, \quad (1.388)$$

which follows the energy-wavelength Planck–Einstein relation described previously by Eq. (1.371).

Let us consider an example of a 1710 keV beta particle from ^{32}P ($E_{\max} = 1.71 \text{ MeV}$) striking a nucleus. If the beta particle loses all of its energy in the collision, the wavelength of the bremsstrahlung emitted from this interaction according to Eq. (1.388) would be

$$\lambda = \frac{hc}{h\nu_{\max}} = \frac{12.4 \text{ keV} \cdot \text{\AA}}{1710 \text{ keV}} = 0.00725 \text{ \AA} \quad (1.389)$$

See Eq. (1.380) for the conversion of the constant hc to convenient units of eV m or eV Å. Bremsstrahlung production by high-energy beta particles in absorber material of high atomic number is significant (see Section XVI). Consequently to reduce the production of bremsstrahlung in radiation shielding against the harmful effects of

high-energy beta particles, an absorber of low atomic number (*e.g.*, plastic) may be preferred over one of high atomic number (*e.g.*, Pb-glass).

Ionization and electron excitation were previously described as predominant mechanisms by which a traveling beta particle may lose its kinetic energy in matter. However, the production of bremsstrahlung may also be another significant mechanism for the dissipation of beta-particle energy, particularly as the beta-particle energy and the atomic number of the absorber increase (Kudo, 1995; Czarnecki et al., 2016, 2017). A more thorough treatment is found in Section XVI.A of this chapter, which includes examples of calculations involved to determine the degree of bremsstrahlung production as a function of beta-particle energy and absorber atomic number. In general terms we can state that for a high-energy beta particle such as the beta particle of highest-energy emitted from ^{32}P ($E_{\max} = 1.71 \text{ MeV}$) in a high-atomic-number absorber such as lead ($\text{Pb} = 82$), bremsstrahlung production is significant. In a substance of low atomic number such as aluminum ($\text{Al} = 13$) bremsstrahlung production by a 1.71 MeV beta particle is reduced to more than six-fold as compared to lead (see Table 1.21 in Section XI.D.3.a).

In view of the wide spectrum of beta-particle energies emitted from radionuclides and the wide variations of degree of beta-particle interactions with atomic particles, the production of a broad spectrum, or smear, of photon energies of bremsstrahlung is characteristic. This contrasts with X-radiation, which is emitted as a result of atomic electron rearrangement processes, resulting in the emission of discrete lines of photon energy.

b. Artificially produced bremsstrahlung

An apparatus used to produce artificially X-rays, such as those employed in medical diagnosis or X-ray diffraction, functions on a similar principle of bremsstrahlung described previously. The X-ray apparatus consists of an evacuated tube containing a cathode filament and a metal anode target such as tungsten ($A = 74$). A voltage potential is applied to the tube so that electrons emitted from the cathode accelerate toward the anode. Upon colliding with the tungsten anode the accelerated electrons lose energy as bremsstrahlung X-radiation. For example, an electron accelerated in an X-ray tube to an energy of 40 keV, which loses all of its energy upon impact with a tungsten nucleus would produce a single X-ray photon of wavelength calculated as

$$\lambda = \frac{hc}{h\nu} = \frac{12.4 \text{ keV} \cdot \text{\AA}}{40 \text{ keV}} = 0.31 \text{ \AA} = 0.031 \text{ nm} \quad (1.390)$$

A broad spectrum of bremsstrahlung is produced due to the various degrees of deflection or collision of the accelerated electrons with the target nuclei.

Electron accelerators are a good source of bremsstrahlung currently employed in food irradiation for the preservation and extension of the shelf-life of food (Miller, 2003, 2005; Mehta et al., 2003; Auslender et al., 2004; Farkas, 2004, 2006; L'Annunziata, 2007, 2016; Farkas and Mohácsi-Farkas, 2010; Solanki et al., 2012; Sokovnin and Balezin, 2017). Food irradiation is the process where food is exposed to ionizing energy, utilizing gamma-ray photons emitted by ^{60}Co (or less frequently by ^{137}Cs), machine-generated X-rays (bremsstrahlung) of max. 5 MeV, or accelerated electrons of max. 10 MeV kinetic energy (Farkas, 2004). The use of accelerator sources is gradually replacing the use of radioisotope sources for the irradiation of food, mainly because the generation of the radiation can be controlled by a simple on-off switch (Cleland et al., 1991; Miller, 2003). The accelerators may be used to irradiate food directly with the electron beam or indirectly with the bremsstrahlung radiation produced after the electron beam strikes a converter material. To avoid the possibility of measurable food activation via photonuclear reactions, the kinetic energy of the electron beam is limited by regulation to 10 MeV, and the kinetic energy regulation for bremsstrahlung irradiation of foods is limited to 5 MeV.

Bremsstrahlung, electron beams, and gamma radiation have numerous industrial applications, which include, in addition to food preservation, the sterilization of health care products, the irradiation of blood to prevent transfusion-associated graft versus host disease, the sterilization of tissue for transplant surgery, the synthesis of radiation-cured rubber, and the manufacture of radiation-cured wood polymer composites, etc. These applications are reviewed in previous texts by the author (L'Annunziata, 2007, 2016).

c. Inner or internal bremsstrahlung

Bremsstrahlung of very low intensity, referred to as *inner* or *internal bremsstrahlung*, also occurs during the transforming nucleus in EC decay processes and beta particle emission. This is a continuous spectrum of X-ray photons that originates within the transforming atoms and can be attributed to the sudden change of nuclear charge when the beta particle is emitted or when an orbital electron is captured (Evans, 1955). Internal bremsstrahlung is explained by Cengiz and Almaz (2004) to occur during the emission of a β^- particle from the nucleus, as the β^- particle undergoes an acceleration at its birth and emits bremsstrahlung in the field of the emitting nucleus. The magnitude of inner bremsstrahlung

was calculated to be approximately 1/137 quantum of internal bremsstrahlung per beta particle emitted from the nucleus (Knipp and Uhlenbeck, 1936; Evans, 1955). Internal bremsstrahlung spectra for radionuclides that emit β^- particles were calculated by Cengiz and Almaz (2004), Khalil (2011), and Singh and Dhaliwal (2014, 2015). This radiation was named inner or internal bremsstrahlung, because it originates from the nucleus the internal part of the atom in contrast to external bremsstrahlung that occurs when an external beta particle approaches an atom external to it from another source and is deflected by the nucleus of that atom.

In the EC decay process, the quantum of energy not carried away by the neutrino is emitted as internal bremsstrahlung. Thus, in EC decay, internal bremsstrahlung may possess energies between zero and the maximum, or transition energy of a radionuclide. When gamma radiation is also emitted, the internal bremsstrahlung may be masked by the more intense gamma rays and go undetected. However, in the absence of gamma radiation, the upper limit of the internal bremsstrahlung can be used to determine the transition energy of a nuclide in EC decay. Some examples of radionuclides that decay by EC without the emission of gamma radiation are as follows:

and

where $h\nu$ is the internal Bremsstrahlung, the upper energy limits of which are expressed in MeV.

d. Nuclear bremsstrahlung (nuclear startstrahlung)

Nuclear bremsstrahlung was recently identified by Nie Luo, Magdi Ragheb, and George Miley at the University of Illinois (Luo et al., 2010). This class of bremsstrahlung refers to electromagnetic radiation of low energy (*i.e.*, soft X-rays of a few hundred eV to a few keV) emitted by a proton or deuteron or both as these undergo acceleration during the fusion of a proton with a neutron or the fusion of a proton with a deuteron. Luo et al. (2010) loosely assigned the name of nuclear bremsstrahlung to this phenomenon and have ventured to also call it nuclear startstrahlung from the German meaning “take-off radiation” depicting the acceleration of these nuclear particles as the origin of the soft X-rays. The identification of this class of bremsstrahlung opens the door to new plasma diagnostics such as in the identification of the parasitic D–D fusion reaction in future thermonuclear energy

based on D–T fusion. The D–D fusion reaction, previously described by Eq. (1.319), produces protons according to

The D–T thermonuclear reaction is also an excellent source of neutrons, as described previously in this chapter (see Eq. 1.317). The protons and neutrons generated can, in turn, participate in the thermonuclear process via other reactions including the fusing of a proton with a neutron according to

and the fusion of a proton with unreacted deuterium fuel according to the reaction

Both of which give rise to the nuclear bremsstrahlung, which are included in the above two reactions.

The process of nuclear bremsstrahlung, in the simplest case of p – n capture, is illustrated in Fig. 1.112. As described by Luo et al. (2010), the proton and neutron are attracted to each other by the strong nuclear force, and this attraction causes both particles to accelerate toward each other. Due to the charge on the accelerating proton, electromagnetic radiation is generated of the bremsstrahlung type. Luo et al. (2010) refer to this as a nuclear bremsstrahlung or nuclear startstrahlung to accentuate its origin in acceleration due to the strong nuclear force.

The fusion of the proton with deuterium yields the nuclear bremsstrahlung similar to the case of the proton and neutron fusion. However, Luo et al. (2010) explain that the Coulomb repulsion of proton and deuterium add a degree of complication to the process. They explain that the Coulomb barrier is overcome by quantum mechanical tunneling, and the strong nuclear force still causes both particles to accelerate toward each other, although the particles accelerate at different rates because of their mass difference. As both the proton and deuteron are charged they radiate quanta of electromagnetic radiation. Because the two charged particles are accelerating toward each other, they travel in opposite directions, the radiation they emit will tend to cancel each other; however, the cancellation is not complete, because the two particles accelerate at different rates due to their mass difference. Dhibar et al. (2018) describe large $\text{LaBr}_3\text{:Ce}$ solid scintillation detectors, which can serve potentially in the measurement of nuclear bremsstrahlung.

3. Bremsstrahlung and line spectra X-rays from beta-particle emitters

All beta-particle emissions from radionuclides, even those radionuclides classified as pure beta-emitters that are not

FIGURE 1.112 The nuclear bremsstrahlung process that releases soft X-rays in the proton-neutron capture and proton-deuteron fusion. The solid curves represent the attractive nuclear potential of a neutron (or deuteron) felt by a proton. The length dimension shown is ~ 10 fermi. (A) The proton, having an initial positive kinetic energy of several keV, is moving toward the neutron (or deuteron) due to nuclear attraction. (B) The proton accelerates in the process, and therefore starts radiating electromagnetic waves, *i.e.*, photons. (C) The proton, having lost all of its initial kinetic energy and maybe more, now has a total energy of negative value, *i.e.*, it is now a bound state around the neutron (or deuteron). Afterward it may emit a gamma of 2.23 MeV for proton-neutron fusion (or 5.49 MeV for proton-deuteron fusion) and then combine with the neutron (or deuteron) to finally form ${}^2\text{H}$ (or ${}^3\text{He}$). The acceleration of the neutron is radiation-free, because the neutron is without charge. In p – d fusion, the accelerating deuteron also radiates, but this is not illustrated in the figure for clarity. From Luo et al. (2010) with permission of Elsevier © 2010.

the source of any gamma radiation, including ${}^3\text{H}$, ${}^{14}\text{C}$, ${}^{32}\text{P}$, ${}^{35}\text{S}$, ${}^{45}\text{Ca}$, ${}^{63}\text{Ni}$, ${}^{89}\text{Sr}$, ${}^{90}\text{Y}$, and ${}^{123}\text{Sn}$, among others, will produce bremsstrahlung X-ray photons. For example, the measurement of bremsstrahlung from the beta particles of ${}^3\text{H}$ has been demonstrated as a method for the monitoring of the fuel processing system in the development of thermonuclear fusion reactors (Shu et al., 2004, 2006; Röllig et al., 2013; Matsuyama and Abe, 2016). In addition, this section will describe X-ray production by beta particles in thick-target materials. Thick-target materials include any absorber within which a beta particle will come to a complete stop. When beta particles are emitted from decaying nuclei and escape the atom from which they originated, X-ray photons are created by several distinct physical phenomena, which are enumerated as follows:

- External bremsstrahlung** is a continuous spectrum of X-rays produced when the accelerating beta particle traverses atoms of absorber material and is deflected by the Coulomb field of atomic nuclei causing the beta particle

to decelerate and emit electromagnetic radiation. This is the major source of X-ray energy that a beta particle will radiate. As discussed previously, the energy of the electromagnetic radiation emitted ($E = h\nu$) is proportional to the initial energy of the beta particle and the atomic number (Z) of the absorber. Thus, the bremsstrahlung energy loss (I) in MeV is written as

$$I \approx kZE^2 \quad (1.397)$$

or

$$I/E \approx kZE \quad (1.398)$$

where I/E is the fraction of incident beta-particle energy lost as bremsstrahlung, and $k \approx 0.0007 \text{ MeV}^{-1}$ is a normalization constant (Evans, 1955; Faw and Shultis, 2004). Table 1.21 illustrates the effect of atomic number Z on the conversion of beta-particle energy to bremsstrahlung in a thick target according to the approximation given by Eq. (1.398).

The estimates of energy conversion in Table 1.21 for a 0.5 MeV electron absorbed in copper agrees with that reported by Evans (1955), and that of a 1 MeV electron in aluminum and a 2 MeV electron in lead listed in Table 1.21 agree with estimates quoted by Choppin et al. (2002) and Faw and Schultis (2004), respectively. Molybdenum (Mo) and tungsten (W), listed in Table 1.21, are relatively high- Z materials with heat stability used as target materials for the production of bremsstrahlung X-rays in commercial medical diagnostic X-ray tubes (Mavunda et al., 2004).

b. Internal bremsstrahlung occurs during the emission of the beta particle from the nucleus, as the beta particle accelerates at its birth and emits a continuous spectrum

of X-rays in the field of the emitting nucleus (Cengiz and Almaz, 2004; Khalil, 2011; Singh and Dhaliwal, 2014, 2015). This mechanism of bremsstrahlung production is in direct contrast to that of outer bremsstrahlung whereby the beta particle approaches a nucleus from outside the atom described in the previous section.

c. X-rays corresponding to line spectra characteristic of the absorber material are produced when the beta particle traverses the absorber and produces ionization in inner electron shells (K, L, M, \dots shells). The electron vacancies in the inner shells are filled by electrons from outer shells with the concomitant emission of X-rays. These X-rays consist of discrete lines of energy characteristic of X-ray lines of the absorber material.

d. X-rays corresponding to line spectra characteristic of the emitting atom are produced when the beta particle produces ionization as it accelerates out of the atom from which it was created. Ionization of internal electron shells (K, L, M, \dots shells) of the emitting atom leaves electron vacancies, which are filled by electrons from outer shells, producing X-rays of discrete energy lines characteristic of the emitting atom. The probability of this internal ionization followed by X-ray emission by the β -emitting atom is of the order of 10^{-4} (Levinger, 1953; Boehm and Wu, 1954; Evans, 1955).

E. Cherenkov radiation

Charged particles, when they possess sufficient energy, may travel through a transparent medium (gas, liquid, or solid) at a speed greater than the speed of light in that medium. This occurrence, known as the Cherenkov effect, causes the emission of photons of light referred to as Cherenkov

TABLE 1.21 Approximate incident beta-particle energy loss (I/E) as bremsstrahlung in various thick targets.^a

Incident energy (E)	Fraction of incident beta-particle energy loss (I/E)					
	H ₂ O ($Z = 6.6$) ^b	Al ($Z = 13$)	Cu ($Z = 29$)	Mo ($Z = 42$)	W ($Z = 74$)	Pb ($Z = 82$)
0.1 MeV	0.05%	0.09%	0.2%	0.3%	0.5%	0.6%

^aCalculated according to $I/E \approx (0.0007 \text{ MeV}^{-1}) ZE$ where I is the total bremsstrahlung energy (MeV), E is the incident electron or beta-particle energy (MeV), and Z is the atomic number of the thick-target absorber.

^bFor H₂O, a compound absorber, the effective or modified atomic number is used as calculated by Markowics and VanGriken (1984) and Manjunatha and Rudraswamy (2009, 2010), namely, $Z_{\text{mod}} = \left(\sum_i W_i Z_i^2 / A_i \right) / \left(\sum_i W_i Z_i / A_i \right)$ where W_i , Z_i , and A_i are the weight fraction, atomic number, and mass number, respectively, of the i th element.

photons or Cherenkov radiation. These photons extend over a range of wavelengths from the ultraviolet into the visible portion of the electromagnetic radiation spectrum.

1. Origin and characteristics

Cherenkov photon emission is a result of a coherent disturbance of adjacent molecules in matter caused by the traveling charged particle, which must possess a certain threshold energy. This phenomenon has practical applications including (i) the measurement and detection of radionuclides that emit relatively high-energy beta particles, (ii) the measurement of gamma radiation via the Cherenkov effect produced by Compton electrons, and (iii) the identification of subatomic particles. The history of discovery, theory, and the applications of Cherenkov photons are discussed in detail in Volume 2, Chapter 6 of this book, and only a brief treatment is provided in this chapter.

Cherenkov radiation was discovered by Pavel A. Cherenkov (1934a,b, 1936) while working on his PhD dissertation under the direction of Sergei I. Vavilov, who was director of the P. N. Lebedev Institute of Physics in Moscow. For detailed accounts of the history of this discovery and Cherenkov's experimental technique, see papers by Cherenkov's daughter, Elena Cherenkova (2005, 2008) and previous books by the author (L'Annunziata, 2007, 2016). Once Cherenkov had discovered this unique visible radiation produced by high-energy Compton electrons or high-energy β -particles, and once Cherenkov found that this light was polarized and that the light emission was asymmetric, that is, it was emitted only in the direction of the fast electrons (Cherenkov, 1934a; b, 1936) did Cherenkov and his doctoral dissertation advisor Sergei I. Vavilov, know that they were dealing with a yet unknown phenomenon. Il'ja Frank and Igor Tamm of the Theoretical Physics Division of the same institute took notice and went to work on the interpretation of this new phenomenon. Their findings were published in a joint paper entitled "Coherent Visible Radiation of Fast Electrons Passing through Matter" (Frank and Tamm, 1937). They explained the phenomenon as caused by a charged particle

traveling in a medium at a speed in excess of the speed of light in that medium. It was known from Einstein's theory of relativity that matter could not travel in excess of the speed of light in a vacuum ($c = 2.99 \times 10^8$ m/s); however, in gaseous, liquid, or solid media, the velocity of light will be less than its velocity in a vacuum and, an elementary charged particle with sufficient energy could travel in such media at speeds exceeding that of light. The charged particle in passing through the electron clouds of a transparent medium (liquid, solid or gaseous) would create an electromagnetic shock wave analogous to that of a "sonic boom" created by a jet airplane or projectile traveling in the atmosphere at a speed exceeding that of sound. In the words of Frank and Tamm (1937) with authors remarks in brackets:

We shall consider an electron moving with constant velocity v along [an] axis through a medium characterized by its index of refraction n . The field of the electron may be considered as the result of superposition of spherical waves of retarded potential, which are being continually emitted by the moving electron and are propagated with the velocity (c/n) . [See Fig. 1.113] It is easy to see that all these consecutive waves emitted will be in phase along the directions making the angle θ with the axis of motion [of the particle], if only v , n , and θ do satisfy the condition

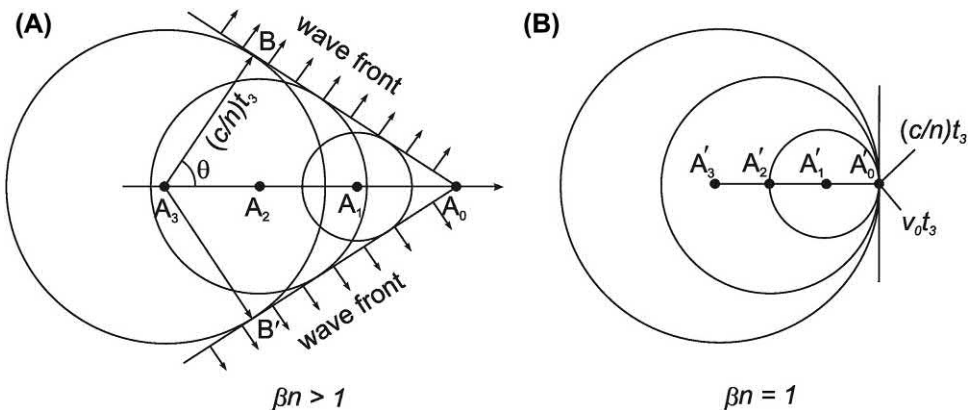

$$\cos \theta = \frac{1}{\beta n} \quad (1.399)$$

where $\beta = v/c$. Thus, there will be a radiation emitted in the direction θ , whereas the interference of waves will prevent radiation in any other direction. Now the condition [of radiation emission] can be fulfilled only if

$$\beta n > 1, \quad (1.400)$$

that is, only in the case of fast electrons in a medium, whose index of refraction n for frequencies in question is markedly larger than 1.

FIGURE 1.113 A Huygens construction of the spherical waves of retarded potential produced by a charged particle traveling along an axis in a refractive medium from points A_3 to A_0 at two velocities, namely, (A) $\beta n > 1$ and (B) $\beta n = 1$. From Nobel Lecture of Il'ja Frank (1958) with permission © The Nobel Foundation 1958.

The index of refraction, n , is by definition the ratio of the speed of light in a vacuum to its speed in a particular medium, and the value of n will vary from one medium to another. The term “fast electrons” used by Frank and Tamm (1937), quoted above, refers to electrons of such energy that they travel at a speed in excess of the speed of light in a particular medium. Also, the term β is called the relative phase velocity of the particle ($\beta = v/c$) or the velocity of the particle in a medium divided by the speed of light in a vacuum.

Eq. (1.399), derived by Frank and Tamm, can be found from the distance of travel of the spherical wave front relative to the distance traveled by the electron, as depicted in Fig. 1.113. In the words of Frank (1958) in his Nobel Lecture (© The Nobel Foundation):

... We have to consider each point of the particle trajectory as a source of waves. In this case the wave phase is determined by the instant of passage of the particle through a given point. Let us assume that at moment $t = -t_3$ the emitter was at point A_3 , at moment $t = -t_2$ at point A_2 , at moment $t = -t_1$ at A_1 , and, finally, at the moment of observation $t = 0$ at A_0 .

... the velocity of the waves is equal to the phase velocity of light c/n ... The surfaces of the rays are simply spheres whose radii for points A_3, A_2, A_1 , and A_0 are $(c/n)t_3, (c/n)t_2, (c/n)t_1$, and 0, respectively [See Fig. 1.113A]. The envelope of these spheres evidently represents a cone of circular cross section with the apex at A_0 . Its generatrices in the plane of the drawing are A_0B and A_0B' .

According to the Huygens' principle, the directions of the rays are defined by the radius vectors drawn from some centre of the waves to the point of tangency with the envelope. For example, in Fig. 1.113A, it is A_3B and A_3B' coinciding with the generatrices of the wave normal cone ...

From Fig. 1.113 it is not difficult to determine the magnitude of the threshold velocity. When the velocity diminishes, the distances between points A decrease. The threshold case arises when point A , occupies the position A'_0 on the surface of the sphere (This case is depicted separately in Fig. 1.113B.) At lower velocities, one of the spheres lies completely within the other and they do not have a common envelope. In the threshold case [$\beta n = 1$], they have only a common point of tangency, A'_0 . Thus evidently $(c/n)t_3 = vt_3$, i.e. $v_0 = c/n$. The cone of wave normals is compressed in the direction of velocity v , and the wave cone transforms into a plane perpendicular to the axis of motion at point A'_0 [Fig. 1.113B].

From Fig. 1.113A the equation defining the angle θ as a function of the particle phase velocity β and index of refraction n , i.e., $\cos \theta = 1/\beta n$, is derived from the distances

of travel of the wave front with respect to that traveled by the charged particle. The velocity v of travel of the wave front in a particular medium is a function of the index of refraction n of the medium, since by definition $n = c/v$. The distance traveled by the wave front from A_3 to B of Fig. 1.113A is the product of velocity and time t or $A_3B = vt_3$, and the distance traveled by the charged particle in the same time span from A_3 to A_0 is the product of the particle velocity in the medium v_p and time t_3 or $A_3A_0 = v_p t_3$, which may be written as $A_3A_0 = (v_p/c)ct_3$. Since the particle phase velocity β is defined as v_p/c , the distance A_3A_0 traveled by the charged particle becomes $A_3A_0 = \beta ct_3$. The angle of emission θ of the Cherenkov radiation with respect to the direction of travel of the charged particle is defined as

$$\cos \theta = \frac{AB}{A_3A_0} = \frac{(c/n)t_3}{\beta ct_3} = \frac{1}{\beta n} \quad (1.401)$$

Thus, the Cherenkov photons are anisotropic, that is, the photons are not emitted in all directions; rather, the photons are conical, i.e., they are emitted as a cone at an angle θ . The angle of emission is a function of the phase velocity of the particle (β) and the index of refraction (n) of the medium within which the particle is traveling. If the particle is assigned a maximum velocity, where β approaches unity, there will be a maximum angle of emission θ of the Cherenkov photons in liquids, and the angle would be a function of the index of refraction of the medium or

$$\cos \theta_{\max} = \frac{1}{n} \quad \text{when } \beta = 1 \quad (1.402)$$

For example, if an electron traveling in water is assigned a maximum velocity, where $\beta = 1$, and the index of refraction of water at the sodium D line, $n_D^{20} = 1.3330$, the maximum angle of emission of Cherenkov photons in water would be calculated according to Eq. (1.402) as

$$\theta_{\max} = \cos^{-1} \frac{1}{1.3330} = 41.4^\circ \quad (1.403)$$

In another medium such as benzene, where the index of refraction, $n_D^{20} = 1.50108$, the maximum angle of emission of the Cherenkov photons would be 48.2° calculated according to Eq. (1.401). Thus, Cherenkov photons are emitted as a cone at various angles between zero and a maximum value depending on the velocity of the particle and the index of refraction of the medium within which the particle travels. The conical properties of Cherenkov radiation, illustrated in Fig. 1.114, was described by Cherenkov in 1958 in his Nobel Lecture (Cherenkov, 1958), with the authors comments in brackets as follows:

“If we consider the picture [of the radiation] not in the [2-dimensional] plane but spatially, then the radiation must spread out along the surface of a cone whose axis forms the

FIGURE 1.114 Diagram of an experimental arrangement for obtaining photographs of the cone section in the plane of a photographic plate placed perpendicular to the path of high-speed (600 MeV) protons in an accelerator beam. For the color version of this figure, the reader is referred to the electronic version of the book.

path of an electrically charged particle while the surface line forms with this axis the angle $[\theta]$.

If we place [a] photographic plate perpendicular to the beam of high-speed particles [See Fig. 1.114], we shall obtain, in addition to an image of the track of the beam, also a photograph of the radiation in the form of a ring. This photograph was obtained with the aid of a fine beam of protons in the accelerator of the United Institute for Nuclear Research at Dubna.

... we have in our considerations assumed some fixed frequency. In reality, however, the radiation spectrum is continuous. Since the medium exhibits dispersion, i.e., the refractive index is dependent on the frequency, this means that the light of different wavelengths is propagated at angles which, even with strictly constant velocity of the particles, differ somewhat from one another.

Thus, the radiation is broken up as in spectral analysis. The radiation cone will consequently show a definite intensity, and in the case of a medium with normal dispersion the spectral red will lie in the inner part of the cone while the violet is on the outside. That this is actually so was shown by a photograph showing part of the ring with a colour plate."

2. Threshold condition

As discussed in the previous section, the threshold condition for the production of Cherenkov radiation in a transparent medium is given by

$$\beta n = 1 \quad (1.404)$$

where β is the relative phase velocity of the particle, that is, the velocity of the particle divided by the speed of light in a

vacuum, and n is the refractive index of the medium (i.e., the ratio of the velocity of light in a vacuum to its velocity in the medium). Only charged particles that possess

$$\beta > 1/n \quad (1.405)$$

produce Cherenkov photons in transparent media (Frank and Tamm, 1937). The value of β of the charged particle is dependent on its kinetic energy, which is obtained from the equation describing the total energy of the particle. As described previously in this chapter, the total energy (E_{tot}) of a particle is the sum of its kinetic (E_K) and rest energies (m_0c^2) or

$$E_{\text{tot}} = E_K + m_0c^2 = \gamma m_0c^2 \quad (1.406)$$

and

$$E_K = \gamma m_0c^2 - m_0c^2 \quad (1.407)$$

where

$$\gamma = \frac{1}{\sqrt{1 - (u^2/c^2)}} \quad \text{and} \quad u/c^2 = \beta^2 \quad (1.408)$$

u is the particle speed and $u < c$. (The particle speed is often represented with the symbol v or u .) If m_0 is the particle rest mass, then the particle relativistic mass, m_r , which is the speed-dependent mass of the particle would be defined as

$$m_r = \frac{m_0}{\sqrt{1 - (u^2/c^2)}} = \frac{m_0}{\sqrt{1 - \beta^2}} \quad (1.409)$$

Thus, for a particle traveling at relativistic speed, Eq. (1.407) can be expressed as

$$E_K = m_0c^2 \left[\frac{1}{(1 - \beta^2)^{1/2}} - 1 \right] \quad (1.410)$$

where m_0 is the particle rest mass in grams, c is the velocity of light in a vacuum (equal to 2.99×10^{10} cm/s), and E_K is the kinetic energy in erg (where 1.602×10^{-12} erg = 1 eV). Eq. (1.410) can be solved for β to give the expression for the phase velocity of the particle as a function of its energy or

$$\beta = \left[1 - \left(\frac{1}{(E_K/m_0c^2) + 1} \right)^2 \right]^{1/2} \quad (1.411)$$

The value of the rest energy for an electron is $m_0c^2 = (9.109 \times 10^{-28} \text{ g}) (2.9979 \times 10^{10} \text{ cm/s})^2 = 8.19 \times 10^{-7}$ erg. The energy in ergs may be converted to electron volts as follows: $(8.19 \times 10^{-7} \text{ erg}) / (1.602 \times 10^{-12} \text{ erg/eV}) = 511 \text{ keV}$. Substituting the value of 511 keV for m_0c^2 in Eq. 1.411 and solving for β gives

$$\beta = \left[1 - \left(\frac{1}{(E_K/511 \text{ keV}) + 1} \right)^2 \right]^{1/2} \quad (1.412)$$

Thus, the value of β , where electrons or beta particles are concerned, is dependent upon the electron or beta-particle energy, E_K , in keV according to Eq. (1.412).

3. Threshold energies

As noted above, the particle phase velocity, β , is a critical factor in the production of Cherenkov photons in a medium of given index of refraction, n , that is, Cherenkov radiation will occur only when $\beta > 1/n$. Consequently the particle energy, upon which the particle phase velocity is dependent, is a critical factor. Thus, a minimum or threshold energy of the particle must be reached when traveling in a medium of given index of refraction before Cherenkov photons will be produced. If we apply the threshold value of β for the production of Cherenkov photons from Eq. (1.404), that is, $\beta = 1/n$, to Eq. (1.410), we will obtain the threshold energy that particles must possess for the production of Cherenkov radiation as a function of the index of refraction of the medium as

$$E_{th} = m_0 c^2 \left[\left(1 - \frac{1}{n^2} \right)^{-1/2} - 1 \right] \quad (1.413)$$

where m_0 is the particle rest mass and c is the velocity of light in a vacuum (2.9979×10^{10} cm/s). Eq. 1.413 is dealt with in more detail in Volume 2, Chapter 6. Thus, the threshold energy for Cherenkov photon production will vary according to the particle rest mass and index of refraction of the medium. The energy required for the production of Cherenkov photons, E_{th} , increases with particle mass, and it will be lower for media of higher index of refraction.

The value of the rest energy for an electron is $m_0 c^2 = (9.109 \times 10^{-28} \text{ g}) (2.9979 \times 10^{10} \text{ cm/s})^2 = 8.19 \times 10^{-7} \text{ erg}$. The energy in ergs may be converted to electron volts as follows: $(8.19 \times 10^{-7} \text{ erg}) / (1.602 \times 10^{-12} \text{ erg/eV}) = 511 \text{ keV}$. Substituting the value of 511 keV for $m_0 c^2$ in Eq. 1.413 will yield the equation for the calculation of the threshold energy that electrons or beta particles must possess for the production of Cherenkov radiation as a function of the index of refraction of the medium as

$$E_{th} = 511 \text{ keV} \left[\left(1 - \frac{1}{n^2} \right)^{-1/2} - 1 \right] \quad (1.414)$$

The counting of Cherenkov photons for the analysis of radionuclides is a common technique, and Eq. (1.414) may be used to assess the potential of a given medium for the detection of beta particles that are emitted by particular radionuclides. For example, the radionuclides ^{33}P and ^{32}P are commonly used as radionuclide tracers in the bio-sciences, and aqueous solutions are generally the medium within which the radionuclides are analyzed. Eq. (1.414) may be used to determine the threshold energy for the

production of Cherenkov photons by beta particles (*i.e.*, electrons) in water with the index of refraction of water ($n_D^{20} = 1.3330$) to give

$$\begin{aligned} E_{th} &= 511 \text{ keV} \left[\frac{1}{\sqrt{1 - \frac{1}{(1.333)^2}}} - 1 \right] \\ &= 511 \text{ keV} \left[\frac{1}{\sqrt{0.43721}} - 1 \right] \\ &= 511 \text{ keV} \left[\frac{1}{0.66121} - 1 \right] \\ &= (0.5110 \times 10^6 \text{ eV})(0.51236) = 0.262 \text{ MeV} \end{aligned} \quad (1.415)$$

Thus, the beta particle must possess a minimum of 0.262 MeV energy to produce Cherenkov photons in water. Comparing the maximum energies of the beta emissions of ^{32}P ($E_{\max} = 1.710 \text{ MeV}$ and ^{33}P ($E_{\max} = 0.249 \text{ MeV}$) clearly indicate that the beta emissions from ^{33}P will not produce any Cherenkov photons in water, and only those beta-particle emission from ^{32}P in water with energies in excess of 0.262 MeV can be detected by Cherenkov photon counting. Thus, the Cherenkov effect may be used to discriminate between ^{32}P and ^{33}P in water by detecting only the ^{32}P fraction. Cherenkov photon counting is discussed in detail in Volume 2, Chapter 6 together with other applications of the Cherenkov effect.

4. Applications

There are numerous applications of the Cherenkov effect, and these are discussed in detail in Volume 2, Chapter 6. Among these applications are (i) the analysis of radionuclides that emit beta particles with sufficient energy to produce Cherenkov photons in the medium in which they are analyzed, (ii) the discrimination of beta-emitting radionuclides by the selection of a medium with an index of refraction that would allow or prevent the Cherenkov effect, (iii) the measurement of gamma radiation via the detection of Cherenkov photons produced by Compton electrons, and (iv) high-energy particle identification with ring-imaging Cherenkov (RICH) detectors.

Cherenkov Photon ring imaging has developed into a field of its own. Special ring-imaging Cherenkov (RICH) detectors have been developed, which are used for particle identification. Such detectors can provide information on the particle velocity, β , and discriminate between very high-energy relativistic particles of different mass, such as protons ($m = 938.27 \text{ MeV}/c^2$), kaons

($m = 493.67 \text{ MeV}/c^2$), pions ($m = 139.56 \text{ MeV}/c^2$), and electrons ($m = 0.511 \text{ MeV}/c^2$). The RICH detectors can be used to discriminate between kaons and pions of momentum of approximately $50 \text{ GeV}/c$. These detectors are discussed in detail in Volume 2, Chapter 6, and reviewed by Engelfried and Paic (2005), Bressan et al. (2008), Engelfried (2011), and Inami (2017).

F. Synchrotron radiation

Synchrotron radiation is electromagnetic radiation emitted by charged particles of low mass (*e.g.*, negatrons or positrons) traveling at relativistic speeds (*i.e.*, close to the speed of light) as the particles are caused to undergo radial acceleration when deflected in a magnetic field. The radiation emitted covers a broad spectrum from the long microwaves to the shorter wavelengths of hard X-rays. Synchrotron radiation is produced both naturally and artificially.

1. Synchrotron radiation from natural sources

A natural source of synchrotron radiation is observed in certain light emissions from astronomic bodies. An example is provided by the light emitted from the Crab Nebula, which is the remnant of a supernova explosion of a massive star. An excellent image of the Crab Nebula obtained by the Spitzer Space Telescope is illustrated in Fig. 1.115, which shows the bluish-white light originating from Synchrotron radiation caused by clouds of relativistic electrons deflected radially by the magnetic field of a rotating neutron star.

2. Discovery of synchrotron radiation

The first artificial production of synchrotron radiation was reported in 1947 by Frank Elder, Anatole Gurewitsch, Robert Langmuir, and Herb Pollock in a letter entitled “Radiation from Electrons in a Synchrotron” in the journal *Physical Review* (Elder et al., 1947). They followed their initial observations with a paper on the properties of the radiation and it’s origin the following year entitled “Radiation from Electrons Accelerated in a Synchrotron” (Elder et al., 1948). In this work they concluded that the radiation emissions were due to “high-energy electrons subjected to large radial accelerations”. The radiation was named synchrotron radiation as it was discovered to occur when electrons are accelerated to relativistic speeds in a synchrotron where the electron path is diverted radially with a magnetic field. The phenomenon is illustrated in Fig. 1.116, which depicts electrons traveling near the speed of light in a storage ring. The storage ring is a ring-shaped chamber within which electrons traveling at near-light speed originating from a booster synchrotron, are stored for research. The synchrotron radiation is emitted when the path of travel of the electron is forced to bend in a magnetic field.

FIGURE 1.115 Image of the Crab Nebula photographed by the NASA Hubble Space Telescope’s Wide Field and Planetary Camera released to the public on December 1, 2005. The bluish-white regions originate from synchrotron radiation produced by clouds of high energy electrons traveling radially at relativistic speeds under the influence of a magnetic field of a rapidly rotating neutron star. The Crab Nebula is located in the Constellation Taurus about 6500 light years from earth and the image along the bottom measures 12 light years. Courtesy of NASA, ESA, J. Hester and A. Loll, Arizona State University. For the color version of this figure, the reader is referred to the electronic version of the book. From Owens (2012); reprinted with permission from Elsevier © 2012.

FIGURE 1.116 Synchrotron radiation from electrons traveling at relativistic speeds when the electrons are caused to travel radially by a bending magnet in a storage ring linked to a booster cyclotron. The high-energy electrons produce synchrotron radiation every time they are deflected by a magnetic field. The synchrotron radiation is concentrated into a cone with an angle of the order of γ^{-1} . From Yagi (2014); reprinted with permission from Elsevier © 2014.

The discovery of synchrotron radiation followed the construction of the synchrotron and the testing of the synchrotron principle. It was foreseen in the early 1940s that, as a charged particle is accelerated to relativistic speeds (*i.e.*, speeds approaching the speed of light), the relativistic mass of the particle would increase to the point that it would not be possible to maintain that particle in a constant

orbit. Thus, current thought prevailed that there would be a limit to the speed to which the charged particle could be kept in a constant orbit. Wilson (1996) and Wei (2003) provide good historical accounts that led to the discovery of the synchrotron. In 1943, Sir Marcus Oliphant (1901–2000), an Australian physicist was working with Earnest Lawrence at the Oak Ridge National Laboratory on the Manhattan Project. As related by Wilson (1996), Marcus Oliphant, while at the Oak Ridge National Laboratory, was planning to return to his professorship post at the University of Birmingham, and in September of 1943, he wrote a memorandum to the Department of Scientific and Industrial Research (DSIR) in the UK (Oliphant, 1943) in which he proposed a new method of acceleration as follows:

Particles should be constrained to move in a circle of constant radius thus enabling the use of an annular ring of magnetic field ... which would be varied in such a way that the radius of curvature remains constant as the particles gain energy through successive accelerations by an alternating electric field applied between coaxial hollow electrodes.

Oliphant is thus considered as the originator of the synchrotron concept (Wilson, 1996; Wei, 2003). However, shortly thereafter the Russian Physicist Vladimir I. Veksler (1907–66) and Edwin M. McMillan (1907–91) at the University of California, Berkeley independently proposed the concept of phase stability upon which the operation of the synchrotron is based (Veksler, 1944, 1945; McMillan, 1945). As defined by Wei (2003), synchrotrons are circular accelerators in which charged particles are accelerated with electric fields and constrained to move in fixed orbits by magnets whose fields vary in time such that the radius of curvature of the particle beam remains constant as the particles gain energy. Increasing energy and acceleration are attributed to the particles, as described in Oliphant's memo, by alternating electric fields, which are produced by resonating radiofrequency (rf) cavities.

At the General Electric Company in Schenectady, New York, Frank Elder, Anatole Gurewitsch, Robert Langmuir, and Herb Pollock and their staff constructed a 70-MeV synchrotron to test the synchrotron principle of phase stability (Elder et al., 1947, 1948). During a test-run of the newly constructed synchrotron, synchrotron radiation was discovered. As related in a published memoir on "The Discovery of Synchrotron Radiation", Pollock (1983) recorded in his laboratory notebook the following accounts taken on 24 April 1947 (Reproduced with permission © 1983 American Association of Physics Teachers):

Frank Elder worked on the design of the power circuit and the laminated magnet, which was assembled by machinist Floyd Haber. Anatole Gurewitsch focused on the 163-Mc rf

cavity resonator design ... Robert Langmuir and Pollock put the various components together and on 24 October 1946 we were able to tell Edwin McMillan in Berkeley that we had a synchrotron beam and that no problem had been encountered ... for synchrotron acceleration to 70 MeV ... On that day in April [24 April 1947] Langmuir and Pollock were running the machine and as usual were trying to push the electron gun and its associated pulse transformer to the limit. Some intermittent sparking had occurred, and Haber was asked to observe with a mirror around the protective concrete wall which separated the machine from the control room ... When Haber looked around the corner of the wall he noticed a very bright spot of light ... At first we thought it might be due to Cerenkov radiation, but it soon became clear that we were seeing Ivanenko and Pomeranchuk radiation ... We observed the bright spot with mirrors, looking tangent to the orbit at two or three points in the room ... The beam appeared stable and of small cross section (perhaps 1 mm square).

The Ivanenko and Pomeranchuk radiation, referred to in Pollock's notes, is the prediction made in 1944 by the Russian physicists Dimitri Iwanenko (1904–94) and Isaak Pomeranchuk (1913–66) in their joint papers (see Iwanenko and Pomeranchuk, 1944a,b) on the emission of radiation by electrons traveling at relativistic speeds in a magnetic field. Iwanenko and Pomeranchuk (1944a,b) thought that this radiation emission might be a limiting factor in achieving maximal electron energies in the development of electron accelerators. However, the radiation emission (*i.e.*, synchrotron radiation) is named after the instrument within which it was first observed and which today remains the principle source of this radiation for experimental research. A very thorough review of the history of synchrotron radiation, including the theory on radiation from accelerated electrons from as early as 1912, is provided by Blewett (1988).

3. Synchrotron radiation and accelerated electron properties

Synchrotron radiation is currently the brightest source of X-rays available for numerous practical research applications, which will be discussed further on in this section. Suortti (2003), Owens (2012) and Eberhardt (2015) describe the very intense light emission properties of synchrotron radiation, and the brilliance is measured in the number of photons per second per mm² per mrad². Modern synchrotrons yield a brilliance of up to 10²⁰ photons/s/mm²/mrad² (Owens, 2012). The X-ray beam of synchrotron radiation is generally very highly collimated with an angular spread of only 1 mrad (Terasawa and Kihara, 1996). As illustrated previously in Fig. 1.116, the angular spread of the synchrotron radiation cone is

$$\gamma^{-1} = \sqrt{1 - \beta^2} \quad \text{where } \beta = v/c \quad \text{and} \quad (1.416)$$

$$\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}}$$

The variable β is the relative phase velocity of the electron, that is, the ratio of the velocity of the electron (v) to the speed of light in a vacuum (c), and γ is the Lorentz transformation factor described previously for relativistic calculations of mass, length and time. According to Eq. (1.269) described previously in this chapter, the total energy (E) of a particle is the sum of its kinetic (K) and rest energies (mc^2) or

$$E = K + mc^2 = \gamma mc^2 \quad (1.417)$$

According to Eq. (1.417) the synchrotron cone angle γ^{-1} can be expressed as

$$\frac{1}{\gamma} = \frac{mc^2}{E} \quad (1.418)$$

where the rest energy (mc^2) for the electron is 0.511 MeV. Thus, as the electron energy E increases, the synchrotron cone angle decreases. [Terasawa and Kihara \(1996\)](#) report $1/\gamma = 0.064$ mrad for $E = 8.0$ GeV electron, which is calculated according to Eq. (1.418) as

$$\begin{aligned} \frac{1}{\gamma} &= \frac{mc^2}{E} = \frac{0.511 \text{ MeV}}{8 \times 10^3 \text{ MeV}} = 0.0000638 \text{ rad} \\ &= 0.064 \text{ mrad} \end{aligned} \quad (1.419)$$

which represents only a 0.64 mm spread of the synchrotron radiation at a distance of 10 m from the source or a 6.4 mm spread at a distance of 100 m. Synchrotron radiation is thus a very highly collimated beam. The radiation is highly polarized and emitted as pulsed light with short durations of 1 ns or less ([Owens, 2012](#)).

[Terasawa and Kihara \(1996\)](#) provide an example of electrons accelerated in a synchrotron to an energy of 1.0 GeV. They report the phase velocity $\beta = 0.999999868$, that is, the velocity (v) of the electron would be $0.999999868c$ and $\gamma = 1957$, which corresponds to an electron traveling at the relativistic speed, close to that of light and possessing a mass 1957 times that of its rest mass. This is found according to Eq. (1.418) or

$$\begin{aligned} E &= \gamma mc^2 \quad \text{and} \quad \gamma = \frac{E}{mc^2} = \frac{1 \text{ GeV}}{0.511 \text{ MeV}} \\ &= \frac{1 \times 10^3 \text{ MeV}}{0.511 \text{ MeV}} = 1956.95 \end{aligned} \quad (1.420)$$

Also from the value of γ , the velocity of the electron (v) relative to the speed of light in a vacuum (c) can be calculated with the expression for the Lorentz transformation factor as

$$\gamma = \frac{1}{\sqrt{1 - (v/c)^2}} \quad (1.421)$$

Substituting the value of 1957 for γ and calculating the velocity (v) of the electron according to Eq. (1.421) gives

$$1957 = \frac{1}{\sqrt{1 - (v/c)^2}}$$

$$1 - (v/c)^2 = \left(\frac{1}{1957}\right)^2$$

$$(v/c)^2 = 0.9999997389$$

$$v/c = \sqrt{0.9999997389}$$

$$v = 0.999999869c$$

Thus, the 1 GeV electron in the synchrotron is measured to have a relativistic mass of 1957 times that of its rest mass and travels at a velocity of 0.999999869 times the velocity of light in a vacuum.

The Advanced Photon Source at Argonne National Laboratory is a synchrotron radiation source, which can achieve an electron energy output of 7.0 GeV. The calculated mass of an electron of 7.0 GeV energy in the synchrotron according to Eq. (1.420) would possess a 7-fold increase in mass over the previously calculated 1.0 GeV electron, that is, a mass of 13698.6 times its rest mass. However, the velocity of the 7.0 GeV electron is calculated as above in Eq. (1.421) to be $0.999999974c$, which is essentially the same as the 1.0 GeV electron, close to that of the unattainable speed of light in a vacuum.

4. Synchrotron radiation production and applications

Synchrotron radiation sources generally consist of the following basic elements: (i) an electron gun and linear accelerator (LINAC), (ii) a booster synchrotron, (iii) a storage ring, (iv) synchrotron radiation beam lines, and (v) experimental work stations at each synchrotron radiation beam line. An illustration of a modern synchrotron light source with an identification of its basic elements is illustrated in Fig. 1.117. The electron gun provides the initial source of electrons, which are emitted by thermionic emission from a heated cathode, which consists of a heated block of negatively charged metal. A linear accelerator or LINAC, which is labeled as the injector in Fig. 1.117, will accelerate the electrons to an energy sufficient for the electrons to be injected into a booster synchrotron ring. The energy output of the LINAC of the Advanced Photon Source (Synchrotron) of the Argonne National Laboratory will accelerate the electrons to 375 MeV (0.375 GeV).

FIGURE 1.117 Essential elements of the third-generation 2.75-GeV Soleil Light Source at Saint-Aubin, France (<http://www.synchrotron-soleil.fr/>; printed with permission © Synchrotron SOLEIL—EPSIM/J.F. SANTARELLI). Its major components are (1) the injector, (2) booster ring, (3) storage ring, (4) experimental station consisting of (5) a beam-line, (6) optics and monochromator hutch, (7) experimental hutch, and (8) control room. Generally the experimental stations are custom designed for specific applications. For the color version of this figure, the reader is referred to the electronic version of the book. From Owens (2012); reprinted with permission from Elsevier © 2012.

These electrons travel at a speed of $0.9999990715c$ or 99.99990715% of the speed of light calculated according to Eqs. (1.420) and (1.421) described previously. The high-energy electrons are then fed into a booster synchrotron ring to accelerate the electrons further with radio frequency energy sources. Electron energies achieved at the booster synchrotron will vary from 2 to 8 GeV at different synchrotron facilities around the world (Clarke, 2005). The booster synchrotron at the Advanced Photon Source (Synchrotron) of the Argonne National Laboratory produces an electron energy output of 7.0 GeV with an electron velocity of $0.9999999974c$ or 99.99999974% of the velocity of light. The high-energy electrons produced by the booster synchrotron are then fed into a storage ring where the electrons will travel at relativistic speed in a circular path controlled by bending magnets, which also serve as the source of synchrotron radiation needed for practical research with X-rays in numerous fields of science. The synchrotron radiation beam-lines, illustrated in Fig. 1.117, lead into individual experimental stations where individualized experimentation with the synchrotron radiation, generally the X-radiation, is carried out. The circulating electrons will lose energy with the emission of synchrotron radiation, and the lost energy is replenished with surges of energy from radio frequency cavities as the electrons circulate in the ring. Eventually electrons are lost by interactions with molecules of gas that reside in the imperfect vacuum chamber within which the electron beam travels; however, beams can last in storage rings for many hours (e.g., over 60 hours). Electron beams in storage rings are regularly replenished with the booster synchrotron to

FIGURE 1.118 Schematic of a synchrotron radiation source showing the linac, inner synchrotron booster ring, outer storage ring, and the magnetic devices that produce synchrotron X-ray radiation. In the storage ring are illustrated bending magnets and wiggler and undulator insertion devices with synchrotron radiation emitting from each device. The properties of the source and resulting X-ray beam are described by a flux (photons/second/unit energy bandwidth), a brilliance (photons/second/mm²/mrad²/unit energy bandwidth) and a divergence (mrad). For the color version of this figure, the reader is referred to the electronic version of the book. From Mitchell et al. (1999); reprinted with permission from Elsevier © 1999.

maintain the production of synchrotron radiation according to the needs of the research community.

The storage ring is not a perfect circle; rather it is considered as a polygon, as it will contain straight sections allowing for the insertion devices, referred to as wigglers and undulators, as illustrated in the simplified diagram of Fig. 1.118. The wigglers and undulators consist of varying poles of numerous magnets (see Fig. 1.119) to provide tightly curved transverse displacements of the particle beam (Clarke, 2005; Geloni et al., 2016). The wigglers use the poles of the various magnets to deflect the electron beam back and forth or from side to side, such as to “wobble” the electron beam, and at each wiggle, synchrotron radiation is emitted as a wide horizontal fan of X-rays capable of feeding more than one work station with X-rays where each work station can take a portion of slice of the fan for research (Mitchell et al., 1999). An undulator, as described by Mitchell et al. (1999), operates in a similar fashion as the wiggler, but with a shorter period between each magnetic pole maintaining the deflected beam within the original beam envelope. The photons emitted at each pole result in partially coherent X-rays concentrated in a more narrow beam with enhanced

FIGURE 1.119 Basic structure and mechanism of a wiggler or undulator insertion device. For the color version of this figure, the reader is referred to the electronic version of the book. *Courtesy of Advanced Photon Source, Argonne National Laboratory, Argonne, IL, USA; <http://www.aps.anl.gov/>.*

brilliance. With N bending magnets, the brilliance is enhanced in undulators by a factor of N^2 emitted over a narrow bandwidth (Owens, 2012), whereas with wigglers, the brilliance is enhanced only by a factor of N bending magnets.

Many insertion devices are installed generally within the storage ring, which provide numerous synchrotron radiation beamlines for research and practical applications. Synchrotron radiation facilities can have large storage rings with a circumference exceeding a kilometer and with well over 40 beamlines and their associated workstations. Some storage rings of this magnitude include the European Synchrotron Radiation Facility (ESRF) in Grenoble, France, the Advanced Photon Source (APS) at Argonne, IL, USA, and the 8-GeV Super Photon Ring (Spring-8) at Nishi Harima, Japan. An example of the magnitude of such facilities is provided by an aerial photograph of the APS, and an illustration of its associated work stations in Figs. 1.120 and 1.121, respectively.

There are over 70 synchrotrons worldwide, and many of these are wholly or partially dedicated to the generation of synchrotron radiation for research (Sorensen et al., 2006). The IAEA maintains a database of synchrotron radiation facilities worldwide with links to the individual websites of these synchrotron radiation sources (<http://www.iaea.org/>). Synchrotron radiation facilities generally provide the opportunity for research groups to reserve a workstation coupled to a beamline for independent research.

Many applications of synchrotron radiation are available in almost every field of science including the

FIGURE 1.120 Aerial photograph of the Advanced Photon Source of the Argonne National Laboratory, Argonne, IL, USA, which houses a 1.1 km storage ring for the production and application of synchrotron radiation. - et al., 2012; Almeida et al., 2014; Basnayaka et al., 2014; Garcea et al., 2017),
- (ii) X-ray spectroscopy (Sayen and Guillon, 2014; Young, 2014; Sindhupakorn et al., 2017),
 - (iii) infrared spectroscopy (McKellar, 2010; Miura et al., 2010; Marcelli et al., 2012; Li et al., 2017),
 - (iv) X-ray fluorescence analysis (Lis et al., 2014; Baldasini et al., 2015; Ghosh et al., 2017a,b), and
 - (v) nanotechnology (Wu and Becker, 2011; Zhu et al., 2014; Miao et al., 2017), among other fields where an X-ray or infrared or other suitable bandwidth of radiation source of high collimation and brilliance can be applied.

For a general review of the many applications of synchrotron radiation, the reader may peruse reviews by Abela et al. (2010) and Martins and Silva (2014), Grochulski et al. (2017), Sayers et al. (2017), and Zolotarev et al. (2016).

XII. Interaction of electromagnetic radiation with matter

The lack of charge and rest mass of electromagnetic gamma and X-radiation hinder its interaction with matter and the dissipation of its energy in matter. Consequently, gamma radiation and X-rays have greater penetration power and longer ranges in matter than the more massive and charged alpha and beta particles of the same energy. Nevertheless, gamma and X-radiation are absorbed by matter, and the principal mechanisms by which this type of radiation interacts with matter are discussed in this section.

A. Photoelectric effect

The energy of a photon may be completely absorbed by an atom in a single interaction. Under such circumstances, the entire absorbed photon energy is transferred to an electron of the atom and the electron is ejected, resulting in the formation of an ion pair. In such an interaction, known as the photoelectric effect, the energy of the emitted electron is equal to the energy of the impinging photon less the binding energy of the electron. This is described by the photoelectric equation of Einstein:

$$E_e = h\nu - \phi \quad (1.422)$$

where E_e is the energy of the ejected electron, $h\nu$ is the energy of the incident photon, and ϕ is the binding energy of the electron or the energy required to remove the electron from the atom. The ejected electron is identical in properties to a beta particle and produces ionization as it travels through matter as previously described for beta particles.

The photoelectric effect occurs in the inner electron shells, predominately in the K-electron shell, of the atom as described in Section XII.D of this chapter. When an electron from an inner atomic K or L shell is ejected, electrons from outer shells fall to inner electron shells to fill the resulting gap. These transitions in electron energy states require a release of energy by the atomic electrons, which appears as soft (low-energy) X-rays. X-radiation is identical in properties to gamma radiation. The essential difference lies in the origin of the two radiations. As previously described, gamma radiation originates from energy state transformations of the nucleus of an atom, whereas X-radiation originates from energy state transformations of electrons.

B. Compton effect

There is a second mechanism by which a photon (e.g., X-ray or gamma ray) transfers its energy to an atomic orbital electron. In this interaction, illustrated in Fig. 1.122, the photon, E_γ , imparts only a fraction of its energy to the electron and in so doing is scattered with energy E'_γ at an angle Θ to the initial trajectory of the photon, while the bombarded electron is ejected from the atom. This interaction is known as the Compton effect and also as Compton scattering. The result of this interaction is the formation of an ion pair, as in the case of the photoelectric effect. However, the deflected photon continues traveling through matter until it dissipates its entire kinetic energy by interacting with other electrons in a similar fashion or via other mechanisms of interaction with matter discussed in this section. The ejected electron, being identical in properties to a beta particle, loses its energy through the ionization it causes according to mechanisms previously described.

FIGURE 1.122 The Compton effect. An incident photon collides with an atomic electron and imparts energy to it, the photon is scattered at an angle Θ to the trajectory of the incident photon, and the electron is ejected from the atom.

Our understanding of the Compton effect comes from the original work of Arthur H. Compton (1923a,b) and the collaboration of his graduate student Wu Youxun (Woo, 1924, 1925a,b,c). They demonstrated that X-ray photons scattered by thin foils underwent a wavelength shift. The shift in wavelength of the scattered photon with respect to that of the incident photon was a function of the angle of scatter Θ . To interpret this effect Compton and Wu treated X-radiation as photon particles or quanta according to the Einstein–Planck relation $E = h\nu$ (see Eq. 1.371) and the scattering to occur as photon–electron collisions somewhat like billiard-ball collisions as illustrated in Fig. 1.122. Compton derived the equation, which describes the wavelength shift between the incident and scattered photons and angle of scatter as

$$\lambda' - \lambda = \frac{h}{m_0 c} (1 - \cos \Theta) \quad (1.423)$$

where λ' and λ are the wavelengths of the deflected and incident photons, respectively, h is Planck's constant, m_0 is the rest mass of the electron, c is the speed of light, and Θ is the angle of scatter of the photon relative to its original direction of travel.

The Compton-scatter photon will always be of longer wavelength (lower energy) than the incident photon, because of energy lost in the collision with the electron. For example, let us calculate the wavelength shift and energy loss by an incident photon of wavelength 0.300 nm that collides with an electron, and where the photon is scattered at an angle of 70 degrees. The wavelength of the scattered photon is calculated according to Eq. (1.423) as

$$\begin{aligned} \lambda' &= \lambda + \frac{h}{m_0 c} (1 - \cos \Theta) \\ &= 3.0 \times 10^{-10} \text{ m} + \frac{6.626 \times 10^{-34} \text{ J sec}}{(9.109 \times 10^{-31} \text{ kg})(2.997 \times 10^8 \text{ m/sec})} (1 - \cos 70^\circ) \\ &= 3.0 \times 10^{-10} \text{ m} + 2.43 \times 10^{-12} \text{ m}(1 - 0.342) \\ &= 0.3016 \text{ nm} \end{aligned}$$

The energy lost by the incident photon according to the Einstein–Planck relation is given by

$$\begin{aligned} \Delta E &= E_\gamma - E'_\gamma \\ &= \frac{hc}{\lambda} - \frac{hc}{\lambda'} \\ &= \frac{12.4 \text{ keV } \text{\AA}}{3.00 \text{ } \text{\AA}} - \frac{12.4 \text{ keV } \text{\AA}}{3.016 \text{ } \text{\AA}} \\ &= 4.133 \text{ keV} - 4.111 \text{ keV} = 0.022 \text{ keV} \end{aligned}$$

and the fraction of photon energy lost becomes

$$\frac{\Delta E}{E} = \frac{0.022 \text{ keV}}{4.133 \text{ keV}} = 0.0053 = 0.53\%$$

We can calculate directly the energy of the Compton scatter photon, λ' , if we know the incident X-ray or gamma-ray photon energy and angle of scatter of the photon according to the equation

$$E'_\gamma = \frac{E_\gamma}{1 + (E_\gamma/mc^2)(1 - \cos \Theta)} \quad (1.424)$$

where E'_γ is the energy of the Compton scatter photon, E_γ is the incident photon energy, mc^2 is the rest energy of the electron (511 keV or 0.511 MeV, see Section XII.C), and Θ is the Compton photon angle of scatter (Tait, 1980). If we take the data from the previous example, where the incident photon energy was 4.133 keV and the angle of scatter was 70 degrees, we can calculate the energy of the Compton photon according to Eq. (1.424) to be

$$\begin{aligned} E'_\gamma &= \frac{4.133 \text{ keV}}{1 + (4.133 \text{ keV}/511 \text{ keV})(1 - \cos 70^\circ)} \\ &= 4.111 \text{ keV} \end{aligned}$$

The result is in agreement with the calculations above using Eq. (1.423) derived by Compton.

It has been shown by Compton that the angle of deflection of the photon is a function of the energy imparted to the electron. This angle may vary from just above $\Theta = 0$ degrees for low Compton electron energies to a maximum $\Theta = 180$ degrees for the highest Compton electron energy. Compton electrons are thus emitted with energies ranging between zero and a maximum energy referred to as the Compton edge. The Compton edge is the Compton electron energy corresponding to complete backscattering of the gamma ray photon. With $\Theta = 180$ degrees or $\cos \Theta = -1$, Eq. (1.424) is reduced to the following equation describing the energy, E'_γ , of the gamma ray photon at the Compton edge in MeV units:

$$E'_\gamma = \frac{E_\gamma}{1 + (E_\gamma/0.511 \text{ MeV})(1 - \cos 180^\circ)} \quad (1.425)$$

or

$$E'_\gamma = \frac{E_\gamma}{1 + (2E_\gamma/0.511)} \quad (1.426)$$

or

$$E'_\gamma = \frac{E_\gamma}{1 + 3.914E_\gamma} \quad (1.427)$$

As an example, the energy of the gamma-ray photon in MeV at the Compton edge for an incident gamma ray from ^{137}Cs ($E_\gamma = 0.662$ MeV) is calculated according to Eq. (1.427) to be

$$E_\gamma = \frac{0.662}{1 + 3.914(0.662)} = 0.184 \text{ MeV}$$

A Compton scatter photon is of longer wavelength and lower energy than the incident photon. Deflected Compton photons occur with a broad spectrum of energies. Spectra of Compton-scattered photon energies contain a peak known as the backscatter peak (see Chapter 9 of this volume). The backscatter peak arises from Compton scattering into a gamma photon detector [e.g., NaI(Tl) crystal] from the surrounding detector shielding and housing materials. The backscatter peak occurs at increasing values of energy (MeV) in proportion to the incident photon energy and approaches a constant value of 0.25 MeV, according to Eq. (1.427), for incident photon energies greater than 1 MeV (Tait, 1980). The energy of the Compton electron, E_e , may be described by

$$E_e = E_\gamma - E'_\gamma - \phi \quad (1.428)$$

where E_γ and E'_γ are the energies of the incident and deflected photons, respectively, and ϕ is the binding energy of the electron. As the binding energy of the atomic electron is relatively small, the energy of the ejected electron is essentially the difference between the incident and deflected photon energies. Substituting the value of E'_γ from Eq. (1.424) into Eq. (1.428) and ignoring the electron binding energy, the Compton electron energy can be expressed as

$$E_e = E_\gamma - \frac{E_\gamma}{1 + (E_\gamma/mc^2)(1 - \cos \Theta)} \quad (1.429)$$

$$E_e = E_\gamma - \frac{E_\gamma}{1 + (E_\gamma/0.511 \text{ MeV})(1 - \cos \Theta)} \quad (1.430)$$

where the electron energies are given in MeV. For example, the energy of a Compton electron, E_e , scattered at 180 degrees (Compton edge: $\cos \Theta = -1$) and originating from an incident gamma ray photon from ^{137}Cs ($E_\gamma = 0.662$ MeV) is calculated according to Eq. (1.430) as

$$\begin{aligned} E_e &= 0.662 - \frac{0.662}{1 + (0.662/0.511)(1 - \cos 180^\circ)} \\ &= 0.478 \text{ MeV} \end{aligned}$$

Alternatively, if we ignore the negligible electron binding energy and know the incident photon energy and Compton scatter photon energy, we can calculate the Compton electron energy by difference according to Eq. (1.428)

$$E_e = 0.662 \text{ MeV} - 0.184 \text{ MeV} = 0.478 \text{ MeV},$$

which is in agreement with the electron energy calculated above. The Compton edge and backscatter peak due to interactions of Compton electrons and Compton backscatter photons, respectively, in a scintillation crystal detector are described in Chapter 9 of this volume.

C. Pair production

The interactions of gamma radiation with matter, considered earlier, involve the transfer of γ energy, in whole or in part, to atomic electrons of the irradiated material. Pair production, as another mechanism of γ -energy dissipation in matter, results in the creation of matter (i.e., electrons) from the γ energy. The particles produced are a negatron and a positron from an individual gamma-ray photon that interacts with the coulombic field of a nucleus (see Figs. 1.4 and 1.123). Consequently, this phenomenon involves the creation of mass from energy. Carl D. Anderson at the California Institute of Technology (Caltech) received the 1936 Nobel Prize in physics for his discovery of the positron, the first experimental evidence of antimatter. He and his graduate student Seth Neddermeyer also reported in their findings (Anderson and Neddermeyer, 1933) the first observation of pair production, which they described as follows:

One of the most striking phenomena, which have been observed in this experiment is the occasional simultaneous appearance of paired tracks consisting of one positive particle and one negative with a common point of origin ... The process, which gives rise to the positrons is at present not known, but so far as these data go they are in accord with the view expressed by Blackett and Occhialini (1933) that the two particles may be formed by a process in which the energy of approximately 1 MeV required for the for-

FIGURE 1.123 Pair production. The conversion of a gamma-ray photon into a negatron and positron pair.

mation of a positive and negative electron is supplied by the impinging radiation.

It was Nobel Laureate Patrick Blackett and his coworker G.P.S. Occhialini (Blackett and Occhialini, 1933) who recognized that the two particles, positron and negatron, are formed by the process known as “pair production” whereby the energy of 1.02 MeV required for the production of the two particles is provided by the gamma radiation. In his Nobel Lecture, Anderson (1936) explained the pair-production phenomena as follows:

... that the appearance of pairs of positive and negative electrons could be understood in terms of this theory [Dirac's theory] as the 'creation' of a positive-negative electron pair in the neighborhood of an atomic nucleus. The energy corresponding to the proper mass of both of the particles, as well as to their kinetic energies is supplied, according to this view, by the incident radiation. Since the energy corresponding to the proper mass of a pair of electrons is approximately 1 MeV, one should expect gamma rays of energy greater than this amount to produce positrons in their passage through matter, and further that the sum of the kinetic energies of the positive and negative electrons should be equal to the energy of the radiation producing them diminished by approximately 1 MeV.

In the above statement Anderson described the process of pair-production, first theorized by Dirac (1928a,b), observed through cloud-chamber track photographs by Anderson and Neddermeyer (1933), and interpreted by Blackett and Occhialini (1933). The gamma-ray photon energy required for pair production is, as noted above by Anderson, equivalent to the sum of the masses of the electron and positron described by the equation

$$E_{\text{pair}} = m_e c^2 + m_e c^2 = 2mc^2 = 2(0.511 \text{ MeV}) = 1.022 \text{ MeV} \quad (1.431)$$

The gamma-ray photon energy in excess of 1.022 MeV appears as the kinetic energy of the electron and positron created, and the overall pair-production phenomena can be expressed as

$$h\nu = 2mc^2 + E_{e^-} + E_{e^+} \quad (1.432)$$

where $h\nu$ is the gamma-ray photon energy, $2mc^2$ is the energy equivalence of the mass of two electrons, and E_{e^-} and E_{e^+} are the kinetic energies of the electron and positron, respectively. In pair production, gamma-ray energy in excess of 1.02 MeV appears as kinetic energy of the negatron and positron produced. By the time of Anderson's Nobel Lecture in 1936, three sources of positrons were known, and Anderson took the opportunity of his lecture to describe these, which are the following: (1) cosmic ray

showers of electron-positron pairs via pair production from cosmic gamma radiation, (2) pair production via the absorption of gamma radiation in excess of 1 MeV from radionuclide sources, and (3) positron emission via beta decay from radioactive elements, such as ^{30}P , ^{13}N , and ^{27}Si , artificially produced by Joliot-Curie and Joliot (1934a,b,c), which decay by positron emission.

The creation of an electron requires a certain quantum of energy of a gamma-ray photon, which may be calculated according to Einstein's equation for the equivalence of mass and energy

$$E = m_e c^2 \quad (1.433)$$

where E is energy, m_e is the electron rest mass, and c is the speed of light in a vacuum. Thus, the rest energy of the electron (negatron or positron) is calculated as

$$E = (9.109 \times 10^{-31} \text{ kg})(2.997 \times 10^8 \text{ m/sec})^2 = 8.182 \times 10^{-14} \text{ J}$$

Since by definition, $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$, the electron rest energy in joules is converted to electron volts as

$$8.182 \times 10^{-14} \text{ J} / 1.602 \times 10^{-19} \text{ J/eV} = 0.511 \text{ MeV}$$

Thus, the creation of an electron (negatron) requires a minimum energy of 0.511 MeV. However, a gamma ray of 0.511 MeV energy cannot alone create a negatron, as there must also be the simultaneous creation of its antiparticle, the positron of equal mass and opposite charge. The minimum gamma ray photon energy required for the creation of the negatron-positron pair is, as described by Eq. (1.431) above, $2(0.511)$ or 1.022 MeV. Thus, the absorption by matter of gamma radiation greater than 1.02 MeV may result in pair production. The probability of pair production increases in proportion to the magnitude of gamma-ray photon energy above 1.02 MeV, and pair production is the predominant mechanism of absorption of photons of energies of 10 MeV and above (see Figs. 1.124 and 1.125).

As discussed previously in Section XI.C, positrons will produce annihilation radiation when they come to rest in the proximity of a negative electron, *i.e.*, their antiparticle, resulting in the simultaneous conversion of two electron masses into two gamma-ray photons of 0.511 MeV energy.

Pair production does not occur only in the vicinity of atomic nuclei bombarded by gamma radiation. It may also originate from nuclei that emit gamma radiation with transition energies greater than 1.02 MeV. This is referred to as **internal pair production**, and the mechanism competes to a small extent with the emission of gamma radiation. The degree to which this competition occurs is measured by the ratio of intensities of positron–negatron pairs to gamma radiation or (e^\pm/γ) . Some examples of nuclides that emit such positron–negatron pairs and the

FIGURE 1.124 Mass attenuation coefficients for photons in aluminum. intensities of these pairs relative to gamma radiation are given in [Table 1.22](#).

The threshold nuclear transition energy $E_\gamma > 1.022$ MeV for internal pair production is intuitively obvious as electrons each of rest mass 0.511 MeV must be created from the transition energy. The decaying nucleus undergoes de-excitation with the creation of the positron–negatron pair which are ejected from the nucleus with a total kinetic energy, as described by [Allan \(1971\)](#) according to the equation

$$T = E_\gamma - 2m_0c^2 \quad (1.434)$$

where T is the total kinetic energy shared between the positron and negatron, E_γ in the nuclear transition energy, and $2m_0c^2$ is the energy equivalence of two electron rest masses (i.e., 1.02 MeV). [Eq. \(1.434\)](#) is described by [Lombard et al. \(1968\)](#) according to the shared positron and negatron energies or

$$W_+ + W_- = E_i - E_f - 2m_0c^2 \quad (1.435)$$

where W_+ and W_- are the kinetic energies of the positron and negatron, respectively, E_i and E_f are the initial and final energies of the nuclear states, respectively, and $2m_0c^2$ is the

energy equivalence of two electron rest masses, as described previously.

Internal pair production may accompany nuclear energy state transitions that may follow alpha or beta decay when the decaying nucleus remains at an energy state in excess of 1.022 MeV. In the case of internal pair production following alpha decay, Staníček and Povinec (1986) describe two possible mechanisms, which are the following:

- i) The alpha particle accelerates in the Coulomb field of the daughter nucleus, which creates bremsstrahlung with energy above $2m_e c^2$ (i.e., $E > 1.022$ MeV, energy

in excess of two electron rest masses). The bremsstrahlung above 1.022 MeV converts to a positron–electron pair; or

- ii) the daughter nucleus at an excited energy state in excess of 1.022 MeV and a resultant gamma quantum (real or virtual) converts into a positron–electron pair.

A practical application of internal pair production to the nondestructive activity analysis of ^{90}Y and ^{90}Sr was reported by Selwyn et al. (2007). The nuclide ^{90}Y decays by negatron emission with a Q value of 2280.1 keV as illustrated in Fig. 1.126. The activity of ^{90}Y is determined traditionally by liquid scintillation or Cherenkov counting

of the high-energy negatron emissions, which have an E_{max} of 2280.1 keV as described in Chapter 6, of this volume and Chapter 6 of Volume 2, as this beta transition occurs at an intensity of 99.999% to the ground state of stable ^{90}Zr . There is a very small branching beta transition with an E_{max} of 519.4 keV, which occurs at an intensity of 0.011%, to metastable ^{90}Zr at the energy level of 1760.7 keV (see Fig. 1.126). This is well above the 1022 keV required for internal pair production that can occur in the transition from 1760.7 keV to the ground state of ^{90}Zr . Selwyn et al. (2007) measured the internal pair production branching ratio for this transition to be $(31.86 \pm 0.47) \times 10^{-6}$ by measuring the count rate of the

511 keV peak with a high-purity germanium detector (HPGe) produced by the positron (β^+) annihilation that follows pair production. The high-energy beta emissions of ^{90}Y produce bremsstrahlung background radiation, which had to be subtracted from the overall count rate to get an accurate measurement of the net count rate at the 511 keV peak. With the known branching ratio for the internal pair production, and measurement of the net count rate and detection efficiency of the 511 keV positron (β^+) annihilation photons, the ^{90}Y activity of unknown samples can be determined. The activity of ^{90}Sr can be calculated from the measured activity of ^{90}Y , as their activities are equal when in secular equilibrium (see Section XVII.C).

D. Combined photon interactions

Because of its zero rest mass and zero charge, gamma radiation has an extremely high penetration power in matter in comparison with alpha and beta particles.

Materials of high density and atomic number (such as lead) are used most often as absorbers to reduce X- or gamma radiation intensity. Radiation intensity, I , is defined here as the number of photons of a radiation beam that traverse a given area per second, the units of which can be photons/cm²/s. Suppose a given absorber material of thickness x attenuates or reduces the intensity of incident gamma radiation by one-half. Placing a similar barrier of the same thickness along the path of the transmitted gamma radiation would reduce the intensity again by one-half. With three barriers each of thickness x and an initial gamma-ray intensity I_0 , there is a progressive drop in the transmitted gamma-ray intensities: $I_1 = \frac{1}{2}I_0$, $I_2 = \frac{1}{2}I_1$, $I_3 = \frac{1}{2}I_2$, and $I_n = \frac{1}{2}I_{n-1}$. Obviously, incident X- or gamma radiation may be reduced from I_0 to I_3 by using a $3x$ thickness of the same material as an absorber. Consequently, the intensity of the transmitted electromagnetic radiation is proportional to the thickness of the absorber material and to the initial intensity of the radiation. An increasing absorber thickness increases the probability of photon removal, because there is a corresponding increase of absorber atoms that may attenuate the incident photons via the photoelectric effect, the Compton effect, and pair production mechanisms.

If gamma-ray attenuation with respect to absorber thickness is considered, the change in gamma-ray intensity, ΔI , with respect to the absorber thickness, Δx , is proportional to the initial gamma-ray photon intensity, I . This may be written as

$$\Delta I / \Delta x = -\mu I \quad (1.436)$$

where μ is the proportionality constant, referred to as the linear attenuation coefficient or linear absorption coefficient. Its value is dependent on the atomic composition and density of the absorber material. The change in intensity over an infinitely thin section of a given absorber material may be expressed as

$$dI/dx = -\mu I \quad (1.437)$$

or

$$dI/I = -\mu dx. \quad (1.438)$$

Integrating Eq. (1.438) over the limits defined by the initial intensity, I_0 , to the transmitted intensity, I , and over the limits of absorber thickness from zero to a finite value x , such as

$$\int_{I_0}^I dI/I = -\mu \int_0^x dx \quad (1.439)$$

gives

$$\ln I - \ln I_0 = -\mu x \quad (1.440)$$

or

$$\ln(I/I_0) = -\mu x \quad (1.441)$$

Eq. (1.441) may be written in exponential form as

$$I = I_0 e^{-\mu x} \quad (1.442)$$

Because gamma ray absorption is exponential, the term half-value thickness, $x_{1/2}$, is used to define the attenuation of gamma radiation by matter. Half-value thickness is the thickness of a given material of defined density that can reduce the intensity of incident gamma radiation by one-half. The half-value thickness may also be defined according to Eq. (1.441), in which the initial gamma ray intensity, I_0 , is given an arbitrary value of 1 and the transmitted intensity must, by definition, have a value of 1/2, or

$$\ln(0.5/1) = -\mu x_{1/2} \quad (1.443)$$

where $x_{1/2}$ is the half-value thickness; and

$$\ln 0.5 = -\mu x_{1/2} \quad (1.444)$$

and

$$-0.693 = -\mu x_{1/2} \quad (1.445)$$

and

$$x_{1/2} = 0.693/\mu \quad (1.446)$$

From the linear attenuation coefficient, μ , of a given material and gamma-ray photon energy, it is possible to calculate the half-value thickness, $x_{1/2}$. The linear attenuation coefficient has units of cm⁻¹, so that the calculated half-value thickness is provided in units of material thickness (cm). Linear attenuation coefficients for some materials as a function of photon energy are provided in Table 1.23. The table refers to these as total linear attenuation coefficients, because they constitute the sum of coefficients due to Compton, photoelectric, and pair production interactions. Celiktas (2011) reports on the development of the experimental methods that may be used to determine gamma-ray linear attenuation coefficients. Calculated half-value thicknesses of various absorber materials as a function of gamma-ray energy are illustrated in Fig. 1.127 to illustrate some examples of the varying amounts of absorber material required to attenuate gamma-ray photons. The linear attenuation coefficient is a constant for a given absorber material and gamma-ray photon energy and has units of reciprocal length such as cm⁻¹. It is, however, dependent on the state of the absorber or the number of atoms per unit volume of absorber.

^aData from Argonne National Laboratory, ANL-5800 (1963), Hubbell (1969), and Berger et al. (2017b), and NIST (2017) database: <https://physics.nist.gov/PhysRefData/FFast/html/form.html>.

A more popular coefficient is the mass attenuation coefficient, μ_m , which is independent of the physical state of the absorber material and is defined as

$$\mu_m = \mu/\rho \quad (1.447)$$

where ρ is the density of the absorber in units of g/cm^3 , and μ_m has units of cm^2/g . Some examples of mass attenuation coefficients according to X- and gamma-ray photon energy are provided in Table 1.24. Using the mass attenuation coefficient, Eq. (1.442) transforms to

$$I = I_0 e^{-\mu_m \rho x} \quad (1.448)$$

and the half-value thickness is calculated according to Eq. (1.446) as

$$x_{1/2} = 0.693/\mu_m \rho \quad (1.449)$$

Mass attenuation coefficients for X- or gamma-ray photons over a wide range of energies from 1 keV to 1000 MeV in 100 elements are available from Berger and Hubbell (1997). In addition, mass attenuation coefficients for any element, chemical compounds, mixtures of elements, or mixtures of compounds over the X-ray- or gamma-ray photon energy range of 1 keV to 10^5 MeV are

FIGURE 1.127 Half-value thicknesses of various materials as a function of gamma-ray energy. D is the density of each material. From L'Annunziata (1987) reprinted with permission from Elsevier © 1987 Academic Press.

available from a database, which can be found at the National Institute of Standards and Technology (NIST) Photon Cross Section Database XCOM: <https://www.nist.gov/pml/xcom-photon-cross-sections-database> (Accessed 12 December 2017).

A sample of mass attenuation coefficients over the range of 5 keV–10 MeV in a few materials are listed in Table 1.24. The following calculation illustrates the use of the data from Tables 1.23 and 1.24 to calculate half-value thickness and radiation attenuation:

Let us calculate the half-value thickness of lead ($\rho = 11.3 \text{ g/cm}^3$) for 2.0 MeV gamma radiation, and further calculate what the reduction in radiation intensity would result if we positioned four times the half-value thickness of lead in the path of the radiation beam. First, the linear attenuation coefficient, μ , or mass attenuation coefficient, μ_m , for 1.0 MeV photons in lead are obtained from either Table 1.23 or 1.24, respectively, and the half-value thickness of lead for 2.0 MeV photons is calculated as

$$x_{1/2} = \frac{0.693}{\mu} \quad \text{or} \quad \frac{0.693}{\mu_m \rho} \quad (1.450)$$

or

$$x_{1/2} = \frac{0.693}{0.5182 \text{ cm}^{-1}} \quad \text{or} \quad \frac{0.693}{(0.0457 \text{ cm}^2/\text{g})(11.3 \text{ g/cm}^3)}$$

$$x_{1/2} = 1.34 \text{ cm}$$

Thus, a barrier of 1.34 cm thickness of lead is sufficient to reduce the radiation intensity of 2.0 MeV photons by 1/2

or 50%. According to Eq. (1.442) the relation between the initial radiation intensity, I_0 , and the transmitted intensity, I is

$$\frac{I}{I_0} = e^{-\mu x} \quad (1.451)$$

and for $x = 1.34 \text{ cm}$, if the initial radiation intensity is given an arbitrary value of 2, the transmitted intensity would be 50% of the initial intensity or equal to 1. We then can write

$$\frac{I}{I_0} = \frac{1}{2} = e^{-1.34\mu} \quad (1.452)$$

If we employ four times the half-value thickness of lead or $4 \times 1.34 \text{ cm} = 5.36 \text{ cm}$, we can calculate that the transmitted radiation would be reduced to the following:

$$\frac{I}{I_0} = (e^{-1.34\mu})^4 = \left(\frac{1}{2}\right)^4$$

or

$$e^{-5.36\mu} = \frac{1}{16} = 0.0625 = 6.25\% \text{ transmitted}$$

The remaining 15/16 or 93.75% of the initial radiation is attenuated by the 5.36 cm lead barrier. In general, we need not know the half-value thickness of the material or shield, but simply obtain the linear or mass attenuation coefficient for a given energy of X- or gamma radiation from reference tables and use Eqs. (1.442) or (1.448) to calculate the magnitude of radiation attenuation for any thickness of the absorber material. For example, if we used

TABLE 1.24 Total mass attenuation coefficients (cm^2/g) for X- or gamma-ray photons in various materials.^a

^aData from Argonne National Laboratory, ANL-5800 (1963), Hubbell (1969), and Berger and Hubbell (1997), and Berger et al. (2017b), available at National Institute of Standards and Technology (NIST) Photon Cross Section Database XCOM: <https://www.nist.gov/pml/xcom-photon-cross-sections-database> (Accessed 12 December 2017).

only 2.5 cm of lead barrier, the attenuation of 2.0 MeV gamma rays could be calculated as

$$\frac{I}{I_0} = e^{-\mu x} = e^{-\mu_m \rho x} \quad (1.453)$$

and

$$\begin{aligned} \frac{I}{I_0} &= e^{-(0.5182 \text{ cm}^{-1})(2.5 \text{ cm})} \\ &= e^{-(0.0457 \text{ cm}^2/\text{g})(11.3 \text{ g/cm}^3)(2.5 \text{ cm})} \\ &= e^{-1.29} = 0.275 = 27.5\% \end{aligned}$$

Thus, the 2.0 MeV radiation transmitted through a shield of 2.5 cm of lead would be 27.5% of the initial radiation intensity.

As previously discussed, the absorption of gamma radiation is a process that principally involves three mechanisms of attenuation: the Compton effect, the photoelectric effect, and pair production. The attenuation coefficients just discussed above are also referred to as total attenuation coefficients, because they consist of the sum of three independent coefficients or

$$\mu = \mu_c + \mu_e + \mu_p \quad (1.454)$$

where μ_c , μ_e , and μ_p are attenuation coefficients for Compton, photoelectric, and pair production processes. The attenuation coefficients are proportional to the probabilities of occurrence of these radiation attenuation processes and can be used as a measure of the relative roles these processes play in the absorption of gamma-ray photons.

Accordingly, the total and partial mass attenuation coefficients can be written as

$$\mu_m = \mu/\rho = \mu_c/\rho + \mu_e/\rho + \mu_p/\rho \quad (1.455)$$

Figs. 1.124 and 1.125 illustrated earlier in this chapter provide a graphic representation of the relative frequency of occurrence of the Compton, photoelectric, and pair production processes in aluminum and sodium iodide absorbers as a function of photon energy. From these curves, it is seen that the photoelectric effect plays an increasing role in total gamma-ray attenuation at lower gamma-ray energies and with absorber materials of higher atomic number. We can also note from these figures, that pair production becomes significant at photon energies above 1 MeV; as the threshold energy for pair production is 1.022 MeV. Data on the total and partial mass attenuation coefficients as a function of photon energy for any element, chemical compound, mixture of elements, or mixture of compounds over the photon energy range of 1 keV to 10^5 MeV are available from the National Institute of Standards and Technology (NIST) Photon Cross Section Database XCOM: <https://www.nist.gov/pml/xcom-photon-cross-sections-database>.

In some absorber materials of relatively high density, absorption edges can be measured for low photon energies, such as the *K* edge illustrated in Fig. 1.125. The absorption edge is a discontinuity in the attenuation coefficient curve for the photoelectric effect that is caused when photon energies are less than the binding energies of electrons of a certain shell (e.g., *K* shell) and that reduces the number of electrons which may be ejected by the photoelectric effect. When photons possess the threshold binding energy of electrons of that shell, there is a sudden surge in attenuation owing to the ejection of electrons from that shell via photoelectric interactions. The photoelectric effect will occur primarily in the *K*-electron shell. At higher photon energies ($>K$ -shell binding energy) the probability of the photoelectric effect occurring diminishes, for example, the photoelectric effect in the *L*-shell is only about 20% and even less probable for outer shells (Friedlander et al., 1964). Such a phenomenon may appear strange, considering that the binding energies of the electrons are lower in shells further away from the nucleus. If one considers only the binding energies of the electrons, it would appear, although incorrectly, that for photon energies in excess of the *K*-shell binding energy, electrons further away from the nucleus (e.g., *L*-, *M*-, *N*-shells) would be ejected as photoelectrons more easily. This is not the case, because energy and momentum must be conserved in the process, and the atom, because of its much higher mass, will carry off the excess momentum while taking away negligible energy in the process. The entire photon energy is transferred to the photoelectron less its binding energy. Consequently, the photoelectric effect cannot occur with a free electron, because there is no atom to carry off excess momentum, as demonstrated by Gautreau and Savin (1999). In the same sense, when the photon energy is much greater than the electron binding energy, the electrons, such as those in the outer shells with very low binding energies, act more like free electrons. These electrons contribute less to photon attenuation by the photoelectric effect. As explained by Lilley (2001), the conservation of energy and momentum is the reason why the most tightly bound electrons contribute most to photoelectric absorption for $E_\gamma > B_K$, where E_γ is the photon energy and B_K is the *K*-shell electron binding energy, and also why there is a marked dependence of photon attenuation on photon energy and absorber atomic number. The photon absorption in NaI, illustrated in Fig. 1.125, shows a *K* edge at ~ 0.033 MeV or 33 keV. This corresponds to the electron binding energy in the *K* shell of iodine, which from reference tables (Lide, 2010) is reported to be 33,169 eV or 33.1 keV. Photon attenuation by the photoelectric effect for photon energies in excess of 33 keV occur predominantly with the *K*-shell electrons. There is no *K* edge observed for sodium in Fig. 1.125 for the NaI absorber, because the binding energy of the *K*-shell of sodium is only 1070 eV or 1.07 keV, a factor of 10 lower than the photon energy scale provided in the figure. At much lower photon energies, corresponding to *L*- and *M*-shell electron binding energies, characteristic *L* and *M* edges can be

observed. The binding energies of electrons in the various atomic electron shells of the elements are listed in reference tables, such as those provided by Lide (2010).

As illustrated in Figs. 1.124 and 1.125 the pair production process does not occur at gamma-ray energies below the threshold value of 1.02 MeV, as expected, in accord with the combined positron and negatron rest energies (*i.e.*, 2×0.511 MeV) required for pair production. A thorough treatment of the attenuation and absorption of gamma radiation in matter is available from Hubbell (1969), Krane (1988), Turner (1995), Lilley (2001), Serway *et al.* (2005), and Murray and Holbert (2015).

XIII. Radioactive nuclear recoil

When a decaying nucleus discharges or emits a particle such as an alpha particle, beta particle, gamma- or X-ray photon, or neutrino, the nucleus will recoil in a fashion somewhat like a cannon recoils when it shoots a cannon ball from its barrel. The energy of recoil is a function of the mass and energy of the particle that is emitted as well as the mass of the nucleus. This may appear intuitively obvious, if we relate the process to that of a cannon, that is, the heavier the cannon for a given mass and velocity of cannon ball, the less will be the recoil energy. Even radionuclides that emit electrons or photons from their atomic shell, such as Auger electrons and X-rays, respectively, will experience some recoil effect, albeit much less than would occur when a heavy particle, such as the alpha-particle, is emitted from a nucleus at high energy. In accord with the principles of conservation of momentum, nuclear recoil will occur in all nuclear decay processes with the conservation of momentum between the emitted particle and the product nucleus, as illustrated in Fig. 1.128.

In various textbooks one can find reference to some equations for calculating nuclear recoil energies for some particular particle emissions. Van Rooyen *et al.* (2008) and Szucs *et al.* (2009) provide relativistic and nonrelativistic nuclear recoil expressions for all particle emissions including alpha particles, beta particles, Auger electrons, neutrinos, and gamma- and X-ray photons. Detailed derivations of the equations will be provided here.

FIGURE 1.128 Nuclear recoil resulting from the emission of a particle from a nucleus similar to the shooting of a bullet from a gun. In the process there is conservation of energy shared between the emitted particle (E_p) and recoil nucleus (E_N) as well as conservation of momentum between the emitted particle (P_p) and recoil nucleus (P_N).

A. Relativistic expressions

When a particle is emitted by a decaying nucleus, it possesses a kinetic energy (K_p), which is the difference of the total particle energy (E_p) and its rest energy ($m_p c^2$) or

$$K_p = E_p - m_p c^2 \quad (1.456)$$

And if the expression of energy, momentum, and particle mass is written as (see Eq. 1.374)

$$E_p^2 = p_p^2 c^2 + (m_p c^2)^2 \quad (1.457)$$

where p_p is the particle momentum and c is the speed of light in a vacuum. From Eqs. (1.456) and (1.457) we can write

$$(K_p + m_p c^2)^2 = p_p^2 c^2 + (m_p c^2)^2 \quad (1.458)$$

which becomes

$$K_p^2 + 2m_p c^2 K_p + (m_p c^2)^2 = p_p^2 c^2 + (m_p c^2)^2 \quad (1.459)$$

and reduces to

$$K_p^2 + 2m_p c^2 K_p = p_p^2 c^2 \quad (1.460)$$

Solving Eq. (1.460) for the particle momentum, gives

$$p_p = \frac{\sqrt{K_p^2 + 2m_p c^2 K_p}}{c} \quad (1.461)$$

As the momentum of the system is conserved whereby changes in momentum between the recoil nucleus and particle are equal in magnitude and opposite in direction, as in the nonrelativistic case where

$$m_N \Delta v_N = -m_p \Delta v_p \quad (1.462)$$

we can express the changes in nuclear recoil momentum and particle momentum according to Eq. (1.461) as

$$\frac{\sqrt{K_N^2 + 2m_N c^2 K_N}}{c} = -\frac{\sqrt{K_p^2 + 2m_p c^2 K_p}}{c} \quad (1.463)$$

where K_N and m_N are the kinetic energy and mass, respectively, of the recoil nucleus. If the total energy of the nucleus (E_N), in terms of its momentum and mass, is written according to Eq. (1.457) as

$$E_N^2 = p_N^2 c^2 + (m_N c^2)^2 \quad (1.464)$$

we can input the expression of the particle momentum into Eq. (1.464) to give

$$E_N^2 = \left(\frac{\sqrt{K_p^2 + 2m_p c^2 K_p}}{c} \right)^2 c^2 + (m_N c^2)^2 \quad (1.465)$$

which becomes

$$E_N^2 = K_p^2 + 2m_p c^2 K_p + m_N^2 c^4 \quad (1.466)$$

Eq. (1.466) is reduced to the simple expression of the total energy of the nucleus as

$$E_N = \sqrt{K_p^2 + 2m_p c^2 K_p + m_N^2 c^4} \quad (1.467)$$

If by definition, the kinetic energy of the nucleus K_N , that is, it's recoil energy, is the difference of it's total energy, E_N , and it's rest energy, $m_N c^2$, then

$$K_N = E_N - m_N c^2 \quad (1.468)$$

From Eqs. (1.467) and (1.468) we can arrive at the final expression for the kinetic energy of the recoil nucleus in terms of the particle kinetic energy (K_p), particle mass (m_p), and mass of the recoil nucleus (m_N) to be

$$K_N = \sqrt{K_p^2 + 2m_p c^2 K_p + m_N^2 c^4} - m_N c^2 \quad (1.469)$$

Eq. (1.469) is the fully relativistic expression for the calculation of the nuclear recoil energy for particle emissions that possess nonzero rest mass, such as alpha particles, beta particles, and Auger electrons.

For particle emissions consisting of gamma- and X-ray photons, which have a zero rest mass, the term $2m_p c^2 K_p$ will fall out of Eq. (1.469), and in the case of the neutrino, which has a near-zero rest mass, the term $2m_p c^2 K_p$ becomes negligible and can be dropped out of Eq. (1.469) so that it simplifies to

$$K_N = \sqrt{K_p^2 + m_N^2 c^4} - m_N c^2 \quad (1.470)$$

Eq. (1.470) is thus used to calculate the nuclear recoil energies for gamma-ray photon, X-ray photon, or neutrino emissions. The recoil nucleus is that of the daughter nucleus, because it is the daughter nucleus that recoils after the nucleus emits a particle.

Van Rooyen et al. (2008) and Szucs et al. (2009) utilized Eq. (1.469) for the calculation of the nuclear recoil energies arising from ^{103}Pd Auger electron emissions and Eq. (1.470) for nuclear recoil energies resulting from gamma-photon emissions of $^{103\text{m}}\text{Rh}$.

B. Nonrelativistic expressions

1. Nuclear recoil energy from alpha-particle emissions

For relatively heavy particles, such as the alpha particle, the more simple nonrelativistic calculation of the nuclear recoil energy may also be used. The nonrelativistic expression of the nuclear recoil energy for alpha-particle emissions is derived subsequently. The nonrelativistic expression of the kinetic energy of the alpha particle is defined as

$$K_\alpha = \frac{1}{2} m_\alpha v^2 \quad (1.471)$$

where m_α and v are the mass and velocity of the particle, respectively. It's nonrelativistic momentum would be simply

$$p_\alpha = m_\alpha v \quad (1.472)$$

Multiplying Eq. (1.471) by $2m_\alpha$ gives

$$2m_\alpha K_\alpha = (m_\alpha v)^2 = p_\alpha^2 \quad (1.473)$$

And the momentum of the alpha particle can be expressed as

$$m_\alpha v = \sqrt{2m_\alpha K_\alpha} \quad (1.474)$$

which relates the alpha-particle mass, energy, and momentum. Conservation of momentum of the alpha particle (p_α) and recoil nucleus (p_N) dictates that changes in momentum between the recoil nucleus and particle are equal in magnitude and opposite in direction, we can express the momentum between the alpha particle and nucleus as

$$\sqrt{2m_\alpha K_\alpha} = -\sqrt{2m_N K_N} \quad (1.475)$$

where m_N and K_N are the mass and kinetic energies of the recoil nucleus. Squaring both sides of Eq. (1.475) and solving for K_N gives

$$K_N = \left(\frac{m_\alpha}{m_N}\right) K_\alpha \quad (1.476)$$

Eq. (1.476) was used in Section X.A.1 (Eq. 1.160) for the calculation of the recoil energy resulting from the 5.545 MeV alpha particle emitted from ^{241}Am . The relativistic expression, provided in Eq. (1.469), yields the same result.

2. Nuclear recoil energy from gamma-ray photon, X-ray photon, and neutrino emissions

For gamma-ray and X-ray photons, which have zero rest mass, and neutrinos, which have near-zero rest mass, we can express their momentum (see Eq. 1.376) as

$$p_p = \frac{E_p}{c} \quad (1.477)$$

where p_p is the momentum of the gamma-ray photon, X-ray photon, or neutrino, E_p is the particle energy, and c is the speed of light in a vacuum. If the nonrelativistic expression of the kinetic energy of the recoil nucleus is

$$K_N = \frac{1}{2} m_N v^2 \quad (1.478)$$

where K_N is the kinetic energy of the recoil nucleus, m_N is the mass of the recoil nucleus and v is it's velocity. Multiplying both sides of Eq. (1.478) by $2m_N$ gives

$$2m_N K_N = (m_N v)^2 = p_N^2 \quad (1.479)$$

where p_N is the momentum of the recoil nucleus. As momentum is conserved, we can write

$$2m_N K_N = \frac{E_p^2}{c^2} \quad (1.480)$$

where E_p is the energy of the emitted particle, albeit a gamma-ray photon, X-ray photon, or neutrino.

Solving Eq. (1.480) for the energy of the recoil nucleus gives

$$K_N = \frac{1}{2} \left(\frac{E_p^2}{m_N c^2} \right) \quad (1.481)$$

where E_p^2 is the square of the energy of the gamma-ray photon, X-ray photon, or neutrino, and m_N is the mass of the recoil nucleus.

The reader may peruse the works of Van Rooyen et al. (2008) and Szucs et al. (2009) for additional derivations and applications of the above equations for calculating recoil energies.

C. Sample calculations

1. Nuclear recoil from alpha emissions

Earlier in this chapter (Section X.A.1, Eq. 1.160), the nonrelativistic expression for the recoil energy was used to determine the recoil energy imparted to a nucleus as a result of alpha-particle emission of 5.545 MeV that occurs in the following decay of ^{241}Am :

The relativistic expression provided by Eq. (1.469) will be used. Since nuclear recoil occurs after the nucleus emits a particle, it is the daughter nuclide that recoils. We will use atomic mass units (u) and the conversion factor of 931.494013 MeV/u to convert mass to energy units. Relevant data from nuclear tables (e.g., Lide, 2010) are the mass of the alpha particle and that of ^{237}Np which are 4.00150617 u and 237.048166 u, respectively. Updated atomic mass data can be obtained online from the Atomic Mass data Center (AMDC) via the website <http://amdc.impcas.ac.cn/web/masseval.html>. Thus, from Eq. (1.469), the nuclear recoil energy is calculated as

$$\begin{aligned} K_N &= \sqrt{K_p^2 + 2m_p c^2 K_p + m_N^2 c^4} - m_N c^2 \\ &= \left\{ \begin{aligned} &(5.545 \text{ MeV})^2 + 2(4.00150617 \text{ u}) \\ &(931.494013 \text{ MeV/u})(5.545 \text{ MeV}) \\ &+ [(237.048166 \text{ u})(931.494013 \text{ MeV/u})]^2 \end{aligned} \right\} \\ &\quad - (237.048166 \text{ u})(931.494013 \text{ MeV/u}) \\ &= 0.0936 \text{ MeV} \end{aligned} \quad (1.483)$$

The recoil energy of 0.0936 MeV agrees with the nonrelativistic calculation made earlier in Section X.A.1 (see Eq. 1.160) of this chapter. In general, the nuclear recoil energy

resulting from alpha-particle emissions will be higher than that of other nuclear decay emissions for a nuclide of given mass and alpha-particle of given energy (see Table 1.25). This is characteristic of alpha-particle emissions, because the alpha particle is massive. We will notice much smaller nuclear recoil energies resulting from beta-particle emissions, if we compare emissions of the same energy from nuclides of similar mass. This is obviously due to the large difference in mass of the alpha particle compared to the electron or beta particle. The mass of the alpha particle is 7294 times that of the electron (i.e., $\alpha/e = 4.00150617 \text{ u}/0.000548579 \text{ u}$). An analogy can be made by comparing the recoil imparted to a cannon upon firing a cannon ball compared to the kick imparted to a pistol upon firing a 0.45 caliber bullet.

2. Nuclear recoil from beta emissions

Let us calculate the recoil energy imparted to a nucleus by the emission of a beta particle. The following decay of ^{109}Pd by beta-particle emission may serve as an example:

Beta particles are emitted with a broad spectrum of energies from zero to E_{\max} , because the decay energies are shared with a neutrino. We will select the maximum energy (1.03 MeV) that the negative beta particle may possess when the antineutrino energy is at its minimum (near zero) in order to calculate the maximum recoil energy that the particle may impart to the nucleus. We will not calculate here any nuclear recoil energy that the gamma ray may impart to the nucleus. Again, as in the previous example, the nucleus that undergoes the recoil is that of the daughter nuclide, because it is the daughter that is produced when the beta particle is emitted from the nucleus. Also, we will use the relativistic expression of the recoil energy (Eq. 1.469) for the calculation. Relevant data from nuclear reference tables for the calculation are the mass of the beta-particle (i.e., electron mass) and that of ^{109m}Ag , which are 0.000548579 u and 108.904756 u, respectively. The nuclear recoil energy is calculated as

$$\begin{aligned} K_N &= \sqrt{K_p^2 + 2m_p c^2 K_p + m_N^2 c^4} - m_N c^2 \\ &= \left\{ \begin{aligned} &(1.03 \times 10^6 \text{ eV})^2 + 2(5.48579 \times 10^{-4} \text{ u}) \\ &(931494013 \text{ eV/u})(1.03 \times 10^6 \text{ eV}) \\ &+ [(108.904756 \text{ u})(931494013 \text{ eV/u})]^2 \end{aligned} \right\} \\ &\quad - (108.904756 \text{ u})(931494013 \text{ eV/u}) \\ &= 10.41 \text{ eV} \end{aligned} \quad (1.485)$$

TABLE 1.25 Recoil energies in electron volts (eV) Imparted to nuclei of various masses by emitted particles of various energies in MeV.

Nuclear mass	Alpha particles ^a				
	$E_\alpha = 1.5 \text{ MeV}$	$E_\alpha = 2 \text{ MeV}$	$E_\alpha = 4 \text{ MeV}$	$E_\alpha = 6 \text{ MeV}$	$E_\alpha = 8 \text{ MeV}$
150 u	4.0E4 eV	5.3E4 eV	10.7E4 eV	16.0E4 eV	21.3E4 eV

200	0.67	2.68	10.74	42.94	96.62
250	0.54	2.15	8.59	34.35	77.29

^aNuclear recoil energies resulting from alpha-particle emission are expressed in exponential form. For example, the nuclear recoil energy imparted to a nucleus of mass 150 u by an alpha-particle emitted with energy of 1.5 MeV is 4.0E4 or 4.0×10^4 eV. Also, nuclear recoil energies for nuclear masses <150 u are not listed for alpha particle emissions, because only nuclei of relatively high mass ($A > 140$ u) are unstable to alpha-particle emission. The recoil energies resulting from alpha-particle emissions were calculated by Eq. (1.476), i.e., $K_N = (m_\alpha/m_N)K_\alpha$.

^bThe recoil energies resulting from beta-particle emissions were calculated according to Eq. (1.469), i.e., $K_N = \sqrt{K_\beta^2 + 2m_\beta c^2 K_\beta + m_\beta^2 c^4} - m_\beta c^2$.

^cRecoil energies resulting from gamma-ray photon, X-ray photon or neutrino emissions were calculated according to Eq. (1.470), i.e.,

$$K_N = \sqrt{K_p^2 + m_N^2 c^4} - m_N c^2.$$

As we see from this example, the previous example, and from Table 1.25, the energies imparted by the massive alpha particles to recoil nuclei are measured in the tens of thousands of electron volts; whereas, energies imparted by the relatively miniscule beta particle range mostly from a few to several hundred electron volts, and energies imparted to nuclei by gamma-ray and X-ray photons and neutrino emissions are yet smaller.

3. Nuclear recoil from gamma-ray photon, X-ray photon, or neutrino emissions

Let us consider an example of a nuclide that decays exclusively by EC with the emission of neutrinos and

gamma radiation. The nuclide ${}^7\text{Be}$ decays to ${}^7\text{Li}$ with the emission of neutrinos of 0.862 MeV at 89.6% relative intensity and 0.384 MeV at the remaining 10.4% intensity. The ${}^7\text{Li}$ daughter nuclides resulting from the lower 0.384 MeV neutrino emissions decay to the ground state with the emission of gamma radiation of 0.478 MeV. The decay scheme of ${}^7\text{Be}$ is illustrated in Fig. 1.54 and the decay equation is the following:

We can use Eq. (1.470) to calculate the nuclear recoil energy resulting from the emission of a neutrino or gamma-ray photon. Let us calculate the recoil energy

imparted to the ${}^7\text{Li}$ nucleus resulting from the emission of a 0.862 MeV neutrino. The mass of ${}^7\text{Li}$ obtained from physical data tables is 7.016004 u and the constant for conversion of mass units to energy is 931.494013 MeV/u.

$$\begin{aligned}
 K_N &= \sqrt{K_p^2 + m_N^2 c^4} - m_N c^2 \\
 K_N &= \left\{ \sqrt{(8.62 \times 10^5 \text{ eV})^2 + [(7.016004 \text{ u})(931.494013 \text{ eV/u})]^2} \right. \\
 &\quad \left. - (7.016004 \text{ u})(931.494013 \text{ eV/u}) \right\} \\
 &= 56.84 \text{ eV}
 \end{aligned}
 \tag{1.487}$$

This calculated value is in agreement with the experimental measurement of the ${}^7\text{Li}$ recoil energy of $56 \pm 1 \text{ eV}$ by 2002 Physics Nobel Laureate Raymond Davis Jr (see Davis, 1952). The recoil energy is higher than that calculated above for the recoil energy imparted by the beta-particle emission to a ${}^{109\text{m}}\text{Ag}$ nucleus (Eq. 1.485), because of the relatively small mass of the ${}^7\text{Li}$ nucleus. We can see from Table 1.25 that, when comparing particle emissions of the same mass and energy, higher recoil energies will result with nuclei of smaller mass.

For further examples of the practical application of the equations derived here for recoil energy, namely, Eq. (1.469), Eq. (1.470), Eq. (1.476) and Eq. (1.481), see Van Rooyen et al. (2008) and Szucs et al. (2009).

D. Radioactive recoil effects

The implications of nuclear recoil are numerous including applications of hot-atom chemistry where chemical bonds are broken by recoiling nuclei facilitating the preparation of high specific activity radionuclides by means of the Szilard–Chalmers Effect. Also, nuclear recoil during radioactive decay of naturally occurring radionuclides can create disequilibrium when the recoil liberates the nuclide from its mineral lattice. These recoil effects will be discussed subsequently.

1. Szilard–Chalmers process

Prior to discussing the Szilard–Chalmers process, which is important in the preparation of radionuclides with high specific activity, the historical background that led to its discovery is relevant and will be presented briefly. A more thorough account is given in previous books by the author (L’Annunziata, 2007, 2016). On 12 September 1933, Leo Szilard (1898–1964) read a news report in the *Times* where

Ernest Rutherford was interviewed. The reporter had asked Rutherford what were his thoughts concerning nuclear transmutations and nuclear energy. Rutherford replied that charged particles, such as the proton, could eventually be accelerated with sufficient high voltage to eventually transform all of the elements. He added that the energy released would be too small to produce energy on a large scale for power and anyone who looked for transmutation as a source of power was talking “moonshine”. Szilard agreed with Rutherford’s comments concerning accelerated protons, that these would not be a useful source of energy. He knew that the proton had to overcome the Coulombic barrier of the repelling positive nuclear charge of atoms. However, he thought, that the neutron, because of its neutral charge, should be able to penetrate the Coulombic barrier of an atom and collide with the nucleus without any external force and cause a reaction or transmutation of the nucleus. Szilard’s mind was restless. While standing at a street corner in London in the following month of October and during the time that it took a traffic light to change, the idea of the possibility of a neutron-induced nuclear chain reaction hit him. Szilard knew, that in chemistry, there existed chain reactions where one reaction could yield two products that could further interact with other reactants to produce four products and these could react to produce eight products, etc. resulting in an exponential increase in reactions. The chain reactions could be very numerous and limited only by the quantity of reactants available. He thought that if a chain reaction with neutrons could occur, that is, if a neutron would be able to interact with an atomic nucleus to produce more than one neutron and the additional neutrons created would interact with other atomic nuclei to produce yet more neutrons, a chain reaction would ensue and a tremendous amount of energy could be liberated. Szilard could foresee that the initial neutron reaction and the resultant multiplication of neutrons should occur in a very short period of time, in microseconds, as nuclear reactions would be fast, producing an explosion of unforeseeable magnitude. Leo Szilard was the first to conceive the possibility of obtaining large amounts of energy and even an explosion from nuclear transmutations.

Having formulated further his initial idea of the potential energy that could be released from neutron-induced chain reactions, on 12 March 1934, Szilard filed for a patent, which contained the basic concepts of a nuclear chain reaction, the concept of “critical mass”, that is, the minimum mass of a material required for a sustained nuclear chain reaction, and the “explosion” that could result. He was awarded British Patent No. 630,726 entitled *Improvements in or Relating to the Transformation of Chemical Elements*. In his patent Szilard described the concept of critical mass in his statement “If the thickness is larger than the critical value ... I can produce an explosion.” (Feld and Weiss-Szilard, 1972; Loeber, 2002). Otto

Hahn and Fritz Strassmann with the assistance of Lise Meitner had not discovered nuclear fission until 1939. Consequently, the fissile materials required to produce neutron-induced nuclear chain reactions had not yet been discovered and there is no record of any such nuclear chain reactions ever discussed prior to Szilard's patent. Szilard was clearly ahead of his time. The patent, as written by Szilard, stated "This invention has for its object the production of radioactive bodies and the liberation of nuclear energy for power production and other purposes through nuclear transmutation." (Feld and Weiss-Szilard, 1972). Szilard was a pacifist and idealist, and the objective of his patent was not personal gain but for control over the harmful use of nuclear weapons. After a year's time he convinced the British Government to accept the patent in order to keep the concepts of the patent secret and inaccessible to the world. Later in life, Leo Szilard joined the Manhattan Project, which was the secret American project for the production of the atomic bomb, out of fear that Germany could become the first to acquire the weapon. Rhodes (1986) and Loeber (2002) point out that Szilard tried to use his patent as a means to gain control of the decision-making process for the atomic bomb. He felt that the control of the bomb and its use should be in the hands of the wisest scientists and not in the hands of government officials. Rhodes (1986) noted that the US Government rejected Szilard's claim to the atomic bomb on simple legalistic grounds, because he did not disclose the existence of his patent before joining the Manhattan Project.

When Szilard first conceived of neutron-induced chain reactions in 1933, he did not know what element or isotope would undergo such reactions. His patent had made a slight mention of uranium and thorium, but his thoughts were mistakenly on beryllium. He therefore, started a search for the chain-reacting element. With this in mind, Szilard began a collaboration of nuclear research with T. H. Chalmers at the Physics Department of the Medical College of St. Bartholomew's Hospital, London. This research did not lead to the discovery of a neutron-induced chain reaction, but lead to other important discoveries including (i) the discovery of a photoneutron (γ, n) source, that is, the induction of neutron emission by gamma- or X-radiation, and (ii) the Szilard–Chalmers Effect, which is the rupture of a chemical bond between an atom and a molecule of which the atom is a constituent, as a result of nuclear recoil during radioactive decay of that atom. The Szilard–Chalmers Effect led to the Szilard–Chalmers Process or Reaction, which has enabled the isolation of high-specific activities of radionuclides. The two discoveries and their applications will be discussed subsequently.

In his search for neutron emission that might initiate a neutron-induced chain reaction, Leo Szilard and T.H. Chalmers irradiated beryllium with radium gamma-rays. They discovered a radiation from the beryllium that would

induce radioactivity in iodine and concluded that neutrons were emitted from the beryllium by the gamma rays (Szilard and Chalmers, 1934a; b, 1935). Their report was the first where neutron emission was initiated by gamma radiation, and the reaction that they observed can be abbreviated as

which reads:

${}^9\text{Be}$ target nuclide (gamma-ray projectile, neutron emitted) ${}^8\text{Be}$ product nucleus.

This discovery was significant, because today photoneutron (γ, n) sources are useful portable sources of neutrons. A very common neutron source of this nature used today is the mixture of ${}^{124}\text{Sb} + \text{Be}$ where the gamma-rays from ${}^{124}\text{Sb}$ yield neutrons via a photonuclear reaction (see Table 1.16).

Szilard and Chalmers (1934b) used iodine as the indicator for neutrons as the neutrons would induce radioactivity in iodine by creating radioiodine via neutron capture. A subsequent work was reported shortly thereafter by Brasch and coworkers together with Szilard and Chalmers and assistance of Lise Meitner in Berlin (Brasch et al., 1934) whereby the neutron emission from beryllium was induced by X-ray photons and neutron-capture by bromine, and the isolation of the product nuclide, radiobromine, was used as the neutron indicator.

An important outcome of this work was the discovery of the Szilard–Chalmers process whereby radionuclides may be easily separated and isolated from their parent atoms and consequently high specific activities of radionuclides may be obtained which otherwise would be difficult when both the target and product atoms are isotopes. For example, Szilard and Chalmers (1934 a,b) surrounded 150 mg of radium (gamma-ray source) with 25 g of beryllium in a sealed container of 1-mm thick platinum. The Ra–Be neutron source was immersed in 100 mL of ethyl iodide. The neutrons produced radioactive ${}^{128}\text{I}$ from stable ${}^{127}\text{I}$ by neutron capture. The ${}^{128}\text{I}$ would precipitate as radioactive silver iodide (Ag^{128}I) after the addition of water containing silver ions (Ag^+). However, a control experiment without the neutron source produced no radioactivity over background in the silver iodide precipitate. This experiment indicated that the chemical bond between the carbon atom of the ethyl group and the ${}^{128}\text{I}$ was broken after ${}^{127}\text{I}$ neutron capture, because free unbound ionic ${}^{128}\text{I}^-$ would precipitate with the Ag^+ to produce radioactive Ag^{128}I precipitate in the aqueous phase according to the sequence illustrated in Fig. 1.129.

The energy of bonding between the carbon and iodine atoms is about 2 eV, which is higher than the neutron recoil energy. Consequently, the rupture of this bond is due to the gamma-recoil when the ${}^{128}\text{I}$ undergoes gamma emission upon de-excitation after neutron capture. Some atoms of

FIGURE 1.129 Szilard–Chalmers Process. High specific activity ¹²⁸I is separated from the stable ¹²⁷I as a result of the Szilard–Chalmers Effect. The capture of a neutron by the stable isotope ¹²⁷I in the ethyl iodide molecule created radioactive ¹²⁸I. The neutron capture process leaves the ¹²⁸I nucleus in an excited state, which emits a gamma-ray upon de-excitation. The gamma-recoil causes a rupture of the chemical bond between the carbon atom of the ethyl group and the ¹²⁸I thereby liberating the ¹²⁸I as an anion. The addition of water containing silver cations (Ag⁺) to the organic solution enables the ionic ¹²⁸I⁻ to enter the aqueous phase and separate out as precipitated Ag¹²⁸I. The radioactivity of ¹²⁸I is detected by its beta-particle emissions, and it decays with a half-life of 25 minutes.

¹²⁸I could recombine with the free ethyl group and even exchange with some stable atoms of ¹²⁷I, but if these processes are slow and, if these processes are further reduced by the addition of water or even alcohol to dilute the organic phase, the precipitate of radioactive inorganic iodide proceeds yielding a highly enriched radioactive ¹²⁸I with minimal ¹²⁷I.

The Szilard–Chalmers process remains to this day a very practical application to the isolation of high specific activity radioactive sources from the medium in which the radionuclide sources were synthesized. A few examples that can be taken from the literature are an editorial review by Eckelman et al. (2008), the isolation of high specific activity radioisotopes after cyclotron production (Bonardi et al., 2004; Birattari et al., 2001), and a list of some radionuclides isolated with high specific activity listed in Table 1.26.

2. Radioactive disequilibrium

When chemical bonds are broken as a result of radioactive nuclear recoil, the recoiling nucleus may be displaced from the chemical structure (e.g., mineral lattice) within which it resided. The liberated nuclide, which may be part of a natural decay chain, may then be leached from mineral deposits into ground water creating disequilibrium among the natural radionuclides. For example, Labidi et al. (2010) measured

the isotopic levels of ²³⁴U/²³⁸U and ²²⁶Ra/²³⁴U in waters of Tunisia and found a disequilibrium between the two members of the ²³⁸U decay series, which may be due to the direct action of nuclear recoil during radioactive decay and preferential leaching. This decay series was discussed and illustrated previously in Fig. 1.9. The researchers estimated the annual effective radiation doses due to the ingestion of the mineral waters to be well below the 0.1 mSv/year reference dose level. Fernandez et al. (2006) studied the radioecological characteristics of a uranium mining site in Brazil and point out that, as suggested by Ivanovich (1994) and Ivanovich and Harmon (1992) and Kobashi et al. (1979), disequilibrium between Ra and U isotopes may be due to (i) precipitation/dissolution reactions, (ii) alpha recoil, (iii) diffusion, and (iv) the Szilard–Chalmers effect. Almayahi et al. (2012) found elevated ²²⁶Ra/²³⁸U ratios in soil and sand systems, which may be the result of the Szilard–Chalmers effect causing disequilibrium in the decay series and elevated radon concentrations.

The activity ratios of ²³⁴U/²³⁸U were studied by Paces et al. (2002) for evidence of ground-water flow patterns in the United States. They found that ²³⁴U enters solution preferentially from rocks as a result of mechanisms related to its origin by radioactive decay of ²³⁸U including alpha recoil damage of crystal-lattice sites containing ²³⁴U and the Szilard–Chalmers effect as well as radiation-induced oxidation of ²³⁴U. Similar disequilibrium effects of natural radioactivity that may be due to nuclear recoil following alpha decay in the ²³⁸U decay series was observed by Dowell and O’Dea (2002) and Davis and Krogh (2000). Disequilibrium among radionuclides in the natural decay series was underscored by Adloff (1989) to occur by “natural Szilard–Chalmers reactions” all along the radioactive decay series, and that this is triggered mostly by nuclear recoil effects after alpha decay. Adloff summarizes that these effects have found a wide range of applications in environmental studies such as geochronology, weathering, sedimental processes, and oceanic chemistry.

Kurosaki et al. (2014) provide evidence of isotopic disequilibrium between Pu in groundwater and sediment that may be explained by (i) ²⁴⁰Pu produced by decay of ²⁴⁴Cm at a higher oxidation state Pu^VO₂⁺ and/or Pu^{VI}O₂²⁺ as a result of the electronstripping Szilard–Chalmers process, and (ii) the oxidized forms of Pu have much lower tendencies to sorb onto sediments than the reduced forms of Pu. Their conclusions are supported by studies by Buesseler et al. (2009) and Dai et al. (2002) on Pu oxidation states and migration in groundwater.

XIV. Cosmic radiation

Stable charged particles and nuclei with lifetimes of 10⁶ years or longer originating from space that strike the top of the atmosphere (TOA) from all directions constitute

what is known as the cosmic radiation. Air showers of the cosmic radiation consist of cascades of subatomic particles and electromagnetic radiation resulting from nucleon–nucleon collisions of high-energy cosmic-ray particles from space with atomic nuclei of the earth's atmosphere. Cosmic rays are classified according to their origin in space, and the air showers of the cosmic radiation are characterized according to the products of collisions of high-energy cosmic-ray particles and nuclei with atoms of the earth's atmosphere.

The discovery of cosmic radiation is attributed to Victor Hess, who made seven balloon ascents in Austria during 1911–13 into the atmosphere during the daytime, during the evening darkness, and even during a solar eclipse. On these ascents he took along three electroscopes that would measure the ionization caused by external radiation. He thought it best to make simultaneous measurements of ionization with more than one instrument to eliminate

doubt in the event one instrument might give erroneous readings. Hess found that at an altitude of 500 m, the ionization dropped to about half that obtained from the soil surface. However, the readings would increase proportionally with altitude as he would ascend beyond 1000 m. He found the ionization at 1500 m would increase to be approximately equal to that at the soil surface, and further ascents to altitudes of 5000 m would provide ionization readings of several times that at the ground level (Hess, 1912, 1936, 1940). It was obvious to Hess that gamma rays, from radium in air, could not cause any increase in ionization with altitude where air got thinner, and he interpreted his results in the following words:

The only possible way to interpret my experimental findings was to conclude to the existence of a hitherto unknown and very penetrating radiation, coming mainly from above and being most probably of extra-terrestrial (cosmic) origin ...

Victor Hess was awarded the Nobel Prize in 1936 for his discovery of cosmic radiation.

The dose to the human body from cosmic radiation is of concern to astronauts, airline pilots, and persons living at high altitudes, as our atmosphere attenuates considerably cosmic radiation and the dose to the human body consequently increases with altitude. Cosmic radiation is also of much concern as background interference in the measurement of low levels of radioactivity. The accurate measurement of radionuclides in our environment requires the suppression and accurate measurement of the background interference from cosmic rays.

A. Classification and properties

Cosmic radiation incident on the earth's atmosphere is classified into "primary" or "secondary" cosmic rays. As defined by [Patrignani et al. \(2016\)](#), [Beringer et al. \(2012\)](#), and [Gaisser and Stanev \(2002\)](#), **primary cosmic rays** are stable charged particles and nuclei with lifetimes of 10^6 years or longer accelerated at astrophysical sources, and **secondary cosmic rays** are particles produced via the interaction of the primaries with interstellar gas. The nuclear interactions of the accelerated primary cosmic-ray particles with interstellar medium produce stable nuclei of the light elements (*e.g.*, Li, Be, and B), as well as many fundamental particles including pions or π mesons of zero charge (π^0), that decay into gamma rays. Galactic gamma radiation has been mapped by the Compton Gamma Ray Observatory satellite. The satellite has provided an image of the galaxy produced by gamma rays of approximately 100 MeV ([Simpson, 2001](#)). The gamma-ray image compares closely to the visible-light image of the galaxy of which we are most familiar. Galactic gamma rays can cover the full energy range from <100 MeV to >10 TeV.

Primary cosmic-ray particles include protons, helium nuclei, electrons, and nuclei of most elements of the periodic table (*e.g.*, carbon, iron, oxygen, etc) of stellar origin. Nuclei of the light elements lithium, beryllium, and boron ($Z = 3-5$) are classified as secondary radiation. The abundance of these light elements in cosmic radiation is highly enriched over the abundance of these elements in the universe, which is evidence that these are secondary nuclei created via collision (nuclear spallation interactions) with heavier primary particles during the interstellar propagation of primary nuclei. The radionuclide ^{10}Be ($t_{1/2} = 1.6 \times 10^6$ y) is found among other isotopes of the light elements in cosmic rays. From the measured abundance analysis of ^7Be , ^9Be and the radioactive ^{10}Be in cosmic radiation, it is found that cosmic-ray particles remain contained in galactic magnetic fields for approximately 10^7 years before escaping into our atmosphere or intergalactic space. The mean interstellar density for propagation of the cosmic radiation is ~ 0.2 atom/cm³ ([Simpson, 2001](#)).

Nucleons of practically all elements of the periodic table will be found in cosmic radiation. Free protons account for about 80% of the primary nucleons, and approximately 15% are nucleons bound in helium nuclei (equivalent to alpha particles). Electrons constitute about 2% of the primaries. Nuclei of the elements of the periodic table other than the previously mentioned (H and He) make up the remaining components of cosmic radiation. Nuclei of the light elements (Li, Be, and B), which constitute secondary cosmic ray particles, account for a small fraction ($\sim 0.3\%$) of cosmic ray nuclei (see [Table 1.27](#)).

The composition of cosmic radiation will vary according to the 11-year solar cycle and the earth's magnetic latitude ([Potgieter, 2008a,b](#); [Patrignani et al., 2016](#)). The earth's magnetic field, which extends well into space, affects the composition of the charged particles of cosmic

TABLE 1.27 Approximate composition of cosmic radiation of galactic origin incident on the top of the atmosphere (TOA)^a.

Radiation type	Approximate fraction (%)
H nuclei or protons (p^+ and p^-) ^b	80
He nuclei (equivalent to α particles)	15
Electrons (e^- and e^+) ^c	2
Heavier nuclei (<i>e.g.</i> , C, O, Mg, Fe, Si, etc) ^d	1
Lighter nuclei ($Z = 3-5$, <i>i.e.</i> , Li, Be, and B) ^e	0.2

^aCosmic radiation incident at the top of the terrestrial atmosphere includes all stable charged particles and nuclei with lifetimes of the order of 10^6 years or longer ([Gaisser and Stanev, 2002](#)).

^bThe ratio of antiprotons to protons (\bar{p}/p) is about 2×10^{-4} in the particle energy range of 10–20 GeV. Antiproton/proton ratios at lower energies are listed in this chapter.

^cThe positron fraction ($e^+/(e^+ + e^-)$) varies from ~ 0.2 below 1 GeV to ~ 0.1 around 2 GeV and to ~ 0.05 at higher electron energies of 5–20 GeV.

^dNucleons of all of the elements of the periodic table stripped of their atomic electrons with the exception of the lighter nucleons listed above.

^eThe nuclei of Li, Be, and B are classified as secondary cosmic radiation, that is, particles produced by the interaction of the primaries with interstellar gas.

radiation. The geomagnetic latitude effect was first reported by Clay (1928) and confirmed by Compton (1932, 1933), who measured cosmic ray showers with ionization detectors while traversing latitudes onboard ocean vessels. Cosmic-ray particles will concentrate in the earth's Van Allen radiation belts, which extend from about 1000 to 60,000 km from the earth. The sea-level latitude effect of the electromagnetic and meson components of cosmic-ray interactions in the earth's atmosphere measured by Compton corresponded to an approximately 12–15% increase between the geometric equator and high latitudes. However, no information was obtained then on the latitude effect on the nucleonic component of cosmic radiation at sea level. Subsequent studies (Simpson, 1948, 1951, 2001) demonstrated a dramatic increase of 300–400% in the nucleonic component compared with a 10–15% increase in the meson component of cosmic radiation at sea level as one traveled from 0 degrees to 70 degrees latitude. This is particularly relevant to international airline pilots who are concerned about the cosmic radiation dose they accumulate when they travel frequently at high altitudes (12 km) and high latitudes (40–60 degrees) where the radiation intensities are higher.

Positrons and antiprotons are components of secondary cosmic radiation (Patrignani et al., 2016). Positrons are much lower in abundance than electrons (see Table 1.27 footnote). They are produced mainly via proton and nuclei interactions in the interstellar medium (Grimani, 2009). The differential flux of negatrons and positrons incident at the top of the atmosphere from galactic space is a function of particle energy. The positron fraction, measured as $e^+/(e^+ + e^-)$, decreases from ~ 0.2 below 1 GeV, to ~ 0.1 around 2 GeV and to ~ 0.05 at higher energies of 5–20 GeV (Grimani, 2009, 2005; Clem and Evenson, 2002; Gaisser and Stanev, 2002; Sundaresan, 2001). Antiprotons in the cosmic radiation were discovered by Golden et al. (1979, 1984). These are classified as secondaries, as antiprotons as well as positrons are produced by the interactions of primary cosmic radiation, principally protons with the interstellar matter, such as cosmic-ray nuclei (Adriani et al., 2010; Gaisser and Schaefer, 1992; Webber and Potgieter, 1989; Gaisser and Maurer, 1973). The proportions of antiprotons to protons (\bar{p}/p) is a function of energy with ratios varying from $\sim 0.3 \times 10^{-5}$ to 1×10^{-5} in the energy range of ~ 0.2 –1 GeV, from $\sim 2 \times 10^{-5}$ to 1×10^{-4} in the energy range of ~ 1 –10 GeV, and from $\sim 2 \times 10^{-3}$ to 3×10^{-3} in the energy range of 10–180 GeV (Adriani et al., 2010; Beach et al., 2001; Basini et al., 1999; Mitchell et al., 1996; Hof et al., 1996; Patrignani et al., 2016). In summary, the approximate composition of galactic cosmic ray particles is provided in Table 1.27.

Most galactic cosmic ray particles possess energies from about 0.5 to 50 GeV as illustrated in Fig. 1.130, which provides the fluxes of nuclei of primary cosmic radiation as a function of energy per nucleus. Protons (H) and He nuclei are the most abundant, as illustrated in Fig. 1.130. A series of very precise measurements of primary protons and helium nucleon intensities have been made by several groups including the AMS Collaboration (2000), Menn et al. (2000) and Sanuki et al. (2000), Bellotti et al. (1996, 1999), and Boezio et al. (1999), as described by Beringer et al. (2012) and Patrignani et al. (2016). Particle energies up to 10^{15} eV were first observed by Auger and Maze (1938, 1939), and a cosmic-ray particle of about 10^{20} eV energy was observed by Linsley (1963).

Protons in the kinetic energy range of 100 MeV to 10 GeV would have relativistic speeds ranging from 42.8% to 99.6% the speed of light (*i.e.*, 0.428*c* to 0.996*c*) calculated according to Eq. (1.278). For example, the relativistic speed of a proton with 10 GeV kinetic

FIGURE 1.130 Fluxes of nuclei of the primary cosmic radiation in particles per energy-per-nucleus plotted versus energy-per nucleus. Acronyms in the lower left are those of research groups cited by Patrignani et al. (2016). The figure was created by P. Boyle and D. Muller. For the color version of the figure, the reader is referred to the online or electronic version of the book. Reprinted with permission from Beringer et al. (2012), © 2012 by the American Physical Society, <https://journals.aps.org/prd/abstract/10.1103/PhysRevD.86.010001>, and Patrignani et al. (2016), © Regents of the University of California, <http://pdg.lbl.gov/2016/figures/figures.html>.

energy would be calculated according to the following equation:

$$u = c \sqrt{1 - \left(\frac{K}{mc^2} + 1 \right)^{-2}} \quad (1.489)$$

The rest energy of the proton (mc^2) is calculated as

$$\begin{aligned} mc^2 &= (1.6726 \times 10^{-27} \text{ kg}) (2.9979 \times 10^8 \text{ m/sec})^2 \\ &= 1.503 \times 10^{-10} \text{ J} \end{aligned} \quad (1.490)$$

which can be expressed in units of eV as follows:

$$\frac{1.503 \times 10^{-10} \text{ J}}{1.602 \times 10^{-19} \text{ J/eV}} = 0.9382 \times 10^9 \text{ eV} = 938.2 \text{ MeV} \quad (1.491)$$

The relativistic speed of the 10 GeV proton can then be calculated as

$$u = c \sqrt{1 - \frac{1}{(10^4 \text{ MeV}/938.2 \text{ MeV} + 1)^2}} = 0.996c \quad (1.492)$$

A higher kinetic energy 100-GeV (10^5 MeV) cosmic-ray proton would have a relativistic speed of

$$\begin{aligned} u &= c \sqrt{1 - \frac{1}{(10^5 \text{ MeV}/938.2 \text{ MeV} + 1)^2}} \\ &= 0.999956c \end{aligned} \quad (1.493)$$

The speed of the 100 GeV proton may also be calculated on the basis of the definition of the kinetic energy of the particle being the difference between the *total energy* of the particle and its rest energy (see Eq. 1.270) or

$$K = \gamma mc^2 - mc^2 = (\gamma m - m)c^2 \quad (1.494)$$

or

$$10^5 \text{ MeV} = (\gamma m - m)c^2$$

Converting the units of electron volts in the above equation to joules and imputing the speed of light provides

$$\begin{aligned} &(10^{11} \text{ eV})(1.602 \times 10^{-19} \text{ J/eV}) \\ &= (\gamma m - m)(2.9979 \times 10^8 \text{ m/sec})^2 \end{aligned} \quad (1.495)$$

from which the differences of the relativistic and rest masses of the proton can be calculated as

$$\begin{aligned} \gamma m - m &= \frac{1.602 \times 10^{-8} \text{ J}}{8.9874 \times 10^{16} \text{ m}^2/\text{sec}^2} \\ &= 0.1782495 \times 10^{-24} \text{ kg} \end{aligned} \quad (1.496)$$

Inputting the known rest mass m of the proton ($1.6726 \times 10^{-27} \text{ kg}$) permits the calculation of the relativistic mass of the 100 GeV proton as

$$\begin{aligned} \gamma m &= 178.2495 \times 10^{-27} \text{ kg} + 1.6726 \times 10^{-27} \text{ kg} \\ &= 179.9221 \times 10^{-27} \text{ kg} \end{aligned} \quad (1.497)$$

Since by definition, $\gamma m = m / \sqrt{1 - (u^2/c^2)}$ (see Eq. 1.271), we can write

$$\frac{\gamma m}{m} = \frac{1}{\sqrt{1 - (u^2/c^2)}} \quad (1.498)$$

which transforms to read

$$\left(\frac{m}{\gamma m} \right)^2 = 1 - \frac{u^2}{c^2} \quad (1.499)$$

or

$$\frac{u^2}{c^2} = 1 - \left(\frac{m}{\gamma m} \right)^2 \quad (1.500)$$

Inputting the values for the relativistic and rest masses of the proton yields

$$\begin{aligned} \frac{u^2}{c^2} &= 1 - \left(\frac{1.6726 \times 10^{-27} \text{ kg}}{179.9221 \times 10^{-27} \text{ kg}} \right)^2 \\ \frac{u^2}{c^2} &= 1 - (0.00929624)^2 \end{aligned} \quad (1.501)$$

$$\frac{u^2}{c^2} = 1 - 8.64200 \times 10^{-5}$$

$$u^2 = (0.9999135)c^2$$

and

$$u = 0.999956c$$

where u is the relativistic speed of the 100 GeV proton exactly as calculated previously by Eq. (1.493).

High-energy cosmic-ray protons, as demonstrated above, approach the speed of light. Primary cosmic ray nucleon intensity drops rapidly according to energy beyond several GeV as illustrated in Fig. 1.130. The primary nucleon intensity from a few GeV to 100 TeV is described according to the power law

$$I_N(E) = 1.8E^{-\alpha} \text{ nucleons/cm}^2 \text{ sec sr GeV} \quad (1.502)$$

where E is the energy per nucleon (including rest mass energy) and α is approximately 2.7.

As illustrated in Fig. 1.130, primary nucleon energies in excess of 1 TeV (*i.e.*, 10^{12} eV or 10^6 MeV) are relatively few in number, and primary cosmic-ray particles with energies in excess of 10^{20} eV or 10^{14} MeV are very rare, but

have been reported (Hörandel, 2010; Pierre Auger Collaboration, 2010; Scherini, 2011; Zavrtanik, 2011; Nagano and Watson, 2000; Bird et al., 1995; Hayashida et al., 1994; Linsley, 1963). The rarity of such extremely high-energy primary cosmic ray particles can be visualized with the graph of primary cosmic ray flux as a function of nucleon energy illustrated in Fig. 1.131.

The cosmic-ray scientific community is studying the knee and ankle regions of the cosmic-ray spectrum illustrated in Fig. 1.131. The knee region at particle energies of 10^{15} – 10^{16} eV shows a decline in the particle flux while the ankle region of the spectrum occurring between 10^{18} to 10^{19} eV shows a rise in particle flux. The origins of the knee and ankle regions of the energy spectrum is not fully understood, and these are now under intense research as described by Patrignani et al. (2016), Beringer et al. (2012), Chiavassa (2010), Marcelli (2011), Blümer et al. (2009), Giller (2008), and Hörandel (2008a). The knee portion of the energy spectrum at about 4 PeV (*i.e.*, $\sim 4 \times 10^{15}$ eV),

as described by Hörandel (2008a), is caused by a break in the energy spectra of the light elements. The mean mass of the cosmic rays is found to increase as a function of energy in the knee region. The knee in the energy spectrum is most likely caused by a combination of the maximum energy reached during acceleration and leakage from the Galaxy during propagation (Patrignani et al., 2016; Beringer et al., 2012; Hörandel, 2008a). A current thinking for the production of the ankle region of the spectrum is summarized by Patrignani et al. (2016). It appears that the ankle is caused by a higher energy cosmic-ray population mixed in with a lower energy population at energies a couple of orders of magnitude below the ankle, which could result from a higher-energy extragalactic flux dominating over a galactic flux. The spectrum below 10^{18} eV is considered to be of galactic origin, and the higher energy population in excess of 5×10^{18} eV is considered to be of extragalactic origin (Patrignani et al., 2016; Marcelli, 2011; Allard et al., 2007; Cronin, 1999; Sundareshan, 2001).

Much attention in the cosmic-ray community is also focused on the mechanisms by which the cosmic-ray nucleons are accelerated in space to energies in excess of 10^{20} eV. Enrico Fermi (1949) proposed and calculated the acceleration of cosmic rays resulting from a series of collisions with magnetic fields or magnetic clouds traversing the universe whereby the cosmic ray particles gain energy each time they bounce off the magnetic fields. This is now referred to as Fermi acceleration, and Cronin (1999) explains that subsequent work has shown that multiple “bounces” off turbulent magnetic fields associated with supernova shock waves is the more efficient acceleration process (Drury, 1983). The energy spectrum of cosmic rays supports the “standard picture”, as described by Patrignani et al. (2016) and Hörandel (2008a), that the bulk of galactic cosmic rays is accelerated in shocks of supernova remnants.

B. Showers of the cosmic radiation

Cosmic radiation consisting of high-energy nucleons striking the top of the atmosphere (TOA) collide with atoms of the air to produce a cascade of secondary subatomic particles and electromagnetic radiation referred to as **showers of the cosmic radiation**. During the years that preceded the development of man-made high-energy particle accelerators, cosmic rays provided much information to the field of high-energy particle physics. The collisions of high-energy nucleons with atomic nuclides of the atmosphere provided natural “atom-smashers” that led to the early discovery of subatomic particles.

When a cosmic-ray particle strikes an atomic nucleus of a gaseous molecule of the atmosphere (*e.g.*, N_2 , O_2 , etc.) a nuclear disintegration follows producing high-energy secondary nucleons and charged and neutral π mesons (pions).

FIGURE 1.131 The all-particle spectrum of cosmic rays greater than 100 MeV. The cosmic rays consist predominantly of nucleons ranging in species from protons to iron nuclei with traces of nuclei of the heavier elements. Not included in the figures are notations for estimated cosmic ray fluxes of about 1 particle/cm²/sec at the low energy end of 10^8 eV and only of the order of 1 particle/km²/century at the high-energy end of 10^{20} eV of the spectrum (This figure was produced by S. Swordy, University of Chicago from published results of the LEAP, Proton, Akeno, AGASA, Fly’s Eye, Haverah Park, and Yakutsk experiments. Reprinted from Bhattacharjee and Sigl (2000), Marcelli (2011) with permission from Elsevier © 2000.

These secondary nucleons collide with additional atomic nuclei of the atmosphere producing a cascade of particles including mesons, nucleons of various masses, neutrons, and products of meson-nuclear interactions and meson decay, namely, photons of electromagnetic radiation, positrons, negatrons, and neutrinos. Fig. 1.132 provides a good schematic of the various possible nucleon interactions that produce the cascade of secondary cosmic radiation in the atmosphere.

Mesons are strongly interacting particles of mass intermediate between that of the electron ($0.511 \text{ MeV}/c^2$) and the proton ($938 \text{ MeV}/c^2$). Among the mesons produced are (a) kaons (K -mesons), which have a mass of about $490 \text{ MeV}/c^2$, lifetimes of approximately 10^{-10} and 10^{-8} seconds for the neutral (K^0) and charged (K^\pm) kaon, respectively, decaying to pions and/or muons as illustrated in Fig. 1.133, and (b) the pions (π -mesons) that can decay into muons, such as described by Eqs. (1.507) and (1.508). A neutral pion has a mass of $135 \text{ MeV}/c^2$ and a lifetime of 8.3×10^{-17} seconds. It decays into two gamma-ray photons, as illustrated in Fig. 1.132, or into a positron–negatron pair and gamma ray with branching ratios of approximately 98.8% and 1.2%, respectively, for the two decay modes (Sundaresan, 2001; Glasser et al., 1961) as follows:

$$\pi^0 \rightarrow \gamma + \gamma \quad (98.798 \pm 0.032\%) \quad (1.503)$$

$$\pi^0 \rightarrow e^+ + e^- + \gamma \quad (1.198 \pm 0.032\%) \quad (1.504)$$

FIGURE 1.132 Schematic representation of the typical development of the secondary cosmic radiations within the atmosphere arising from an incident primary particle. From Simpson et al. (1953), <https://journals.aps.org/pr/abstract/10.1103/PhysRev.90.934>, reprinted with permission © 1953 The American Physical Society.

The positron and negatron pair (e^+e^-), as products of the neutral pion decay, illustrated by Eq. (1.504), is a result of internal conversion of a gamma-ray photon (i.e., internal pair production). The neutral pion decay may also manifest itself in yet a more rare form of dual internal conversion whereby two gamma-ray photons are converted to two positron–negatron pairs. The decay scheme is illustrated by Eq. (1.505), and the tracks from such a decay scheme produced in a bubble chamber are illustrated in Fig. 1.134.

$$\pi^0 \rightarrow e^+ + e^- + e^+ + e^- \quad (1.505)$$

Out of eight million π^0 decays in 836,000 bubble chamber pictures, Samios et al. (1962) were able to find only 206 neutral pion decays with double internal conversion. The numerous neutral pions were produced by Samios et al. (1962) by the interactions of π^- mesons from a cyclotron, with protons of the bubble chamber liquid according to the reaction

$$\pi^- + p^+ \rightarrow n + \pi^0 \quad (1.506)$$

The π^- mesons were slowed down with a polyethylene absorber and then allowed to stop in the hydrogen bubble chamber. The numerous bubble chamber photographs could be analyzed for the identification of specific tracks by a digitized scanning machine.

Any of the gamma rays can, in turn, produce positron–negatron pairs via pair production, and the positron can undergo annihilation to gamma radiation. The positive and negative pions are antiparticles. Charged pions have a mass of $139.6 \text{ MeV}/c^2$ and a lifetime of 2.6×10^{-6} seconds, much longer than that of the neutral pion. The positive pion decays to a positive muon and muon neutrino, whereas the negative pion decays into a negative muon and muon antineutrino as illustrated by the following:

$$\pi^+ \rightarrow \mu^+ + \nu_\mu \quad (1.507)$$

$$\pi^- \rightarrow \mu^- + \bar{\nu}_\mu \quad (1.508)$$

The muon has a mass of $106 \text{ MeV}/c^2$ and lifetime of 2.2×10^{-6} seconds. The positive muon decays to a positron and muon neutrino, and the negative muon to a negatron and anti-muon neutrino as illustrated in Fig. 1.132 and by the following:

$$\mu^{+/-} \rightarrow e^{+/-} + \nu_\mu + \bar{\nu}_\mu \quad (1.509)$$

Slow negative muons undergo nuclear absorption by nucleons with sufficient high atomic number ($Z \approx 10$ or greater); however, for low Z nuclides such as carbon ($Z = 6$), slow negative muon decay occurs rather than absorption by the nucleus (Sundaresan, 2001).

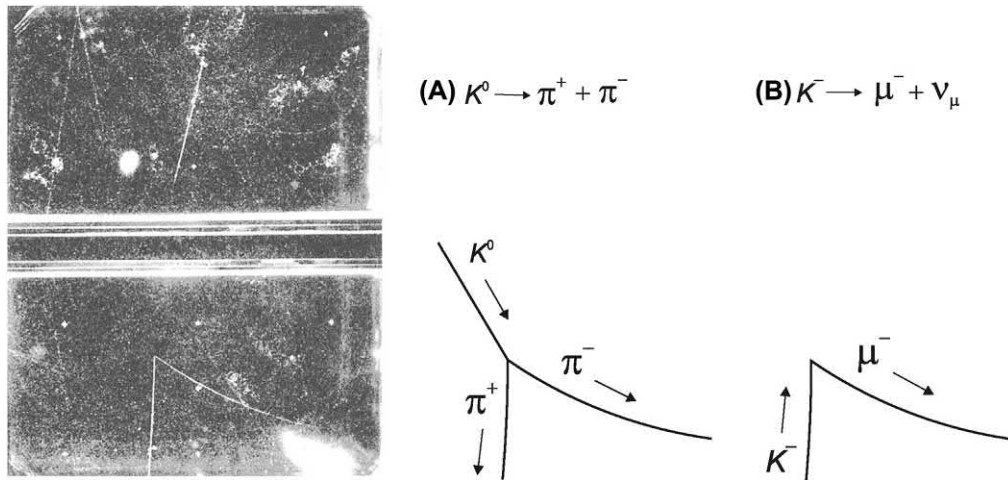

FIGURE 1.133 A cloud-chamber photograph of the tracks of a probable V^0 particle in a magnetic field of 5000 gauss. V particles got their name from the V-shaped tracks, that they formed from a given point in the cloud chamber. The cloud chamber consists of upper and lower chambers separated by the glass walls and copper tubing of a central Geiger counter. The V-shaped track appears left center in the lower-chamber. The track was the result of one of two possible modes of kaon decay, namely, (A) a neutral kaon (K^0) decaying into positive and negative pions where the neutral kaon does not leave a track because of its lack of charge, or (B) a negative kaon (K^-) entering the cloud chamber from below and decaying into a negative muon and neutrino. The neutrino obviously does not leave a track. The cloud chamber photograph is from the work of Nobel Laureate Carl D. Anderson and coworkers. Reprinted with permission from Leighton et al. (1953), <https://journals.aps.org/pr/abstract/10.1103/PhysRev.89.148>, © 1953 by the American Physical Society.

FIGURE 1.134 Photograph of a typical double internal conversion following π^0 decay on the left with a drawing of the specific tracks provided on the right. The tracks were produced in a hydrogen bubble chamber 30.5 cm in diameter and 15.25 cm in depth. A magnetic field of 5.5 gauss produced the curved deflection of the oppositely charged electrons. Reprinted with permission, from Samios et al. (1962), <https://journals.aps.org/pr/abstract/10.1103/PhysRev.126.1844>, © 1962 by the American Physical Society.

At sea level muons are the most numerous of the charged particles resulting from cosmic ray interactions with atomic nuclei of the atmosphere. These have been measured with an intensity of $100/\text{m}^2 \text{ s}$ at sea level. The relative abundances of the cosmic radiation shower components in the atmosphere at different altitudes with energies in excess of 1 GeV are illustrated in Fig. 1.135. As illustrated in the figure, most muons are produced high in the atmosphere at an altitude of ~ 15 km where high-energy cosmic-ray nucleons encounter and undergo collision with nuclei of the atmospheric gases. Pions likewise are produced high in the atmosphere; however, their number at sea level is highly diminished due to the

prompt decay of the neutral pion to gamma radiation and the decay of the charged pions to muons. The muon produced high in the atmosphere loses about 2 GeV of energy to ionization before reaching the ground, and the mean energy of the muon at the ground is ≈ 4 GeV (Gaisser and Stanev, 2002), and these travel at speeds close to the speed of light ($>0.99c$).

The intensity of protons and neutrons in the atmosphere (i.e., cosmic ray showers) is the highest at the top of the atmosphere. The high flux of protons at the top of the atmosphere is intuitively obvious, because the proton is the most abundant component of the primary cosmic rays of galactic origin arriving from space, as depicted

FIGURE 1.135 Vertical fluxes of cosmic rays in the atmosphere with $E > 1$ GeV estimated from the nucleon flux of Eq. (1.502). The points show measurements of negative muons with $E_\mu > 1$ GeV. For the color version of this figure, the reader is referred to the electronic version of the book. Reprinted with permission from and Beringer et al. (2012), © 2012 by the American Physical Society, <https://journals.aps.org/prd/abstract/10.1103/PhysRevD.86.010001>, and Patrignani et al. (2016), © Regents of the University of California, <http://pdg.lbl.gov/2016/figures/figures.html>.

previously in Table 1.27 and Fig. 1.130. These protons collide with nuclei in the atmosphere producing elementary particles and neutrons, as illustrated previously in Fig. 1.132. Thus the proton flux will diminish with atmospheric depth, and the integral intensity of protons with momentum >1 GeV/c at sea level is $\approx 0.9/\text{m}^2 \text{ s sr}$ (Greider, 2001; Patrignani et al., 2016). The n/p ratio at the top of the atmosphere is $\approx 10\%$, and the neutron intensity increases to $1/3$ of the nucleons at sea level (Patrignani et al., 2016).

C. Cosmic-ray muon detection and measurement

Muons in the cosmic-ray showers are produced high in the atmosphere at an altitude of ~ 15 km as a result of collisions of the galactic primary cosmic ray nuclei with nuclei of the atoms of our atmosphere. The muons have an average lifetime of only 2.2×10^{-6} seconds. A classical calculation of distance of travel in the earth's atmosphere for a particle with such a short lifetime would demonstrate that the muons should never be detected on earth at sea level. However, in

Section VII.C of this chapter, calculations are made of time dilation in relativity whereby the muons traveling at relativistic speed are observed in the earth's time frame of reference as having a dilated lifetime, which would provide muons created at an altitude of 15 km sufficient time to reach earth's sea level. The calculations of time dilation in relativity made previously in this chapter (Section VII.C) also provide experimental evidence with respect to the muon lifetime measured on earth when the muons travel at relativistic speed. Section VII.D of this chapter also provides evidence of time dilation in relativity from bubble-chamber measurements of the dilated lifetimes of elementary particles produced by proton collisions with atomic nuclei.

D. Cosmic rays underground

The only significant cosmic radiation with energy sufficient to penetrate considerable depths of earth are charged muons and muon neutrinos. Thus, Patrignani et al. (2016) and Tueros and Sciutto (2010) describe muons as the “penetrating component” of the cosmic-ray-induced showers, capable of reaching deep underground without interacting in the atmosphere. High-energy muons will traverse rock and lose energy via either direct ionization or radiative processes. The radiative processes include (i) bremsstrahlung production with concomitant (ii) positron–electron pair production and (iii) photonuclear interactions. Muon-induced spallation is another mechanism of energy loss.

The muon cosmic-ray intensities diminish with depth, as illustrated in Fig. 1.136. This is a subject of concern in the measurement of very low levels of radiation. Consequently, underground laboratories have been built to achieve lowest possible background radiation interference in the counting of very low levels of natural radioactivity. Muon energy loss is described by Patrignani et al. (2016) and Beringer et al. (2012). The mechanisms of muon energy loss is via ionization and three radiative process, namely, (i) bremsstrahlung production followed by (ii) positron–electron pair production, and (iii) photonuclear interactions of which the latter two mechanisms originate from the bremsstrahlung produced by the muons. Patrignani et al. (2016) expressed the muon energy loss as a function of the amount of matter traversed as

$$-\frac{dE_\mu}{dx} = a + bE_\mu \quad (1.510)$$

where a is the ionization loss and b is the fractional energy loss by the three radiative process described earlier in this paragraph. They provide the parameters for a and b of the above equation for standard rock.

Muon ranges in rock are measured in units of km-water-equivalent (km.w.e) where $1 \text{ km.w.e.} = 10^5 \text{ g/cm}^2$ of

FIGURE 1.136 Vertical muon intensity versus depth measured in km-water-equivalent (km.w.e.) where, by definition, 1 km.w.e. = 10^5 g/cm². The experimental data are from several research collaborations, namely \blacklozenge : the compilations of Crouch (1987); \bullet : BAKSAN (Andreev et al., 1987), \circ : LVD 9 (Aglietta et al., 1995), \bullet : MACRO (Ambrosio et al., 1995), \blacksquare : Frejus (Berger et al., 1989), and Δ : SNO (Waltham et al., 2001). The shaded area at large depths represents neutrino-induced muons of energy above 2 GeV. The upper line is for horizontal neutrino-induced muons, the lower one for vertically upward muons. Darker shading shows the muon flux measured by the Super-Kamiokande experiment. The inset shows the vertical intensity curve for water and ice. Reprinted with permission from and Beringer et al. (2012), © 2012 by the American Physical Society, <https://journals.aps.org/prd/abstract/10.1103/PhysRevD.86.010001>, and Patrigan et al. (2016), © Regents of the University of California, <http://pdg.lbl.gov/2016/figures/figures.html>.

standard rock. Average ranges in standard rock ($Z = 11$, $A = 22$, $Z/A = 0.5000$, $\rho = 2.650$ g/cm³) for muons of 10, 100, 1000, and 10,000 GeV are 0.05, 0.41, 2.45, and 6.09 km.w.e. (Patrignani et al., 2016). The vertical muon intensity versus underground depth of standard rock has been determined. The muon vertical intensity drops from 10^{-6} cm⁻²sr⁻¹s⁻¹ to 10^{-12} cm⁻²sr⁻¹s⁻¹ over the range of rock depths from 1 to 10 km.w.e., respectively (Gaisser and Stanev, 2002, see also Fig. 1.136).

Radiation from muons of the cosmic-ray showers is significant underground. The mechanisms of muon energy loss are dependent on the muon energy. Tueros and Sciutto (2010) report a Monte Carlo program that simulates high energy cosmic-ray showers underground. From nuclear data tables of Groom et al. (2001), they calculated the muon energy losses in standard rock by plotting the stopping power versus muon energy illustrated in Fig. 1.137 (Stopping power calculations are discussed in

FIGURE 1.137 Muon energy loss versus muon energy in standard rock. From Tueros and Sciutto (2010), reprinted with permission from Elsevier © 2010.

Section XVI.A of this chapter.) Muons traveling through matter will lose energy by several mechanisms including ionization, bremsstrahlung production, pair production, photonuclear reactions including spallation caused by muon collisions with nuclei. Tueros and Sciutto (2010) demonstrate from Fig. 1.137 that ionization losses are dominate at low muon energies (<100 MeV) and ionization losses predominate among the other mechanisms of energy loss and remain fairly constant at 1.5–2.2 MeV cm²/g below 10^4 MeV muon energy in standard rock. At muon energies >10 GeV, radiative energy losses steadily increase and reach the critical energy at ~ 0.7 TeV (693 GeV, See Fig. 1.137), which is the energy at which the ionization loss is equal to the radiative loss. The critical energy for muons in air is a much higher 3.6 TeV as reported by Grieder (2001). Thus, Tueros and Sciutto (2010) point out that bremsstrahlung and pair production energy losses for muons in air is negligible with the exception of very high muon energies; whereas it is increasingly important underground for muon energies > 50 GeV.

Another source of underground background interference from muons of the cosmic radiation showers is the production of gamma ray photons from radiative neutron capture reactions in hydrogen and elements encountered in rock and other soil materials. Neutrons are produced by muon spallation reactions as well as photonuclear reactions arising from bremsstrahlung radiative energy loss. Araújo et al. (2008) and Lindote et al. (2009) report a Monte Carlo simulation, which provides a very good estimate of the absolute neutron yield in lead as $(1.31 \pm 0.06) \times 10^{-3}$ neutrons/muon/g/cm² for a mean muon energy of 260 GeV.

E. Origins of cosmic radiation

The origins of galactic and extragalactic cosmic rays remains an unsolved problem, and reviews on current research and thinking are provided by Tjus et al. (2016), Potgieter (2010), Blasi (2013, 2008), Hörandel (2008b), and Gaisser (2001). The subject of cosmic ray origin is somewhat out of scope of this chapter, and the reader is invited to peruse the review papers on this subject cited above. In brief, cosmic rays can originate from (i) energetic particles associated with mass ejections from solar flares and similar energetic solar events; (ii) anomalous cosmic rays, which are particles of interstellar origin accelerated at the edge of the heliopause and accelerated at the termination shock in the solar wind; (iii) high-energy particles of galactic origin far outside the heliosphere or our solar system; and (iv) extragalactic sources, which give rise to particles of the highest energies $\sim 10^{18}$ eV or higher.

F. Cosmic microwave background radiation

Cosmic microwave background (CMB) radiation does not have a direct relevance to the measurement of radioactivity; however, our knowledge of the CMB radiation helps us understand the hot beginning of the universe and the formation of atoms.

In 1965 Arno Penzias and Robert Wilson at Bell Telephone Laboratories in New Jersey accidentally discovered a cosmic microwave background radiation. They were building and testing a new sensitive radio receiver, when they observed an excess noise that was of equal intensity regardless of the direction that the detector or antenna was pointing in the atmosphere. They concluded that the microwave radiation had originated from deep space even beyond our solar system and even our galaxy, because as the earth orbited the sun and rotated on its axis the antenna would be pointing to a different direction in space. At the same time, a team of physicists led by Robert Dicke at Princeton University was studying microwaves to devise a system that would demonstrate the cosmic microwave background predicted by Gamow (1948) and Alpher and Herman (1949). When Penzias and Wilson learned about this research work in search of the cosmic microwave background, they realized that they had discovered it. For this discovery, Penzias and Wilson were awarded the Nobel Prize in Physics (1978). In the Nobel Presentation Speech, Prof. Lamek Hulthén of the Royal Academy of Sciences on December 8, 1978 in Stockholm, Sweden, underscored the importance of the work and discovery of Penzias and Wilson. An excerpt of his speech is the following:

“... they [Penzias and Wilson] had found a background radiation, equally strong in all directions, independent of the time of the day and the year, so it could not come from

FIGURE 1.138 Measurement of the cosmic microwave background radiation (CMBR) spectrum. The line represents a 2.73 K blackbody. FIRAS, DMR, UBC, LBL-Italy, Princeton, and Cyanogen are sources of the experimental data points. From Gawiser and Silk (2000). See also Hagiwara, K. et al. (2002). Reprinted with permission from Elsevier © 2000.

the sun or our Galaxy ... Continued investigations have confirmed that this background radiation varies with wavelength in the way prescribed by well known laws for a space, kept at the temperature [of] 3K. Our Italian colleagues call it “la luce fredda” — the cold light ... Starting from the fact that the universe is now expanding uniformly, they concluded that it must have been very compact about 15 billion years ago and ventured to assume that the universe was born in a huge explosion, the ‘Big Bang’. The temperature must then have been fabulous: 10 billion degrees [K], perhaps more. At such temperatures lighter chemical elements can be formed from existing elementary particles, and a tremendous amount of radiation of all wavelengths is released. In the ensuing expansion of the universe, the temperature of the radiation rapidly goes down ...”

The precise determination of the CMB radiation spectrum involved large teams of researchers and decades of work, and the significance of this work was underscored by the Nobel Committee with the award of the Nobel Prize in Physics (2006) to John C. Mather (NASA Goddard Space Flight Center, USA) and George F. Smoot (University of California, Berkeley, USA) “for their discovery of the blackbody form and anisotropy of the cosmic microwave background radiation”. In his Nobel address John C. Mather explained the impact of the determination of the precise cosmic microwave background radiation spectrum as follows:

In the beginning was the Big Bang, so we now say with great certainty. The COsmic Background Explorer (COBE) satellite, proposed to NASA in 1974 and launched in 1989,

provided very strong evidence for it: the spectrum of the cosmic microwave background radiation (CMBR) has the spectrum of an almost-perfect blackbody emitter at 2.725 ± 0.001 K [See Fig. 1.138], and the radiation is isotropic ... This radiation is interpreted as the relic of an incredibly hot and dense early phase of the universe. In such a hot and dense phase, the creation, destruction, and energy equilibration of photons with one another and with all other forms of matter and energy would occur very rapidly compared with the expansion time scale of the universe. Such a state would immediately produce a blackbody radiation field. The expanding universe should preserve this blackbody spectrum, so measurement of any significant deviation from a perfect blackbody spectrum would either invalidate the whole idea of the Big Bang, or show that energy (e.g., from decay of primordial particles) was added to the CMBR after the rapid equilibration ended ...

The fact that the radiation is isotropic to such a high degree is key evidence for its origin in the Big Bang ... Not only was the spectrum beautiful to look at, but at one stroke it banished the doubts of almost everyone about the Big Bang theory. For so many decades, the intense combat between the Big Bang and Steady State advocates had continued, and for so many years, a series of small discrepancies between theory and measurement had been explained by ingenious people. Now it was over ... The Big Bang theory was safe, and the universe was simple, simple enough for theorists to go on to the next problem."

The precise spectrum of the cosmic microwave background radiation (CMBR) has been determined over 3 decades of frequency via many satellite, rocket, balloon, and ground measurements, and the cumulated data of radiant flux intensity as a function of radiation frequency is plotted in Fig. 1.138. The CMBR spectrum fits exactly to that predicted by a 2.73 K blackbody radiation spectrum whereby the brightness (B_ν) or intensity (I_ν) per unit of radiation frequency or wavelength is a function of the absolute temperature of the black body. The term "brightness" is used when measuring the radiant flux from a projected area of the surface of a blackbody, while the term "intensity" is used when reception of the radiant flux is measured (Woan, 2000). The Planck functions for the brightness or intensity are given by the following

$$I_\nu(T) = B_\nu(T) = \frac{2h\nu^3}{c^2} \left[\exp\left(\frac{h\nu}{kT}\right) - 1 \right]^{-1} \quad (1.511)$$

and

$$I_\lambda(T) = B_\lambda(T) = B_\nu(T) \frac{d\nu}{d\lambda} = \frac{2hc^2}{\lambda^5} \left[\left(\frac{hc}{\lambda kT} \right) - 1 \right]^{-1} \quad (1.512)$$

where I_ν and B_ν are the intensity or brightness, respectively, of blackbody radiation per unit frequency ($\text{W/m}^2 \text{ Hz sr}$) and I_λ and B_λ are the intensity and brightness, respectively, of blackbody radiation per unit wavelength ($\text{W/m}^2 \text{ m sr}$), h is Planck's constant (6.626×10^{-34} J s), c is the speed of light (2.99×10^8 m/sec), k is the Boltzmann constant (1.38×10^{-23} J/K), and T is the temperature Kelvin (Woan, 2000).

The hot Big Bang hypothesis describes the universe as having a very hot ($\sim 10^{10}$ K a second after the Big Bang) and small, dense beginning with an expansion and cooling of the universe ever since the Big Bang. The measured cosmic microwave background radiation spectrum illustrated in Fig. 1.138 provides evidence for the prediction of the Big Bang creation and the ever expansion and cooling of the universe. When the universe expands to twice its size, its temperature falls by half (Hawking, 1988). Consequently, when the universe was one-half its present size, its temperature would have been twice as hot (5.4 K) and the CMB radiation would have had a brightness peaking at a higher photon frequency. Likewise, if we go further back in time when the universe was 1/100th its current size, the universe would have been a hundred-fold hotter than now or 273 K equivalent to 0°C . The CMB radiation would have had a spectrum shifted to yet higher frequencies and shorter wavelengths.

XV. Radiation dose

Radiation dose, also referred to as absorbed radiation dose, is the amount of energy deposited in a given mass of a medium by ionizing radiation. The measurement of radiation dose, i.e., radiation dosimetry, is not a subject of this book. Nevertheless, the basic units used in the measurement of radiation dose will be mentioned briefly here, as the monitoring of radiation workers for the dose received by the body is essential.

Radiation exposure was historically measured by the roentgen (R), which is a measure of the quantity of radiation deposited in air from the amount of charge or ionization produced by the radiation in air. By definition $1 R = 2.58 \times 10^{-4}$ C/kg of air at STP, that is, 1 roentgen will produce 2.58×10^{-4} coulombs of ion pairs in 1 kilogram of air. The roentgen is a unit of exposure that is mostly historical and seldom used; it still occasionally appears on some dosimeter readings. Of more significance is the measure of absorbed dose, that is, the energy of radiation absorbed per unit mass of absorber. The original unit of absorbed dose is the rad, which is derived from the term "radiation absorbed dose". The rad has been replaced with the gray (Gy), which is the SI unit of absorbed dose. The use of SI units is recommended by the International Commission on Radiation Units and

Measurements (ICRU). The rad and gray have the following equivalents:

$$100 \text{ rad} = 10^4 \text{ erg/g} = 1 \text{ Gy} = 1 \text{ J/kg} \quad (1.513)$$

$$1 \text{ rad} = 10 \text{ mGy} = 100 \text{ erg/g} \quad (1.514)$$

$$1 \text{ mrad} = 10 \text{ } \mu\text{Gy} \quad (1.515)$$

As $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$, we can convert the gray to units of electron-volt energy deposited in a kg of absorber or

$$1 \text{ Gy} = 6.24 \times 10^{12} \text{ MeV/kg} \quad (1.516)$$

The following example illustrates the calculation of radiation dose:

A 1.5-cm^2 beam of gamma radiation consisting of 1 MeV photons with an emission rate of 5×10^8 photons/sec is irradiated onto human tissue of density 1.1 g/cm^3 . If 6.25% of the gamma radiation is absorbed by 1.25 cm thickness of the tissue (*i.e.*, 93.75% transmitted through the tissue), the rate of radiation dose administered to the tissue per second may be calculated as

$$\text{dose} = \frac{\text{energy}}{\text{mass}} \quad (1.517)$$

and

$$\begin{aligned} \text{dose/sec} &= \frac{\text{energy/sec}}{\text{mass}} \\ &= \frac{(5 \times 10^8 \text{ photons/sec})(0.0625)(1 \text{ MeV/photon})}{(1.1 \text{ g/cm}^3)(1.5 \text{ cm}^2)(1.25 \text{ cm})} \\ &= \frac{3.12 \times 10^7 \text{ MeV/sec}}{2.0625 \text{ g}} = 1.51 \times 10^7 \text{ MeV/sec/kg} \end{aligned} \quad (1.518)$$

If 1 Gray (Gy) is equivalent to $6.24 \times 10^{12} \text{ MeV/kg}$ (Eq. 1.516), the dose rate in MeV/sec/kg is converted to units of the Gray (Gy) as

$$\begin{aligned} \text{dose(Gy / sec)} &= \frac{1.51 \times 10^7 \text{ MeV/sec/kg}}{6.24 \times 10^{12} \text{ MeV/kg/Gy}} \\ &= 2.42 \text{ } \mu\text{Gy/sec} \end{aligned} \quad (1.519)$$

Another formerly very common and historical unit of radiation dose is the rem. The rem is a measure of absorbed dose in biological tissue. This unit of measure is derived from the term “roentgen equivalent for man” or “roentgen equivalent mammal”. The rem was created as a measure of dose of ionizing radiation to body tissue in terms of its estimated biological effect; its SI unit is the sievert (Sv) and

$$100 \text{ rem} = 1 \text{ Sv} \quad \text{and} \quad 1 \text{ rem} = 10 \text{ mSv} \quad (1.520)$$

The rem or Sv (sievert) are referred to as units of equivalent dose, because the dose is measured on the basis of a weighting factor (w_R), which defines the relative hazard of radiation on the basis of the types and energies of the radiations by placing all radiation classes on the same dose level or equivalent (L’Annunziata, 1987). The weighting factor, formerly known as the quality factor (QF), is defined as the ratio of the gamma-ray or X-ray dose to the dose required to produce the same biological effect by the radiation in question. Table 1.28 lists the radiation weighting factors (w_R) according to radiation type and energy. The weighting factor of a given radiation is a function of the radiation linear energy transfer (LET), that is, the radiation energy loss per path length of travel. As discussed in Section XVI of this chapter, radiations of high mass and charge, such as alpha particles or fission products will have a higher LET than electrons or beta particles, muons, or X-ray, or gamma-ray photons. Because photons will produce electrons as secondary particles, X- or gamma-ray photons are classified to have the same radiation weighting factor as electrons. According to the weighting factors provided in Table 1.28, alpha particles are considered to be 20 times more damaging to cells of the human body than beta particles, muons, and X- or gamma radiation. However, alpha particles and other heavy nuclei have short ranges in

TABLE 1.28 Radiation weighting factors.

Radiation type	w_R
Photons, electrons and muons	1
Neutrons, $E_n < 1 \text{ MeV}$	$2.5 + 18.2 \times \exp[-(\ln E_n)^2/6]$
$1 \text{ MeV} \leq E_n \leq 50 \text{ MeV}$	$5.0 + 17.0 \times \exp[-(\ln (2E_n))^2/6]$
$E_n > 50 \text{ MeV}$	$2.5 + 3.25 \times \exp[-(\ln (0.04E_n))^2/6]$
Protons and charged pions	2
Alphas, fission fragments, heavy ions	20

matter compared to other radiation types. Thus, distance provides the best protection from alpha particles and other heavy nuclei. Also, the weighting factors for neutrons in Table 1.28 classify the neutrally charged neutrons as more hazardous to biological tissue than the charged electrons or muons. This is because neutrons will produce recoil protons and ions of higher mass via neutron collisions in body tissue.

The equivalent dose in Sv can be calculated from the weighting factors as

$$\text{Sv} = \text{absorbed dose in grays} \times w_R \quad (1.521)$$

where the weighting factor expresses potential damage to cells, and long-term risk (primarily cancer and leukemia) from low-level chronic exposure, which is dependent on radiation type and other factors (ICRP, 1991 and Donahue and Fassò, 2002). Using the notation of Lilley (2001) for average absorbed dose in tissue Eq. (1.521) can be written as

$$\text{Sv} = D_{T,R} \times w_R \quad (1.522)$$

where Sv is the equivalent dose in sieverts and $D_{T,R}$ is the average absorbed dose in tissue T from a given type of radiation R. For example, from the weighting factors of Table 1.28 and Eq. (1.522) we can calculate that an average absorbed dose of 0.01 Gy from alpha particles ($w_R = 20$) will produce the same biological effect as a 0.2 Gy dose from X- or gamma radiation ($w_R = 1$). When more than one radiation type contributes to the absorbed dose, the equivalent dose is calculated according to the weighted sum of the contributions from each radiation type.

The ICRP (1991) and ICRU (2007) recommendations for limits of exposure for radiation workers (i.e., occupational exposure) for whole body dose is 20 mSv/yr (2 rem/yr) averaged over 5 years (i.e., 100 mSv in 5 years), with the effective dose in any 1 year not to exceed 50 mSv. It is estimated by the United States Environmental Protection Agency (EPA) that the average yearly radiation dose per person in the United States is only 6.2 mSv (0.62 rem or 620 mrem) of accumulated radiation dose per year from all sources including cosmic radiation, medical X-rays, and natural radioactivity, etc (<https://www.epa.gov/radiation/calculate-your-radiation-dose>). The Particle Data Group (Patrignani et al., 2016) and United Nations (2008) report a worldwide average for the annual whole-body dose equivalent from all sources of natural background radiation to range from 1.0 to 13 mSv (0.1–1.3 rem) with an annual average of 2.4 mSv; although in some areas annual averages of up to 50 mSv (5 rem) have been measured. Patrignani et al. (2016) report that a large fraction (>50%) of the exposure from natural background radiation originates from inhaled natural radioactivity, which includes mostly radon and radon daughters. Average dose from inhaled natural radioactivity will depend on the environment,

namely, in open areas (0.1–0.2 mSv), within a house (2 mSv), or in a poorly ventilated mine (20 mSv).

As discussed previously in Section XIV.B, the atmosphere serves as an excellent shield against intense cosmic radiation, as cosmic-ray particles collide with nuclei of nitrogen, oxygen, and other gaseous atoms of the atmosphere and produce the less hazardous particles that constitute the cosmic-ray showers. Exposure to cosmic radiation is of some concern to intercontinental airline pilots, who fly at high altitudes (7–12 km above the earth) and high degrees of latitude and who compile large numbers of flight hours per year over long careers. Hammer et al. (2000) report a mean cosmic radiation dose estimate of 35 mSv for 509 pilots, who averaged 26.6 years of employment at an average of 481 flight hours per year. The accumulated cosmic radiation dose of 35 mSv over 26.6 years will yield an average dose rate of 1.3 mSv/y. The dose rates are well within the ICRP (1991) recommendations for limits of exposure for radiation workers for whole body dose set at 20 mSv/y. For pregnant women, however, the ICRP limit of dose is 2 mSv for the duration of pregnancy. Consequently, the study by NRL (1998) concludes that airline companies may apply a limit of 2 mSv for a pregnant member of the aircrew from the time of conception. Astronauts, who circle the earth in orbit for extended periods of time, those who have traveled and plan to travel to the moon and back, and those who may travel to Mars have reason for concern of exposure to cosmic radiation where there is no protection from the earth's partially protective atmospheric shield. Fujitaka (2005) reports that a 1-week mission on the space shuttle will result in a radiation dose of 3.5 mSv; while astronauts would accumulate a dose of 43 mSv during a trip to the moon. Travel from Earth to Mars would take 280 days and the return trip 256 days during which time astronauts would accumulate 1850 mSv, and a stay on Mars for 439 days would expose astronauts to an additional 410 mSv whereby each astronaut would accumulate a grand total of 2.26×10^3 mSv (Pachoa and Steinhäusler, 2010). A very interesting and stimulating note for thought is reported by Fujitaka (2005), that space travel to Pluto, which is at the boundaries of our solar system would expose astronauts to a cosmic radiation dose of 70 Sv or 70,000 mSv, which is enough radiation to kill every cell in the human body. This may be so at current speeds of space travel, as NASA's New Horizons Mission spacecraft to Pluto was launched in June 2006, and it reached Pluto after 9 years in July of 2015. However, with the proper thrust systems, high speeds of space travel in a manned spacecraft would be possible (Westmoreland, 2010; Walter, 2006), which would minimize space travel time well out of our solar system and thus keep cosmic radiation dose to acceptable limits.

For further information on radiation dosimetry, the reader is invited to peruse books dedicated to this subject matter such as those by [Andreo and Burns \(2017\)](#), [Bevelacqua \(2010\)](#), [Stabin \(2009\)](#), and [Cember and Johnson \(2008\)](#).

XVI. Stopping power and linear energy transfer

Previous sections in this chapter provide information on the mechanisms of interaction of radiation with matter. In summary, we can state that the principle mechanisms of interaction of charged particles with matter, which result in significant charged-particle energy loss are (i) ionization via coulombic interactions of the charged particles with atomic electrons of the absorbing medium; (ii) electron orbital excitation of the medium, which occurs when the energy transfer through coulombic interaction is not sufficient to actually eject an electron from an atom; and (iii) the radial emission of energy as bremsstrahlung (x radiation) when a charged particle decelerates as it is deflected by an atomic nucleus. Release of particle energy by bremsstrahlung radiation becomes increasingly significant as the charged particle (*e.g.*, beta-particle) energy and absorber atomic number increase. On the other hand, electromagnetic radiation dissipates its energy in matter via three mechanisms, namely, (i) the photoelectric effect, (ii) Compton scattering, and (iii) pair production. The photoelectric effect and Compton scattering generate ion pairs directly within the absorbing medium, whereas, pair production results in the creation of charged particles (positrons and negatrons) that will subsequently dissipate their energy via ionization, electron excitation and, in the case of positrons, the production of annihilation radiation. Also, we have seen that energetic neutrons will dissipate their energy in matter through elastic collisions with atomic nuclei of the absorbing medium. When hydrogen is present in the absorbing material, the bulk of fast-neutron energy is passed on to the hydrogen nuclei. In turn, the kinetic energy of these protons is absorbed in the medium via ionization and excitation processes. We have seen also that low- and high-energy neutrons are absorbed principally via inelastic neutron reactions, which can result in the production of charged particles and gamma radiation.

The radiation properties (*e.g.*, charge, mass, and energy) and mechanisms of interaction previously described govern the rate of dissipation of energy and consequently the range of travel of the nuclear radiation in the absorber. This brings to bare the concepts of stopping power and linear energy transfer (LET), which are described subsequently.

A. Stopping power

Stopping power is defined by The International Commission on Radiation Units and Measurements (ICRU, 2007) as the average energy dissipated by ionizing radiation in a medium per unit path length of travel of the radiation in the medium. It is, of course, impossible to predict how a given charged particle will interact with any given atom of the absorber medium. Also, when we consider that the coulombic forces of charged particles will interact simultaneously with many atoms as it travels through the absorbed medium, we can only predict an average effect of energy loss per particle distance of travel. Taking into account the charge, mass, and speed (energy) of the particle, and the density and atomic number of the absorbing medium, [Bethe \(1933\)](#) and [Bethe and Ashkin, \(1953\)](#) derived a formula for calculating the stopping power resulting from coulombic interactions of heavy charged particles (*e.g.*, alpha particles, protons, and deuterons) traveling through absorber media. [Rohrlich and Carlson \(1954\)](#) have refined the calculations to include energy losses via bremsstrahlung radiation, significant when high-energy electrons and beta particles interact with absorbers of high atomic number. Also, refinements to the stopping power formulae in the low energy ranges of heavy particles have been made by several researchers including [Bohr and Lindhard \(1954\)](#), [Lindhard and Scharff \(1960, 1961\)](#), [Northcliffe \(1963\)](#), and [Mozumber et al. \(1968\)](#). Derivations of stopping power formulas can be obtained from texts by [Evans \(1955\)](#), [Friedlander et al. \(1964\)](#), [Roy and Reed \(1968\)](#), and [Segré \(1968\)](#), [Gümüş \(2005, 2008\)](#), [Nguyen-Truong \(2015\)](#), and [Taborda et al. \(2015\)](#). Stopping power and range tables for electrons and protons over the energy range of 10^{-3} to 10^5 MeV and for helium ions (alpha particles) over the energy range of 10^{-3} to 10^3 MeV in 74 materials are available from [Berger \(1993\)](#) and [Berger et al. \(2017c\)](#); and these can be calculated online at the website of the National Institute of Standards and Technology (NIST, 2018), *i.e.*, <https://www.nist.gov/pml/stopping-power-range-tables-electrons-protons-and-helium-ions>, for electrons in any user-specified materials, and for protons and helium ions in 74 materials.

The formulas for the stopping power of charged particles due to coulombic or collisional interactions (*i.e.*, ionization and electron orbital excitation) are clearly defined by [Tsoulfanidis \(1995\)](#) as the following:

- (i) for heavy charged particles (*e.g.*, protons, deuterons, and alpha particles),

$$\frac{dE}{dx} = 4\pi r_0^2 z^2 \frac{mc^2}{\beta^2} NZ \left[\ln \left(\frac{2mc^2}{I} \beta^2 \gamma^2 \right) - \beta^2 \right] \quad (1.523)$$

- (ii) for electrons or negatrons (negative beta particles),

$$\frac{dE}{dx} = 4\pi r_0^2 mc^2 NZ \left\{ \ln \left(\frac{\beta \gamma \sqrt{\gamma - 1}}{I} mc^2 \right) + \frac{1}{2\gamma^2} \left[\frac{(\gamma - 1)^2}{8} + 1 - (\gamma^2 + 2\gamma - 1) \ln 2 \right] \right\} \quad (1.524)$$

and (iii) for positrons (positive beta particles),

$$\frac{dE}{dx} = 4\pi r_0^2 mc^2 NZ \left\{ \ln \left(\frac{\beta \gamma \sqrt{\gamma - 1}}{I} mc^2 \right) - \frac{\beta^2}{24} \left[23 + \frac{14}{\gamma + 1} + \frac{10}{(\gamma + 1)^2} + \frac{4}{(\gamma + 1)^3} \right] + \frac{\ln 2}{2} \right\} \quad (1.525)$$

where dE/dx is the particle stopping power in units of MeV/m, r_0 is the classical electron radius $= 2.818 \times 10^{-15}$ m, z is the charge on the particle ($z = 1$ for p, d, β^- , β^+ and $z = 2$ for α), mc^2 is the rest energy of the electron $= 0.511$ MeV (see Section XII.C of this chapter.), N is the number of atoms per m^3 in the absorber material through which the charged particle travels ($N = \rho(N_A/A)$ where ρ is the absorber density in units of g/cm^3 , N_A is Avogadro's number $= 6.022 \times 10^{23}$ atoms per mol, A is the atomic weight (not the mass number) of the absorber material, and Z is the atomic number of the absorber, $\gamma = (T + mc^2)/mc^2 = 1/\sqrt{1 - \beta^2}$ where T is the particle kinetic energy in MeV and m is the particle rest mass, (e.g., proton $= 938.2$ MeV/ c^2 , deuteron $= 1875.6$ MeV/ c^2 , alpha particle $= 3727.3$ MeV/ c^2 , and β^- or $\beta^+ = 0.511$ MeV/ c^2 , and β the relative phase velocity of the particle $= v/c$, that is, the velocity of the particle in the medium divided by the speed of light in a vacuum $= \sqrt{1 - (1/\gamma^2)}$ (see Section XI.E of this chapter and Chapter 6, Volume two for a treatment on β .), and I is the mean excitation potential of the absorber in units of eV approximated by the equation

$$I = (9.76 + 58.8Z^{-1.19})Z, \quad \text{when } Z > 12 \quad (1.526)$$

where pure elements are involved as described by Tsoulfanidis (1995). However, when a compound or mixture of elements is concerned, a mean excitation energy, $\langle I \rangle$, must be calculated according to Bethe theory as follows

$$\langle I \rangle = \exp \left\{ \frac{\left[\sum_j w_j (Z_j/A_j) \ln I_j \right]}{\sum_j w_j (Z_j/A_j)} \right\} \quad (1.527)$$

where w_j , Z_j , A_j , and I_j are the weight fraction, atomic number, atomic weight, and mean excitation energy, respectively, of the j th element (Seltzer and Berger, 1982a). See Anderson et al. (1969a,b), Janni (1982),

Seltzer and Berger (1982a,b, 1984), Berger and Seltzer (1982), and Tsoulfanidis (1995) for experimentally determined values of I for various elements and thorough treatments of stopping power calculations. Values of mean excitation potentials, I , for 100 elements and many inorganic and organic compounds are provided by Seltzer and Berger (1982a, 1984).

An example of the application of one of the above equations would be the following calculation of the stopping power for a 2.280 MeV beta particle (E_{\max}) emitted from ^{90}Y traveling through a NaI solid scintillation crystal detector. This would be a practical example, as the NaI detector is used commonly for the measurement of ^{90}Y . The solution is as follows:

Firstly, the calculation of relevant variables are

$$\gamma = \frac{2.280 \text{ MeV} + 0.511 \text{ MeV}}{0.511 \text{ MeV}} = 5.462$$

$$\beta = \sqrt{1 - \frac{1}{\gamma^2}} = 0.9831 \quad \text{and} \quad \beta^2 = 0.9665$$

The atomic weight A for NaI would be the average atomic weight (A_{av}) based on the weight-fraction w_{Na} for Na (15.3%) and w_{I} for I (84.7%) in NaI or

$$\begin{aligned} A_{\text{av}} &= (0.153)(A_{\text{Na}}) + (0.847)(A_{\text{I}}) \\ &= (0.153)(23) + (0.847)(127) = 111 \end{aligned}$$

Also, on the basis of the weight averages for Na and I, the atomic number Z would be the effective atomic number Z_{ef} calculated according to the following equation described by Tsoulfanidis (1995) and Andreo et al. (2005):

$$Z_{\text{ef}} = \frac{\sum_{i=1}^L (w_i/A_i) Z_i^2}{\sum_{i=1}^L (w_i/A_i) Z_i} \quad (1.528)$$

where L is the number of elements in the absorber, w_i is the weight fraction of the i th element, A_i is the atomic weight of the i th element, Z_i is the atomic number of the i th element, and $w_i = N_i A_i / M$ where N_i is the number of atoms of the i th element and M is the molecular weight of the absorber. If we apply Eq. (1.528) to the absorber NaI we find

$$\begin{aligned} Z_{\text{ef}} &= \frac{(0.153/22.989)(11)^2 + (0.847/126.893)(53)^2}{(0.153/22.989)(11) + (0.847/126.893)(53)} \\ &= 45.798 \end{aligned} \quad (1.529)$$

For pure elements the value of the mean excitation potential, I , can be calculated according to the empirical formula provided by Eq. (1.526). However, for the compound NaI, the mean excitation energy, $\langle I \rangle$, will be calculated according to Eq. (1.527) as follows

$$\begin{aligned} \langle I \rangle &= \exp \left\{ \left[\frac{(0.153)(11/22.989) \ln 149 +}{(0.847)(53/126.893) \ln 491} \right] \right. \\ &\quad \left. / \left[\frac{(0.153)(11/22.989) +}{(0.847)(53/126.893)} \right] \right\} \\ &= 400 \text{ eV} \end{aligned} \quad (1.530)$$

where the values of the mean excitation energy, I_j , for the elements Na and I of 149 and 941 eV, respectively, were obtained from [Seltzer and Berger \(1982a\)](#). From [Eq. \(1.524\)](#) the stopping power, due to collisional interactions, for the 2.280 MeV beta particle traveling through a NaI crystal is calculated as

This calculated value of stopping power is due to collision or coulombic interactions, and it agrees with the on-line computer-calculated value of 1.203 MeV cm²/g for a 2.280 MeV beta particle or electron in NaI (see [NIST, 2018](#), <https://physics.nist.gov/PhysRefData/Star/Text/method.html>). Slight variations on the calculated stopping power are expected, because of the statistical variations of charged particle interactions with matter and, as a consequence, there are small variations to the Bethe stopping power formula derived by researchers, described previously in this section.

[Eq. \(1.524\)](#) used above to calculate the stopping power for the 2.280 MeV beta particle from ⁹⁰Y in NaI accounts only for energy of the beta particle lost via collision interactions resulting in ionization and electron-orbital excitations. The equation does not account for radiative energy loss via the production of bremsstrahlung radia-

$$\begin{aligned} \frac{dE}{dx} &= 4(3.14)(2.818 \times 10^{-15} \text{ m})^2 \left(\frac{0.511 \text{ MeV}}{0.9665} \right) (3.67 \text{ g/cm}^3) \times \left(\frac{6.022 \times 10^{23} \text{ atoms/mol}}{111 \text{ g/mol}} \right) \left(\frac{10^6 \text{ cm}^3}{\text{m}^3} \right) \\ &\quad \times (45.798) \left\{ \ln \left(\frac{(0.9831)(5.462)\sqrt{4.462}}{400 \text{ eV}} (0.511 \text{ MeV})(10^6 \text{ eV/MeV}) \right) \right. \\ &\quad \left. + \frac{1}{2(5.462)^2} \left[\frac{(4.462)^2}{8} + 1 - (5.462^2 + 2(5.462) - 1) \ln 2 \right] \right\} \\ &= 441.4 \text{ MeV/m} \end{aligned} \quad (1.531)$$

The term (10⁶ cm³/m³) is included in the above calculation to maintain consistency of units, thus converting the units of density expressed in g/cm³ to g/m³. In SI units, the stopping power can be expressed in units of J/m or

$$\begin{aligned} &(441.4 \text{ MeV/m})(1.602 \times 10^{-13} \text{ J/MeV}) \\ &= 7.07 \times 10^{-11} \text{ J/m} \end{aligned} \quad (1.532)$$

The stopping power is often expressed in units of MeV cm²/g or J m²/kg, which provides values for stopping power without defining the density of the absorber medium ([Taylor et al., 1970](#); [Tsoulfanidis, 1995](#); [NIST, 2018](#)). In these units the above calculation can be expressed as

$$\frac{1}{\rho} \left(\frac{dE}{dx} \right)_{\text{col.}} = \frac{4.414 \text{ MeV/cm}}{3.67 \text{ g/cm}^3} = 1.203 \text{ MeV cm}^2/\text{g} \quad (1.533)$$

tion, which can be very significant with beta particles of high energy and absorber materials of high atomic number. Thus, a complete calculation of the stopping power must include also the radiative energy loss via bremsstrahlung as described by [Eq. 1.250](#) earlier in this chapter, that is,

$$\left(\frac{dE}{dx} \right)_{\text{total}} = \left(\frac{dE}{dx} \right)_{\text{col.}} + \left(\frac{dE}{dx} \right)_{\text{rad.}} \quad (1.534)$$

where $(dE/dx)_{\text{total}}$ is the rate of total beta particle or electron energy loss in an absorber, $(dE/dx)_{\text{col.}}$ is the rate of energy loss due to collision or ionization interactions, and $(dE/dx)_{\text{rad.}}$ is the rate of radiative energy loss due to bremsstrahlung production. We must keep in mind that each stopping-power calculation, such as the above example, provides values for only one beta particle or electron energy. Beta particles, on the other hand, are emitted from decaying radionuclides with a broad spectrum of energies

from zero to E_{\max} , the majority of which may possess an average energy, E_{av} , of approximately one-third of E_{\max} .

The ratio of beta-particle energy loss via radiative energy emission as bremsstrahlung to energy loss via collision interactions causing ionization and excitation is described by the approximation

$$\frac{E_{\text{brems.}}}{E_{\text{ion.}}} \approx \frac{EZ}{750} \quad (1.535)$$

where E is the beta-particle energy in MeV and Z is the atomic number or effective atomic number Z_{ef} (e.g., 45.798 for NaI calculated by Eq. (1.529)) of the absorber material (Evans, 1955; Friedlander et al., 1964; Faw and Schultis, 2004). From Eqs. (1.534) and (1.535), we can approximate the radial energy loss for the 2.280 MeV beta particle in NaI using the previously calculated ionizational energy loss (Eq. 1.531) as

$$\begin{aligned} \left(\frac{dE}{dx}\right)_{\text{rad.}} &\approx \frac{ZE}{750} \left(\frac{dE}{dx}\right)_{\text{col.}} \\ &\approx \frac{(45.798)(2.280)}{750} (4.414 \text{ MeV/cm}) \\ &\approx 0.614 \text{ MeV/cm} \end{aligned} \quad (1.536)$$

This radiative energy loss expressed in units of MeV cm^2/g would be

$$\frac{1}{\rho} \left(\frac{dE}{dx}\right) \approx \frac{0.614 \text{ MeV/cm}}{3.67 \text{ g/cm}^3} = 0.167 \text{ MeV cm}^2/\text{g} \quad (1.537)$$

This agrees closely to the online computer calculated value of 0.16 MeV cm^2/g for the radiative energy loss a 2.280 MeV beta particle or electron in NaI (see NIST, 2018, <https://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html>). The total stopping power of the 2.280 MeV beta particle in NaI according to Eq. (1.534) is calculated as

$$\begin{aligned} \left(\frac{dE}{dx}\right)_{\text{total}} &= \left(\frac{dE}{dx}\right)_{\text{col.}} + \left(\frac{dE}{dx}\right)_{\text{rad.}} \\ &= 4.41 \text{ MeV/cm} + 0.61 \text{ MeV/cm} \\ &= 5.02 \text{ MeV/cm} \end{aligned} \quad (1.538)$$

The above total stopping power expressed in units of MeV cm^2/g is calculated as

$$\frac{1}{\rho} \left(\frac{dE}{dx}\right)_{\text{total}} = \frac{5.02 \text{ MeV/cm}}{3.67 \text{ g/cm}^3} = 1.37 \text{ MeV cm}^2/\text{g} \quad (1.539)$$

which agrees closely to the computed-calculated value of 1.36 MeV cm^2/g for the total stopping power of a 2.280 MeV beta particle in NaI calculated online via the NIST (2018) ESTAR computer program (<https://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html>).

Beta-particle loss via bremsstrahlung radiation of the 2.280 MeV beta particles from ^{90}Y is significant in NaI, namely, 0.61/5.02 or 12% of the total energy loss. Consequently, NaI solid scintillation detectors are at times used for the analysis of ^{90}Y (Coursey et al., 1993). The actual detection efficiencies reported by Coursey et al. (1993) for the solid scintillation analysis of ^{90}Y fall in the range of 9.9–18% depending on sample and detector counting geometries. The detection efficiencies exceed the above-calculated 12% energy loss via bremsstrahlung production, because the NaI detector will also respond to collision-excitation energy of the beta-particle in addition to bremsstrahlung radiation excitation. Caution is warranted in making correlations between detector response to beta-particle radiation and stopping-power calculations, because we must keep in mind that each stopping-power calculation, such as the above example, provides values for only one beta-particle energy. Beta particles, on the other hand, are emitted with a broad spectrum of energies from zero to E_{\max} .

Bremsstrahlung production will increase as the absorber atomic number (Z) and beta-particle or electron energy increase. Bremsstrahlung is highly penetrating electromagnetic radiation, and thus low atomic number absorbers such as aluminum or plastic (high in carbon and hydrogen) may be used as shields against beta-particle radiation. Shielding material containing high atomic number elements, such as lead glass, against high-energy beta particles can yield high levels of bremsstrahlung radiation. The effect of atomic number (Z) and beta-particle or electron energy (E) on the ratio of energy loss via bremsstrahlung production to ionization energy is illustrated in Fig. 1.139. The effective atomic numbers of compounds such as polyethylene ($-\text{C}_2\text{H}_4)_n$, $Z_{\text{ef}} = 5.28$), water ($Z_{\text{ef}} = 6.60$), and air ($Z_{\text{ef}} = 7.3$), included as absorbers in Fig. 1.139, are a function of the weight fraction of each element in the compound or mixture calculated according to Eq. (1.528). As illustrated in Fig. 1.139, absorbers of low atomic number yield less bremsstrahlung radiative energy loss from high-energy beta-particle or electron interactions in matter.

B. Linear energy transfer

The International Commission on Radiation Units and Measurements defines linear energy transfer (L) of charged particles in a medium as

$$L = \frac{dE_L}{dl} \quad (1.540)$$

FIGURE 1.139 Ratio of energy loss via radiative bremsstrahlung production to energy loss via ionization or collision energy loss, expressed as a percent and calculated according to the approximation $E_{\text{brem}}/E_{\text{ion.}} \approx EZ/750$, for beta-particles or electrons of energies E ranging from 1 to 5 MeV as a function of atomic number (Z) of the absorber material. Some common absorbers are identified above data points corresponding to their atomic number (Z) or effective atomic number (Z_{eff}) for absorbers that are compounds. From *L'Annunziata* (2007, 2016), reprinted with permission of Elsevier © 2007.

where dE_L is the average energy locally imparted to the medium by a charged particle of specified energy in traversing a distance dl (ICRU, 2007; Taylor et al., 1970). The term “locally imparted” refers either to a maximum distance from the particle track or to a maximum value of discrete energy loss by the particle beyond which losses are no longer considered as local. Linear energy transfer or LET is generally measured in units of keV/ μm . The ICRU recommends, when a restricted form of LET is desired, that the energy cut-off form of LET be applied, because this can be evaluated using restricted stopping-power formulae (Taylor et al., 1970). The energy-restricted form of LET or L_Δ is therefore defined as that part of the total energy loss of a charged particle, which is due to energy transfers up to a specified energy cut-off value

$$L_\Delta = \left(\frac{dE}{dl} \right)_\Delta \quad (1.541)$$

where the cut-off energy (Δ) in eV units must be defined or stated. If no cut-off energy is applied, then the subscript ∞ is used in place of Δ , where L_∞ would signify the value of LET, which includes all energy losses and would therefore be equal to the total mass stopping power.

Fig. 1.140 illustrates charged particle interactions within an absorber involved in the measurement of LET. The possible types of energy loss, ΔE , of a charged particle of specified energy, E , traversing an absorber over a track length Δl is illustrated, where O represents a particle traversing the observer without any energy loss, U is the energy transferred to a localized interaction site, q is the energy transferred to a short-range secondary particle

FIGURE 1.140 Diagram of the passage of a particle of energy E through a thickness Δl of material illustrating the several types of energy loss that may occur. From Taylor et al. (1970) reprinted with permission from ICRU © 1970.

when $q \leq \Delta$, and Δ is a selected cut-off energy level (e.g., 100 eV), Q' is the energy transferred to a long-range secondary particle (e.g., formation of delta rays) for which $Q' > \Delta$, γ is the energy transferred to photons (e.g., excitation fluorescence, Cherenkov photons, etc.), r is a selected cut-off distance from the particle's initial trajectory or path of travel, and θ is the angle of particle scatter. The interactions q , Q , and γ are subdivided in Fig. 1.140 when these fall into different compartments of the absorber medium. See Taylor et al. (1970) and (ICRU, 2007) for methods used for the precise calculations of LET. Some examples of LET in water for various radiation types are given in Table 1.29. The table clearly illustrates that radiation of a given energy with shorter range in a medium will yield higher values of LET than radiations of the same energy with longer ranges in the same medium. This may be intuitively obvious because the shorter the range of the radiation, the greater is the energy dissipated per unit path length of travel. We can take this further and generalize that the following radiation types will yield LET values of decreasing orders of magnitude (the heavier charged particles are considered here to be of the same energy for purposes of comparison) according to the sequence:

Decreasing LET:

- Fission Products
- Alpha Particles
- Deuterons
- Protons
- Low-energy x Rays and Beta Particles
- High-energy x Rays and Beta Particles
- Gamma Radiation and High-energy Beta Particles

Although the electromagnetic X- and gamma radiations are not charged particles, these radiations do have the characteristics of particles (photons) that produce ionization in matter. They are, therefore, included in the above sequence and among the radiations listed in Table 1.29.

TABLE 1.29 Track-average values of LET (L_{Δ}) in water irradiated with various radiations.^a

Radiation	Cut-off energy, Δ (eV)	L_{Δ} (keV/ μ m)
⁶⁰ Co gamma rays	Unrestricted	0.239
	10,000	0.232
	1000	0.230
	100	0.229
22-MeV X-rays	100	0.19
2-MeV electrons (whole track)	100	0.20
200-kV X-rays	100	1.7
³ H beta particles	100	4.7
50-kV X-rays	100	6.3
5.3 MeV alpha particles (whole track)	100	43

^aFrom Taylor et al. (1970).

The term delta rays (δ — rays), referred to in the previous paragraph, is used to identify high-energy electrons that produce secondary ionization. When a charged particle, such as an alpha particle, travels through matter, ionization occurs principally through coulombic attraction of orbital electrons to the positive charge on the alpha particle with the ejection of electrons of such low energy that these electrons do not produce further ionization. However, direct head-on collisions of the primary ionizing particle with an electron does occur occasionally whereby a large amount of energy is transferred to the electron. These high-energy electrons are referred to as delta rays. Delta rays form ionization tracks away from the track produced by the primary ionizing particle (Anderson et al., 2017; Payne, 2015; Braby and Ford, 2006; Horowitz, 2006; Cucinotta et al., 1998; Laulainen and Bichsel, 1972). Also, most of the muon induced background in Ge gamma spectrometers is caused by bremsstrahlung radiation of delta electrons (Povinec et al., 2008).

When we compare particles of similar energy, we can state that, the ranges of particles of greater mass and charge will obviously be shorter and the magnitude of their LET values would be consequently higher in any given medium. The relationship between mass, charge, energy, and the range of particles and their corresponding LET values are compared in Table 1.30. The LET values in Table 1.30 are estimated by dividing the radiation energy by its range or path length in the medium. Such a calculation provides only an estimate of the LET, because the energy dissipated by the radiation will vary along its path of travel, particularly in the case of charged particles, more energy is released when the particle slows down before it comes to a stop as illustrated in Fig. 1.44 illustrated earlier in this chapter, when energy liberated in ion-pair formation is the highest.

Nevertheless, the approximate LET values provided in Table 1.30 give good orders of magnitude for comparative purposes.

The concept of LET and the calculated values of LET for different radiation types and energies can help us interpret and sometimes even predict the effects of ionizing radiation on matter. For example, we can predict that heavy charged particles, such as alpha radiation, will dissipate their energy at shorter distances within a given absorber body than the more penetrating beta- or gamma radiations. Also, low-energy X-radiation can produce a similar effect as certain beta-radiations. The order of magnitude of the LET will help us predict the penetration power and degree of energy dissipation in an absorber body, which is critical information in studies of radiation chemistry, radiation therapy, and dosimetry, among others. For additional information on linear energy transfer and its applications, the reader is referred to works by Koshimizu et al. (2017, 2016), Yanagida et al. (2015), Liu et al. (2012), Jones et al. XVII. Radionuclide decay, ingrowth, and equilibrium

The activity of a radioactive source or radionuclide sample is, by definition, its strength or intensity or, in other words, the number of nuclei decaying per unit time (*e.g.*, dpm or dps). The activity decreases with time as a result of radionuclide decay. A unit of time in which there is an

TABLE 1.30 Range and approximate LET values for various charged-particle radiations in water in order of decreasing mass and charge.^a

Nuclide	Radiation, energy (MeV)	Range in water (mm)	Approximate LET in water (keV/μm)

^aThe deuteron (d) and proton (p) energies were arbitrarily selected to correspond to the alpha-particle (α) energies to facilitate the comparison of the effects of particle mass and charge on range and LET.

^bCalculated according to Eqs. (1.170) and (1.171).

^cThe deuteron range is calculated from the equation $R_{Z,M,E} = (M/Z^2)R_{p,E/M}$. The equation provides the range of a particle of charge Z , mass number M , and energy E , where $R_{p,E/M}$ is the range in the same absorber of a proton of energy E/M (Friedlander et al., 1964).

^dCSDA ranges from Stopping Power and Range Tables for Protons (PSTAR) <https://physics.nist.gov/PhysRefData/Star/Text/PSTAR.html>.

^eCalculations are based on the maximum energy (E_{\max}) of the beta particles. The range was calculated according to the empirical formula $R = 0.412E^{1.27-0.0954 \ln E}$ available from the curve provided in Fig. B.4, Appendix B. Ranges are also available from the online data base Stopping Power and Range Tables for Electrons <https://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html>.

observable change in the activity of a given quantity of radionuclide may be very short, of the order of seconds, or very long, of the order of years. The rate of decay of some nuclides is so slow that it is impossible to measure any change in radioactivity during our lifetime.

A. Half-life

Rates of radionuclide decay are usually expressed in terms of half-life. This is the time, t , required for a given amount of radionuclide to lose 50% of its activity. In other words, it is the time required for one-half of a certain number of nuclei to decay. The decay curve of ^{32}P (Fig. 1.141) illustrates the concept of half-life. In Fig. 1.141, the activity of the ^{32}P is plotted against time in days. It can be seen that, after every interval of 14.3 days, the radioactivity of the ^{32}P is reduced by half. Thus, the half-life, $t_{1/2}$, of ^{32}P is 14.3 days. It is not possible to predict when one particular atom of ^{32}P will decay; however, it is possible to predict statistically for a

large number of ^{32}P radionuclides that one-half of the atoms would decay in 14.3 days.

The phenomenon of radioactivity decay and its measurement in terms of half-life was first observed by [Rutherford \(1900\)](#). He published his observations on the rate of decay of a certain isotope of thorium in the *Philosophical Magazine* in January 1900 less than 4 years after Henri Becquerel first reported the existence of radioactivity to the French Academy of Sciences in February and March 1896. [Rutherford \(1900\)](#) measured the rate of decay by the level of ionization that the radiation would produce in air as a function of time, and he noted the following [with the writer's comments in brackets]:

... the intensity of the radiation has fallen to one-half its value after an interval of about one minute. The rate of leak [meaning rate of decay or rate of ionization caused by the radiation] due to the emanation was too small for measurement after an interval of 10 minutes [i.e., 10 half-lives] ... The current [produced by the ionization] reaches half its

FIGURE 1.141 Decay of ^{32}P represented as a linear plot of activity in disintegrations per minute (dpm) against time in days. Horizontal and vertical lines between the ordinate and abscissa delineate ^{32}P activities (dpm) after six half-lives identified by the symbols $t_1, t_2, t_3, \dots, t_6$. From L'Annunziata (1965), unpublished work of the writer.

value in about one minute — a result which agrees with the equation given, for $e^{-\lambda t} = 1/2$ when $t = 60$ seconds.

In his original paper [Rutherford \(1900\)](#) did not use the term “half-life”; but he defined mathematically the concept of half-life. As we shall see subsequently in [Eq. \(1.547\)](#) that the ratio of the number of radionuclides, N , in a sample at a given time, t , to the original number of nuclides, N_0 , in that sample at time $t = 0$, is equal to $e^{-\lambda t}$ where e is the base to the natural logarithm, λ is a decay constant of that radionuclide, and t is the interval of time.

When radionuclide decay can be recorded within a reasonable period of time, the half-life of a nuclide can be determined by means of a semi-logarithmic plot of activity versus time, as shown in [Fig. 1.142](#). Radionuclide decay is a logarithmic relation, and the straight line obtained on the semi-logarithmic plot permits a more accurate determination of the half-life.

Ernest Rutherford and Frederick Soddy ([1902](#)) in the *Philosophical Magazine* summarized their findings on radioactivity and radionuclide decay as follows [the writer's insertions in brackets]:

Turning from the experimental results to their theoretical interpretation, it is necessary to first consider the generally accepted view of the nature of radioactivity. It is well established that this property is the function of the atom and not of the molecule. Uranium and thorium, to take the most definite cases [example], possess the property in whatever molecular condition they occur ... So far as the radioactivity of different compounds of different density and states

of division can be compared together, the intensity of the radiation appears to depend only on the quantity of active element [radioisotope] present.

The above statement by Rutherford and Soddy in [1902](#) that “the intensity of the radiation appears to depend only on the quantity of active element present” is defined subsequently in mathematical terms.

The number, ΔN , of atoms disintegrating in a given time, Δt , is proportional to the number, N , of radioactive atoms present. This relationship may be written as

$$\Delta N / \Delta t = \lambda N \quad (1.542)$$

or

$$dN/dt = -\lambda N \quad (1.543)$$

where λ is a proportionality constant, commonly referred to as the decay constant, and the negative sign signifies a decreasing number of radionuclides with time.

One condition must be fulfilled for [Eq. \(1.543\)](#) to be rigorously applicable: the total number of radioactive atoms being considered must be large enough to make statistical methods valid. For example, in the case of a single isolated atom of ^{32}P there is no way to predict when the atom will decay. In fact, the atom might decay in the first second after $t = 0$ (the moment observations are initiated) or it might decay days or weeks later. The concept of half-life is a statistical one, which, when applied to a large number of atoms, as is usually the case, allows an accurate calculation of the activity of radionuclides after a given time interval.

FIGURE 1.142 Semi-logarithmic plot of the decay of ^{32}P . Two half-lives (t_1 and t_2) are delineated by horizontal and vertical lines between the ordinate and abscissa. From L'Annunziata, M. F. (1965), unpublished work of the writer.

For radionuclide decay calculations, Eq. (1.543) may be transformed into the derivative as

$$dN/N = -\lambda dt, \quad (1.544)$$

which can be integrated between the limits N_0 and N and between t_0 and t , where t_0 is 0 (the moment observations are initiated), N_0 is the number of atoms originally present at time t_0 , and N is the number of atoms remaining after time t :

$$\int_{N_0}^N dN/N = -\lambda \int_{t_0}^t dt \quad (1.545)$$

to give

$$\ln N/N_0 = -\lambda t \quad (1.546)$$

Eq. (1.546) may be written in exponential form as

$$N = N_0 e^{-\lambda t} \quad (1.547)$$

where e is the base of the natural logarithm, λ is the decay constant, and t is the interval of time. Eq. (1.547) is the

form used to determine the decay of a radionuclide sample after a given time interval. To use Eq. (1.547), the value of the decay constant λ , must be known, and this is different for each radionuclide. To determine λ for a particular radionuclide, a relationship between the decay constant and the half-life may be derived from the decay Eq. (1.546), which may be transposed to

$$\ln N_0/N = \lambda t \quad (1.548)$$

By definition, we know that, after an interval of time corresponding to the half-life, half of the original activity remains. Therefore, we may assign the original activity N_0 as unity whereby after one-half life, where $t = t_{1/2}$, the remaining activity N would be one-half of unity, and Eq. (1.548) would become

$$\ln \frac{1}{1/2} = \lambda t_{1/2} \quad (1.549)$$

or

$$\ln 2 = \lambda t_{1/2} \quad (1.550)$$

and

$$0.693 = \lambda t_{1/2} \quad (1.551)$$

The decay constant can then be defined as

$$\lambda = 0.693/t_{1/2} \quad (1.552)$$

The value of λ can be calculated easily from the half-life of a radionuclide with Eq. (1.552). The units used for λ are expressed in reciprocal time, s^{-1} , m^{-1} , h^{-1} , d^{-1} , or y^{-1} , depending on the units used for the half-life of the radionuclide and also on the time interval t used in Eq. (1.552). For example, if ^{32}P , which has a half-life of 14.3 days, is used in an experiment, λ may be expressed in d^{-1} . The unit of the decay constant must agree with the time interval t of Eq. (1.547).

The following example illustrates the use of Eq. (1.547) to calculate the decay of a radionuclide sample within any time interval.

If a sample contained 3.7 MBq of ^{32}P on a given date and an investigator wished to determine the amount remaining after a 30-day period, he would first determine the decay constant for ^{32}P according to Eq. (1.552) and then calculate the activity after the specified time period using the decay Eq. (1.553) as follows. The decay constant in units of d^{-1} is determined by

$$\lambda = 0.693/t_{1/2} = 0.693/14.3 \text{ d} = 4.85 \times 10^{-2} d^{-1}$$

With the calculated value of λ and the known time interval t , the activity of the remaining ^{32}P is determined according to Eq. (1.547) expressed in terms of activity (A) or

$$A = A_0 e^{-\lambda t} \quad (1.553)$$

and

$$\begin{aligned} A &= 3.7 \times 10^6 \text{ dps} \left(e^{-[(4.85 \times 10^{-2} \text{ day}^{-1}) 30 \text{ days}]} \right) \\ &= 3.7 \times 10^6 \text{ dps} (e^{-1.455}) \\ &= 3.7 \times 10^6 (0.2334) \\ &= 8.64 \times 10^5 \text{ dps} = 0.864 \text{ MBq} \end{aligned}$$

where A is the activity of the radionuclide in units of decay rate (e.g., dps) after time t , and A_0 is the initial activity at time t_0 where in this example, $A_0 = 3.7 \text{ MBq} = 3.7 \times 10^6 \text{ dps}$ since by definition $1 \text{ MBq} = 1 \times 10^6 \text{ dps}$. Thus, after the 30-day period, the activity of ^{32}P decayed from an initial activity of 3.7 to 0.864 MBq.

The decay equation has many practical applications, as it can be used also to calculate the time required for a given radionuclide sample to decay to a certain level of activity. Let us consider the following example:

A patient was administered intravenously 600 MBq of ^{99m}Tc -methylene diphosphate, which is a radiopharmaceutical administered for the purposes of carrying out a diagnostic bone scan. The doctor then wanted to know how

much time would be required for the ^{99m}Tc radioactivity in the patient's body to be reduced to 0.6 MBq (0.1% of the original activity) from radionuclide decay alone ignoring any losses by bodily excretion. The half-life $t_{1/2}$ of ^{99m}Tc is 6.00 hours. To calculate the time required we can write Eq. (1.553) as

$$A/A_0 = e^{-\lambda t} \quad (1.554)$$

where A is the activity in dps (disintegrations per second) after time t and A_0 is the initial activity at time t_0 . Eq. (1.554) can be transposed to

$$\ln A_0/A = \lambda t \quad (1.555)$$

or

$$t = \frac{1}{\lambda} \ln \frac{A_0}{A} \quad (1.556)$$

By definition (Eq. 1.552) the decay constant λ of ^{99m}Tc is $0.693/t_{1/2}$ or $0.693/6.00 \text{ h}$. Solving Eq. (1.556) after inserting the value of λ and the relevant activities of ^{99m}Tc gives

$$\begin{aligned} t &= (6.00 \text{ h} / 0.693) \ln(600 \text{ MBq} / 0.6 \text{ MBq}) \\ &= 59.8 \text{ hours} = 2.5 \text{ days} \end{aligned}$$

In the case of a mixture of independently decaying radionuclides, the rate of decay of each nuclide species does not change. However, the rate of decay of the overall sample is equal to the sum of the decay rates of the individual nuclide species. The cumulative decay of a mixture of independently decaying nuclides from the most simple case of a mixture of two nuclides to a more complex case of n number of nuclides is described by

$$N = N_1^0 e^{-\lambda_1 t} + N_2^0 e^{-\lambda_2 t} + \dots N_n^0 e^{-\lambda_n t} \quad (1.557)$$

where N is the number of atoms remaining after time t , and N_1^0 , N_2^0 , and N_n^0 are the numbers of atoms originally present at time t_0 of 1, 2, and n number of nuclide species, respectively.

The semilogarithmic decay plot of a mixture of two independently decaying nuclides is not a straight line, contrary to pure radionuclide samples; rather, it is a composite plot, as in the case of a mixture of ^{32}P and ^{45}Ca (see Fig. 1.143). If the half-lives of the two nuclides are significantly different, the composite curve may be analyzed so that the decay curves of the two radionuclides may be determined. If the decay of the composite mixture can be observed over a reasonable period of time, the composite curve will eventually yield a straight line representing the decay of the longer-lived nuclide after the disappearance of the shorter-lived nuclide (depicted in Fig. 1.143). This straight line may be extrapolated to time $t = 0$ so that the activity (dpm) of this nuclide at $t = 0$ can be found. The difference between the activity at $t = 0$ of the longer-lived nuclide and the total activity of the sample at $t = 0$ gives the activity at $t = 0$ of the shorter-lived nuclide.

FIGURE 1.143 Semi-logarithmic decay curves of ^{32}P and ^{45}Ca isolated from a composite decay curve of a mixture of $^{32}\text{P} + ^{45}\text{Ca}$. From L'Annunziata, M. F. (1965), unpublished work of the writer.

Likewise, further subtraction of points of the extrapolated decay curve from the composite curve yields the decay curve of the shorter-lived nuclide.

The half-lives of the two radionuclides are determined from the slopes of the two decay curves isolated from the composite curve. Eq. (1.548), which is expressed in natural logarithms, may be transformed to logarithms to the base 10 by

$$2.303 \log(N_1 / N_2) = \lambda(t_2 - t_1) \quad (1.558)$$

or

$$\log(N_1 / N_2) = \frac{\lambda}{2.303}(t_2 - t_1) \quad (1.559)$$

where N_1 and N_2 are the numbers of atoms or activity of the sample at times t_1 and t_2 , respectively. As $\lambda/2.303$ of Eq. (1.559) is equal to the slope, the decay constant, λ , may be calculated from a graphical determination of the slope. With a calculated value of λ , the half-life of the nuclide is then calculated from Eq. (1.552).

Edwin M. McMillan (1907–91), who shared the Nobel Prize in Chemistry in 1951 with Glenn T. Seaborg (1912–99) for their discoveries in the chemistry of the transuranium isotopes, utilized the composite decay curve similar to that illustrated in Fig. 1.143 to determine graphically the half-lives of a mixture of ^{239}U ($t_{1/2} = 23.5$ minutes) and ^{239}Np ($t_{1/2} = 23.6$ days), which were prepared for the first time from the neutron capture following irradiation of ^{238}U with fast neutrons (McMillan, 1951). The detailed historical account and methods used by McMillan and Seaborg in their discovery of transuranium elements 94–103 and element 106 is provided by the writer in a previous text (L'Annunziata, 2016).

Many radionuclides have very long half-lives, which make the graphic representation of their decay impossible. Some examples are ^3H ($t_{1/2} = 12.3$ y), ^{14}C ($t_{1/2} = 5.73 \times 10^3$ y), ^{40}K ($t_{1/2} = 1.3 \times 10^9$ y), and ^{174}Hf ($t_{1/2} = 2 \times 10^{15}$ y) (see Appendix A). In such cases the half-lives can be calculated from Eqs. (1.543) and (1.552). The decay rate or activity, A , in disintegrations per year (DPY) of a

given nuclide sample, defined by dN/dt of Eq. (1.543), is measured experimentally. The number of atoms of the radioassayed sample, defined by N of Eq. (1.543), must be known or determined. This is simple for pure samples. For example, the number of atoms of ^{40}K in a pure sample of KCl is easily calculated from Avogadro's number (6.022×10^{23} molecules/mol or atoms/mol) and the percentage natural abundance of ^{40}K (0.012%). Samples of unknown purity and isotopic abundance require a quantitative analysis of the element such as that provided by a mass spectral analysis of the isotopic abundance. The value of λ in y^{-1} is calculated as

$$\lambda = \frac{dN/dt}{N} = \frac{A}{N} = \frac{\text{CPM}/E}{N} (5.25 \times 10^5 \text{ min / year}) \quad (1.560)$$

where A is the sample nuclide activity in DPY, N is the number of atoms of the nuclide in the sample, CPM is the sample count rate provided by the instrument radioactivity detector, E is the instrument counting efficiency, and 5.25×10^5 minutes/year is the factor used to convert counts per minute (CPM) to counts per year (CPY). The half-life can then be calculated according to Eqs. (1.552) and (1.560) both of which define the value of λ .

Let us look at a practical example of the use of the above equations to determine the half-life of ^{40}K taken from the work of Grau Malonda and Grau Carles (2002). The accurate determination of the half-life of ^{40}K has very practical implications, as it is currently used by geologists to date a rock's formation based on the measurement of the quantity of the stable daughter nuclide ^{40}Ar . Grau Malonda and Grau Carles (2002) report the accurate determination of the half-life of ^{40}K by measuring the activity of ^{40}K in a sample of pure KNO_3 and applying the relationships of half-life to λ according to Eqs. (1.552) and (1.560). They measured the ^{40}K specific activity in KNO_3 by the very accurate CIEMAT/NIST efficiency tracing liquid scintillation standardization method (see Chapter 6 of this volume) to be 12.24 ± 0.014 Bq/g. Also, applying the known isotopic concentration of ^{40}K in KNO_3 of 0.01167% and the value of Avogadro's number 6.022×10^{23} atoms per mole, they could calculate the number of atoms of ^{40}K in 1 g of KNO_3 as follows:

$$\begin{aligned} & \left(\frac{6.022 \times 10^{23} \text{ atoms K/mole KNO}_3}{(101.103 \text{ g KNO}_3/\text{mole KNO}_3)} \right) \\ & \times \left(\frac{0.01167 \text{ atoms } ^{40}\text{K}}{100 \text{ atoms K}} \right) \\ & = 6.951 \times 10^{17} \text{ atoms } ^{40}\text{K/g KNO}_3 \end{aligned}$$

From Eqs. (1.552) and (1.560), we can write

$$\frac{1}{\lambda} = \frac{t_{1/2}}{0.693} = \frac{N}{A} \quad (1.561)$$

or

$$t_{1/2} = 0.693 \left(\frac{N}{A} \right) \quad (1.562)$$

From the specific radioactivity of ^{40}K in KNO_3 (*i.e.*, dps $^{40}\text{K/g KNO}_3$) determined by the very accurate CIEMAT/NIST efficiency tracing liquid scintillation standardization method, and the calculated number of atoms of ^{40}K per gram of KNO_3 , Grau Malonda and Grau Carles (2002) calculated the half-life of ^{40}K as

$$t_{1/2} = 0.693 \left(\frac{6.951 \times 10^{17} \text{ atoms } ^{40}\text{K/g KNO}_3}{(12.24 \text{ dps } ^{40}\text{K/g KNO}_3)(60 \text{ s/m})(5.25 \times 10^5 \text{ m/y})} \right)$$

and

$$t_{1/2} = 1.248 \times 10^9 \text{ y}$$

From the mean of nine determinations, Grau Malonda and Grau Carles (2002) were able to assign the value of the half-life ($t_{1/2}$) of ^{40}K to be $(1.248 \pm 0.004) \times 10^9$ y at a 95% confidence level.

Other radionuclides have very short half-lives such as ^{209}Ra ($t_{1/2} = 4.6$ seconds), ^{215}At ($t_{1/2} = 1.0 \times 10^{-4}$ seconds) and ^{212}Po ($t_{1/2} = 2.98 \times 10^{-7}$ seconds). Half-lives of such short duration can be determined by delayed-coincidence timing methods (Rudigier et al., 2017; Dias et al., 2014; Kojima et al., 2014; Suliman et al., 2013, 2012; D'Olympia et al., 2013; Takau et al. 2012; Jakubek et al., 2011; Kurtukian-Nieto et al., 2008; Morozov et al., 2006, 2002; 1998; Schwarzschild, 1963; Oms, 2004; Petkov et al., 2003; Ohm et al., 1990), which involve the use of multiple detectors (*e.g.*, scintillation and semiconductor detectors) with detector response times as short as 10^{-11} seconds. The technique has also been applied to the measurement of the half-lives of excited nuclear states, such as the 8.7 and 98.1 ns half-lives of the 14.4 and 136.5 keV excited states of ^{57}Fe daughter nuclides, that emit gamma radiation, following the decay of ^{57}Co (Morozov et al., 2006, 2002). Radiation detectors with resolving times of fractions of a microsecond are set electronically so that a delay circuit will detect a radiation-induced pulse from the parent in coincidence with a radiation pulse produced from the daughter. Varying the delay time of the coincidence circuit results in a delay of the coincidence pulse rate from which a decay curve of the very short-lived daughter nuclide can be plotted and the half-life determined.

B. General decay equations

The simplest decay relationship between parent and daughter nuclides that can be considered is that of a parent nuclide which decays to form a stable daughter nuclide.

The decay of the radionuclide ^{33}P serves as an example. The parent nuclide ^{33}P decays with a half-life of 25 days

with the production of the stable daughter ^{33}S , as indicated by

Numerous radionuclides, such as ^3H , ^{14}C , ^{32}P , ^{35}S , ^{36}Cl , ^{45}Ca , and ^{131}I (see Appendix A), decay by this simple parent-daughter relationship.

However, numerous other radionuclides produce unstable daughter nuclides. The simplest case would be that in which the parent nuclide A decays to a daughter nuclide B, which in turn decays to a stable nuclide C:

In such decay chains, the rate of decay and production of the daughter must be considered as well as the rate of decay of the parent. The decay of the parent is described by the simple rate equation

$$-dN_A/dt = \lambda_A N_A \quad (1.565)$$

which is integrated to the form

$$N_A = N_A^0 e^{-\lambda_A t} \quad (1.566)$$

where N_A^0 is the number of atoms of the parent at the time $t = 0$ and N_A is the number of atoms after a given period of time $t = t_1$.

The decay rate of the daughter is dependent on its own decay rate as well as the rate at which it is formed by the parent. It is written as

$$-dN_B/dt = \lambda_B N_B - \lambda_A N_A \quad (1.567)$$

where $\lambda_B N_B$ is the rate of decay of the daughter alone and $\lambda_A N_A$ is the rate of decay of the parent or rate of formation of the daughter. Eqs. (1.566) and (1.567) may be transposed into the linear differential equation

$$dN_B/dt + \lambda_B N_B - \lambda_A N_A^0 e^{-\lambda_A t} = 0 \quad (1.568)$$

which is solved for the number of atoms of daughter, N_B , as a function of time to give

$$N_B = \frac{\lambda_A}{\lambda_B - \lambda_A} N_A^0 (e^{-\lambda_A t} - e^{-\lambda_B t}) + N_B^0 e^{-\lambda_B t} \quad (1.569)$$

Although unnecessary in this treatment, the solution to Eq. (1.568) is given by Friedlander et al. (1964).

In decay schemes of this type, the following three conditions may predominate: (1) secular equilibrium, (2) transient equilibrium, and (3) the state of no equilibrium. Each of these cases will now be considered in detail.

C. Secular equilibrium

The phenomenon of radioisotope decay equilibrium was first observed by Ernest Rutherford and Frederick Soddy in 1902, which they reported in their classic paper on "The

Cause and Nature of Radioactivity". They reported their observations as follows:

Radioactivity is shown to be accompanied by chemical changes in which new types of matter are being continuously produced. These reaction products are at first radioactive, the activity diminishing regularly from the moment of formation. Their continuous production maintains the radioactivity of the matter producing them at a definite equilibrium value.

Secular equilibrium is a steady-state condition of equal activities between a long-lived parent radionuclide and its short-lived daughter. The important criterion upon which secular equilibrium depends is the following: The parent must be long-lived compared to the life of the daughter nuclide; that is, the half-life of the daughter must be negligible compared to that of its parent (Evans, 1955). In other words, the activity of the parent does not decrease measurably during many half-lives of the daughter (Friedlander et al., 1964), that is,

$$\lambda_A \ll \lambda_B \quad (1.570)$$

where λ_A and λ_B are the respective decay constants of the parent and daughter nuclides. The importance of this criterion can be clearly seen, if the ^{90}Sr (^{90}Y) equilibrium is taken as an example.

The nuclide ^{90}Sr is the parent in the decay scheme

The long half-life of ^{90}Sr definitely satisfies the criterion for secular equilibrium, because over a quarter of a century is needed for it to lose 50% of its original activity. As will be seen, less than 3 weeks are required for secular equilibrium to be attained and, in this interim period, negligible decay of ^{90}Sr occurs. Also, the decay constants for ^{90}Sr and ^{90}Y , λ_A and λ_B , respectively, may be compared. The decay constants for ^{90}Sr and ^{90}Y are easily calculated from their half-lives, and the values are $6.60 \times 10^{-5} \text{ d}^{-1}$ and $2.57 \times 10^{-1} \text{ d}^{-1}$, respectively. In the comparison $\lambda_A/\lambda_B = 2.57 \times 10^{-4}$, and this is in agreement with the order of magnitude required for secular equilibrium where $\lambda_A \ll \lambda_B$.

An equation for the growth of daughter atoms from the parent can be obtained from Eq. (1.569) by consideration of the limiting requirements for secular equilibrium. Since $\lambda_A \approx 0$ and $\lambda_A \ll \lambda_B$, $e^{-\lambda_A t} = 1$ and λ_A falls out of the denominator in the first term of Eq. (1.569). If the daughter nuclide is separated physically from the parent (L'Annunziata, 1971), $N_B^0 = 0$ at time $t = 0$ (time of parent-daughter separation) and the last term would fall out of Eq. (1.569). Thus, in the case of secular equilibrium, the expression of the ingrowth of daughter atoms with parent can be written as

$$N_B = \frac{\lambda_A N_A^0}{\lambda_B} (1 - e^{-\lambda_B t}) \quad (1.572)$$

If the observation of the ingrowth of the daughter is made over many half-lives of the daughter, it is seen that the number of atoms of daughter approaches a maximum value $\lambda_A N_A^0 / \lambda_B$, which is the rate of production of daughter divided by its decay constant. The final form of Eq. (1.572) to be used for the calculation of the ingrowth of daughter can be expressed as

$$N_B = (N_B)_{\max} (1 - e^{-\lambda_B t}) \quad (1.573)$$

Since the activity of the daughter atoms, A_B , is proportional to the number of daughter atoms, or $A_B = k \lambda_B N_B$, where k is the coefficient of detection of the daughter atoms, Eq. (1.573) may also be written as

$$A_B = (A_B)_{\max} (1 - e^{-\lambda_B t}) \quad (1.574)$$

Rutherford and Soddy (1902) were the first to write and interpret Eqs. (1.573) and (1.574) when they studied the equilibrium existing between radioactive thorium and a daughter radionuclide. They noted the following [with the author's comments in brackets]:

The radioactivity of thorium at any time is the resultant of two opposing processes: 1. The production of fresh radioactive material at a constant rate by the thorium compound, and 2. The decay of the radiating power of the active material with time. The normal or constant radioactivity possessed by thorium is an equilibrium value, where the rate of increase of radioactivity due to the production of fresh active material [daughter nuclide] is balanced by the rate of decay of radioactivity of that already formed ... The experimental curve obtained with the hydroxide [This was the chemical form they used to separate the parent nuclide from the daughter.] for the rate of rise of its activity from a minimum to a maximum value will therefore be approximately expressed by the equation $I_t/I_0 = 1 - e^{-\lambda t}$, where I_0 represents the amount of activity recovered when the maximum is reached, and I_t the activity recovered after time t , λ being the same constant as before.

(Notice the similarity of Rutherford and Soddy's equation, which may be transposed to read $I_t = (I_0)(1 - e^{-\lambda t})$ and Eqs. (1.573) and (1.574).)

Let us take an arbitrary example of equal activities of 100 dpm of parent ^{90}Sr and 100 dpm of daughter ^{90}Y , in secular equilibrium. From these activities we can calculate and graphically represent the ingrowth of ^{90}Y with its parent and also the decay of ^{90}Y subsequent to the separation of parent and daughter nuclides (L'Annunziata, 1971). Identical activities of ^{90}Sr and ^{90}Y are arbitrarily chosen, because their activities are equal while in secular equilibrium prior to their separation. Fig. 1.144 illustrates

the calculated growth of ^{90}Y (curve B) as produced by ^{90}Sr using Eq. (1.574) with $(A_B)_{\max} = 100$. The decay of separated ^{90}Y (curve A) is plotted by simple half-life decay ($t_{1/2} = 2.7$ d). The dashed line (line C) represents the decay of ^{90}Sr , which is negligible ($t_{1/2} = 28.8$ y) during the period of observation. The total activity (curve D) is the result of both ^{90}Sr decay and the ingrowth of ^{90}Y after the separation of the latter, and it is obtained by the addition of curve B to line C. It may be noted from Fig. 1.144, that after approximately six half-lives of ^{90}Y (~ 18 d), the activity of ^{90}Y has increased to essentially the same activity of ^{90}Sr , after which both nuclides decay with the same half-life, that of the parent ^{90}Sr (28.8 y).

Ernest Rutherford and Frederick Soddy in their classic paper on "The Cause and Nature of Radioactivity" in 1902 in the *Philosophical Magazine* made the first published observation of what is now known as secular equilibrium. They were studying the radioactivity of an isotope of thorium and a daughter isotope, which they called ThX. The term "daughter isotope" for an isotope decay product was not then established, because knowledge of radioactivity was only then at its infancy. They summarized their findings with the following:

The foregoing experimental results may be briefly summarized. The major part of the radioactivity of thorium — ordinarily about 54 percent — is due to a non-thorium type of matter, ThX, possessing distinct chemical properties, which is temporarily radioactive, its activity falling to half value in about four days. The constant radioactivity of thorium is maintained by the production of this material at a constant rate. Both the rate of production of the new material and the rate of decay of its activity appear to be independent of the physical and chemical condition of the system.

(We now know that the activity of parent and daughter nuclides are equal in secular equilibrium and the value of "about 54%" reported by Rutherford and Soddy was precisely 50%.)

As an example of the practical utility of this phenomenon, the application of secular equilibrium theory to the analysis of ^{90}Sr in the environment is discussed.

One method reported by the Los Alamos National Laboratory (see Gautier, 1995) entails the initial chelation (complex formation) of the sample strontium with the sodium salt of ethylenediaminetetraacetic acid (EDTA). The complexed strontium is then isolated by elution on an ion exchange column. The eluted strontium is then precipitated as a carbonate. The activity of radioactive strontium, which will include $^{89}\text{Sr} + ^{90}\text{Sr}$ in the sample, is determined by low-background counting. Low-background liquid scintillation counting is most often used for the total $^{89}\text{Sr} + ^{90}\text{Sr}$ analysis, as described by Passo and Cook (1994), Salonen et al. (2012) and Chapter 2 in Volume two of this book. The

FIGURE 1.144 Growth and decay curves following the separation of ^{90}Sr (^{90}Y) in secular equilibrium. (A) Decay of isolated ^{90}Y . (B) Ingrowth of ^{90}Y with ^{90}Sr . (C) Decay of isolated ^{90}Sr . (D) Total activity from isolated ^{90}Sr , representing both ^{90}Sr decay and ^{90}Y growth until secular equilibrium is attained. From *L'Annunziata (1971)*; reprinted with permission © 1971 American Chemical Society.

isolated radiostrontium is then allowed to remain in the sample without further treatment for a period of about 2 weeks to allow ingrowth of ^{90}Y . About 2 weeks are needed to ensure the parent and daughter radionuclides are in secular equilibrium before the chemical separation of yttrium from strontium. From Eq. (1.574) it is calculated, that after 2 weeks, the activity of ^{90}Y grows to 97.4% of its original level. Carrier yttrium is then added to the dissolved radiostrontium, and the yttrium is precipitated as the hydroxide, redissolved, and reprecipitated as an oxalate (see Section XVIII.C of this chapter for a discussion of the concepts of carrier and carrier-free radionuclides). The step involving the precipitation of yttrium from the sample results in the separation of ^{90}Y from the radiostrontium. The separated ^{90}Y can then be assayed by suitable low-background counting using liquid scintillation or Cherenkov counting (Passo and Cook, 1994; L'Annunziata and Passo, 2002). The ^{90}Sr activity in the sample is determined from the activity of ^{90}Y by calculating the ^{90}Y decay from the time of separation (precipitation) of yttrium from strontium. This is possible because the parent and daughter

radionuclides were at secular equilibrium (i.e., ^{90}Sr dpm = ^{90}Y dpm) at time $t = t_0$ when the precipitation and separation of yttrium from strontium were carried out. The ^{89}Sr activity in the sample is determined from the difference between the total radiostrontium activity ($^{89}\text{Sr} + ^{90}\text{Sr}$) and the measured activity of ^{90}Sr . A review of radioanalytical methods for the analysis of radioactive isotopes of strontium including ^{90}Sr , which involves the concept of secular equilibrium, is provided by Vajda and Kim (2010) and Chapter 2 in Volume two of this book.

D. Transient equilibrium

Like secular equilibrium, transient equilibrium is a steady-state condition between the parent and daughter nuclides. However, in transient equilibrium the parent-daughter nuclides do not possess the same activities, but rather they decay at the same half-life, that of the parent nuclide.

The criterion upon which transient equilibrium rests is that the parent nuclide must be longer lived than its

daughter, but not of the order of magnitude described by Eq. (1.570); that is, it is necessary that $\lambda_A < \lambda_B$; and, contrary to secular equilibrium, in transient equilibrium, the decay (i.e., half-life) of the daughter nuclide is not negligible compared to that of the parent. In transient equilibrium the ratio of half-life of the parent over the difference of half-lives of the parent (t_A) and daughter (t_B) should be clearly greater than unity (Evans, 1955) or

$$\frac{t_A}{t_A - t_B} > 1 \quad (1.575)$$

The decay chain of ^{100}Pd serves as an example of parent-daughter nuclides that may attain transient equilibrium. ^{100}Pd decays by electron capture to ^{100}Rh with a half-life of 96 hours. The daughter nuclide ^{100}Rh decays by electron capture and positron emission to the stable nuclide ^{100}Ru . The half-life of the daughter nuclide is 21 hours. The decay scheme may be represented as

The half-life of the parent nuclide is greater than that of the daughter, and the ratio

$$\frac{t_A}{t_A - t_B} = \frac{96\text{ h}}{96\text{ h} - 21\text{ h}} = 1.28 \quad (1.577)$$

is clearly greater than unity. Also, the value of λ_A , given by $0.693/96$ hours, is $7.2 \times 10^{-3}\text{ h}^{-1}$, and that of λ_B , given by $0.693/21$ hours, is $3.3 \times 10^{-2}\text{ h}^{-1}$ whereby $\lambda_A < \lambda_B$.

If the general decay Eq. (1.569) of the daughter nuclide is considered, the term $e^{-\lambda_B t}$ is negligible compared with $e^{-\lambda_A t}$ for sufficiently large values of t . Thus, the terms $e^{-\lambda_B t}$ and $N_B^0 e^{-\lambda_B t}$ may be dropped from Eq. (1.569) to give

$$N_B = \frac{\lambda_A}{\lambda_B - \lambda_A} (N_A^0 e^{-\lambda_A t}) \quad (1.578)$$

for the ingrowth of the daughter nuclide as a function of time. Because $N_A = N_A^0 e^{-\lambda_A t}$, Eq. (1.578) may be written as

$$\frac{N_B}{N_A} = \frac{\lambda_A}{\lambda_B - \lambda_A} \quad (1.579)$$

From Eq. (1.579), it can be seen that the ratio of the number of atoms or the ratio of the activities of the parent and daughter nuclides is a constant in the case of transient equilibrium.

Since $A_A = k_A \lambda_A N_A$ and $A_B = k_B \lambda_B N_B$, where A_A and A_B are the activities of the parent and daughter nuclides, respectively, and k_A and k_B are the detection coefficients of these nuclides, Eq. (1.579) may be written in terms of activities as

$$\frac{A_B}{k_B \lambda_B} (\lambda_B - \lambda_A) = \frac{A_A}{k_A \lambda_A} \lambda_A \quad (1.580)$$

or

$$\frac{A_B}{A_A} = \frac{k_B \lambda_B}{k_A (\lambda_B - \lambda_A)} \quad (1.581)$$

If equal detection coefficients are assumed for the parent and daughter nuclides, Eq. (1.581) may be written as

$$\frac{A_B}{A_A} = \frac{\lambda_B}{(\lambda_B - \lambda_A)} \quad (1.582)$$

Thus, for transient equilibrium Eq. (1.582) indicates that the activity of the daughter is always greater than that of the parent by the factor $\lambda_B/(\lambda_B - \lambda_A)$. Eq. (1.582) may likewise be written as

$$\frac{A_A}{A_B} = 1 - \frac{\lambda_A}{\lambda_B} \quad (1.583)$$

whereby the ratio A_A/A_B falls within the limits $0 < A_A/A_B < 1$ in transient equilibrium.

If an activity of 100 dpm is arbitrarily chosen for the daughter nuclide ^{100}Rh in transient equilibrium with its parent ^{100}Pd , the activity of ^{100}Pd can be found using either Eq. 1.582 or 1.583. Eq. (1.582) gives

$$\frac{100\text{ dpm}}{A_A} = \frac{3.3 \times 10^{-2}\text{ h}^{-1}}{3.3 \times 10^{-2}\text{ h}^{-1} - 7.2 \times 10^{-3}\text{ h}^{-1}}$$

or

$$A_A = 78\text{ dpm}$$

With the use of Eq. (1.582) or 1.583, the decay of the daughter nuclide may be calculated as a function of parent decay in transient equilibrium. The ^{100}Pd – ^{100}Rh parent-daughter decay in transient equilibrium is illustrated by curves A and B, respectively, of Fig. 1.145. The parent and daughter nuclides are shown to have respective activities of 78 dpm and 100 dpm at time $t = 0$. As curves A and B show, the parent and daughter nuclides in transient equilibrium decay with the same half-life, that corresponding to the half-life of the parent.

If the parent and daughter nuclides were to be separated, the daughter nuclide would decay according to its half-life as indicated by curve C. The isolated parent nuclide would, however, show an increase in activity with time owing to the ingrowth of daughter until transient equilibrium is attained. Curve D of Fig. 1.145 shows the ingrowth of daughter nuclide from a freshly isolated parent. Because $N_B^0 = 0$ at time $t = 0$ (time of separation of parent and daughter), the last term of Eq. (1.569) falls out to give

$$N_B = \frac{\lambda_A N_A^0}{\lambda_B - \lambda_A} (e^{-\lambda_A t} - e^{-\lambda_B t}) \quad (1.584)$$

The term $\lambda_A N_A^0/(\lambda_B - \lambda_A)$ approaches a maximum value, which is the rate of production of the daughter divided by the

FIGURE 1.145 Growth and decay curves following the separation of ^{100}Pd (^{100}Rh) in transient equilibrium. (A) Decay of isolated parent nuclide ^{100}Pd . (B) Decay of ^{100}Rh daughter nuclide in transient equilibrium. The dashed portion of this curve represents ^{100}Rh decay if parent and daughter nuclides were not separated. (C) Decay of ^{100}Rh after separation from its parent. (D) The ingrowth of ^{100}Rh with the isolated parent ^{100}Pd . (E) Total activity from the isolated ^{100}Pd representing both ^{100}Pd decay and ^{100}Rh growth until transient equilibrium is attained. From L'Annunziata (1987), original work of the writer.

difference between the daughter and parent decay constants, and Eq. (1.548) may be written as

$$N_B = (N_B)_{\max}(e^{-\lambda_A t} - e^{-\lambda_B t}) \quad (1.585)$$

similar to the case of Eq. (1.573). Since the activity, A_B , of the daughter atoms is proportional to the number of daughter atoms, or $A_B = k_B \lambda_B N_B$, where k is as defined previously, Eq. (1.585) may also be written as

$$A_B = (A_B)_{\max}(e^{-\lambda_A t} - e^{-\lambda_B t}) \quad (1.586)$$

Because the maximum daughter activity in this sample is 100 dpm, Eq. (1.586) may be used to calculate the ingrowth of daughter nuclide with $(A_B)_{\max} = 100$.

Curve E of Fig. 1.145 illustrates the total activity of the isolated parent and daughter nuclides. It is found by summing curves A and D and consequently accounts for the simultaneous decay of the parent nuclide and the ingrowth of the daughter. Notice that the slopes of curves A, B, and E are identical when transient equilibrium is attained, that is, the rates of decay of both the parent and daughter are identical.

Additional practical examples of decay and ingrowth calculations may be obtained from Harms and Jerome (2004).

E. No equilibrium

The cases of secular equilibrium and transient equilibrium, which involve decay schemes whereby the parent nuclide is longer lived than its daughter, were just considered. In other cases in which the daughter nuclide is longer lived than its parent, $\lambda_A > \lambda_B$, no equilibrium is attained. Instead, the parent nuclide of shorter half-life eventually decays to a negligible extent, leaving only the daughter nuclide, which decays by its own half-life. The following decay scheme of ^{56}Ni serves as an example:

The parent nuclide ^{56}Ni decays by EC with a half-life of 6.4 d, whereas its daughter ^{56}Co decays with the longer half-life of 77.3 d by EC and β^+ emission. Curve A of Fig. 1.146 illustrates the decay of the ^{56}Ni parent nuclide. The decay of isolated ^{56}Ni is followed by the ingrowth (production) of the ^{56}Co daughter nuclide, shown by curve B. The ingrowth of daughter is calculated from Eq. (1.569) described earlier, of which the last term, $N_B^0 e^{-\lambda_B t}$, falls out because $N_B^0 = 0$ at time $t = 0$. The number of daughter atoms N_B of Eq. (1.569) may be converted to activity, A_B , by the term $A_B = k_B \lambda_B N_B$ as discussed previously. The total activity illustrated by curve C of Fig. 1.146 depicts

FIGURE 1.146 Growth and decay curves of the $^{56}\text{Ni}/^{56}\text{Co}$ parent-daughter nuclides following the isolation or fresh preparation of the parent nuclide ^{56}Ni . (A) Decay of the parent nuclide ^{56}Ni . (B) Ingrowth of daughter nuclide ^{56}Co . (C) Total activity representing both ^{56}Ni decay and the simultaneous growth and decay of ^{56}Co daughter. From *L'Annunziata* (1987), original work of the writer.

both the simultaneous decay of parent nuclide and the ingrowth and decay of daughter determined by summing curves A and B. Notice from Fig. 1.146, that the parent nuclide activity in this example becomes negligible after around 55 d, after which the total activity, curve C, has a slope corresponding to the decay rate of the daughter nuclide.

F. More complex decay schemes

Other decay schemes exist that involve a chain of numerous nuclides such as

$$A \rightarrow B \rightarrow C \rightarrow \dots N \quad (1.588)$$

where nuclides A, B, and C are followed by a chain of a number N of decaying nuclides. Long decay chains of this type may be observed in the complex decay schemes of high-atomic-number natural radionuclides such as the ^{232}Th , ^{238}U , and ^{235}U natural decay chains illustrated previously in Figs. 1.8–1.10. These decay schemes are described by the general Eq. (1.588). However, within each of the natural decay schemes, illustrated in

Figs. 1.8–1.10, there are one or more branching decays of the type

For example, in Fig. 1.8, ^{212}Bi , within the ^{232}Th natural decay chain, is the parent of the two daughter nuclides ^{212}Po and ^{208}Tl . The half-life of the parent nuclide in branching decays is a function of the two decay processes and may be written as

$$t_{1/2} = 0.693/(\lambda_A + \lambda_B) \quad (1.589)$$

where λ_A and λ_B are the decay constants of the two separate decay processes.

XVIII. Radioactivity units and radionuclide mass

A. Units of radioactivity

The units used to define the level of radioactivity are written in terms of the number of atoms, N , disintegrating per unit of time, t . We can use Eq. (1.542), previously discussed in this chapter, to calculate the activity of any given mass of radionuclide. The equation, namely $\Delta N/\Delta t = \lambda N$, defines the proportionality between the rate of decay of a radionuclide and the number of atoms of the radionuclide in a sample. As an example, we may use Eq. (1.542) to calculate the activity of 1 g of ^{226}Ra as follows:

$$\Delta N/\Delta t = \lambda N \quad (1.590)$$

and

$$\Delta N/\Delta t = (0.693/t_{1/2})(N) \quad (1.591)$$

where $\lambda = 0.693/t_{1/2}$ was derived previously. If we take the half-life, $t_{1/2}$, of ^{226}Ra to be 1600 years and substitute for N , in the preceding equation, the number of atoms per mol of ^{226}Ra , we can write

$$\Delta N/\Delta t = (0.693/1600 \text{ y})(6.022 \times 10^{23} \text{ atoms}/226 \text{ g}) \quad (1.592)$$

where, according to Avogadro's number, there are 6.022×10^{23} atoms per gram mole of substance. If we now convert the half-life of ^{226}Ra from units of years to minutes, we can calculate the number of atoms of ^{226}Ra disintegrating per minute (dpm) per gram according to

$$\Delta N/\Delta t = \left[\frac{0.693}{(1600 \text{ y})(365 \text{ d/y})(24 \text{ h/d})(60 \text{ min/h})} \right] \times \left(\frac{6.022 \times 10^{23} \text{ atoms}}{226 \text{ g}} \right) \quad (1.593)$$

$$\begin{aligned} \Delta N/\Delta t &= \left(\frac{0.693}{8.41 \times 10^8 \text{ min}} \right) (2.665 \times 10^{21} \text{ atoms/g}) \\ &= 2.19 \times 10^{12} \text{ atoms per minute per gram} \end{aligned}$$

The activity of 1 g of ^{226}Ra is the basis of the unit of radioactivity known as the curie (Ci). One curie is almost equal to the activity of 1 g of ^{226}Ra or, by definition,

$$1 \text{ Ci} = 2.22 \times 10^{12} \text{ dpm} = 3.7 \times 10^{10} \text{ dps} \quad (1.594)$$

Therefore, 1 curie of activity or any multiple of the curie of any radionuclide defines the number of atoms disintegrating per unit of time in minutes or seconds.

The rate of decay in terms of time in seconds gives rise to the Système International d'Unités (SI) unit of activity, which is the Becquerel (Bq), where by definition

$$1 \text{ Bq} = 1 \text{ dps} \quad (1.595)$$

Therefore, we can interrelate the curie and Becquerel as follows:

$$1 \text{ Ci} = 2.22 \times 10^{12} \text{ dpm} = 3.7 \times 10^{10} \text{ dps} = 37 \text{ GBq} \quad (1.596)$$

Likewise, smaller units of the curie, namely the millicurie (mCi) and microcurie (μCi), may be interrelated with the becquerel as follows:

$$1 \text{ mCi} = 2.22 \times 10^9 \text{ dpm} = 3.7 \times 10^7 \text{ dps} = 37 \text{ MBq} \quad (1.597)$$

and

$$1 \mu\text{Ci} = 2.22 \times 10^6 \text{ dpm} = 3.7 \times 10^4 \text{ dps} = 37 \text{ kBq} \quad (1.598)$$

Another unit of activity recommended in the early 1960s by the International Union of Pure and Applied Physics, but less frequently used, is the rutherford, where 1 rutherford = 10^6 dps and 1 microrutherford would be equivalent to 1 dps or 1 Bq (Buttlar, 1968; Das and Ferbel, 1994).

B. Correlation of radioactivity and radionuclide mass

From Eq. (1.591) and calculations made in the previous Section XVIII.A, we can see that, for samples of a given level of activity, radionuclides of shorter half-life will contain a smaller number of radioactive atoms than radionuclides of longer half-life.

We can use Eq. (1.591) again to compare two radionuclides of relatively short and long half-lives to see the magnitude of the differences in radionuclide masses we would encounter for any given level of radioactivity. For example, we may take the radionuclide ^{32}P of 14.3-day half-life and the radionuclide ^{14}C of 5730-year half-life and calculate the activity per gram (e.g., dpm/g) and grams per curie (e.g., g/Ci) of each radionuclide for comparative purposes. These calculations are as follows.

1. ^{32}P , half-life = 14.3 days:

$$\begin{aligned} \Delta N/\Delta t &= (0.693/t_{1/2})(N) \\ &= \left[\frac{0.693}{(14.3 \text{ d})(24 \text{ h/d})(60 \text{ m/h})} \right] \left(\frac{6.022 \times 10^{23}}{32 \text{ g}} \right) \\ &= 6.32 \times 10^{17} \text{ dpm/g}^{32}\text{P} \end{aligned} \quad (1.599)$$

If, by definition, 1 curie = 2.22×10^{12} dpm, we can convert the above calculated activity per gram of ^{32}P to grams ^{32}P per curie as follows:

$$\begin{aligned} \frac{2.22 \times 10^{12} \text{ dpm/Ci}}{6.32 \times 10^{17} \text{ dpm/g } ^{32}\text{P}} &= 3.51 \times 10^{-6} \text{ g } ^{32}\text{P per Ci} \\ &= 3.51 \times 10^{-6} \text{ mg } ^{32}\text{P per mCi} \end{aligned} \quad (1.600)$$

2. ^{14}C , half-life = 5730 years:

$$\begin{aligned} \Delta N/\Delta t &= (0.693/t_{1/2})(N) \\ &= \left[\frac{0.693}{(5730 \text{ y})(365 \text{ d/y})(24 \text{ h/d})(60 \text{ m/h})} \right] \left(\frac{6.022 \times 10^{23}}{14 \text{ g}} \right) \\ &= 9.90 \times 10^{12} \text{ dpm/g } ^{14}\text{C} \end{aligned} \quad (1.601)$$

This activity per gram of ^{14}C is converted to grams ^{14}C per curie as follows:

$$\begin{aligned} \frac{2.22 \times 10^{12} \text{ dpm/Ci}}{9.90 \times 10^{12} \text{ dpm/g } ^{14}\text{C}} &= 0.224 \text{ g } ^{14}\text{C per Ci} \\ &= 0.224 \text{ mg } ^{14}\text{C per mCi} \end{aligned} \quad (1.602)$$

The calculated mass of ^{32}P in 1 curie of activity is almost a million fold less than the calculated mass of ^{14}C in 1 curie of activity. In general, research with radionuclides often involves the applications and analysis of lower levels of radioactivity in microcuries, and picocuries, and so on. The masses of radioactive atoms in the micro-, and picocurie levels of radioactivity are obviously much smaller than encountered at the curie or millicurie level. It is important, therefore, to be aware of the order of magnitude of radioactive atom masses involved, which leads us to the concept of “carrier-free” samples of radionuclides, discussed subsequently.

C. Carrier-free radionuclides

A carrier-free radionuclide sample is, by definition, a sample in which all of the atoms of a particular element consist of the radioactive isotope; that is, no stable isotope of that element is present. A stable isotope of the particular element is referred to as carrier. Carrier-free radioisotopes are commonly used in research in the bio-, medical, and chemical sciences (Kobayashi, 2016; Chakraborty et al., 2014; Abbas et al., 2012; Aizatskiy et al., 2011; Elmore, 2009; Lin and Chao, 2009; Li and Deutscher, 2008; Steinman and Mulholland, 2007; Buchtela, 2005; Horányi,

2004; Lamson et al., 1975). Often chemical compounds are labeled as carrier-free, but are not literally carrier-free. Commercial suppliers of radionuclides and radioisotope-labeled compounds used in research will specify the specific activity of the radionuclide, which is the activity in disintegration rate per mass, *e.g.*, dpm/g, dps/g, Ci/g, Bq/g, or Bq/mol, etc. Organic compounds labeled with ^{14}C or ^3H are generally not carrier-free, and such compounds labeled with high specific-activity radioisotopes may contain >80% ^{14}C and >50% tritium (Elmore, 2009). In the previous section of this chapter Eqs. (1.599) and (1.601) were used to calculate the specific activities of carrier-free radioisotopes ^{32}P and ^{14}C , respectively. It is important, therefore, to be aware of the masses of radioactive isotope in a given sample and any consequences that may be involved when very small quantities (*e.g.*, 10^{-6} to 10^{-12} g or smaller) of radioactive nuclide may be involved.

For example, in Section XVIII.B we calculated that there was only 3.51×10^{-6} g of ^{32}P per curie of radioactivity. A millicurie of carrier-free ^{32}P , which is a level of activity commonly procured from a radioisotope supplier, would contain only 3.51×10^{-9} g of ^{32}P and possibly a small percentage of stable phosphorus. It is a common procedure to dilute the carrier-free ^{32}P to the microcurie level of activity prior to working with the radionuclide, such as in tracer studies. One microcurie of carrier-free ^{32}P would contain only 3.51×10^{-12} g of phosphorus. Obviously, therefore, we should consider the consequences of working with such small amounts of phosphorus in solution. Over the past 50 years of working with carrier-free radioactive nuclides sources, the author has experienced the absorption of significant quantities of radionuclides onto the surface of glassware. If we consider the ionic characteristics of the chemical forms of certain radionuclide sources and the minute quantities these may possess in the carrier-free form, significant quantities of certain radionuclides could be lost from solution by absorption onto the surface of glassware, onto the surface of precipitates, and so forth. The addition of carrier (*i.e.*, stable isotope or organic compound without the radioisotope label) may be added to a high specific activity sample to facilitate radioisotope tracer studies. For example, when working with sources of high specific activity, if a particular experiment calls for the addition of carrier, the author will add carrier to the radionuclide source during the dilution procedure. If carrier is not desired, the procedure recommended by Chase and Rabinowitz (1968) can be utilized. For example, if it is desired to dilute a carrier-free solution of $\text{NaH}_2^{32}\text{PO}_4$ in a volumetric flask, it is best to treat the flask first with a 1% solution of NaH_2PO_4 prior to the addition of the carrier-free solution. The volumetric flask and any other glassware used in the dilution may be rinsed with the 1% NaH_2PO_4 . Alternatively, the volumetric flask may be filled with the 1% NaH_2PO_4 solution and allowed to sit for several hours.

The flask is then rinsed with deionized water to remove unabsorbed phosphorus. The flask can then be used to prepare a dilution of carrier-free or high specific activity $\text{NaH}_2^{32}\text{PO}_4$. It is important, however, to rinse the flask with a solution of the same chemical form as the radioisotope, if it is desirable to prevent contamination of the radioisotope with another chemical form.

Michael F. L'Annunziata

Michael F. L'Annunziata, Ph.D. is the Founding Editor and co-author of the *Handbook of Radioactivity Analysis* now in its Fourth Edition. His graduate thesis research at the University of Arizona, Tucson, AZ, USA, in the 1960s, financed by the then US Atomic Energy Commission, dealt with the analysis of ^{89}Sr and ^{90}Sr in the event of nuclear fallout. During 1970–71, he worked in the chemical industry (Amchem Products, Inc., Ambler, PA, USA) as ^{14}C -tracer chemist. Michael was then appointed Professor at the Postgraduate College, Chapingo, Mexico (1972–75) and Senior Research Scientist and graduate thesis advisor at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico City during (1975–77). Michael served as Scientific Officer in the

Department of Research and Isotopes and Department of Technical Co-operation of the International Atomic Energy Agency (IAEA) in Vienna, Austria during 1977–91 and Head of IAEA Fellowships and Training during 1987–91. Michael F. L'Annunziata was first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as the chemical pathway and origin of the various inositol phosphate stereoisomers in soils (Ph.D. dissertation, 1970, <https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum=>) and in 1975 (*SSSA Journal* 39(2), 377–379), and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–736, <https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733>). From 1977 to 2007, he served as IAEA Expert in peaceful applications of nuclear energy in over 50 countries of the world in Europe, Asia, Africa, Latin America and the Middle East. His book entitled *Radioactivity: Introduction and History*, First Edition, published by Elsevier, was on the Best Sellers List in Physics (*LibraryJournal Academic Newswire* in 2008), and his much expanded Second Edition entitled *Radioactivity: Introduction and History, From the Quantum to Quarks* published by Elsevier in 2016 (<https://www.sciencedirect.com/book/9780444634894/radioactivity>) was awarded an Honorary Mention in the 2017 PROSE AWARDS in the category of Chemistry & Physics.

Gas ionization detectors

I. Introduction: principles of radiation detection by gas ionization

When radiation penetrates matter, energy of the radiation is passed on to the matter and the radiation is shielded or even stopped. The atoms or molecules of matter are brought to a

state of higher energy, an excited state, or they are ionized if the energy of the radiation is high enough.

Alpha, beta, and gamma rays are known as ionizing radiation. On passing through a gas, these radiations create positive ions and electrons. Those charged particles either cause chemical reactions or recombine, finally producing

neutral specimens again. However, if an electric field is applied, the positive ions start to migrate to the cathode, and the electrons are attracted by the anode. If the field strength, the applied voltage per unit length, is high enough to prevent recombination during migration of the ions and electrons, all of them arrive at the electrodes. They are collected at the electrodes, and by the detection of this electric charge using a suitable electric circuit, an indication of the presence of ionizing radiation is given.

Gas ionization detectors consist of a gas volume in an enclosure that is either sealed or constructed in such a way as to permit a continuous flow of the filling gas. Within that gas volume, an electric field is applied across the electrodes. The outer wall frequently serves as one of the electrodes, the cathode, whereas a wire rod, a grid, or a plate in the middle of the gas volume serves as the anode.

Although there are many different variations in the design of gas ionization counters, a cylindrical system with a central wire or rod, called a “counting tube,” is very common. Many designs with different shapes and geometries have been realized. Some of them are suitable for a very wide range of useful applications, some were designed for a very special investigation, and others have been realized only to learn more about the operating principles of ionization detectors to improve the performance of this type of radiation detection device.

In this chapter, a selection is given from numerous developments in the field of gas ionization detectors. The principle of modern gas ionization detectors has been developed and used early in the “golden” era of radioactivity research in the early and mid-20th century. These detectors have made possible many discoveries, and their historic value cannot be overestimated. Although gas ionization detectors are still widely used in routine applications such as contamination monitors, α/β -gross counters, or dose rate instruments, it should be mentioned that radioactivity measurement methods today place emphasis mainly on radiation spectroscopy. Solid-state and scintillation detectors offer unique advantages in radiation spectroscopy and often outcompete classic gas ionization detector types/designs. The principle of gas ionization detectors also remains utilized in very special applications for high energy physics (Braccini et al., 2015; Siketic et al., 2015) or accelerator-based detectors, e.g., for accelerator mass spectrometry (AMS) facilities (Nadeau et al., 2015; Martschini et al., 2019; Suter et al., 2007; Zondervan et al., 2015) or in support of Mössbauer spectroscopy (Velasquez and Arroyave, 2014), in addition to the direct analysis of a radionuclide, where gas ionization detectors are increasingly replaced by other methods.

Many interesting developments have been made over the past decade or more in the field of tissue-equivalent proportional counter (TEPC), position-sensitive gaseous detectors such as the microstrip gas chamber (MSGC) and

gas electron multiplier (GEM) detectors with good localization properties. These detectors are often referred to as micropattern gas detectors (MPGDs) because of their accurate position accuracy.

Although gas ionization detectors are extremely useful, problems and limitations have to be faced and careful planning of experiments to recognize and deal with those limitations is extremely important (Bateman et al., 1994). The suitability of gas ionization detector systems for a given kind and energy of radiation depends on the type (composition, pressure) of filling gas to be ionized; the applied field strength; the size, shape, and geometry of the detector volume and electrodes; and the type and thickness of the construction material that surrounds the detector gas volume. Also, environmental factors such as temperature should not be entirely ignored. Last but not least, the design of the electric circuit that handles the output signal plays a very important role.

The geometric design of a detector also depends mainly on its application. The size and shape have to be chosen appropriately if small or large areas have to be surveyed by the detector; if it has to be submerged in a liquid; or if, by use of a suitably thin wall, alpha and low-energy beta particles are permitted to enter the detector volume; finally, if radiation energy has to be determined or if the localization or distribution of the radioactive material in a given specimen is of primary importance.

There are three kinds of gas-filled detectors: ion chambers, proportional counters, and Geiger–Müller (GM) counters. They differ mainly in the strength of the electric field applied between their electrodes. Their common and different characteristics are discussed in this chapter.

II. Characterization of gas ionization detectors

A. Ion chambers

Gas ionization detectors can be characterized by the effects created by different field strengths between the charge-collecting electrodes. The relationship between the pulse size produced and the potential applied across the electrodes of a gas ionization detector is shown in Fig. 2.1. The pulse size depends on the field strength and also on the type of radiation that enters the detector volume and creates ions.

At low field strength, many slowly migrating ion pairs still have the opportunity to recombine. This recombination region is not used for radioactivity detectors. As more voltage is applied, more ions and electrons produced by the ionizing radiation are collected at the electrode. Finally, a field strength is reached at which the now rapidly migrating ions do not have a chance to recombine. Thus, a saturation region is reached where all the ions produced directly by

FIGURE 2.1 Relationship between the pulse size produced and the potential applied across the electrodes of a gas ionization chamber exposed to alpha, beta, and gamma radiation. Various regions are labeled by Roman numerals as follows: region I, recombination region; region II, simple ionization region; region III, proportional region; region IV, limited proportional region; region V, Geiger–Müller region; region VI, continuous discharge region. From *L'Annunziata (1987)*, reprinted with permission from Elsevier © 1987.

the radiation event, the primary ions, are collected at the electrodes. A further increase of field strength cannot attract more ions, because all of them have already been collected. Ion chambers operate in this region. The amount of charge collected at the electrodes directly shows the ionization effects of the incident radiation.

The design of ion chambers can be tailored for a special type of radiation, and information about radiation energies can be provided. Since the output signal is directly related to the ionization effect, ion chambers are very useful in radiation dosimetry.

Alpha particles produce a great amount of ions along a short path length of travel (high linear energy transfer, LET). They are easily detected, because they provide a high output signal. Beta particles and gamma rays produce a very low signal, and rather sophisticated circuits are sometimes needed for amplification of such low-voltage signals.

The following short calculation provides an example of the signal requirement of electronic circuits combined with ion chambers:

Let us assume that a radioactive source emits one alpha particle per second (activity 1 Bq) with an energy of 5 MeV, and all the energy of the alpha particles is deposited in the gas volume (air) of the counting chamber. The average ionization energy of that gas is 32.5 eV/ion pair. The rate of ionpair formation in the gas is calculated as

$$\frac{5 \text{ MeV/alpha particle}}{32.5 \text{ eV/ion pair}} = 1.5 \times 10^5 \text{ ion pairs/alpha particle}$$

Thus, 1.5×10^5 ion pairs or 1.5×10^5 electrons are produced by one alpha particle per second, corresponding to an electric charge of

$$\begin{aligned} (1.5 \times 10^5 \text{ electrons/s})(1.6 \times 10^{-19} \text{ coulomb}) &= 2.4 \times 10^{-14} \text{ C/s} \\ &= 2.4 \times 10^{-14} \text{ A.} \end{aligned}$$

B. Proportional counters

If the field strength is increased further, additional ionization starts to occur, because of the higher kinetic energy of the migrating primary ions. These primary ions, now being accelerated to a higher energy than the ionization energy of the detector gas, produce secondary ions by impact. With increasing field strength, a great number of additionally produced ions are accelerated, the number still being proportional to the number of primary ions. This gas ionization detector region (see Fig. 2.1) is called the proportional region. In that region, radiation with different abilities to produce primary ions (alpha, beta, or gamma radiation) can still be discriminated, or they are registered by “gross counting” without separation. Also, radiation of the same type but with different energies can be discriminated (Garcia-Leon et al., 1984).

With further gas multiplication due to higher field strength, some nonlinearities will be observed. This effect marks the beginning of the limited proportional region.

C. Geiger–Müller counters

As the field strength is increased further, excitations of atoms and molecules are observed that, by the emission of ultraviolet (UV) light, can start additional ionization processes. In this region, referred to as the GM region, the total number of ions produced is independent of the number of primary ions and, therefore, also independent of the type and energy of radiation. A further increase of the field strength causes a continuous discharge (see Fig. 2.1).

In the GM region, all primary ionization effects produce the same maximum response in the detector. GM counting tubes operate in this region and thus provide no direct information about the type and energy of radiation. Information related to the type and energy of radiation can be provided only by observing shielding effects related to this radiation. Alpha particles are stopped by a thin layer of matter, beta particles show a maximum range in penetrating a shielding material before they enter the detector, and photons show a somehow logarithmic decrease in intensity with increasing thickness of the material. In the earlier days of radiation measurements, such experimental setups were frequently used for rough determination of radiation type and energy (Chase and Rabinowitz, 1967).

III. Definition of operating characteristics of gas ionization detectors

In the case of ionization detectors, as well as other detector types, some operating parameters are important for characterizing their capabilities: efficiency, resolution, and resolving time of the detector. For some special detector designs, such as position-sensitive detectors, the capability of determining precise information regarding the spatial distribution of particles or photons entering the detector volume is of importance.

A. Counting efficiency

The counting efficiency relates the number of particles or photons emitted by a radiation source to the number of interactions registered by the counting system. This is usually called the absolute efficiency.

Absolute efficiency

$$= \frac{\text{number of signals recorded by the detector}}{\text{number of particles or photons emitted by the source}} \quad (2.1)$$

All particles striking the detector volume may not be registered. Therefore, another kind of efficiency is used, which is called the intrinsic efficiency, defined as:

Intrinsic Efficiency

$$= \frac{\text{number of signals recorded by the detector}}{\text{number of particles or photons striking the detector}} \quad (2.2)$$

With ionization detectors, the absolute efficiency of charged particles can go up to nearly 100%. For gamma rays and X-rays, the efficiency is frequently much lower, because of the relatively poor interaction of the radiation with the gaseous detection volume of the ionization counters. Therefore, a higher density of the gaseous volume can sometimes be obtained by using a counting gas of high atomic number (xenon) and by increasing the gas pressure inside the ionization detector.

B. Energy resolution

The energy resolution characterizes the ability of the detector to discriminate between two types of radiation with energies that are different but rather close to each other. A characteristic figure is given by the full width at half-maximum (FWHM), the width of a peak in a radiation energy spectrum display halfway between the baseline and top of the peak. If E_0 is the energy at the peak maximum and ΔE is the FWHM, the resolution is given as

$$R = \Delta E/E_0, \quad (2.3)$$

which can also be recorded as a percentage.

The value of the FWHM is a measure of the resolution. The smaller its value for a given energy line, the greater the potential of a detector to provide individual information related to two radiations of approximate energy. Because of the statistical nature of any interaction of radiation with matter, resolution never can be perfect. In addition, electronic noise contributes to the deterioration of resolution.

Not all detectors can provide information about radiation energy.

C. Resolving time

The resolving time refers to the minimum time interval a detector needs to recover from the interaction with a radiation event and be able to register a following event. For many counting devices, it is not the resolving time of the detector but the resolving time of the electronic system (e.g., the data handling and processing steps) that sets the limits for dealing with high count rates. Counting losses induced by resolving time of a counting system can be a limiting factor in measurements. Several methods for resolving time determination and correction are presented

in the literature (Gardner and Liu, 1997; Lee and Gardner, 2000; Vinagre and Conde, 2001).

D. Localization

Some detector designs can give information about the entrance region of particles or photons into the detector or about the distribution of radioactive material in a sample. They can give an image of a radioactive specimen by showing the longitudinal or even two-dimensional (2D) distribution of radioactivity.

Position-sensitive detectors based on proportional counting (PC) systems were developed by Nobel Laureate Georges Charpak in the 1960s, and these played a decisive role in many discoveries in particle physics. These types of detectors, providing the opportunity of “nuclear imaging,” are nowadays very important also in many experiments in biology and medicine (Charpak, 1970; Charpak and Sauli, 1978; Geltenbort, 1994; Nickles et al., 2002; Shekhtman, 2004; van der Graaf, 2011; see also Chapter 9 of Volume 2).

IV. Ion chambers

Ionization chambers can be considered as one of the simplest devices for radioactivity measurements. They were used in the very early days of research dealing with the detection of ionizing radiation. However, even today, new designs for special purposes are being developed.

The chamber is made of a nonporous material, the electrodes are usually parallel plates, and the filling gas may have a pressure from a few tenths up to some tens of bars. When ionizing radiation passes through the gas, ion pairs are created. If a sufficiently high-voltage gradient prevents recombination, these ions drift toward the electrodes. The output signal registered by the electric circuit can be a flow of current, a charge or voltage pulse, or a total collected amount of electrical charge. Thus, three types of ion chambers are known: ion chambers operating in the current mode, ion chambers operating in the pulse mode, and electrostatic or charge integration ion chambers.

With ion chambers operating in the current mode, an electrical current flow is registered, which is initiated by the electrons and ions collected at the electrodes during the time of observation. With the pulse mode type of chamber, single signals, such as voltage pulses created by the ions arriving at the electrodes from a single ionization event, are registered by applying suitable electronic amplification circuits. Electrostatic or charge integration ion chambers are similar to electroscopes. A static electric charge is given to a system consisting of a thin foil or fiber that is suspended parallel to a solid support or to a second fiber or foil. Because of the repulsion of like charges, the fiber or foil will be bent to stay at some distance away from the support of the second foil or fiber. Ionizing radiation

gradually discharges the system, and this causes the foils or fibers to move back to their original position.

Because of their simple construction and relatively low cost, ion chambers still have many applications. Information related to the type and energy of radiation can be obtained, and the ion chambers can be designed for the detection of low as well as high radioactivity levels. Many kinds of gases can be used to fill the detector volumes.

A. Operating modes of ion chambers

1. Ion chambers operating in the current mode

One of the most important applications of an ion chamber in everyday radiochemistry is as a portable survey instrument for radiation monitoring purposes. A volume of counting gas, mostly air, is enclosed within walls made of metal-lined plastic or aluminum. These types of walls are “air equivalent.” Thus, accurate measurements can be made for gamma radiation if the energy of the gamma radiation is not only high enough to penetrate the walls without significant attenuation but also low enough to establish electronic equilibrium in these walls. Usually, for gamma radiation with energy lower than 50 keV, attenuation effects have a considerable impact on the efficiency of such detectors. With these instruments, the saturated ion current is measured by using an electrometer circuit that is battery powered. Converting the DC signal of an ion chamber to an AC signal provides a more stable amplification, such as with the vibrating-reed electrometer or dynamic capacitor.

2. Charge integration ionization chambers

A type of ionization counter, which is used frequently, is operated on the charge integration principle. This type of ionization chamber is charged initially. The drop in charge during exposure to a radiation field can be measured using a charger—reader mechanism and provides information regarding the dose from the radiation field to which the ionization chamber was exposed.

A familiar device is the ionization pocket chamber. These ionization chambers are also charged initially, but they are equipped with a small integral quartz fiber electroscope. An initial charging sets the scale of the electroscope to zero. The total integrated dose can be read periodically by observing the migration of the quartz fiber. This can be done very simply by optical observation, just by holding the pen-shaped pocket chamber up to a source of light and looking at the scale of the fiber electroscope through a small integrated magnifying glass. The accuracy and sensitivity of these devices are limited by leakage current across the insulator material of the ionization chamber.

3. Pulse mode ion chambers

Like other ionization detectors, such as proportional counters and GM tubes, ionization counters can also be used in pulse mode, in which each separate alpha particle, beta particle, or gamma quantum creates a distinguishable pulse signal. Advantages of pulse mode ionization chambers are their sensitivity and the ability to measure the energy of radiation and thus to be applicable in radiation spectroscopy. Today, such pulse mode ionization chambers have been mostly replaced by semiconductor detectors. Nevertheless, for special applications, such as neutron counting facilities, such chambers are still in use.

Pulse amplitudes from all types of ion chambers are relatively small. In theory, the maximum signal amplitude accumulated from the ion pairs produced by the interaction of, for example, an alpha particle in air along its track within the chamber is of the order of 10^{-5} V. Such a signal can be processed, but rather sophisticated electronic systems are required. Pulses from a single photon interaction are a hundred times smaller, and successful and accurate amplification is difficult and at times even impossible. Internal amplification within the detector volume, which is described in the section of this chapter dealing with PC tubes, helps to overcome these problems.

In any case, it has to be taken into account that for some filling gases, such as propane, the energy response to beams of heavy ions depends also on the atomic number of the observed ions and, as a consequence, deficits of the pulse heights are sometimes considerable. This is not only due to ion energy loss via elastic collisions in the filling gas (e.g., propane) but most probably also due to electron-ion recombination within the dense ionization column created by the incident ion beam. This may be of importance for many types of gas ionization detectors used for the spectroscopy of ion beams with higher atomic mass (Weijers et al., 2002).

B. Examples and applications of ion chambers

1. Calibration of radioactive sources

Standardization of gamma-emitting radionuclides (e.g., in nuclear medicine applications) is frequently carried out by comparing the ion current from a material with unknown activity with the ion current produced by a standard material of the same radionuclide (see also Chapter 7 of Volume 2). In that way, one takes advantage of the excellent long-term stability and reproducibility of the ion current produced from the same type of radiation. When operating in the saturation region, the current depends only on the geometry and the activity of a given radioactive material. Chamber volumes can be up to several 1000 cm^3 , and the walls are made of solid materials, such as steel or brass. The collecting electrode in the inner part is made of a

thin metal foil to avoid as much as possible attenuation of the radiation. An example is the production of fluorine-18 in clinical settings, where ion chambers are used as calibrators for the activity determination (Wurdiyanto et al., 2012). Using ion chambers as absolute methods of activity analysis allows for the (re)determination of half-lives, as shown by Rezende et al. (2012).

High sensitivity can be obtained if pressurized gas is used for the ionization chamber. Of course, this will cause the background current to increase but not be as great as that produced by radiation sources. Pressurized chambers are used for the measurement of gamma-emitting nuclides.

The ion chamber region is usually reached by adjusting the voltage for the electrodes. Saito and Suzuki (1999) used a multielectrode ion chamber for measuring absolute fluence rate of X-rays. They adjusted the ion chamber region by varying the gas pressure at a given voltage.

2. Measurement of gases

Many radioactive gases can be incorporated into the filling gas of ionization detectors. Also, in ionization chambers, a gas can be sampled on a continuous flow-through basis. The ionization current produced by a gas can be calculated simply and straightforwardly only if the radiation is fully absorbed in the gas volume of the ionization chamber. These types of flow-through ionization chambers are used for monitoring air that contains small amounts of radioactive gas. In any case, a number of difficulties arise if the air is subject to atmospheric changes. Such perturbations of air properties can be due to the content of aerosols, moisture, ions, etc. (Jalbert and Hiebert, 1971; Mustafa and Mahesh, 1978; Waters, 1974).

Some interesting examples of flow-through ionization chambers are those utilized in the activity measurements of ^{76}Kr and ^{85}Kr (Cooper et al., 2004; Yunoki et al., 2010). The flow-through gaseous radiochemical method was demonstrated by Lebedev et al. (2006) as a useful method for monitoring the release of radioactive inert gas molecules formed as a result of nuclear reactions. When a radioactive gas isotope is released from an ampoule-loaded target material, the radioactive gas, which is released, is transported by a carrier gas into a gas counter for flow-through measurements. Lebedev et al. (2006) demonstrated that the activity I in disintegrations per second (dps) of radioactive inert gas in the counter was related to the flux of ionizing radiation (e.g., proton beam)

$$I = \frac{V_C P_C N_0 \sigma \phi}{1.44 t L} \quad (2.4)$$

where V_C is the active volume of the gaseous counting chamber in cm^3 , P_C is the pressure of the counter in physical atmospheres, N_0 is the number of atoms of target material, t is the half-life of the radioactive inert gas in

seconds, σ is the cross section of a nuclear reaction for the formation of a radioactive isotope of an inert gas averaging in a spectrum of ionizing radiation, ϕ is the flux of ionizing radiation in cm^2/s , and L is the consumption of transport gas in cm^3/s .

Yakushev et al. (2004) used a flow-through ionization chamber as a valuable tool in the identification and measurement of the decay properties of element 112. An Ar-CH_4 mixture was used as the carrier and counting gas used to transport element 112 into an ionization chamber 5000 cm^3 in volume. The IUPAC (2010) officially approved the name copernicium, with symbol Cn, for the element with $Z = 112$ on February 19, 2010.

The change of ionization current due to smoke particles is the operational basis for smoke detectors. In such smoke detectors, a built-in alpha source provides a constant ionization current under normal atmospheric conditions. A twin chamber with enclosed air without flow-through capability is used for the reference ion current.

The design of twin chambers can also be used for background compensation. A twin chamber filled with pure air records the background without flow-through of the air to be monitored. In that way, compensation for a changing background can easily be achieved, for example, in case of a changing gamma-ray background during air monitoring.

Current mode ion chambers have been very useful in the measurement of radon. The background is low, and the counting efficiency is high (practically 100%). Experiments have also been reported to provide data for the radon content of groundwater by placing an ion chamber together with a known amount of water for 3 hours in a leak proof container. The amount of radon in the air can be related to the concentration of radon in the water sample (Amrani et al., 2000).

Tritium measurements using ion chambers present a problem if elastomeric seals are applied. Those elastomeric materials are irreversibly contaminated, and the background of the ion chamber is increased. Colmenares (1974) constructed a chamber using ultra high-vacuum metallic seals, a metal construction of negligible water adsorption capacity and sapphire as insulator material. The chamber is bakeable up to 450°C , and the contamination problems are avoided.

3. Frisch grid ion chambers

Because of the slow ion mobility in gases and the slow drift of ions at the applied field strength in ion chambers, the use of pulse-type ion chambers is restricted to low pulse rates if signals are desired that are related accurately to the original charge of ions and electrons generated by the radiation. Pulse-shaping circuits designed for low frequencies also make these systems rather susceptible to interference from microphone signals produced by mechanical vibrations.

Therefore, pulse-type ion chambers are frequently operated in such a mode that they sense the collected electrons only, not the created positive ions, which migrate much slower than the electrons. In that case, the pulse amplitude is related to the drift of the electrons only. The signal therefore has a much faster rise time, and higher counting rates can be successfully registered. However, since the amplitude of the signal now depends also on the position of the interaction within the ion chamber gas, there is no well-defined information related to the total number of ions created, which means that no information about the energy of the radiation is provided. However, methods have been developed to overcome the problem of the dependence of the pulse amplitude on the position of the interaction within the chamber. The region of the chamber volume is divided into two parts by a grid. This grid is maintained at a potential between those of the cathode and anode. The mechanical construction of the grid should allow electrons to pass through; it should be as “transparent” to electrons as possible. By suitable positioning of the radiation source outside the chamber or by effective collimation of its radiation, the emitted particles or rays interact with the gas in the ion chamber in a well-defined region between this grid and the negative electrode of the chamber. Thus, positive ions simply migrate to the cathode. Electrons are attracted by the transparent grid initially but are further accelerated toward the anode, which is at a much more positive potential than the transparent grid.

Electronic circuits are designed in such a way that, with the electron migration from grid to anode, the voltage between grid and anode drops and a signal is created that depends only on the electron drift and not on the migration of both electrons and cations. Therefore, the slow rise related to ion drift is eliminated. Also, since all electrons are accelerated by the same potential difference, the amplitude of the pulse is independent of the position of the interaction. The amplitude is proportional only to the number of ion pairs, the number of electrons produced along the path of the interacting particle or ray. This type of ion chamber is called a Frisch grid chamber after Otto Robert Frisch who designed the detector (Knoll, 1989). Such Frisch grid chambers have been extremely useful in studies dealing with particle physics.

Gridded ionization chambers are ideally suitable for studies related to nuclear fission, because such detectors not only have a practically 100% detection efficiency, but they can also provide information about fission fragment properties such as energy, mass, charge, and emission angle. Tutin et al. (2001) designed an efficient device for such investigations, consisting of a combination of two parallel plate ionization chambers with grids and a common central cathode plate (Fig. 2.2). The central aluminum disk cathode has a hole of 78 mm diameter where two thin aluminum foils, covered with uniform layers of thorium-232 or

FIGURE 2.2 Schematic picture of a parallel gridded ionization chamber with one common cathode. From *Tutin et al. (2001)*, reprinted with permission from Elsevier © 2001.

uranium-238 (fissile upon high-energy neutron capture), are mounted back to back. The grids are mounted on aluminum annular disks with an inner diameter of 160 mm and consist of tungsten wires 0.1 mm in diameter spaced by 1.25 mm. The chamber is filled with 90% argon and 10% methane at atmospheric pressure without continuous gas flow. Fission fragments emitted from the cathode are stopped in the space between the cathode and anode. Free electrons drift to the anode, whereas the slow ions can be treated as being static for a short interval of time. At the end of the electron drift, the collected charges can be related to the emission angle of the fission fragments. In a continuation of these studies, a similar multisection Frisch-gridded ionization chamber was designed by *Ryzhov et al. (2006)* to measure neutron-induced fission cross section of various radionuclides.

There are also applications in the life sciences. *Lohmann et al. (1998, 2003)* used a detector system of the Frisch grid chamber type in angiography for the determination of contrast agent (iodine) by “dichromography.” According to this method, two images with monochromatic X-rays just below and above the absorption edge of the contrast agent are simultaneously obtained and subtracted. Although monochromatic X-rays having suitable intensity to visualize arteries of 1 mm diameter are only provided by synchrotron radiation, the authors concluded that the requirements for application of intravenous coronary angiography are fulfilled with the Frisch-gridded detector.

4. Radiation spectroscopy with ion chambers

Pulse-type ion chambers have attracted some interest again, after years, during which most of the interest was focused

on semiconductor detectors. Ion chambers can be designed and constructed in any shape and size, and for charged particles, the pressure can be tailored to an optimum for a desired stopping power (*Fulbright, 1979*). Also, there is practically no deterioration or degradation due to irradiation, which may adversely affect the application of ion chambers in radiation fields, and ion chambers can be fabricated by using available workshop facilities without high expenses.

Pulse-type ion chambers have been applied in low-level alpha measurements, and good resolutions have been obtained that may even be comparable with the resolution of semiconductor detectors (*Gruhn et al., 1982; Bertolini, 1984; Hoetzel and Winkler, 1984; Shenhav and Stelzer, 1985; Kotte et al., 1987; Nowack, 1987; Domnikov et al., 2001; Beck et al., 2009; Kada et al., 2010*).

It was demonstrated that additional information regarding charged particle properties such as atomic number and charge state can be obtained by designing a chamber in such a way that particle pathways are parallel instead of perpendicular to the direction of the electric field. Thus, the drift time of electrons to the grid will be different for electrons created at the beginning of the track and those from the end of the path. The shape of the output pulse will therefore reflect the distribution of ion pairs along the track according to what is called a Bragg curve. With that technique, known as Bragg curve spectrometry, additional information such as atomic number and particle charge can be obtained. For that, a detailed analysis of the pulse shape is necessary.

Hagiwara et al. (2008) developed a method to extend the energy acceptance of a Bragg curve counter (BCC) at the high-energy end. They applied this method to the measurement of lithium and beryllium ions emitted from carbon in the course of the bombardment by 70 MeV protons. A schematic diagram of the BCC and its signal processing scheme, devised by *Hagiwara et al. (2008)*, is illustrated in *Fig. 2.3*. A Bragg curve derived from the ionization intensity produced by an incident particle is illustrated in the figure by the shaded area above the particle path. From the Bragg curve, the Bragg peak signal PB and energy signal PE are obtained by the use of two pulse-shaping amplifiers with short (0.4 μ s) and long (6 μ s) shaping times, respectively. The long shaping time is longer than the drift time of the free electrons traveling from the cathode to the grid. A charge-sensitive preamplifier (PA) integrates and amplifies the original signals from the BCC before reaching the pulse-shaping amplifiers. *Fig. 2.4* illustrates the 2D spectrum obtained when plotting PB versus PE (*i.e.*, Bragg peak pulse height vs. energy) illustrating clear particle discrimination for particles that deposit all of their energy within the BCC (left-hand spectrum); however, interferences are observed due to high-energy particles capable of passing through the BCC

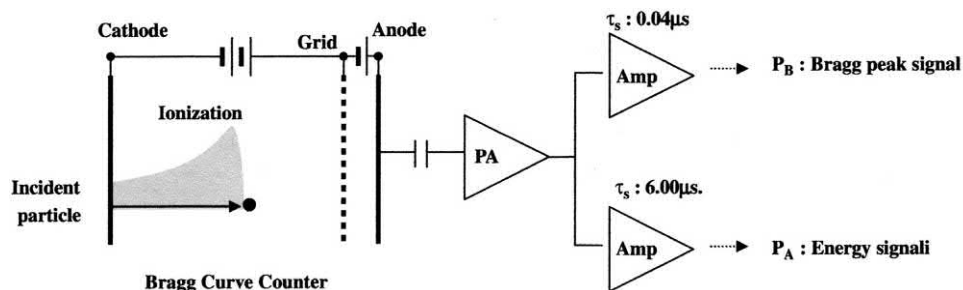

FIGURE 2.3 Schematic diagram of the electronic circuit to derive the incident energy and Bragg peak information from the anode of a BCC. The short and long shaping times are set to be 0.04 and 0.6 μ s, respectively. From Hagiwara et al. (2008), reprinted with permission from Elsevier © 2008.

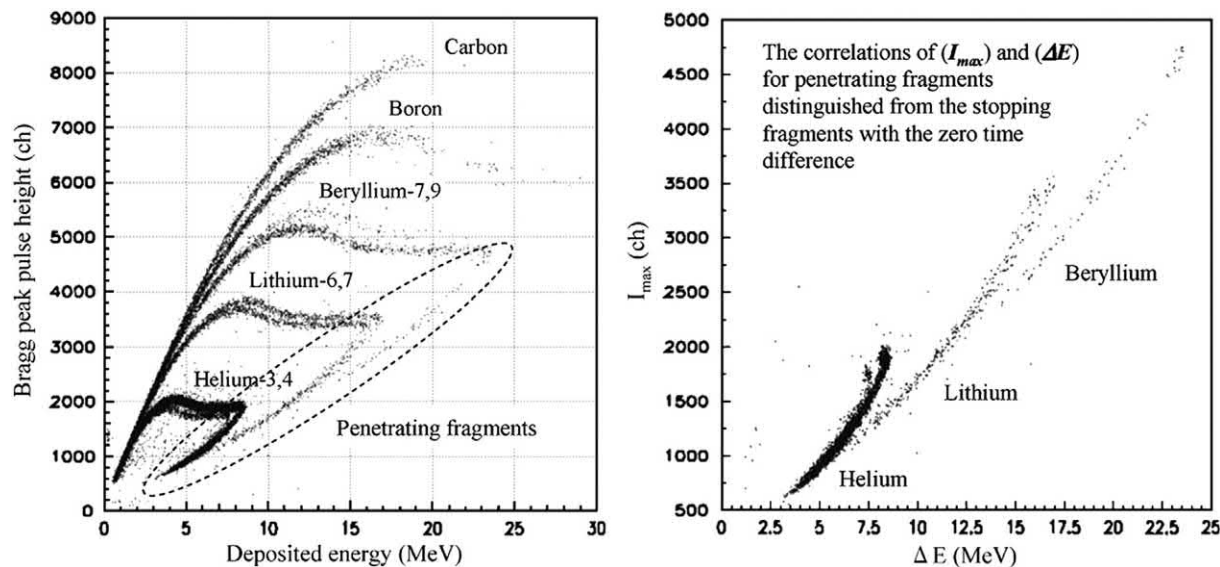

FIGURE 2.4 The two-dimensional spectrum of deposited energy versus Bragg peak of fragments emitted from a 4- μ m-thick polypropylene sample at 30 degrees by 70-MeV proton-induced reaction. The dotted circle indicates the events of the penetrating fragments (i.e., those that pass through the BCC). The left-hand figure shows all events. The right-hand figure shows the correlations of I_{\max} and ΔE for penetrating fragments from the fragments that stop within the active volume of the BCC. From Hagiwara et al. (2008), reprinted with permission from Elsevier © 2008.

(Fig. 2.4, dotted circle). Hagiwara et al. (2008) distinguished the high-energy particles (i.e., fragments) that penetrated the BCC counter by plotting I_{\max} (i.e., maximum ionization) against deposited energy (ΔE) as illustrated in Fig. 2.4.

Khriachkov et al. (2000) used an alpha-particle spectrometer based on a Frisch grid chamber for studies of (n, α) -reactions induced by fast neutrons. Energy and emission angle of alphaparticles could be determined.

Combinations of ionization chambers with position-sensitive ionization detector devices were used by Menk et al. (2000) for small-angle X-ray scattering investigations. These systems are intended to be used for experiments in some European synchrotron centers.

Nariyama et al. (2004) developed a portable free-air ionization chamber for measurements of synchrotron radiation up to 150 keV. For high-energy X-rays, the plate separation becomes rather large, and therefore, the authors developed a special design to overcome that difficulty.

5. Electret detectors

Electret types of ion chambers make use of the drop of surface voltage on a plastic material. The plastic specimen is a dielectric material, usually Teflon, which is quasi-permanently charged. It is called an electret and usually has the shape of a disk about 1 mm thick and 10 mm in diameter. Electrets are prepared by being heated and simultaneously exposed to an electric field. In this process, many dipoles in the material become oriented in a preferred direction. After heating, the material is “frozen,” which keeps the position of its electric dipoles for a long period of time. A voltage gradient of several hundred volts can be maintained between the surfaces of the electret disk.

One surface of the electret is kept in contact with the wall of an ion chamber, which builds up an electric field in the chamber. Ionizing radiation causes a decrease of charge in that system, resulting in a partial neutralization of the charge at the electret. Measurement of the electret voltage

FIGURE 2.5 Scheme of an electret ion chamber for the measurement of radon flux from soil. The radon diffuses through the Tyvek window and into the electret ion chamber. The radon activity (Bq/m^3) is proportional to the potential drop due to radon decay on the positively charged electret located at the top of the ion chamber. From Grossi et al. (2012), reprinted with permission from Elsevier © 2012.

difference before and after irradiation provides a measurement of the amount of ionization. The system has to be calibrated and can be used for the determination of environmental radiation doses.

Amrani et al. (2000) used an electret ion chamber for the determination of the radon content of groundwater. They put an electret ion chamber together with a known amount of water in a leak proof container. The reading of the electret ion chamber provides the radon content in the air, and this value could be related to the concentration of radon in the water sample. Electret detectors are commonly used as radon monitors in the environment, including water and soil (Hamlat et al., 2003; Kitto et al., 2008, and Grossi et al., 2011, 2012), construction materials (Lavi et al., 2009), and in the public living and workplace (Denman et al., 2005; Righi et al., 2005; Papachristodoulou et al., 2010; Clouvas et al., 2011, and Okejiet al., 2012). The electret ion chamber is simple in design. An example of an electret detector used for the measurement of radon flux from soil is illustrated in Fig. 2.5. Radon and thoron gas from the soil surface diffuse through the Tyvek filter into a buffer zone. Tyvek is a brand of flashspun high-density polyethylene fibers, impermeable to water, but permeable to gases. The radon and thoron enter into a buffer zone specifically designed to reduce any thoron that may be present (Kotrappa and Steck, 2009; Grossi et al., 2012).

6. Fission chambers

For power monitoring purposes in nuclear reactors, miniaturized ion chambers have been constructed that are equipped with stainless steel walls lined with highly enriched uranium. Argon at a pressure of several bars is mainly used as a filling gas. Because of the high pressure, the dimensions of the detector volume can easily be kept larger than the range of the fission products created by the uranium-235 (n,f) reaction.

Long-term operation causes problems, because of the burnup of the fissile material (Böck and Balcar, 1975). To

compensate for this, the so-called regenerative chambers have been designed. These chambers contain a combination of fertile (^{238}U , ^{234}U) and fissile (^{235}U , ^{239}Pu) material as a lining of the inner detector walls. Fission chambers may also show a memory effect after a prolonged period of operation in a reactor core. This is due to a buildup of fission products in the detector volume. Because of the fission product activity, some residual ionization still can be measured even without exposure to a flux of neutrons.

Because of the scarcity of conventional enriched uranium-235 material, fission detectors have been developed on the basis of uranium-233. Fig. 2.6 shows a schematic diagram of the uranium-233 fission chamber designed by Prasad and Balagi (1996). The chambers were filled with argon (97%) and nitrogen (3%) at 1 bar. Low and high sensitivities were obtained by using two kinds of electrode coatings. Low-sensitivity counters have a uranium-233 coating on the anode, and high-sensitivity counters have a coating on the cathode. The main disadvantage of uranium-233 is its high specific alpha activity. This can cause pileup effects and spurious counts, if the system is applied in pulse mode operation.

Filliatre et al. (2008, 2009) found ^{242}Pu to be the best suited fissile deposit for the fission chamber online measurement of the fast component of a high neutron flux ($\sim 10^{14} \text{ n/cm}^2/\text{s}$) with significant thermal component. This was confirmed by Cabellos et al. (2010) with tests on the use of various fissionable materials in fission chambers. They found fission chambers with deposits of ^{242}Pu to be stable with fluences as high as 10^{22} n/cm^2 while satisfying high sensitivity coefficients to fast neutrons.

A fission chamber of 3 mm diameter and $300 \mu\text{g}$ of ^{238}U deposit with argon filling gas at 5 atm pressure was used by Rapisarda et al. (2011) for the detection of fast neutrons in mixed neutron-gamma fields. The fission chamber was surrounded with a gadolinium (Gd) screen to

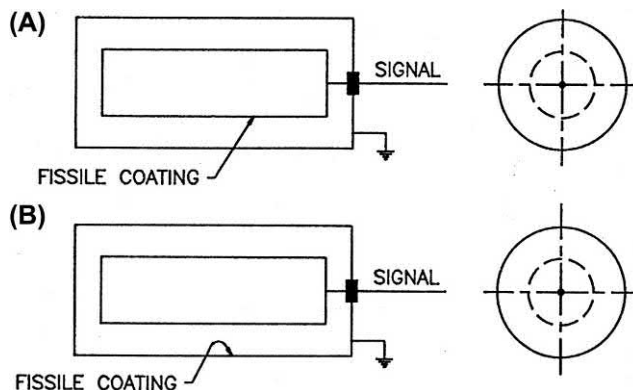

FIGURE 2.6 Schematic diagram of uranium-233 fission chambers. Low-sensitivity counters have a uranium-233 coating on the anode (A), and high-sensitivity counters have a coating on the cathode (B). The electrode spacings are 4 mm. From Prasad and Balagi (1996), reprinted with permission from American Institute of Physics © 1996.

FIGURE 2.7 Calculated neutron spectra from a ^{238}U fission chamber with and without a Gd screen. From *Rapisarda et al. (2011)*, reprinted with permission from Elsevier © 2011.

cut off the thermal neutron component. The typical calculated neutron spectrum at the position of the most sensitive part of the fission chamber with and without the Gd screen is illustrated in Fig. 2.7. The thermal neutron component is completely cut out by the Gd; however, the epithermal part (1 eV to 100 keV) is almost unaffected. The Gd screen obviously has a defined lifetime, due to complete burnup of the ^{155}Gd and ^{157}Gd isotopes, which are completely consumed for a 0.6-mm-thick Gd foil at a thermal neutron fluence of $2 \times 10^{21} \text{ n/cm}^2$.

Transmutation of transuranium elements by fast neutron-induced fission could be a promising way to reduce the long-term radiotoxicity of these materials in radioactive waste. To measure online, the fission rate of actinide targets a new generation of microfission chambers that have been constructed by *Fadil et al. (2002)* for the use at the high flux reactor in Grenoble at a flux density of $10^{15} \text{ cm}^2/\text{s}$. To avoid pulse pileup, the chamber has to operate in current mode. Helium, a gas with high ionization potential, is used under such high flux conditions. Consequently, the problem of gas leakage during operation of the chamber at high temperatures has to be considered.

V. Proportional gas ionization detectors

Proportional gas ionization detectors operate at a higher voltage gradient than ion chambers. The primary ion pairs created by ionizing radiation are accelerated much more and acquire a high kinetic energy. By colliding with other atoms or molecules along their drift, these ions and electrons induce secondary ionization. More ions and electrons are released with energy for further ionization of the filling gas. This multiplication process is called a Townsend avalanche or Townsend cascade. The anode wire must be very thin to obtain a region of sufficient field strength by applying a reasonable voltage. The gas amplification takes place mainly in the region of high voltage gradient near the anode wire. Still, this

amplification can be kept linearly proportional to the original ionization; the number of ions after gas amplification is proportional to the number of primary ions created by the ionizing radiation directly. Detailed explanations and descriptions of phenomena in gas ionization proportional counters are given by *Charpak (1970)* and *Charpak and Sauli (1978)*.

PC tubes can be sealed, with the source of radiation kept outside the tube. A thin window permits radiation penetration into the detector volume. Another configuration is designed for flow-through of gas, and the sample can be inserted into the detector volume. These “windowless” counting systems are useful for the detection of alpha particles and low-energy beta particles. A maximum counting efficiency of 50%, theoretically for a 2π counting geometry, is achieved. A 4π geometry can be achieved by using two flow-through tubes with the sample mounted on a thin foil between the tubes.

Proportional counters usually operate in the pulse mode.

For proportional counters, special gases or mixtures of gases have to be used. The filling gas should not form anions and should not contain components that attract electrons. The noble gases meet this requirement optimally. The formation of secondary Townsend avalanches should also be avoided. Such secondary avalanches are created by the emission of UV photons. This light is produced in the course of deexcitation of molecules or atoms of the filling gas. To prevent this effect, a component is added to the filling gas that absorbs the energy from the excited species. This additive must get rid of the energy through non-radiative modes, such as dissociation. By this mechanism, the ion cascade is localized near its origin and propagates only along the electric field. No other secondary avalanches are created. A frequently used filling gas consists of 90% argon and 10% methane and is called P10 gas (*Alkhazov et al., 1967; Marouli et al., 2007,2010; Phillips et al., 2010*).

Other gas mixtures (Penning gas) consist of a noble gas (neon, argon), the parent gas, with a small amount of an

additive (e.g., methane, acetylene, TMA) of lower ionization energy than the lowest excited state of the parent gas (Jarvinen and Sipila, 1984; Agrawal et al., 1989; Sakurai et al., 2003, and Tokanai et al., 2004).

Gas amplification factors of 10^4 can easily be obtained. Therefore, rather simple electric circuits can be used for pulse amplification and pulse handling. Also, the effects of electronic noise can easily be avoided, because the output pulses created by that phenomenon are small.

Gas gain in PC should be an exponential function of the applied high voltage. However, in proportional counters filled with mixtures of argon and a low amount of a molecular gas, secondary avalanches develop and, as a consequence, gas gain increases faster than exponentially with the applied high voltage (Bronic and Grosswendt, 2001; Curzio et al., 2005).

Proportional counters, using the fast pulses from electron collection, have a short resolving time of less than 1 μ s. Proportional counters have a high intrinsic efficiency for alpha and beta particles. Photons are detected mainly by Compton effects produced in the walls of the counter. Thus, the intrinsic efficiency for gamma rays is rather low, especially for gamma photons with higher energies.

Counting losses with proportional counters are due to wall effects and nondetection of beta particles with very low energy. Stanga et al. (2002) proposed a calculation model for the correction of counting losses. By means of such calculations, the accuracy of internal gas counting methods can be improved, and tedious and time-consuming energy calibration procedures can be shortened or even avoided. PC is frequently applied to the preparation of reference sources by absolute activity measurements also referred to as radionuclide standardization. Such radionuclide standardization methods involving joint proportional and solid scintillation detector arrangements (i.e., $4\pi\beta(\text{PC}) - \gamma\text{NaI(Tl)}$) counting are discussed in Chapter 7, Volume 2.

Aging effects in gas detectors under irradiation have been observed by Niebuhr (2006). The damage depends not only on the amount of radiation on the detector but also on many other parameters such as gas composition, gas quality, particle rate, and particle type.

Pulse shape analysis can be used to reduce background effects or any undesirable events (Pandola et al., 2004). Background pulses frequently show a longer rise time than the desired signals of events to be measured.

A. Examples and applications of proportional counters

1. Gross alpha–beta counting, alpha–beta discrimination, and radiation spectroscopy using proportional gas ionization counters

With gross alpha–beta counting, no attempt at any discrimination is made. Just the sum of all alpha and beta

particles is detected. Gas PC is one of the methods frequently used for gross counting (Passo and Kessler, 1992; PerkinElmer, 1992). Proportional counters may be used in clinical settings, such as the determination of gross alpha and beta activity analysis in human urine (Chen et al., 2014).

Proportional counters are also frequently used to distinguish between alpha and beta particles from a mixed source (Waples et al., 2003; Vasile et al., 2010; Dueñas et al., 2011; Thakur and Mulholland, 2011). Alpha particles, with their high LET, produce a high number of interactions with the gas in the detector volume. A beta particle produces a much lower number of ions per centimeter along its track than an alpha particle. The gas amplification factor is constant at a given voltage, so the output pulse is much higher for interactions of alpha particles compared with beta particles. With a suitable discriminator level or gate, the pulses created by alpha particles can be detected at a rather low voltage setting. For the detection of beta particles, a higher voltage has to be used to overcome the discriminator level.

The alpha particles from a mixed source are registered at a lower voltage, the alpha plateau. At a higher voltage, alpha and beta particles are detected, and gross alpha–beta counting is accomplished (L'Annunziata, 1987).

Alpha and beta radiation can also be discriminated according to the pulse length. Alpha pulses have a different pulse shape than beta pulses. Semkow and Parekh (2001) could demonstrate that alpha-radioactivity can be measured accurately in the presence of beta-radioactivity, but the opposite is not always true due to alpha to beta cross-talk. This cross-talk depends mainly on the alpha-decay scheme and is due to the emission of conversion electrons, Auger electrons, and X-rays.

It is usually assumed that the counting efficiency of a 2π geometry alpha particle detector is 50%. Unfortunately, this is not true in practical measurements, because of self-absorption and backscattering. Several theories have been developed for the calculation of backscattering and self-absorption effects. Rodríguez et al. (1997) have presented a review on these topics and also developed new theories. Backscattering depends on the atomic mass of the backing material of the radiation source. Corrections can be found experimentally by preparing samples of various thickness and extrapolation to zero sample thickness. Such determinations are only possible with a radioactive material with suitable long half-life.

To a limited extent, proportional counters can also be used for radiation spectroscopy (Jarvinen and Sipila, 1984; Jahoda and McCammon, 1988). Pulse height analysis can be applied for radiation spectroscopy for a given type of radiation. To perform pulse height analysis properly, the particles or rays to be analyzed have to release their entire energy within the gas volume of the counter; that is, they

must be totally absorbed within the counter. Proportional detectors are used for X-ray spectrometry in the field of X-ray fluorescence analysis, if high resolution is not required. Because of the gas amplification process, proportional counters have a poorer resolution than ion chambers. Today, mostly semiconductor detectors are used for classic X-ray spectroscopy.

Proportional counters are still widely used for contamination assessment in nuclear facilities. A recent example is the decommissioning of the Korean Research Reactor-1 (Min et al., 2017). Here, together with other techniques, proportional counters were used to find and assess contamination inside the facility.

Szaloki et al. (2000) have reviewed the essential progress in X-ray spectroscopy, and they point out that although the gas-filled proportional detectors are not superior to semiconductor detectors in resolution, microstrip proportional counters are applied for many investigations, including developments in the field of radioisotope excited X-ray fluorescence (XRF) analysis, especially at low energy regions (X-rays below 10 keV).

Xenon gas proportional scintillation counters are used for the detection of X-rays when high detection efficiency and good energy resolution are required (Lopes et al., 2000, 2001; Monteiro et al., 2001, 2004; Simões et al., 2001; Covita et al., 2004; Coelho et al., 2007). An excellent example is the detector used by Rachinhas et al. (2000) for the identification of internal conversion electrons produced by the decay of cadmium-109 and xenon-133m to investigate details of the decay scheme of these radionuclides. The main aim was to selectively detect and identify

conversion electrons of cadmium-109. Fig. 2.8 shows the design of the gas proportional scintillation counting device. The stainless steel enclosure holds also a thin plastic window, which is aluminized on the inner side to provide a uniform field strength at the drift region. Drift and scintillations region are separated by a grid mesh with high electron transparency. A second grid is evaporated directly onto the photomultiplier; therefore, the scintillation region is in direct contact with the photomultiplier, and a high collection efficiency of the UV scintillation photons is guaranteed. Primary electron clouds are produced by ionizing radiation in the absorption region, and these drift under the influence of a low electric field toward and through the first grid into the scintillation region, where due to a much higher field strength, scintillations are produced in the xenon filling gas. The electric pulses of the photomultiplier are fed to an amplifier operating with very short shaping times, and as a result, pulse shapes resemble very closely the scintillation light bursts. This produces an efficient pulse shape discrimination and a very detailed interpretation of the pulse height spectra (see Fig. 2.9).

As reliable detectors, proportional counters are frequently used for the standardization of radionuclides. García-Toraño et al. (2002) compared three methods for the standardization of cesium-134: absolute counting with a 4π NaI(Tl) detector, liquid scintillation, and a proportional counter (argon and methane as counting gas at atmospheric pressure) in coincidence with a NaI(Tl) detector—system. It was shown that all the results of the standardization have been consistent and that any of the three methods that were applied was well suited for this type of application. Pommé

Curve *b* is obtained when pulses with duration outside the range from 3.6 to 4.0 μ s are rejected. Curve *c* (values multiplied by 100) shows pulses that appear within a 20- μ s interval after a 22.1-keV pulse within the range determined by curve *b*. From *Rachinhas et al. (2000)*, reprinted with permission from Elsevier © 2000.

et al. (2005) and Stagna et al. (2006) also compared successfully gas PC with other methods for the standardization of ^{125}I , which decays by electron capture with subsequent emission of conversion and Auger electrons, and the standardization of tritiated water, respectively.

The reliability of 4π pressurized gas proportional counters has been further demonstrated by Altitzoglou et al. (2002) during their work dealing with the comparison of three methods to standardize a strontium-89 solution. Correction for self-absorption of the samples for gas PC was obtained by plotting the activity concentration of the solution against the mass of radioactive sample. A new half-life value for strontium-89 (50.61 ± 0.05 days) was determined in this work.

International comparison and standardization programs frequently result not only in getting more accurate data of radiation properties but also in improving measurement procedures. Self-absorption corrections for beta measurements of solid samples have to be applied depending on the thickness of the specimen. Johansson et al. (2002) demonstrated that the self-absorption of beta particles from thallium-204 shows a linear relation to the logarithm of the dry mass of the source. They described a way to minimize and correct for self-absorption in solid sources of thallium-204 of nuclides with similar decay properties. Also a special device for source drying is described. Warm dry nitrogen jets (60°C) are blown on the rotating source material, which is mixed with colloidal silica (Ludox) to decrease the crystal size of the solid deposit.

Improved gas PC techniques for the standardization of neutron emitters (e.g., ^3H , ^{85}Kr) and positron emitters

(e.g., ^{11}C) are described by Stagna and Cassette (2006), Marouli et al. (2010), and Phillips et al. (2010). The theory and principles of 4π PC are provided in Section III.A of Chapter 7, Volume 2.

2. Position-sensitive proportional counters

a. Single-wire proportional counters

In a proportional counter, the position of the avalanche is limited to a small portion of the anode wire length. Some designs of proportional counters are capable of sensing the position of this avalanche and thus providing information about the position of an event taking place within the volume of the proportional counter. If the PC tube is cylindrical with a central wire, electrons drift along the radial field lines. Thus, the position of the avalanche indicates the axial position of the initial ion pairs and the position of the entering radiation to be detected. Of course, if the incident radiation extends for some distance along the counting tube, only an approximate region of the incident radiation can be determined. The principle of charge division is most frequently used to determine the position of the ion avalanche. For that purpose, the central anode wire is made of a material having a rather high electric resistance per unit length (Ohsawa et al., 2000). By that means, the charge that is collected at the wire electrode is divided between the amplifiers placed at both ends of the anode wire. The charges on those ends are collected in proportions related to the geometric position of the ion avalanche interacting with the wire electrode. A conventional output pulse is provided by summing up the response of the amplifiers and thus getting information about the total charge collected. A signal related to the position is provided by dividing the signal output of one amplifier by the output related to the total charge collected. The pulse height of this new signal indicates the relative position along the length of the central anode wire (Fischer, 1977; Westphal, 1976). Either analog signal handling or digital pulse processing techniques can be applied for this purpose.

Another approach to position sensing is the utilization of pulse rise time measurements. With this technique, the relative rise times of the output pulses of the preamplifiers placed on both ends of the anode wire are determined. Interactions that take place far from one of the preamplifiers result in pulses with a much longer rise time than events close to the preamplifier position. From the rise time difference of the two preamplifiers, a signal can be created that is related to the position of the ion avalanche along the electrode wire. Good results regarding spatial resolution are observed. For well-collimated alpha particles, the FWHM can be 0.15 mm for a tube 200 mm long. Such position-sensitive proportional detectors have been applied for X-rays and neutrons, for magnetic spectroscopy of charged particles, and for the localization of

beta-emitting spots on thin-layer or paper chromatograms (Goulianos et al., 1980).

b. Multiwire proportional counters

For many purposes, proportional counters with a number of anode wires instead of one central anode wire offer advantages. A grid of anode wires can be placed between two flat cathode plates. Near the cathode plate, the field is nearly uniform and electrons drift in that homogeneous field toward the anode wire grid. Near the wires, the field strength increases and, as electrons approach this region, they are accelerated toward the nearest anode wire and an ion avalanche is created. Because of this, the signal appears only at a single anode wire and the position of the primary ionizing event can be localized in the dimension perpendicular to the direction of the anode wires. This multiwire proportional counter was developed by Nobel Laureate Georges Charpak in the 1960s and played a decisive role, not only in many discoveries in particle physics but also in many experiments in biology and medicine (Charpak, 1970; Charpak and Sauli, 1978; Geltenbort, 1994). The technique for position-sensitive counting by using cathode wires of high resistivity has already been discussed. This technique can be used in addition to the plate and multiwire design; and a 2D signal pattern can be obtained. Another technique uses a detector construction with the cathode plate divided into narrow strips perpendicular to the anode wires. The induced charge to the nearest strip is recorded. Such position-sensing detectors with large areas are applied in high-energy particle research (Uozumi et al., 1993; Hayakawa and Maeda, 1994).

The relatively low signal amplitude is a disadvantage of these detectors. Therefore, for some applications, a hybrid detector system, between proportional and GM detectors, may be useful because of the much higher signal amplitude achieved; these are referred to as self-quenched streamer (SQS) detectors (Knoll, 1989).

c. Microstrip and micropattern ionization counters

Wire proportional chambers were mostly developed at the European Organization for Nuclear Research (CERN) and have been a major step forward in particle detector technology. Even now the field of developing new varieties and improving available designs remains very active. MSGCs, micromesh designs, nonplanar variants of MSGCs, like the “compteur a trois (CAT),” secondary electron emission gas detectors, and some other varieties have been developed. A description of design with their special features and advantages is given by Fourme (1997). Christophel et al. (1998) present the development of a 2D microgap wire chamber. Such position-sensitive detectors can be used in other fields in addition to basic research in particle physics. Ortuño-Prados et al. (1999) described the use of a multiwire

proportional counter as a potential detector for protein crystallography and other wide-angle diffraction experiments. Fried et al. (2002) describe a large curved 2D position-sensitive neutron detector, which had been constructed for the protein crystallography station at the Los Alamos National Laboratory. Babichev et al. (2001) report on their experience in medical radiography. The advantage of using multiwire proportional counters as high count rate detectors as well as their usefulness for producing dynamic images of high statistical quality is pointed out by Barr et al. (2002). A detailed summary on gas avalanche radiation detectors and their application in biomedical investigations is given by Breskin (2000) and Guillemot et al. (2007).

MSGCs are ionization counters in which anodes and cathodes are not single plates but are constructed as thin metal strips on a solid insulating support (Barbosa et al., 1992; Bouclier et al., 1992a, 1992b, 1992c, 1995; Oed, 1995; Pallares et al., 1995; Bellazzini et al., 2001, 2002; Clergeau et al., 2001; Sauli, 2001; Bateman et al., 2002; Mir et al., 2009). With such a system, the spot of the ionization track can be localized, because ion production and migration and current flow take place in a well-defined single electrode strip region. Thus, position-sensitive counting can be achieved. Such MSGCs can be obtained with very small spacing between the electrodes. A small pitch results in good resolution. Even at the early stages of their development, results were rather encouraging. At proportional gains above 10^4 with good energy resolution (12% for 5.9 keV), position accuracies around 30 μm , and high rate capabilities were obtained. An example is shown in Fig. 2.10. This microstrip chamber was constructed by Oed (1995) using photolithographic techniques. The small strips are the anodes, and the electric field lines between the electrode strips are plotted in Fig. 2.11. An electron, which is set free in the gas volume in front of the microstrip plate and reaches the microstrip plate, creates an avalanche in a very well-defined small region.

Bateman et al. (2002) presented results of investigations dealing with energy resolution measurements using an MSGC. The effects of gas filling, strip geometry, and other parameters have been examined in detail. A 2D position-sensitive detector was realized by Barbosa et al. (1992). Two sets of microstrips are orthogonally oriented, forming a 2D sensitive electrode, which is used in a multiwire proportional configuration as shown in Fig. 2.12. The two cathode systems are isolated by a silicon dioxide layer only 2 μm thick and are therefore at practically the same distance (3 mm) from the anode wires. Therefore, the signals induced in both orthogonal electrodes are of the same amplitude. The authors aimed to define a 2D X-ray detecting unit that also could be upgraded to a submillimeter spatial resolution detector.

There are some limitations to this detector design. One has to apply manufacturing techniques such as those used

FIGURE 2.10 Structure of a microstrip plate. Electrode spacings are 400 μm , and the metallic layers on the glass support, the electrodes, have a thickness of 150 nm. The small strips are the anodes. From *Oed (1995)*, reprinted with permission from Elsevier © 1995.

FIGURE 2.11 Plot of the electric field lines between the electrode strips of the microstrip plate. From *Oed (1995)*, reprinted with permission from Elsevier © 1995.

in the field of microelectronics. The total sensitive area of such counters seems to be limited. Also, there are charge buildup effects of the supporting insulating materials. This can have a substantial influence on the gas gain at high fluxes. Ion avalanches can cause accumulation of electric charge on the insulating surface between the strips, which modifies the electric field around the electrodes and changes the gas multiplication characteristics. To avoid this, a surface conductivity of the insulating support can be created, for example, by ion implantation. However, the use of all these sophisticated manufacturing techniques imposes

constraints on the size of such radiation detectors. In the beginning, glass and quartz were used for insulating support between the electrodes. Later developments dealt with the application of plastic supports. These materials offer some advantages. They are flexible, and therefore, nonplanar detectors can be designed. Cylindrical geometries with very small radii can be realized. Plastic materials not only have the advantage of lower atomic number of their constituents compared with glass but also can be made much thinner. Multiple scattering and photon conversion can be reduced. Plastic materials are also available with a wide range of electrical resistivities, and the design can be tailored to solve the problem of charge buildup. However, plastic materials have to meet the requirements of suitable mechanical stability. *Bouclier et al. (1995)* accomplished microstrip construction on plastic foils by applying a photolithographic etching technique on a layer of aluminum about 0.3 μm thick on plastic. The distance between the electrodes was about 400 μm . This is somehow wider than the usually applied 200 μm , and it is necessary because of the coarse optical quality of the plastic arrangements compared with glass support microstrips. Also, surface cleaning of plastic before vacuum evaporation of the aluminum cannot be done as perfectly as for glass supports.

Gains close to 10^3 could be reached with the equipment designed by *Bouclier et al. (1995)*. Also, good energy resolution for low-energy X-rays was achieved.

The current tendency in the field of gaseous detectors is the replacement of wire chambers by advanced micro-pattern electron multipliers to obtain an improvement in spatial accuracy and counting rate capability. Electrode patterns are deposited by microlithographic techniques on insulating substrates. Due to the small distances between cathode and anode (50–200 μm), these multipliers offer localization accuracy around a few tens of micrometers. The rapid collection of the ion avalanches considerably reduces space charge buildup, which influences the counting rate limitations. Many types of detectors in this family provide 2D localization in a single detector element.

Many new(er) types of gas detectors with additional microstructures such as the GEM system and other designs continue under development (*Horikawa et al., 2002; Sauli 2003, 2016; 2004a, 2007, 2010; Mörmann et al., 2004; Simon et al., 2009; Bucciantonio et al., 2013a, 2013b; Brunbauer et al., 2017; Veloso and Silva, 2018*). These detectors are often referred to as micro pattern gaseous detectors (MPGDs) because of their position accuracy (*Sauli, 2001; Bellazzini et al., 2001, 2002; Mir et al., 2009*).

The GEM was introduced by *Sauli (1997)*. A GEM detector consists of a thin polymer foil (approximately 25 μm), which is metal clad (approximately 18 μm) on both sides and perforated to yield a density of holes

FIGURE 2.12 Two-dimensional position-sensitive detector arrangement (A). Two sets of microstrips at a distance of $2\ \mu\text{m}$ are orthogonally oriented and connected to delay lines (B). The anode wires are arranged between the microstrips and the entrance window at a distance of $3\ \text{mm}$. From *Barbosa et al. (1992)*, reprinted with permission from Elsevier © 1992.

(approximately $70\ \mu\text{m}$ in diameter and approximately $100\text{--}150\ \mu\text{m}$ apart) (see Fig. 2.13).

Photolithographic techniques have been used for manufacturing of these electrodes. A voltage is applied onto the two faces of the metal clad foil, causing a large difference of potential between the two sides of the foil, thus creating a very strong field inside the holes (Fig. 2.14).

The geometry of the holes and optimization of the device according to its purpose are still intensely researched (Benussi et al., 2016; Karadzhinova et al., 2015). The

device is inserted in a gas detector on the path of drifting electrons (Fig. 2.15).

Primary electrons produced by ionization of the gas layer above the foil are accelerated into the holes where an avalanche process takes place. By that process, the charge drifting through the holes is amplified. Most of the secondary electrons produced in the avalanche are transferred

FIGURE 2.13 Electron microscopic image of a gas electron multiplier electrode (thickness $50\ \mu\text{m}$, pitch of the holes $140\ \mu\text{m}$, diameter of the holes $70\ \mu\text{m}$) (Sauli, 2016). © CC by Sauli (2016).

to the region below the foil where these electrons are collected by an anode and cause a detection signal. Coupled to other devices such as multiwire or micropattern chambers, higher gains are obtained or an operation in less critical field strength conditions is permitted. The fast response time generated by electrons is one of the main characteristic advantages of the GEM detector. The GEM detector has been originally developed for application in particle physics. It has also been applied successfully in other fields of research, though. 2D GEM detectors have been used to obtain X-ray absorption images to show their applicability in medical diagnostics. Fig. 2.16 shows an example of one of the earlier achievements of GEM technology in imaging in the form of an absorption radiography of a small mammal (bat) using 8 keV X-rays. The real size of the image is 3×6 cm. The position resolution depends on the photoelectron range in the gas.

The readout speed of the electronic system used to be the limiting factor in the application of GEM detectors. This

FIGURE 2.16 Absorption radiography of a small mammal recorded with a two-dimensional gas electron multiplier detector (Sauli, 2004b). For the color version of the figure, the reader is referred to the online version of the book. Reprinted with permission from Elsevier © 2004.

challenge has been targeted, for example, by Bucciantonio et al. (2013a) by implementing a fast data acquisition system, thus allowing the application of GEM trackers for imaging and dosimetry in hadrontherapy (i.e., proton or carbon ion beams in cancer therapy). This type of therapy takes advantage of the Bragg peak (deposition of most of the energy of a heavy particle in the final section of its pathway when traveling through matter), which allows treatment of tumors in situ with utmost precision, while delivering only a small dose to the surrounding healthy tissue, as described by L'Annunziata (2016). GEMs have been used to monitor the ion beam in realtime (Aza et al., 2017).

Fraga et al. (2000) have shown that visible light emitted by the GEM avalanches can be successfully used for quality control of the material, to determine their uniformity, and to identify local defects. It is much more effective than the general practice of optical inspection. A modification of a GEM-type detector for medical purposes was presented by Nichiporov et al. (2016). The authors studied a GEM-based scintillation detector for proton beams in a clinical setting. The detector uses a mixture of He and CF₄ that allows (nearly) tissue-equivalent dose imaging. Mixtures of Ar/CF₄ had been studied previously, but the He/CF₄ mixture helps improve the detector's response in the Bragg peak area. The performance of this detector is similar to that of an ion chamber. A TEPC based on a single GEM foil has also been tested with tissue-equivalent gas mixtures and studied by De Nardo and Farahmand (2016).

GEM detectors have been used in fusion experiments to check the quality of the plasma. At the International Thermonuclear Experimental Reactor (ITER), a soft X-ray tomography diagnostic unit is based on GEM detectors. The GEM detectors allow for superb time and space resolution, as well as for the monitoring of the charge spectrum, from which the soft X-ray photon spectrum can be deconvoluted. Another advantage is that they are not prone to neutron damage compared with semiconductor detectors (Chernyshova et al., 2018; Wojenski et al., 2016). Such diagnostics require fast postprocessing computation systems (Krawczyk et al., 2018; Zabolotny et al., 2019).

Several designs of MPGDs are useful for (2D) imaging purposes (Velo and Silva, 2018), including GEMs, thick gas electron multipliers (THGEMs), Micromegas, micro-hole and strip plates (MHSPs), and THCOBRA (Silva et al., 2013), not all of which shall be discussed here. Imaging is very useful for energy-dispersive X-ray fluorescence analysis (EDXRF), which can be pursued in the form of macro-XRF (using a 0D detector) or full-field scanning. The obvious drawback of macro-XRF (which has to scan over the surface of the object) is that, given the small X-ray beam diameter, scanning becomes time-consuming and complex. Data acquisition in full-field scanning mode using 2D detectors and a pinhole camera, however, permits simultaneous data acquisition (Dąbrowski et al., 2016).

The operating principle of MHSP in 2D imaging is shown in Fig. 2.17.

Beautiful examples of this technique in cultural heritage studies have been published by [Zielińska et al. \(2013\)](#) or [Veloso and Silva \(2018\)](#). Fig. 2.18 shows the 2D elemental distribution of a 17th century Portuguese tile. The distribution permits the position-sensitive imaging of Pb (glaze), Fe + Co (blue pigment), and Sb (yellow pigment) ([Veloso and Silva, 2018](#)).

Beyond these examples, there are continuing and promising developments of GEM-type detectors (Sauli, 2001, 2003, 2004a,b, 2010; Fraga et al., 2003; Tsyganov et al., 2008; Dalla Torre, 2011; Villa et al., 2011; Bucciantonio et al., 2013a; Bucciantonio et al., 2013b; Sauli, 2016; Brunbauer et al., 2017; Veloso and Silva, 2018).

GEMs have been included in rather novel designs of radiation detectors, which are constructed for applications in rare event experiments and, as the authors claim, will be of interest in neutrino-nucleus scattering, dark matter search, and probably also in nuclear imaging (Bondar

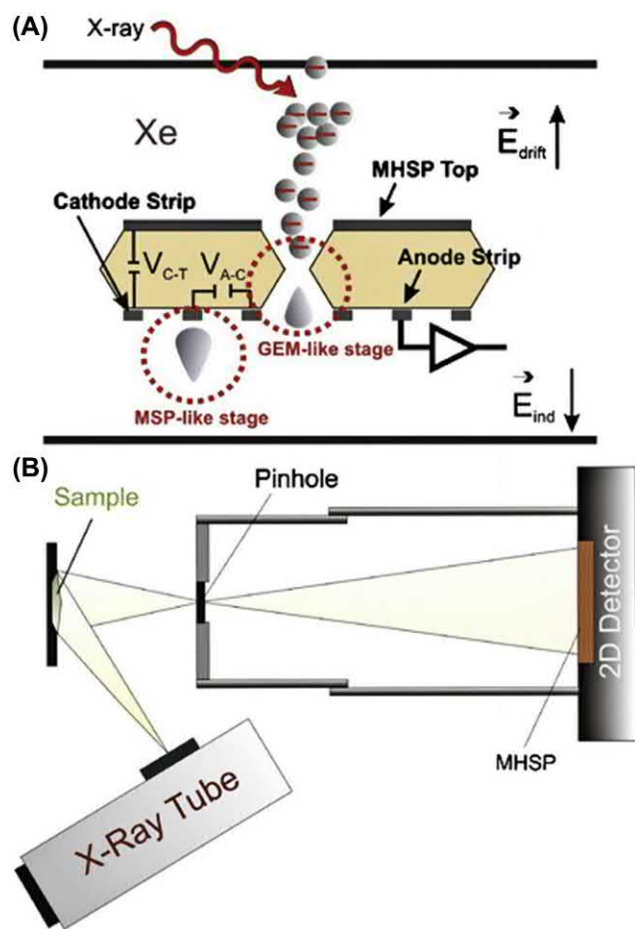

et al., 2010, 2011). The authors describe experiments with a two-phase chamber, filled with liquid and gaseous argon and equipped with an assembly of THGEMs. Ionization signals as well as signals from an attached avalanche photodiode are recorded. Other investigations rely on the information given by the photodiode only (e.g., Renker, 2009; Kreslo et al., 2011). Photomultiplier tubes are frequently used in instrumentation for medical diagnosis such as with gamma cameras or CT equipment where light from large scintillator arrays has to be recorded. An alternative and probably more economic device for light detection and 2D recording would be the use of a thin solid photocathode combined with gas avalanche multipliers and a micropattern device (Fig. 2.19; Breskin, 2000). It is possible to include several GEMs to such a device in cascade (Sauli, 2001; Bachmann et al., 2002; Bondar et al., 2006; Aulchenko et al., 2009; Dalla Torre, 2011). Each GEM operates at a low gain whereby a high total gain is achieved. In addition, the photocathode is shielded from photon feedback induced by ion avalanches (Fig. 2.20; Breskin, 2000).

THGEMs can also be used as microdosimeters, as shown by [Anjomani et al. \(2017\)](#). These devices are sensitive for low-intensity neutron and gamma fields. The detector was found to exhibit enhanced neutron detection efficiency of three times the efficiency of a TEPC that was used as a benchmark. However, the low energy cutoff in gamma dosimetry is about 6 keV/ μm , which is rather high and shall be improved in further studies.

A THGEM-based TEPC was presented by [Darvish-Molla et al. \(2018\)](#) with the purpose of dealing with high dose-rate fields. The microdosimetric response was found to be comparable with a commercially available TEPC.

Novel designs of THGEM-type detectors include the multilayer THGEM (M-THGEM) (Cortesi et al., 2017). This hole-type GEM detector is produced by multilayer printed circuit board technology and consists of a densely perforated assembly of multiple insulating substrate sheets, intercalated between thin metal electrode layers. The authors discuss several advantages of their novel detector, which includes a significant reduction of photon-mediated secondary effects, resulting in a stable high-gain operation in pure elemental gas, thus making the use of a quenching gas unnecessary. One possible disadvantage of the single-element M-THGEM is a higher ion flowback, which has to be accounted for.

Bellazzini et al. (1999) introduced the WELL detector as a rather new type of position-sensitive gas proportional counter. The basic design is similar to the GEM detector. The main difference between the GEM and the WELL detector is that the GEM alone acts only as an amplifying stage, whereas the WELL detector has readout strips directly placed onto the insulating foil providing a position-sensitive compact system. Printed circuit board technology

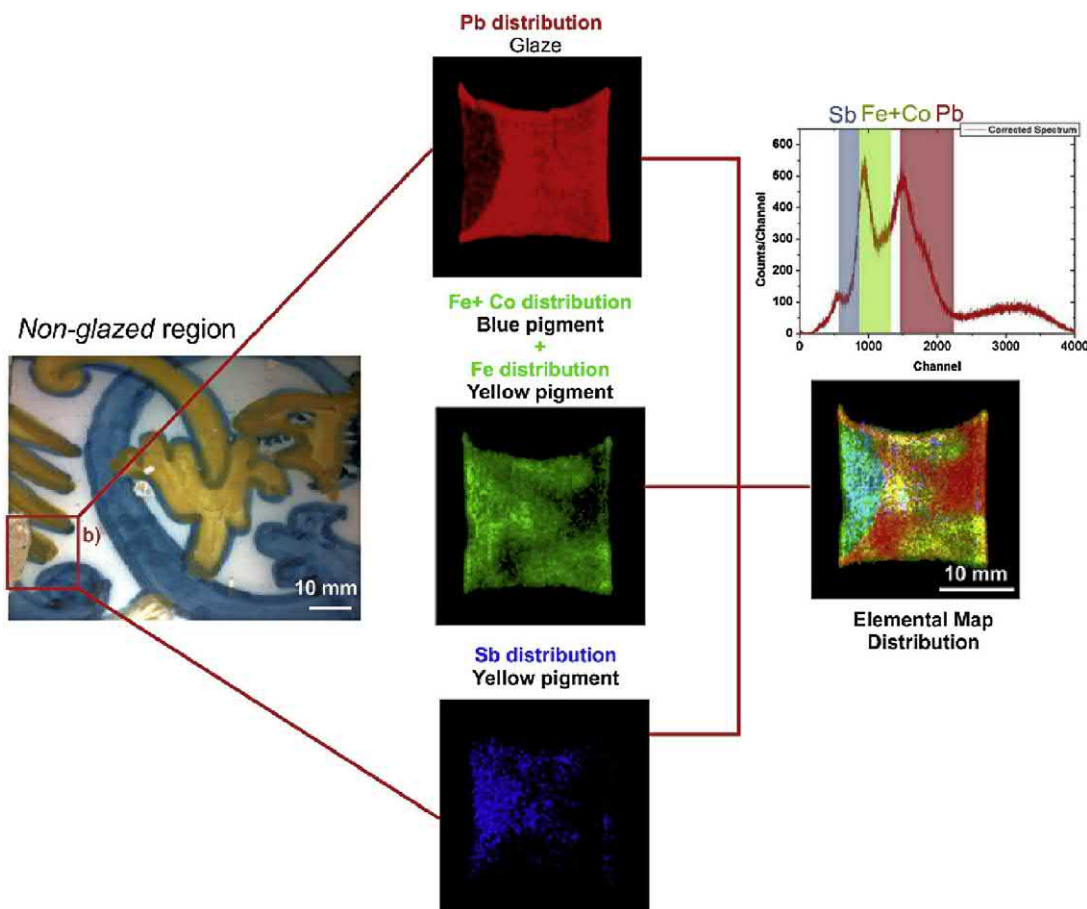

FIGURE 2.18 Pb *L*-lines (from the glaze), Fe + Co *K*-lines (from the blue and yellow pigment), and Sb *L*-lines elemental spatial distribution images, together with the total elemental map distribution of the analyzed region in the Portuguese tile from the 17th century (Veloso and Silva, 2018). FIGURE 2.19 The principle of the gas avalanche photomultiplier: photons stimulate the emission of electrons from the photocathode into the gas, avalanche multiplication takes place near the anodes of the micro-pattern device, ions are collected on neighboring cathodes, and some ions may drift to the photocathode. From Breskin (2000), reprinted with permission from Elsevier © 2000.

was used to fabricate the amplifying structures (Bellazzini et al., 1999; Pitts and Martin, 2001).

Although the development of position-sensitive chambers is mainly dedicated for applications in high energy physics, these types of detectors are also instruments of choice for radiation detection and localization in other fields of basic and applied research. Breskin provides many examples for the application in biology and medicine. Among these are (1) the comparison of images obtained by autoradiographic techniques and ionization detectors, (2) images of ionizing particle track patterns demonstrated for applications in nanodosimetry, and (3) examples of the application of X-ray imaging and neutron imaging (Breskin, 2000).

Yu et al. (1999) designed a position-sensitive X-ray detector with curved electrodes for large angle X-ray diffraction experiments at a synchrotron at the Brookhaven National Laboratory. The detector can cover an angle of 45 degrees and has an arc length of 20 cm with a radius of curvature of 25 cm.

FIGURE 2.21 Schematic cross-sectional view of the double-GEM neutron detector. GEM, gas electron multiplier. From Ohshita et al. (2010), reprinted with permission from Elsevier © 2010.

Comprehensive reviews on the developments in gaseous detectors are presented by Hoch (2004), Tsyganov et al. (2008), Sauli (2010, 2016), and Dalla Torre (2011) and especially in the field of MPGDs by Sauli (1999, 2002, 2010, 2016), Oed (2001), Shektman (2002), Bellazzini et al. (2002), Titov (2007), and van der Graaf (2009, 2011).

Microstrip and micropattern gas chambers are filled with ^3He to be used as neutron counters (Iguchi et al., 1994; Hayakawa and Maeda, 1996; Radeka et al., 1998). The application of micropatterned devices for microdosimetry purposes was reviewed by Waker et al. (2009). By coating the cathode plane of a double-GEM detector with a 0.02- μm -thick layer of ^{10}B , Ohshita et al. (2010) demonstrated an efficient neutron detection, which could provide excellent 2D images of neutron-beam profiles. The neutron beam incident on the GEM was imaged according to the following neutron reactions:

where $^7\text{Li}^*$ represents an excited particle, which spontaneously emits a 0.48 MeV gamma photon while returning to the ground state. Two GEMs were used for gas amplification as illustrated in Fig. 2.21 in a chamber gas mixture of Ar and CO_2 (70:30) providing a gas gain of approximately 400. The detector area was $100 \times 100 \text{ mm}$ with 120×120 readout channels. An example of 2D neutron beam images taken at various distances forming the beam collimator is illustrated in Fig. 2.22. Ohshita et al. (2010) measured the GEM detector position resolution at 1.2 mm in FWHM.

A triple-GEM neutron detector coupled to a CCD readout was devised by Fraga et al. (2002, 2003) for the detection of thermal neutrons. The detector was filled with ^3He and CF_4 . The ^3He in the GEM is used for thermal neutron conversion according to the reaction

FIGURE 2.22 Neutron beam profiles at various distances: (A) 13.7 m, (B) 15.0 m, and (C) 18.8 m measured by the double-GEM neutron detector. GEM, gas electron multiplier. For the color version of the figure, the reader is referred to the online version of the book. From Ohshita et al. (2010), reprinted with permission from Elsevier © 2010.

FIGURE 2.23 Superimposed proton–triton tracks obtained with an exposure time of 1 s with a CCD readout of a gas electron multiplier–based neutron detector. From [Fraga et al. \(2002\)](#), reprinted with permission from Elsevier © 2002.

which releases a 589-keV proton and 193-keV triton, and the CF_4 is needed to decrease the range of the triton and proton in the GEM detector. The He-CF_4 gas mixture scintillates in the GEM with an emission maximum at approximately 625 nm, which is imaged with a CCD coupled to a glass window at the floor of the GEM. A typical image of the proton–triton tracks imaged in the GEM following neutron capture by ^3He is illustrated in [Fig. 2.23](#).

Rocarro et al. (2009) devised a gaseous detector for the determination of the neutron flux, energy distribution, and direction of neutron motion for both fast and thermal neutrons. The detector is filled with CF_4 at low pressure with 1 bar or more of ^4He to provide a target for fast neutrons through elastic scattering and a few Torr of ^3He to detect the thermal neutrons via neutron capture according to the reaction described above. The charged particles leave a trail of electrons along their tracks, and an electron avalanche occurs accompanied by the emission of scintillation light from the CF_4 . The light is then imaged by a lens coupled to a CCD camera, and the detector is referred to as an EMCCD camera (i.e., electron multiplier CCD camera). An example of images taken from events with 14.1 MeV neutrons in the detector is illustrated in [Fig. 2.24](#) where an inelastic reaction with ^{12}C of the CF_4 gas is observed.

For additional information on the application of multiwire and multipattern proportional counters applied in the biological sciences, see Chapter 9, Volume 2.

In 2013, Takahashi et al. presented a novel glass GEM (G-GEM) type of detector that is based on the use of a photosensitive (photoetchable) glass substrate, which exhibits low electrical resistance ([Fujiwara et al., 2016](#)). G-GEMs were found to exhibit high gain and good energy resolution with a single plate. They allow for stable

FIGURE 2.24 Image of three events with an electron multiplier CCD for 14.1 MeV neutrons from a neutron generator. The central event, appearing as an inverted Y, is considered the result of the inelastic reaction $^{12}\text{C} (n, n' + 3\alpha)$, which has an energy threshold of 7.9 MeV. From [Rocarro et al. \(2009\)](#), reprinted with permission from Elsevier © 2009.

radiographic imaging under high X-ray count rates. The manufacturing process of this type of detector is shown in [Fig. 2.25](#) ([Fujiwara et al., 2018](#)). G-GEMs take advantage of the photon yield in the course of the ionization and excitation processes, as illustrated in [Fig. 2.26](#) ([Fujiwara et al., 2017](#)).

As stated above, the detection principle of G-GEM detectors is especially suited for imaging purposes (see [Fig. 2.27](#)). Photoelectrons created by X-ray excitation are multiplied by the G-GEM inside the gas-filled chamber. Scintillation light emitted during the avalanche process is detected with a mirror–lens–optical camera configuration and forms an X-ray transmission image. This method is applicable in industrial settings ([Fig. 2.28](#)) and can even be used for 3D computer tomography of objects ([Fig. 2.29](#)).

Multiwire proportional chambers originally have been designed for high rate applications; the applicability is mainly limited by the low ion drift velocity. Spatial resolutions are limited by wire spacing. To overcome these problems, the wires have been replaced by strips, printed on an insulating support. Developments include combinations and hybrids of the MSGC and GEM position-sensitive gaseous detectors such as the MHSP detector ([Natal da Luz et al., 2007a, b, c](#)), the micropixel gas chamber ($\mu\text{-PIC}$), the MHSP, and Micromegas detectors ([Titov, 2007](#); [Homma et al., 2009](#); [Veloso et al., 2010](#); [Aune et al., 2014](#)).

New structures of gas ionization detectors have been developed during the last years where the wires are replaced by a thin micromesh. Promising results were obtained with a very asymmetric two-stage parallel plate chamber with an arrangement that includes basically three electrodes: a large drift region (about 1 kV/cm) between cathode and a micromesh and a small multiplication region with high field strength between micromesh and anode. Electrons formed in the drift region with moderate electric field pass through the mesh into the multiplication region where avalanches are produced. Typical gains are 10^3 – 10^4 , and due to high field strength, fast pulses of a few

nanoseconds duration are produced and high count rates can be managed. Positive ions from the avalanche are collected by the mesh. The authors use the name Micromegas (micro-mesh gas-structure) for this detector arrangement (Giomataris *et al.*, 1996). If the anode consists of a position-sensitive structure, the center, the avalanche can be spatially recorded. The Micromegas has been used mainly in high-energy particle detection and tracking, but other applications such as the measurement of neutron radiation and imaging in the biological and medical sciences are also described (Derr  t *et al.*, 2001; Delbart *et al.*, 2001; Andriamonje *et al.*, 2001; Pancin *et al.*, 2007; Chefdeville *et al.*, 2008; Donnard *et al.*, 2009; Sauli, 2010; and Oger *et al.*, 2012).

Another variant of the parallel plate counter is a detector device named resistive plate chamber (RPC) described by (Sauli, 2010). The electrodes of this detector are not made of a metallic but of a plastic material, which has a significant electrical resistivity (about 10^9 – $10^{13} \Omega \text{ cm}^{-1}$). Avalanches do not grow too much, and spark formation is avoided. The time resolution is better than 100 ps. Until now, these devices have been used successfully in high energy physics, and further progress in developing this kind of detector can be expected (Santonico, 2003). Belli *et al.* (2007) studied possible applications of resistive plate counters for biomedical applications such as positron emission tomography. Couceiro *et al.* (2007) described the application of position-sensitive resistive plate counters for

FIGURE 2.27 Scheme of a radiographic imaging of an object using a G-GEM (glass gas electron multiplier) detector. From [Fujiwara et al. \(2017\)](#), reprinted with permission from Elsevier © 2017.

animal PET investigations. Other applications (e.g., neutron counting) can be found in the reports of [Jamil et al. \(2010\)](#), [Qian et al. \(2015\)](#), and [Qian et al. \(2009\)](#).

For the first time, a Micromegas counter has been used for in-core measurements in a nuclear reactor by [Pancin et al. \(2008\)](#).

A comprehensive review discussing new developments and future perspectives of gas ionization detectors is presented by [Titov \(2007\)](#). New designs of GEM focus on Micromegas and RPC, such as the coupling of GEM and Micromegas structures to a new type of detector. The

coupling of GEMs and Micromegas into hydride structures is being studied as a current topic of research ([Zhang et al., 2017](#)). Advances in photolithography and microprocessing techniques in the chip industry have triggered a major transition in the field of gas ionization detectors from wire structure to micropattern devices ([Sauli, 2010](#)). It has to be mentioned at this point that most applications are related to charged particle physics, UV detection, and X-ray investigations rather than classical radioactivity analysis. Other review articles available in journals provide information regarding developments, achievements, trends, and future perspectives of position-sensitive gas ionization detectors ([Sauli, 2001, 2003, 2010](#); [Agosteo, 2010](#); [Dalla Torre, 2011](#); [van der Graaf, 2011](#); [Peskov et al., 2012](#)).

3. Low-level counting techniques using proportional gas ionization detectors

For investigations involving low-level counting techniques, e.g., low-level radiocarbon dating experiments or forensic noble gas analysis, a low and stable background is a necessity ([Aalseth et al., 2016](#)). Today, this is achieved mostly by the application of “active shielding.” The counting tube for the sample is surrounded by “guard tubes,” which are combined with the sample counting tube by an anti-coincidence circuit. Only the counts due to the sample counting tube alone are counted and not those registered by both counting systems simultaneously, which are due to background radioactivity. In earlier times, this active shielding was a ring of sometimes more than 20 GM counting tubes. Later, umbrella-shaped guard tubes were designed. Those were, in some cases, displaced by liquid

FIGURE 2.29 Photograph (A) and radiographic image of a microsphere-containing medicinal tablet (B), consisting of X, Y, and Z slices as well as the reconstructed 3D CT image. From *Fujiwara et al. (2017)*, reprinted with permission from Elsevier © 2017.

scintillator guards, which were specially designed for low-level anticoincidence shielding. The liquid scintillation solution is frequently based on a mineral oil solvent and especially suitable for large tanks. Within the guard chamber, several counters based on proportional detectors are sometimes installed. Some systems are equipped with pressure transmitters and temperature sensors to ensure constant conditions for the counting gas. Also, measurement of the peak and median of the pulse height spectrum is used to obtain information about the purity of the counting gas.

Several guard counter designs are described in the literature, and a remarkable construction has been proposed and tested by *Theodórsson and Heusser (1991)*. They suggest an arrangement of flat guard counters on the external sides of the main shield instead of the inner region of the shield as usual. In this way, the weight and space of the inner shield can be reduced. They also claim that the effects of secondary nuclear reactions causing background effects are considerably reduced.

A new detector type for low-level anticoincidence counting is designed and constructed by *Zhang et al. (2002)*. A CdTe semiconductor counter is used as a guard detector forming also the wall of the low-level PC tube. This equipment is applied successfully to radiocarbon dating investigations, and the authors suggest also other fields of application.

Background reduction by electronic circuit design can be accomplished by pulse shape discrimination (*Mäntynen et al., 1987; Äikkä et al., 1992*). By applying pulse shape discrimination, the background is reduced by more than 70%, and only 20% of the efficiency is lost. Figures of merit are improved by a factor of nearly 2. With a counting time of 44 hours, measurable ages up to 56,000 years are achieved.

Carbon dioxide, being a “slower” gas than, for example, methane, is better suited for pulse shape discrimination. On the other hand, purity requirements are much more severe for carbon dioxide. If pulse shape discrimination for background reduction is used, the total length of the rising pulses is measured. The accumulated rise time of an irregular (i.e., a background) pulse is much longer than the rise time of a beta pulse. Yet some background remains, for example, pulses arising from gamma-emitting radionuclides in the construction material. The factors necessary for all these improvements are provided by *Äikkä et al. (1992)*.

At present, three measurement methods for radiocarbon dating are available: AMS, low-level liquid scintillation counting, and low-level gas PC. During the past several years, gas PC methods had become less attractive for radiocarbon dating studies. Some authors are of the opinion that the application of gas PC for radiocarbon dating should be reconsidered, as multidetector gas PC systems offer some advantages.

A modern multidetector system has the advantage of parallel counting, which saves a great deal of time. Also, it takes less time to prepare carbon dioxide from a 1-g carbon sample than to carry out a benzene synthesis from the same amount of sample. The benzene is used as an additive to a liquid scintillation cocktail as discussed in Chapter 2, Volume 2. With parallel counting in a multidetector system based on ionization detectors, one of the samples is always a background sample, thus providing continuous monitoring of the background. Pulse rise discrimination techniques can be used in addition to reduce the number of background counts. If pulse rise analysis techniques are used to reject the slower rising background pulses, the counting efficiency is reduced by 18%, but at the same time

the background is reduced by a factor of 3.3. A dramatic reduction of background counts is obtained by anti-coincidence shielding. Like anticoincidence systems, liquid scintillation guard detectors are frequently used for active shielding.

According to the investigation of [Theodórsson \(1991\)](#), a multidetector gas PC system seems to be highly competitive. Of course, the AMS technique has clear superiority over radiometric methods ([Hou and Roos, 2008](#)), especially for very small samples, but considering the high price of AMS equipment, it seems likely that AMS systems and gas PC will be used in the future and these will complement each other very well. Because of the potential of AMS, scientists hesitated to apply and further improve gas PC.

PC devices still play an important role in radiocarbon dating investigations (e.g., [Chiti et al., 2009](#)).

Low-level liquid scintillation analyzers with active shielding can provide low background count rates of 0.3 cpm for ^{14}C measurements, making liquid scintillation an attractive method for ^{14}C dating. Chapter 6, Volume 1 and Chapter 2, Volume 2 of this book provide detailed information on low-level radiocarbon measurements by liquid scintillation analysis.

At the National Institute of Standards (NBS/NIST), tritium standards are calibrated regularly using liquid scintillation and gas PC methods. Using the available data from measurements over a period of 38 years, [Unterwiesing and Lucas \(2000\)](#) could obtain a more accurate and precise value for the half-life of that radionuclide (4504 ± 9 days).

The available data from international comparison projects have also been used to study the state-of-the-art of tritium low-level measurement techniques. The objective was to find a realistic value for the sensitivity, which could be demanded in ultra-low-level tritium investigations. [Theodórsson \(1999\)](#) reported that during intercomparison investigations, only two laboratories could reach a standard deviation of ≤ 0.03 TU for weak samples. The achievement of a good level of sensitivity and accuracy for tritium measurement is a requirement, because otherwise the possibility of obtaining reliable hydrological information that tritium can give as a natural tracer would be severely limited. Improved future counting systems are discussed. It is again mentioned that gas PC systems can be improved significantly by moving the guard counters to the outer surface of the shield as it had been already proposed by [Theodórsson and Heusser \(1991\)](#).

Measurements have been carried out also to verify theoretical aspects, such as the investigations of [Kuzminov and Osetrova \(2000\)](#) on the shape of the carbon-14 beta-spectrum. Their examinations yielded results, which are consistent with some of the theoretical predictions but which contradict the prediction of others. These findings may help researchers arrive at more accurate theories.

4. Application in environmental monitoring and health physics

a. Radon in water

[Zikovsky and Roireau \(1990\)](#) have developed a simple method for the measurement of radon in water using proportional counters. The method is based on the purging of radon from water with argon, which is bubbled through the water sample and then directed to the counting tube. Argon picks up the radon that was dissolved in the water. A gas purification system removes humidity and oxygen. The high voltage is set for the alpha plateau, and thus a very low background of less than 0.2 cpm and a counting efficiency of 25% are obtained, giving a detection limit of 0.02 Bq per liter. This detection limit compares favorably with that of other methods developed for the determination of radon in water.

Radon daughters (polonium-218, lead-214, polonium-214) contaminate the detector. Unless applying correction factors for the residual activities, a cooling period of at least 1 hour is essential to grant the decay of these daughter nuclides.

Beyond its relevance to health physics, the determination of radium and radon may also be essential for technical purposes. For example, the BOREXINO solar neutrino experiment at the Laboratory Nazionali del Gran Sasso (LNGS, Italy) requires an extremely low radioactivity background ([Simgen et al., 2003](#)). Special care has to be taken to control ubiquitous radon to resolve the low solar neutrino event rate properly. The BOREXINO experiment is discussed in detail in Chapter 6, Volume 1. [Simgen et al. \(2003\)](#) developed a system for the detection of radium and radon based on miniaturized proportional counters with sensitivities of ~ 1 Bq/L (for radium-226) and ~ 0.1 Bq/L (for radon-222), respectively.

b. Measurement of plutonium-241

[Rosner et al. \(1992\)](#) built a PC system that is especially suitable for the measurement of ^{241}Pu . Plutonium-241 is the only significant beta-emitting transuranium nuclide in the wastes from nuclear power plants. Quantitation of plutonium-241 in waste as well as in environmental samples is of interest because ^{241}Pu is a precursor of other transuranium nuclides that have longer half-lives, greater environmental mobility, and greater radiotoxicity. Alpha-emitting americium-241, with a half-life of 432 years, is the daughter product of plutonium-241 and has relatively high radiotoxicity.

Plutonium-241 can be determined indirectly by alpha spectroscopic measurements of its daughter nuclide americium-241. Measurements based on the ingrowth of the daughter radionuclide ^{241}Am can be done only after a long growth period. Even after 4 years, the activity ratio

^{241}Am : ^{241}Pu is only 1:166. Thus a lower limit of detection for ^{241}Pu by direct measurement is desirable and has been achieved using PC in the range of about 10 mBq according to the work of [Rosner et al. \(1992\)](#), whereas via ^{241}Am buildup, about 200 mBq is needed for detection.

Some authors have applied liquid scintillation counting to directly measure plutonium-241. Because of the rather high background of commonly available liquid scintillation equipment, this method can be applied only for samples with a relatively high content of plutonium-241. Investigations of that type have been carried out in regions with elevated fallout levels such as Scandinavia or with samples from the nuclear industry or weapons test sites. Lower limits of detection of 35–65 mBq have been reported. However, a low-level liquid scintillation analyzer equipped with a BGO detector guard and time-resolved liquid scintillation counting (TR-LSC) background discrimination electronics is capable of counting environmental ^{241}Pu at a low background of 2.4 cpm (M. F. L'Annunziata, personal communication).

However, because of the nonspecific character (i.e., continuous energy spectrum) of beta radiation, liquid scintillation and PC require very pure samples for counting. Therefore, the chemical purity of the samples and the self-absorption due to the presence of matrix material in the counting sample are the critical points in the PC procedure. The effects of sample thickness, self-absorption, and energy loss in gas PC were studied in detail by [Martín-Sánchez et al. \(2009\)](#).

For PC, special equipment is needed. This equipment can be obtained by modification of commercially available systems.

c. Measurement of Iron-55

For some radionuclides that are difficult to detect during radioprotection measures, gas ionization detectors still offer good possibilities. Iron-55 is formed by neutron capture of iron-54 and disintegrates via electron capture with a half-life of 2.7 years. Consequently, it is formed by the action of neutrons on steel and hence occurs in and around nuclear reactors or accelerator facilities. During planned repairs, the suspension and dispersion of this radioisotope of iron have to be monitored to avoid uptake by workers. The low-energy X-rays of iron-55 (5.9 keV) are stopped by most detector windows, which makes its detection and quantification difficult. In the presence of other contaminating radionuclides, the measurement of iron-55 is further complicated. [Surette and Waker \(1994\)](#) have designed a monitoring system based on a sealed xenon-filled proportional counter with a thin beryllium window. The detector is combined with a single-channel analyzer and a shuttle mechanism that permits positioning of air filter or swipe media. For a counting time of 100 s, the detection limit is

around 10 Bq. The thin window of the PC tube (0.05 mm) allows more than 90% of photons with an energy of 3 keV or greater to pass through. The monitoring system is sufficiently sensitive to detect well below the maximum permissible level of surface contamination and also below the maximum permissible concentration in air of the facility for which it was designed.

The low X-ray energy of iron-55 suggests its application for testing the performance of new detection instruments and methods in the lower energy region (see, e.g., the work of [Simões et al. \(2003\)](#) and [Masuda et al. \(2002\)](#)).

Alternatively, the 5 keV-Auger electrons emitted from iron-55 can be used for radioactivity analysis. [Tosaki et al. \(2013\)](#) mounted an iron-55 source at the inner cathode surface of a cylindrical proportional counter. By adjusting the gas mixtures (CH_4 , dry air, N_2), a shift of the pulse height has been observed. The authors then studied the electron attenuation cross section of O_2 by evaluating the shifts of the pulse height caused by electron attachment to molecular oxygen.

Recent advances in GEM technology have raised interest in the measurement of iron-55 in activated steel by a small GEM detector coupled to a quad Timepix ADIC for readout (GEMPix) ([Curioni et al., 2017](#)). This method allows for a rapid assessment of compliance with the exemption limit. The technique is planned to be implemented as an operative test phase at CERN.

d. Tritium in air

Proportional counters can also be used for tritium monitoring in air, as demonstrated by [Aoyama \(1990\)](#). Monitoring of tritium in air is required in the environment of 14-MeV neutron generators, heavy-water reactors, and reprocessing plants and will also be necessary at nuclear fusion reactors. Tritium must be detected separately from other radioactive volatile noble gases and air activation products. For occupational radiation protection and emission control, a real-time measurement and high sensitivity are necessary to meet the legal requirements for radiation protection and emission control. To respond to an accidental release, a wide range of detection is essential. High sensitivity can be obtained by using systems equipped with anticoincidence shielding or pulse shape discrimination. Conventional proportional counters suffer from the disadvantage of requiring a counting gas and have a rather short operation range.

[Aoyama \(1990\)](#) described a method for tritium monitoring in air by the use of flow-through proportional counters with air as a counting gas. The counters need no counting gas other than the sampled air. The electronic equipment attached to the counting system comprises pulse height discrimination, anticoincidence shielding, and background compensation. In that way, it is possible to detect and measure tritium in an external gamma background and also

FIGURE 2.30 Cross section of a tritium monitor, which uses air as a counting gas. The detector consists of four layers of multiwire proportional counters. The air flows uniformly through the counter. From Aoyama (1990), reprinted with permission from IEEE © 1990.

in alpha and beta backgrounds originating from other gaseous radioactive materials in the air sample. It was reported that a lower detection limit of 0.005 Bq/cm^3 in the presence of natural background can be obtained in a counting time of 1 minute. Also, a wide range up to 5000 Bq/cm^3 (up to six orders of magnitude) can be managed by this system. The PC detector is rather complicated, consisting of an arrangement of anode wires and cathode meshes. A schematic illustration of this arrangement is shown in Fig. 2.30. Outer layers of the counter were used as guard counters to eliminate gamma background. Gaps between individual arrangements of anode and cathode were kept longer than the maximum range of tritium in air, thereby avoiding coincidence effects caused by tritium. Such coincidence effects were used to exclude other beta rays. The alpha component from radon and its daughter nuclides was eliminated by pulse height discrimination. Data derived from pressure, temperature, and humidity sensors were transferred to a computer and used to control the high voltage and to correct coincidence count rates. Loughlin and Lawrence (2007) carried out a thorough study of methods for the accurate monitoring of tritium in air in conjunction with the operation of the ITER. They conclude a gas proportional counter is best suited for the measurement of HT (i.e., a hydrogen molecule with one tritium atom bound to protium) and HTO (i.e., a water molecule incorporating one tritium atom), when discriminating samplers are used at ventilation outlets from fusion reactions.

e. Positron emitters in air

The increasing demand of positron emitters such as fluorine-18, carbon-11, and oxygen-15 for medical applications (such as positron emission tomography, PET) has resulted in the commissioning of new cyclotron facilities.

Marouli et al. (2007) studied the feasibility of using proportional counters for the monitoring of the emissions from the exhaust ducts at these facilities. The positrons were found to deposit 1.5–2.5 times more energy than negatrons to the counting gas, which affects the minimum detectable activity concentration in a positive way.

f. Monitoring of gaseous fission products

Another important application of proportional counters is the verification of the Comprehensive Nuclear Test-Ban Treaty (CTBT). The detection of fission products (most importantly ^{131}I and the xenon isotopes $^{131\text{m}}\text{Xe}$, $^{133\text{m}}\text{Xe}$, ^{133}Xe , and ^{135}Xe) or activation products (e.g., ^{37}Ar that can be produced from $^{40}\text{Ca}(n,\alpha)^{37}\text{Ar}$ or from $^{40}\text{Ar}(n,n)^{37}\text{Ar}$) from a nuclear test remains the only safe way to verify the nuclear nature of any (underground) explosion. Argon-37 disintegrates solely by electron capture with the emission of Auger electrons. The measurement of its low decay energy (2.8 keV) is done with special low-level gas proportional counters (Saey, 2007) and can act as a smoking gun, especially in the course of on-site inspections (Aalseth et al., 2011; Seifert et al., 2013). Detection of radioxenon is also performed with the help of proportional counters, but usually in combination with other radioanalytical methods such as beta-gated gamma-coincidence counting or high-resolution gamma spectrometry (Saey, 2009, 2010; Xie et al., 2013, 2014).

g. Radiostrontium

Low-level proportional counters are applied for quantitative radionuclide measurement after radiochemical separation procedures. For high sensitivity measurement of low levels of radiostrontium, gas ionization detectors are still preferred over liquid scintillation counters (LSCs). The counting

efficiency of LSC may be twice as high; however, the background level in LSC is approximately 10 times higher than that in gas ionization detectors (proportional counters or GM tubes). [Rodriguez et al. \(2012\)](#) reported on an automated strontium separation and preconcentration system that may achieve minimum detectable activities of strontium-90 as low as 8 mBq.

[Mateos et al. \(2000\)](#) designed and constructed a semi-automatic analysis system for the determination of $^{90}\text{Sr}/^{90}\text{Y}$ in aqueous samples using a sequential injection method. The beta measurements are made twice within 24 hours. From these results, the initial activity of strontium-90 and yttrium-90 is calculated. Thus, the time-consuming yttrium milking method can be overcome.

[Vaca et al. \(2001\)](#) compared strontium-90 measurement methods using a Berthold LB770 counter and a Quantulus 1220 liquid scintillation spectrometer. The proportional counter had a passive shield of 20-cm-thick lead and an active gas proportional guard counter. The samples can be measured simultaneously by that device, and a background from 0.3 to 0.6 cpm is obtained, depending on the detector location along the gas flow pathway. It is surprising that for gas PC, a minimum detectable activity of 0.13 Bq/kg is reported, for Cerenkov counting 0.37 Bq/kg.

Crown ether technologies were used by [Scarpitta et al. \(1999\)](#) to measure the strontium-90 content of Brookhaven National Laboratory groundwater samples. With gas proportional and liquid scintillation counting, minimum detectable levels of 37 Bq/m³ were achieved using a processed sample of 1 L and a counting time of 1 hour.

PC is used also for the determination of strontium-90 in human bones and teeth in Greece. Measurement was performed on yttrium-90 after equilibration with strontium-90 and liquid extraction using bis (2-ethyl-hexyl) hydrogen phosphate. The analyses unfolded an average of 30 mBq strontium-90 per gram calcium, which was found with only a small variation with respect to age and sex. From the variation of the activity in teeth, it could be concluded that the contamination from atmospheric nuclear weapons tests exceeded by far that is caused by the Chernobyl accident ([Stamoulis et al., 1999](#)).

In an extensive study, [Degteva et al. \(2006\)](#) investigated the dose resulting from external and internal exposure to radioactivity in the Techa river region, which was affected by the operation of the Mayak Production Association in the former Soviet Union. The internal dose was dominated by radiostrontium. Hence, investigation of thousands of teeth and bones was the method of choice to assess dose aspects. The authors found that the median doses to the red bone marrow and the bone surface were 0.21 and 0.37 Gy, respectively. The maximum doses to the red bone marrow and bone surface 2.0 and 5.2 Gy, respectively, were reported.

In an analytical and environmental study, the groundwater from the site of the nuclear power plant A1 Jaslovské Bohunice (Slovakia) was investigated ([Ometáková et al., 2011](#)). Several separation methods for the preconcentration of the radionuclides were tested. The ^{90}Y activity was determined by a low-level alpha–beta proportional counter and by Cerenkov liquid scintillation counting.

Much work has also been done to develop faster radioanalytical protocols for emergency response. Authors from Savannah River Nuclear Solutions developed methods for the determination of strontium-90 and alpha-emitting actinides in urine ([Maxwell III and Culligan, 2009a](#)), air filters (2010a), vegetation samples (2010b), milk ([Maxwell III and Culligan, 2009b](#)), and water ([Maxwell III and Culligan, 2009c](#)). The authors used proportional counters for radiostrontium and alpha spectrometry for actinide determination.

[Herranz et al. \(2011\)](#) used a gas proportional counter to measure both ^{89}Sr and ^{90}Sr in environmental samples. The strontium is isolated firstly from the test sample, which also includes its isolation from the ^{90}Y daughter nuclide. Two counting times are required, one after the removal of ^{90}Y and a second count time selected after significant ingrowth of ^{90}Y . They used a proportional counter with a 5 cm diameter and 0.5 μm Mylar window. The detection efficiencies for ^{89}Sr , ^{90}Sr , and ^{90}Y were 43%, 36%, and 44%, respectively, with uncertainties between 0.4 and 0.5% and a typical background count rate of 0.8 cpm.

h. Health physics and dosimetry

Dosimetry ultimately aims at reflecting the radiation dose absorbed by the organism rather than by the dosimeter. To understand the damage induced by radiation, fundamental understanding of radiobiological processes is a prerequisite, which allows the description of radiation action at a microscopic level. Accordingly, much effort is put into bioequivalent dosimetry ([Hajek, 2015](#)).

TEPCs are a field with significant recent advances ([Agosteo, 2010](#); [Broughton and Waker, 2016](#)). First introduced by [Rossi and Zaider \(1996\)](#), they can be used to evaluate the radiation dose and dose equivalent for gamma rays, charged particles, and neutrons. [Agosteo \(2010\)](#) reports on the efforts toward miniaturization of TEPCs, which is important in radiation therapy, because conventional TEPCs are too large in comparison with the beam in many specialized settings and hence suffer pulse pileup effects. TEPCs with cavities in the millimeter-range have been built to tackle this problem. An alternative approach consists in assessing the dose-mean linear energy through the variance method with a microdosimetric ion chamber operating in current mode. This method relies on the higher variance of the charge collected by an ionization chamber in a fixed time interval as the particle stopping power

increases (Agosteo, 2010; ICRU, 1983; Hsu et al., 2008). In many cases, TEPCs use propane as a tissue-equivalent filling gas (Chirioti et al., 2015; Moro et al., 2014).

A mini-TEPC was developed by Nardo et al. (2004a,b) for radiation therapy applications (Agosteo, 2010). Fig. 2.31 shows a sectional view of this detector. Its external diameter (2.7 mm) is the same as that of an 8-French (*i.e.*, 2.7 mm) cannula, which is used for mini-invasive surgery. The aim is to perform microdosimetric measurements directly inside the irradiated organ (for example, during the treatment of prostate tumors or proton radiotherapy of eye tumors; see DeNardo et al., 2010). The mini-TEPC sensitive volume is cylindrical (diameter and height 0.9 mm). The anode is a wire of gold-plated tungsten (diameter 10 μm). The cathode is made of Shonka A-150 plastic, 0.35 mm in thickness. The mini-TEPC is inserted in a titanium probe 2.7 mm in diameter, 170 mm in length, electrically grounded. The insulation between the conductive A-150 cathode and the titanium probe is ensured by a 0.35-mm-thick Rexolite cylinder. The propane-based tissue-equivalent gas flows continuously through the sensitive volume.

Another problem of conventionally sized TEPCs is their low sensitivity and energy response in low-dose rate applications (Waker et al., 2009). For low energy neutrons, the range of the secondary charged particles is lower than the simulated site size of a TEPC. The instrument hence loses its spectrometric properties with respect to LET (Agosteo, 2010). Waker et al. (2009) present and discuss the application of multielement and micropatterned devices to overcome these problems. Aslam et al. (2011) discuss their results on the investigation of the response of a

commercially available spherical TEPC to mixed photon and neutron fields, which may affect the workers in nuclear power plants. They found that moderate dose rates, which do not result in dead times of more than 20%–25% due to either of the component radiation or due to both components of a mixed field, generate acceptable results for radiation monitoring.

A TEPC based on a THGEM has been proposed (Byun et al., 2009). The THGEM thickness ranges from the sub-millimeter to millimeter order, compared with standard GEM insulator foils with a thickness to 50 μm . This makes the THGEM more robust and practical for gas amplification in a 2D microdosimeter (Agosteo, 2010).

Multielement TEPCs based on GEMs have been developed by Farahmand et al. (2003a, 2003b, 2004) and were reviewed by Agosteo (2010). This millimetric device consists of five cylindrical cavities of 4.3 mm³ in a sensitive volume sandwiched between two layers of A-150 plastic and filled with a tissue-equivalent gas. The GEM provides charge multiplication for the electrons from ion pair creation. The microdosimetric response of a TEPC-GEM to 14 MeV neutrons and a ²⁵²Cf neutron source was measured by Farahmand et al. (2004) and found to be in good agreement with spectra available in the literature (Agosteo, 2010).

A twin miniaturized TEPC for application in boron neutron capture therapy was developed by Moro et al. (2006). Here, the wall of one TEPC is enriched in boron-10. For low energy neutron fields below 500 keV, Waker and Aslam (2011a,b) developed a TEPC using a graphite-walled proportional counter. Miniaturization of TEPCs for low-energy neutron dosimetry has also been achieved

FIGURE 2.31 Cross-sectional view of a mini-tissue-equivalent proportional counter used in radiation therapy. The sensitive volume is the gray area in the center. From DeNardo et al. (2004b), reprinted with permission from Elsevier © 2004.

successfully with the development of compact multielement tissue-equivalent proportional counters (METEPCs) (Waker and Aslam, 2010).

More recently, TEPC-based technologies have received much attention in hadrotherapy (proton and carbon ion cancer therapy) for a realistic dose imaging in clinical settings, as they can measure the LET of the incident radiation. Nam et al. (2015) have developed a TEPC that can simulate a site diameter of $2\text{ }\mu\text{m}$ for microdosimetry (Fig. 2.32). The LET calibration factor of this detector is about $0.72\text{ keV}/\mu\text{m}$. Other designs are GEM-based TEPCs that achieve simulated sites down to 140 nm for response to low-energy X-rays (Farahmand and De Nardo, 2016).

As stated above, research on TEPCs is nowadays much focused around the application at hadron therapy facilities. There is plenty of literature available on this field (that goes beyond classic radioactivity analysis). In particular, the application in proton therapy (Farah et al., 2015, 2017) and carbon ion therapy, both in experimental and in modeling studies (Burigo et al., 2013, 2014; Chiriotti et al., 2014; Galer et al., 2017; Mazzucconi et al., 2018; Taylor et al., 2015), has been researched. Novel detectors for application in ^{12}C therapy, such as the avalanche-confinement TEPC, have been presented (Bortot et al., 2017a), which can be calibrated using alpha emitters (Bortot et al., 2017b).

Techniques to separate out the dose and energy spectra of neutrons and charged particles are necessary for health physics investigations in space shuttle conditions. Braby and Badhwar (2001) used a combination of a tissue-equivalent and a hydrogen-free detector. Both have nearly the same response to photons, but the hydrogen-free detector is insensitive to neutrons below about 10 MeV . Thus, the neutron dose can be obtained by subtraction. Similar considerations are used also for the separation of charged particles and neutrons. Nunez-Perez and Braby (2011) report on the replacement of the TEPCs on the International Space Station and the improvements achieved with the new detectors.

A novel type of detector called European TEPC (EuTEPC) has been introduced recently (Moro and Chiriotti, 2015). The EuTEPC is applicable in gamma and neutron fields. Its distinguishing feature is a spherical cathode wall that is subdivided in nine sectors, which are separated by 0.5 mm Rexolite walls. Each sector is properly and differently biased, to obtain a uniform electric field along the anode wire, thus allowing good isotropic response and energy resolution. The authors suggest the application of the EuTEPC in space dosimetry.

Nanodosimetry will be of interest for investigations in microbiological radiation effects. Tamboul and Watt (2001) built a gridded parallel plate proportional counter, operating at low pressure (1 Torr). This corresponds to a mean chord diameter of 1.8 nm . The device is designed to have a response to radiation simulating that of a bimolecular target

(A) Schematic drawing

of about the same sensitive volume, for example, a double-stranded DNA molecule. A TEPC on nanometric level was presented by Cesari et al. (2002). This “avalanche confinement TEPC” is characterized by a high gas gain and good energy resolution. It was defined to study sites in the nanometer scale down to 35 nm (Agosteo, 2010). In many cases, TEPCs nowadays compete with silicon-based microdosimeters; however TEPC-based systems are often considered as a standard method (Zhang et al., 2014), which is why many current studies compare or cross-calibrate the performance of silicon-based microdosimeters (silicon on insulator, SOI) with TEPC-based microdosimeters (Tran et al., 2018; Bolst et al., 2017a, 2017b; Mukherjee et al., 2017; Rosenfeld, 2016). Comparative studies not only are limited to charged particle and photon radiation but also include neutron microdosimetry (Agosteo et al., 2011; Ali et al., 2014; De Saint-Hubert et al., 2016).

Thermoluminescence dating can be applied to objects that have been heated in the past such as bricks or pottery. In certain crystalline minerals, absorbed energy from ionizing radiation is reemitted as light upon heating of the material. This method takes advantage of the fact that the dose received is proportional to the age (past the initial heating). As a consequence, for thermoluminescence dating, the radiation dose the object had been exposed to must be known. Most frequently, this radiation dose is due to the content of alpha- and beta-emitting natural radionuclides within the material of the archeological specimen. PC techniques can be used to determine the activity of the material, and from this analytical result, the radiation dose can be calculated. [Troja et al. \(1995\)](#) give an example for this type of activity measurements and dose calculations.

VI. Geiger–Müller counters

As already mentioned, with GM tubes, much higher electric fields are applied than with ion chambers and proportional counters. Because of the high electric field, the intensity of an individual avalanche is enhanced. As a consequence of the emission of UV photons, which are released during deexcitation of atoms or molecules inside the tube, additional avalanches are created. One avalanche therefore can trigger another at a different position in the detector chamber volume. The number of avalanches grows exponentially. Also, the number of slowly migrating positive ions increases. The increasing number of positively charged ions near the electrode causes the field strength to decrease, and further creation of avalanches is stopped, because ion pair multiplication requires a sufficiently high electric field strength. The discharge in a GM tube is terminated at about the same total produced charge, regardless of the amount of ions initially created by the radiation event. Therefore, all output pulses from a GM tube are of about the same size. The output pulse amplitudes of GM tubes are very large compared with signals of ion chambers and proportional counters, usually of the order of several volts. Simple electronic circuits can be used to register GM output signals, but no information about the type and energy of the incident radiation can be obtained. Apart from this lack of information about the type and energy of radiation, GM tubes have a rather long resolving time compared with PC tubes. Therefore, their use is limited to relatively low count rates, only a few hundred counts per second. [Geiger and Müller \(1928\)](#) hence originally proposed their instrument for the detection of “weakest activities.” Resolving time corrections can be applied, but the resolving time depends not only on the field strength but also on the observed count rate ([Jones and Holford, 1981](#)).

The decaying source method is probably the most general and accurate of the methods for measuring the observed and true counting rates over the entire counting

rate range of interest. For that, a very pure radionuclide source of known half-life is essentially needed. True count rate and observed count rate differ considerably at high activity of the radioactive source; however, with time, the background corrected observed count rate will approach the true count rate. This type of experimental determination of dead time is frequently used to test the usefulness of mathematically based models for correction (e.g., [Gardner and Liu, 1997](#); [Lee and Gardner, 2000](#)).

Counting losses induced by resolving time of a counting system can be a limiting factor in measurements. [Vinagre and Conde \(2001\)](#) presented an interesting method for the determination of resolving time of a counting system. They added an additional pulse to each pulse of the counting system and varied the delay time of this additional pulse. By observing the total count rate as a function of the delay time, good results for the resolving time could be obtained.

It warrants that GM tubes show a remarkable energy-dependent response for high-energy photons above 3 MeV. This was underscored by [Neumann et al. \(2002\)](#) to be a relevant factor in accurate dose determinations.

In summary, GM detectors are often used in industrial radiation gauges. They proved to be robust (even in harsh environments) and relatively cheap, and they only require simple readout electronics ([Meriç et al., 2012](#)).

A. Designs and properties of Geiger–Müller counters

1. Fill gas

The fill gas for GM counting tubes has to meet requirements similar to those for the fill gas of proportional counters. Argon and helium are most frequently used. The gas pressure is in the order of tenths of bars, and depending on the size and shape of the tubes, a voltage in the order of hundreds of volts is applied. GM tubes are usually permanently sealed and operate at low gas pressure, although designs have been realized using atmospheric pressure and flow-through to replenish the fill gas and flush out impurities.

2. Quenching

After the termination of the discharge, the slowly migrating positive ions of the fill gas finally arrive at the cathode, which is usually the outer wall of the counting tube. At this electrode, the cations capture electrons from the cathode surface and a corresponding amount of energy is liberated. If this liberated energy exceeds the ionization energy of the cathode material, additional electrons are set free from this electrode. These newly generated free electrons migrate to the anode and create another avalanche. This finally results in a continuous output of pulses. The probability of this additional electron drift is rather low, but because of the

high number of cations at the field strength conditions in a GM tube, this effect of multiple pulses is observed. With GM tubes, special precautions have to be taken to prevent the formation of additional avalanches. This can be done by reducing the bias voltage after the Geiger discharge. This external quenching can be achieved by using a suitable electronic circuit (resistor and capacitance) that determines the time of restoration of the high voltage following a Geiger discharge. The restoration time is usually on the order of milliseconds, and therefore, this design is suitable only for low count rates.

It is more common today to use internal quenching, which involves the addition of a suitable compound to the fill gas. The ionization energy for this additive to the fill gas (quench gas) must be lower than the ionization energy for the fill gas. Although confusing, the same expression, quench gas, is used for both the additive to a fill gas of proportional counters, which has to absorb UV photons, and the additive to a fill gas in the GM tube, which should be able to neutralize the drifting ions of the original filling gas by electron transfer. The ions of the quench gas migrate to the cathode and are also neutralized. However, the liberated ionization energy is now consumed by the quench gas and causes dissociation of the quench gas molecules. Some quench gases, such as halogens (e.g., chlorine or bromine), show spontaneous recombination; other quench gases, such as organic compounds (e.g., ethanol), are consumed, and therefore the lifetime of an organic-quenched GM tube is limited to about 10^9 counts. Quench gases are usually added at an amount of several percent to the fill gas of the GM tube.

A relatively long time is needed (100–500 μ s) to clean the positive ions that are formed during the avalanche propagation. A mathematical approach for deadtime correction was published by [Arkani et al. \(2013\)](#).

[Abilama et al. \(2015\)](#) investigated the lifetime of bromine-quenched GM counters. The amount of quench gas needed is directly linked to the operational characteristics of the detector. Preserving the halogen is key in maintaining the operating lifetime of the GM tube. However, since halogens are highly corrosive, they will react with the materials they come into contact with and thus deplete themselves over time. [Abilama et al. \(2015\)](#) tested three corrosion-resistant mechanisms (surface treatments) to prevent the quench gas from reacting with the materials of the tube: oxygen-plasma bombarded (“raw”), a passivated surface (using nitric acid passivation followed by oxygen-plasma bombardment), and plating with a thin chromium layer of a few micrometers. The latter was found to be the most resistant surface.

The transition from proportional mode to GM mode takes place at increasing field strength. [Golovatyuk and Grancagnolo \(1999\)](#) could demonstrate that this transition also depends on the concentration of a quenching gas. This

fact may be of relevance if pulse shape analysis is used for particle identification. If the concentration of quenching gas is low, gas amplification, as a function of high voltage, increases more rapidly and the boundary between the proportional region and the GM region may be crossed easily. Results of pulse shape analysis may not be interpreted correctly.

3. Plateau

For the simple electronic circuits that are usually designed for use with GM tubes, a minimum pulse amplitude is required for count registering. At a given voltage, this minimum pulse amplitude is exceeded by all signals, as soon as that voltage, the Geiger discharge region, is reached. Therefore, on increasing the voltage while exposing the GM tube to a radioactive source of constant activity, pulse registering starts rather abruptly and the counts per unit of time remain relatively constant (plateau of a GM counter).

GM tubes are frequently rated on the basis of the slope of the plateau region. The slope of the plateau region of halogen-quenched tubes is usually less flat than that of organic-quenched tubes (2–3% per 100 V). However, halogen-quenched tubes can usually be operated at a lower voltage than organic-quenched tubes.

4. Applications

The design of GM tubes is usually similar to that of proportional tubes. Most frequently, the end-window type is used. GM tubes can also have the shape of “needle tubes,” in which the anode consists of a needle. In the vicinity of the needle point the field strength varies by $1/r^2$ instead of the $1/r$ variation near a wire or rod electrode. Therefore, counters with a very small active volume can be manufactured.

Since a Geiger discharge is created by a single ion pair, alpha and beta particles, once they penetrate the wall or window, are registered with very high efficiency. Gamma rays are detected by the electrons that are observed as a result of interaction of the gamma ray with the walls of the counting tube via the photoelectron effect or Compton effect. The efficiency of GM tubes for gamma rays is relatively low (in the order of a few percent over a wide energy range) and also depends on the atomic number of the material used to make the tubes. The range of medical or industrial applications of GM tubes could further be extended, provided that the stopping power of the tubes can be improved. In a first approach to this problem, [Merici et al. \(2011a, b\)](#) applied Monte Carlo methods for the simulation of the stopping efficiencies of GM counters and benchmarked the results experimentally.

Attempts have been made to enhance the interaction of GM detectors with gamma photons. [Merici et al. \(2012\)](#)

investigated the effect of placing metal disks made of high atomic number metals inside the tube and thus converted gamma photons to photo electrons or Compton electrons. The efficiency of the detection of gamma rays may thus be enhanced by a factor of 3.

Currently, GM tubes are used most frequently for radiation monitoring and contamination control in day-to-day radiochemistry work. For dose rate measurements, GM counters are likely being replaced in the future by novel, scintillating spectrometers based on LaBr_3 , CeBr_3 , SrI_2 , and others (Kessler et al., 2018; Baeza et al., 2017). This could affect the European early warning network that consists of about 5000 stations and that are operated using mainly GM dose rate meters.

Photon doses in mixed fields (neutrons/gamma) are frequently measured with GM counters. However, it has to be mentioned that the response of GM detectors depends on photon energy, especially for photon energies above 3 MeV. Dealing with the analysis of neutron and photon components during calibration experiments, Neumann et al. (2002) point out that the knowledge of spectral distribution of the photons is essential for accurate dose determinations.

Beyond scientific value, GM counters are very suitable also for educational purposes. Blanco et al. (2009) and Perez et al. (2018) showed the application of GM counters for the detection of cosmic rays at different levels (from sea level, to mountains, to airplane cruise altitudes). In the Japanese Misho project (a “citizen science” project involving residents of Fukushima prefecture and Tohoku University), the earliest response to the Fukushima nuclear accident relied on the use of GM counters (and other radioanalytical techniques). The various data sets allowed for the estimation of the cumulative total external exposure as a function of time (Koike et al., 2014).

GM counters are easy to use and can be used for environmental monitoring even by laypersons after a short introduction (Jevtic and Drndarevic, 2015). They are very useful in screening for contaminations. Two recent examples include the screening of contamination after the Chernobyl and Fukushima nuclear accidents, respectively. In combination with other detectors, GM counters were used for the retrospective radiological assessment of personal items (sweaters) of two students from the United Kingdom who lived in Minsk and Kiev at the time of the Chernobyl accident (Alkhomashi and Monged, 2015); a study with a more anecdotal character. For Fukushima, screening of personal items is regarded as more relevant, because the accident happened in 2011 and the owners of the property may still be interested in using their property. Ogino and Hattori (2013) defined in their study the conditions and operational levels for unconditional release of contaminated personal items from the areas surrounding Fukushima Daiichi nuclear power plant. A level of 10 Bq/cm^2 is the limit for clearance of the contaminated property.

By applying a factor for the conversion of the unit surface contamination to the count rate of a GM survey meter, which was widely used after the Fukushima accident, the operational level for the unconditional release of contaminated properties was calculated to be 2300 cpm on average and 23,000 cpm at the highest-contamination part (Ogino and Hattori, 2013).

a. Environmental radioassay

Radon. Bigu (1992) designed a fully automatic system for the unattended quantitation of radon-222 and radon-220 progeny. He used a GM beta particle detector with a pancake configuration. The instrument is a microprocessor-based system that consists of a sampling device, an electronic scaler, and a personal computer. The computer records all sampling and counting routines.

The sampling device consists of a filter about 5 cm in diameter facing the detector at a distance of about 0.5 cm. The air flow rate is 1.4 L/min. However, the measurement and data procedure is rather complex and requires a rather sophisticated computer program. Basically, the following steps are required:

- The sampling and counting for a given period provides results for the combined radon-222 and radon-220 progeny contribution.
- A counting period after the sampling records the beta particle activity versus time and thus permits assay of radon-222 daughter products.
- From the results of the preceding steps, the contribution of radon-220 progeny can be calculated.

Difficulties may arise if measurements have to be made under transient conditions, for example, when there are rapid changes in the concentration of radon-222 or changes in the aerosol concentration or aerosol size distribution. This effect is related to the half-life of the radionuclides of interest. For radon-220, it is particularly acute because of the long half-life of lead-212. The full effect of any of these changes (perturbations) is felt by the detectors after about one half-life of the dominating radionuclide of the decay chain.

Epstein et al. (2009) studied the health hazards caused by drinking water from “radium ore revigator,” which was a pseudoscientific medical device developed in the early 20th century consisting of ceramic water jars lined with a carnotite layer. Direct radiation exposure was measured with a GM tube. Radon and its progeny in water and air from the revigator was measured by liquid scintillation counting. Trace elements were determined by application of inductively coupled plasma mass spectrometry. Interestingly, Epstein et al. (2009) conclude that the potential hazard from the revigator was not radiation but rather the chemically toxic elements such as arsenic and uranium that were extracted into the water.

A more curious and certainly very tragic case of the (failed) application of GM counters in the assessment of radon progeny was the polonium-210 poisoning of Mr. Alexander Litvinenko in London, United Kingdom, in 2006 (Nathwani et al., 2016). When the man was admitted to the hospital, the symptoms initially indicated gastroenteritis. Later poisoning with drugs or thallium was suspected. Only on the 22nd day after he first became ill, 1 day before his death, radiation poisoning was discovered by the characteristic (although extremely weak) 803 keV gamma peak in a gamma spectrometric measurement of his urine. Earlier body surface scans using GM counters failed, because the detector was not suited to detect the alpha emitter polonium-210 (combined with the minute increase of gamma dose rate).

Fluorine-18. Papp and Uray (2002) used a very simple experimental setup for the determination of fluorine-18 attached to aerosol particles in a laboratory where syntheses for positron emission tomography are carried out. Aerosol samples were collected by drawing the air through a glass-fiber filter using a mobile high-volume air sampler. The filter discs were counted under an end-window GM tube (mica window 2 mg/cm² thickness and 35 mm diameter, background about 32 cpm). Following this very simple experimental procedure, subsequent measurements and a rather complicated computation using Bateman-type differential equations have to be carried out to distinguish between the radioactivity of the airborne natural radionuclides such as ²¹⁸Po, ²¹⁴Pb, ²¹⁴Bi, ²¹²Pb, ²¹²Bi, ²⁰⁸Tl, and fluorine-18. Therefore, the method cannot provide instantaneous results, but very low activity concentrations, around 1 Bq/m³, corresponding to 160 atoms/m³, can be detected. This method can be applied also to the determination of any other airborne beta-emitting radionuclide, if its half-life differs sufficiently from those of the progenies of radon and thoron.

Radiostromium. The beta counting of yttrium-90 after ingrowth to equilibrium with strontium-90 had been used during an extensive and remarkable investigation carried out by Russian and Norwegian scientists in the South Ural region near the site of the first weapon grade plutonium production reactor complex in Russia. GM-counting tubes had been used for the determination of beta particles, and Strand et al. (1999) reported that they found 720 kBq/kg of strontium-90 in sediments and 8–14 kBq/L in water.

Cosma (2000) carried out strontium-90 determinations in Romania without previous chemical separation procedures. He used aluminum plates to absorb low-energy beta particles and thereby detect only the high energy beta radiation of yttrium-90. He obtained values between 40 and 75 kBq/kg in sediments and soil in Romania after the Chernobyl accident.

Chu et al. (1998) compared three methods for the determination of radiostromium, the nitric acid

precipitation method, ion exchange, and crown ether separation procedures. They analyzed soil, tea leaves, rice, and milk powder. Their main statement is that by application of the crown ether method, the time-consuming and hazardous nitric acid precipitation method is avoided. Measurements were carried out using gas flow GM tubes and Cerenkov counters. Data are given for strontium-89 and strontium-90.

Currently, attempts are being made to analyze strontium-90 in situ in aqueous solutions without chemical processing and by applying semiconductor and GM detectors (Samardzic et al., 2018). In this study, a methodology to simulate the spectral information obtained by Monte Carlo methods is presented.

VII. Special types of ionization detectors

A. Neutron detectors

Practically, every type of neutron detector consists of a target material that is designed to produce charged particles by interaction with neutrons. Those charged particles can be detected by any suitable detector, such as an ionization detector. The nuclear interactions resulting in the production of charged particles are governed by the reaction cross section. This cross section depends strongly on the energy of the neutrons as described in Chapter 1, Volume 1. In searching for such suitable nuclear reactions, one has to consider that the cross section should be as large as possible, thus allowing the design of detectors with high efficiency and small dimensions.

The most popular nuclear interaction for the measurement of neutrons is the ¹⁰B(n,α)⁷Li reaction. It can be used for the measurement of slow (thermal) neutrons. The cross section decreases rapidly with increasing neutron energy as illustrated in Fig. 1.81 of Chapter 1, Volume 1. This reaction is very useful because of the large cross section for capture of thermal neutrons (3840 b, see Table 1.20 in Chapter 1, Volume 1) and because of the relatively high isotopic abundance of the boron isotope with mass number 10 (19.8%). Usually, boron trifluoride is used as an additive to the host gas in PC tubes.

The reaction ³He(n,p)³H has a significantly higher cross section for thermal neutrons, but the relatively high cost of ³He has limited the application of this target material for proportional neutron counting tubes. Helium-3 is a rare isotope, and the increasing demand due to its unique nuclear properties resulted in a shortage in its supply, which has caused a veritable “helium-3 crisis” (Kouzes, 2011; Shea and Morgan, 2010). Helium-3 counters can be found for what is usually called a hostile environment, and applications are found in well logging investigations. Glesius and Kniss (1988) provide a review of such applications for borehole measurements. Recent developments seek to

replace ^3He by boron-based detector materials, which is not always a simple task. Helium-3 has some considerable advantages, that is, it is relatively insensitive to gamma radiation, nontoxic, and noncorrosive; can be operated at lower voltage; and can withstand extreme environments. Boron trifluoride (BF_3), as the obvious alternative, is not suitable for all situations and environments. It is corrosive, requires much higher voltage, and is more susceptible to interferences with gamma radiation (Lintereur et al., 2011).

The use of helium-3 is still justified for special applications. For example, it was used in a low-background thermal neutron detector for the Chinese Jinping Underground Laboratory (CJPL-II) (Zeng et al., 2017). Helium-3 was necessary to achieve the desired low sensitivity to other radiation. The authors used oxygen-free copper as the material of the tube to guarantee a minimal contribution to the count rate by radioactivity from the wall materials.

For experiments with spallation neutron sources, detectors are required with 2D response, good time resolution, and capability for neutron energy determination. Radeka et al. (1998) built multiwire chambers up to 50×50 cm with helium-3 and propane as filling gas mixture for the construction of a large curved detector for protein crystallography studies at a pulsed spallation source at the Los Alamos National Laboratory. The detector is designed to be placed 16 m from the neutron creation point, and thus a single neutron pulse time would act as a monochromator for neutrons. A review of neutron detector developments around particle accelerators was published by Nakamura (2012).

A new design of a boron-based gaseous neutron detector based on a boron-lined honeycomb neutron converter and a GEM was presented (Fang et al., 2017a, 2017b). Anode wires used in traditional detector designs were removed, and a GEM was used as the electron multiplier (Fig. 2.33). A boron layer on the honeycomb surface reacts with incoming neutrons in the nuclear reaction $^{10}\text{B}(n,\alpha)^7\text{Li}$. The emitted alpha particle or lithium-7 nucleus, respectively, will ionize the working gas. The electrons will migrate along the z-axis and will be multiplied by the GEM and collected by the anode. Various mixtures of working gases have been investigated (Fang et al., 2017a), showing that $\text{Ar}:\text{C}_4\text{H}_{10}:\text{CF}_4 = 90:7:3$, $\text{Ar}:\text{CO}_2 = 95:5$, and $\text{Ar}:\text{DME} = 95:5$ show the most promising results and good performance in terms of stopping power of alpha particles and lithium-7 nuclei and limiting transverse diffusion of electrons. The boron lining is performed by plating a mixture of boron nanoparticles and epoxy resin onto the surface of the converter. This detector design helps overcoming the intrinsic problem of solid boron-based detectors: aiming at the use of a large amount of boron while keeping the boron layer as thin as possible to allow for the entering of the alpha particle or lithium nucleus (both of which have a short range in solid boron layers),

respectively, into the working gas, by providing a large surface area.

Other variants of GEM detectors have also been introduced for neutron measurements. Lopes et al. (1999) combine the principles of proportional scintillation counters and GEMs, and Fraga et al. (2002, 2003) and Rocarro et al. (2009) applied helium-3 as a filling gas in GEM detectors to determine neutrons as described previously in this chapter. Ohshita et al. (2010) used a $0.02 \mu\text{m}$ -thick layer of ^{10}B on the entrance window of a GEM detector for the measurement and imaging of neutrons beams. The present helium-3 crisis further fuels efforts toward “ ^3He -free” detector systems. Albani et al. (2016) proposed several detector systems aiming at the development of a ^3He -free instrument for neutron diffraction experiments. They used $^{10}\text{B}_4\text{C}$ as the neutron absorber and developed three GEM-based detectors. Two of them have a planar; the third one has a three-dimensional (3D) neutron converter. The authors (Crocì et al., 2014) found that the planar detectors exhibit lower efficiency, timing resolution, and signal/background ratio than conventional helium-3-based detectors. By using a 3D design and enriched boron-10, the authors improved the detector’s efficiency from 7% of the 2D design to 25%, relative to the count rate obtained by ^3He -based detector.

The $^6\text{Li}(n,\alpha)^3\text{H}$ reaction cannot be used for gas ionization counters because a lithium-containing gas for proportional counters is not available. However, ^6Li counting scintillators are quite common as detectors for neutrons as described in Chapter 9, Volume 1.

The cross sections of uranium-233, uranium-235, and plutonium-239 for fission reaction with thermal neutrons are very large, and the fission products that form the “charged particles” to be detected in a PC tube have very high kinetic energy (about 160 MeV). This facilitates discrimination from the alpha emission of the fissile materials that are neutron targets of the counting system. Little success was achieved in attempts to produce these neutron targets as a gaseous additive to the host gas of PC tubes. Commonly the surfaces of the electrodes are covered with a deposit of the fissile material. This system is frequently applied, for example, for fission chambers that are used for reactor as well as nonreactor applications.

As mentioned previously, the BF_3 proportional tube is the most widely used detector for slow neutrons. Boron trifluoride can serve both purposes, as a target for slow neutrons and also as a PC gas for the reaction products of the $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction. Although other boron-containing gases have been investigated, BF_3 offers good properties as a proportional gas and also a high boron content compared with other gaseous boron compounds. Usually, boron-10 is enriched for use in boron trifluoride counting tubes. Tubes with enriched boron-10 have about five times

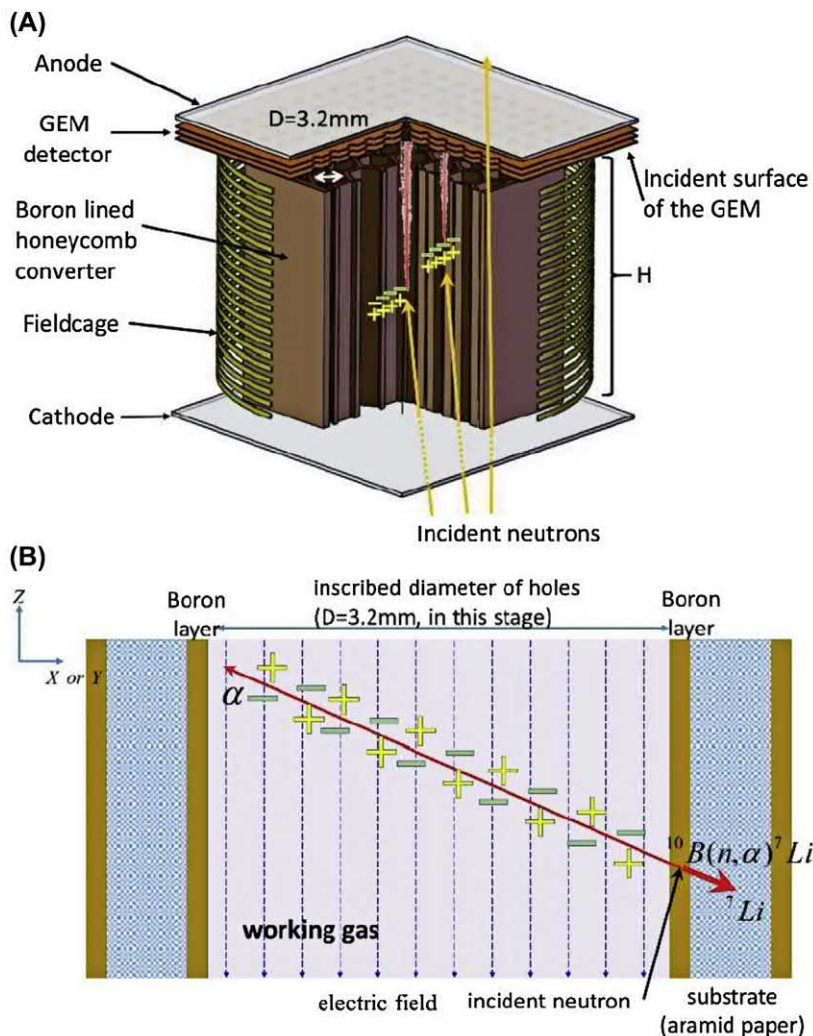

FIGURE 2.33 Physical structure (top) and detection principle (bottom) of the proposed honeycomb converter neutron detector. GEM, gas electron multiplier. For the color version of the figure, the reader is referred to the online version of the book. From Fang *et al.* (2017a), reprinted with permission from IEEE © 2017.

higher efficiency for thermal neutron counting than tubes filled with boron in its natural isotopic abundance.

According to the reaction $^{10}\text{B}(n, \alpha)^7\text{Li}$, the output signal handling may appear simple and straightforward for the application of boron-10 to the detection or even spectroscopy of neutrons. However, the energy spectrum and pulse processing for BF_3 tubes can be rather complicated in detail. Recoil ^7Li also contributes to the energy spectrum, and the nuclear reaction leads to either a ground state (94%) or excited state (6%) of ^7Li . Also, the volume of the counting tube, in general, is not sufficiently large compared with the range of the alpha particles or even the range of ^7Li recoil atoms. Therefore, not the entire energy of these reaction products is deposited in the gas volume, but interaction with the walls of the tube occurs instead. This results in distortion of the energy spectrum recorded from ionizing effects in the gaseous volume. Summarizing, one can say that the BF_3 tube is a detector from which, by differential

pulse height analysis, little useful information is obtained about the energy spectrum of the incident radiation. The pulse height spectrum depends mainly on the size and shape of the detector. Therefore, counting is done only at a high voltage providing a flat region at a plateau, and a discriminator setting is used at which all neutrons are counted but all low-amplitude effects are rejected. Low-amplitude effects are due mainly to gamma rays producing secondary electrons from wall interactions. However, at very high gamma radiation fields, problems arise because of pileup effects. Also, BF_3 suffers from radiation decomposition in gamma fields of high intensity, thus making attempts necessary to absorb decomposition products of BF_3 by applying activated charcoal as an absorbent.

Position-sensitive neutron counters are essential for measuring the neutron flux distribution in critical assemblies. For that purpose, neutron counting tubes with unusual dimensions may be constructed, such as a 1.2-m-long

and 8-mm-diameter tube designed by Uritani et al. (1995). With that device, nonuniformities in a critical assembly could be detected and correction measures are undertaken.

New structures of detectors have been designed, and these developments have also found their application in neutron counting. RPCs using highly neutron-absorbing gadolinium as converters have been constructed and investigated by Jamil et al. (2010), Qian et al. (2015), and Qian et al. (2009).

Although neutron detectors usually rely on the technical principles of proportional counters, modified GM counters can be applied for this purpose. Etaati et al. (2010), Lotfi et al. (2015), and others studied the performance of an activation counter. In this device, neutrons are moderated in a polyethylene packing and activate a silver foil that surrounds the GM tube. The activation products of silver (silver-108 and silver-110) disintegrate with short half-lives under emission of β^- particles, which can be detected by the counter. An alternative concept, where a silver-lined gas ionization neutron detector is operated in PC mode, was presented by Dighe and Das (2015). The authors claim that this concept shows enhanced performance in terms of operating range and dead time.

Moslehi and Raisali (2017, 2018) describe their development and evaluation of a multielement THGEM for use as a microdosimeter that can be applied from thermal to 14 MeV neutrons. The microdosimeter uses propane as a tissue-equivalent gas and has a small weight fraction of ^3He added.

1. BF_3 tube construction

With increasing dimension of BF_3 counting tubes, the detection efficiency is improved and wall effects are suppressed. To some extent, increasing the gas pressure inside the tube has the same effects. Some consideration has to be given to the materials used for tube construction to avoid radioactivation effects due to neutron capture by the materials used for tube wall construction. Because of its rather low neutron interaction, aluminum is frequently the material of choice; however, if a low background is essential, one has to keep in mind that aluminum contains a small amount of alpha-emitting nuclides. For such low-level investigations, stainless steel is preferred as a construction material for BF_3 tubes. Elevated temperature has some adverse effects on counting performance. Above 100–150°C pulse amplitude and pulse height resolutions are decreased, because of desorption of impurities from construction materials inside the tube. Extensive studies of the temperature dependence of BF_3 proportional counters were carried out by Sakamoto and Morioka (1994). Some phenomena that depend on temperature were related to impurities in the enclosed gas and also to construction details of the electrodes.

Usually, BF_3 tubes are operated at a rather higher voltage than ^3He tubes. Therefore, spurious pulses are possible due to leakage current through insulators, especially under conditions of high humidity. Also, detector microphonics have been observed, if the counting system is subject to shock or vibrations, which has been tackled by Czajkowski et al. (2012).

2. Fast neutron detectors

It has to be kept in mind that the gas ionization detectors previously described, namely BF_3 and ^3He detectors, which are based on the conversion of neutrons to directly detectable charged particles, are capable of detecting only slow neutrons. The cross section responsible for the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ and $^3\text{He}(\text{n},\text{p})^3\text{H}$ reactions decreases rapidly for neutrons with higher energies. To use these detectors for the determination of fast neutrons, the high-energy particles have to be slowed down, that is, to be moderated. The low detection efficiency for high-energy neutrons of slow neutron detectors can be greatly improved by surrounding the detector volume with a layer of moderating material, for example, hydrogen- and carbon-containing materials such as paraffin. Fast neutrons lose a fraction of their initial high kinetic energy by impacting the moderator molecules before reaching the sensitive volume of the detector. However, neutrons can escape from the moderator layer by scattering without reaching the detector volume or can be captured by moderator materials. Thus, an increase of the thickness of the moderator layer will not proportionally increase the number of thermalized neutrons counted by the detector. A maximum counting efficiency will be observed at a specific moderator thickness. This optimal thickness depends on the initial energy of the fast neutrons to be detected and varies from a few centimeters for neutrons with energies of keV up to several tens of centimeters for neutrons having energies in the MeV range.

There is no generally established method for neutron spectrometry, especially around the eV region. The “slowing-down time” method can be applied for such investigations, and conventional BF_3 tubes are used (Mae-kawa and Oyama, 1995a, 1995b; 1997).

Toyokawa et al. (1995) described a multipurpose neutron counter, applicable to the measurement of fluence, energy distribution, and radiation dose equivalent. This system consists of a spherical polyethylene moderator and three ^3He position-sensitive tubes inserted into the moderator orthogonally to each other. These three position-sensitive tubes provide information about the thermal neutron distribution in the spherical moderator, and from that information, the foregoing parameters can be evaluated.

For neutron spectrometry in the MeV range, ^3He ionization chambers can be used. Iguchi et al. (1994) carried out investigations dealing with the application of these

detectors in neutron spectrometry. Their ^3He detector consists of a cylindrical gridded ionization chamber (Fig. 2.34). Monte Carlo simulation was applied to estimate the detector response. Four kinds of reactions in the detector gas were considered in the calculations: $^3\text{He}(n,p)t$, $^3\text{He}(n,d)d$, $^3\text{He}(n,n')$, and $^1\text{H}(n,n')$ elastic scattering. Corresponding to these calculations, the response functions were measured with monoenergetic neutrons at various energy points.

An indirect attempt to achieve neutron spectroscopy can be approached by taking advantage of neutron-induced nuclear reactions of target neutrons with fast neutrons. For example, the $^{12}\text{C}(n,2n)^{11}\text{C}$ reaction has a threshold of 20 MeV. Bismuth detectors follow the reaction of $^{209}\text{Bi}(n,xn)^{210-x}\text{Bi}$ ($x = 3-12$), which are suitable for the energy range 20–150 MeV (Nakamura, 2012). The resulting radionuclide can be detected by gamma spectrometry, giving a hint at the neutron energies involved in a high-energy neutron source.

More recently, the prompt fission neutron spectrum of a californium-252 spontaneous fission neutron source was determined by EJ-301 liquid scintillators as well as an EJ-204 plastic scintillator (Blain et al., 2017). The plastic scintillator was used for the lower energy portion of the neutrons between 50 keV and 2 MeV, whereas the liquid scintillator was used for the higher energy neutron from 0.5 to 7 MeV. For more details on the principle of scintillators, see Chapter 6, Volume 1.

Pulse height and rise time distribution analysis of signals from neutron proportional counters were used to reject undesirable signals of hydrogen-filled proton recoil counters, ^3He -filled counters, and BF_3 counters. Gamma ray background and wall effect pulses can be reduced by that method (Sakamoto and Morioka, 1993).

Neutron measurements in an environment with high gamma radiation doses are of interest in the field of nuclear safeguards. Especially, neutron–gamma coincidence counting is of particular interest for spent-fuel measurements for burnup verification and in several steps of nuclear fuel reprocessing. The high gamma background has limited the selection of neutron detectors. Neutron fission chambers do not possess sufficient efficiency to be used in coincidence counting, and BF_3 tubes suffer from radiation damage. Beddingfield et al. (2000) have carried out comprehensive research to optimize the helium-3 neutron proportional counter performance in a high gamma ray dose environment. There are many parameters to be observed, such as tube size, gas pressure, gamma ray dose, gamma ray pileup, gamma ray energy, radiation damage to the gas mixture and to the pre-amplifier system, etc. There is no best option of counting tube design for all mixed field applications; however, from the presented amount of experimental data, a good choice for a useful special design can be made.

An inexpensive sealed ^3He drift-tube neutron detector was designed by Wang et al. (2009) at the Los Alamos National Laboratory. In light of the limited supply and high cost of ^3He , they developed a low-pressure ^3He drift-tube neutron detector that takes advantage of the fraction of thermal neutrons scattered off a polyethylene moderator surface. The basic design of the drift-tube neutron detector is illustrated in Fig. 2.35. Wang et al. (2009) surrounded the tube with approximately 25-mm-thick high-density polyethylene sheet moderator. With a detector diameter of 5 cm and a specific gas mixture and pressure, they could ensure that the full energy of the reaction $^3\text{He}(n,p)^3\text{H}$ would be absorbed by gas ionization, which results in a prominent Q -value peak at 0.764 MeV in the pulse height spectra and a detection efficiency of 5%. The detector was filled with

FIGURE 2.34 Schematic view of an ^3He gas ionization chamber. The detector consists of a cylindrical gridded ionization chamber. The sensitive volume is fixed to 5 cm in diameter and 15 cm in length by guard rings at both ends. The chamber is filled with helium-3, argon, and methane at a pressure of several bars. A calcium purifier in the chamber is used to remove hydrogen produced from the $^3\text{He}(n,p)^3\text{H}$ reaction from the detector gas. Thermal neutrons are shielded by a boron layer outside the tube. From Iguchi et al. (1994), reprinted with permission from Elsevier © 1994.

FIGURE 2.35 Schematic view of the drift-tube neutron detector construction. From Wang et al. (2009), reprinted with permission from Elsevier © 2009.

1 bar of total gas pressure with 25–300 mbar of ^3He with the remaining gas mixture consisting of C_2H_6 , ^4He , CF_4 , and Ar. Due to the relatively low pressure of ^3He , the cost of the ^3He is not more than the cost of the other materials used to construct the detector. The wall of the detector consists of 0.89-mm-thick aluminum, and the tube length can be varied from 30 cm up to 6.1 m in length. The detector length was kept at a minimum of 30 cm (12 in.) to prevent domination of the detector by end effects. The anode wire consisted of 50- μm -diameter gold-plated tungsten. The drift tube operates as a proportional counter at bias voltages ranging from 1400 V (300 mbar ^3He) to 1800 V (25 mbar ^3He). The detector was designed for fissile material detection, and the simple design permits the construction of 100 detectors by a two-person team in 1 work day of 8 h.

a. Long counter

Most neutron detector systems suffer from the disadvantage that the counting efficiency depends strongly on the energy of the neutrons to be detected. The so-called long counters try to avoid that disadvantage. A long counter consists of a neutron detector tube, most frequently a BF_3 tube, which is placed in the central region of a paraffin cylinder. The paraffin cylinder is covered with a layer of B_2O_3 and with an additional layer of paraffin. Only one end of the inner paraffin cylinder is not covered by the boron and additional paraffin. Thus, the device is sensitive only to neutrons coming from the direction of this end. Any neutron arriving from that direction is moderated and has a good chance of arriving at the central BF_3 tube. To give low-energy neutrons a better chance of reaching the tube, holes are drilled in the front end of the inner paraffin layer (Hunt and Mercer, 1978). Such a long counter is in use for the precise measurement of delayed neutrons in the French LOHENGRIN fission fragment separator (Mathieu et al., 2012; Serot et al., 2014) or for the study of the spectrum of cosmic ray–induced neutrons (Pazianotto et al., 2013).

Because of the nearly energy-independent response of this type of counting tube, the long counter is also called a

“flat response” detector. Many variations of such flat response detectors have been designed and constructed, some of them using ^3He tubes, pressurized filling gas, multiple tube arrangements, polyethylene moderators, and so on (Tagziria and Thomas, 2000; Hu et al., 2009; Lacoste, 2010; Lacoste and Gressier, 2010; Roberts et al., 2010; Watanabe et al., 2011; Wang et al., 2015; Utsunomiya et al., 2017). One has to be aware that the counting efficiency of such neutron counting systems is rather low, sometimes much less than 1% (East and Walton, 1982, see Fig. 2.36). For high-energy neutrons (>6 MeV), the response was improved by introducing a tungsten irradiator, which acts as an energy converter through the (n,xn) reaction (Li et al., 2015).

As noted above, many variations of long counters may be used, and two examples of the most simple design and more complex design together with their response to a wide spectrum of neutron energies are illustrated in Figs. 2.36 and 2.37, respectively. The flat response neutron detector geometry illustrated in Fig. 2.36 is quite simple. The detector consists of a 20-cm-long ^3He position-sensitive proportional counter (PSPC) surrounded with polyethylene moderator. Polyethylene is often preferred over paraffin as moderator because it can be machined easily while also having a high content of hydrogen atoms. The neutrons enter from the left surface of the detector illustrated in Fig. 2.36A. The peak positions in the spatial response of the 20-cm-long ^3He PSPC counter shift to deeper positions from the detector surface with increasing neutron energy, as illustrated in the lower part of Fig. 2.36B.

A more complex design of a long counter, described by Lacoste and Gressier (2010) for the IRSN AMANDE facility in France, is illustrated in Fig. 2.37. It was modeled based on studies on the role and variation of different parameters, such as depth of holes in the front face and the position of the thermal neutron detector in the moderator. The long counter (PLC-IRSN), modeled with the Monte Carlo radiation transport code MCNPX, is illustrated in the upper portion of Fig. 2.37, and the response function of the counter over a wide range of neutron energies is illustrated in the lower portion of the figure. The detector measures approximately 40 cm in diameter and 45 cm in length. It is made of polyethylene and borated polyethylene, with a thin cadmium sheet in the front and at the rear. The front of the inner polyethylene layer is designed with an annulus of air and is 5 cm in depth and 3 cm wide. A polyethylene cylinder 6 cm in diameter and 7 cm long is placed in front of the thermal neutron detector. The ^3He gas was confined at a pressure of 10 atm. in an active volume 3.8 cm in diameter and 26.3 cm in length. The uniform response of the long counter to a wide range of neutron energies is illustrated in the lower portion of Fig. 2.37.

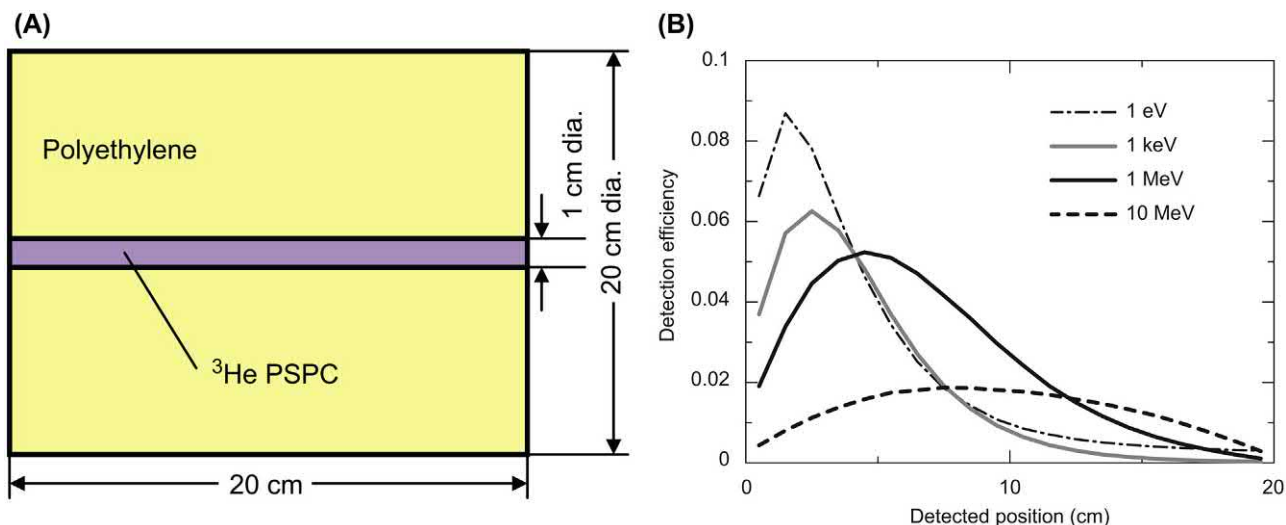

FIGURE 2.36 (A) Basic configuration of a flat response neutron detector. The neutrons enter the detector from the left side of the figure (B) Calculated spectral response distribution (i.e., number of detected neutrons per incident neutron) of neutron detection position in the ^3He position-sensitive proportional counter (PSPC) long counter for various incident neutron energies. From Watanabe et al. (2011), reprinted with permission from Elsevier © 2011.

Long counters are typically bulky because of the voluminous neutron moderator, which is required to achieve a flat detector response. This reduces portability and limits its use to a stationary instrument. A novel design of a compact flat response neutron detector was presented by Harano et al. (2011). Their detector design is based on two small spherical ^3He proportional counters (3.3 cm in diameter) with a reduced moderator volume, consisting of a polyethylene cylinder 20 cm in diameter and 35 cm in length (Fig. 2.38). The detector has shown (in MCNPX calculations) to yield a comparable sensitivity to long counters for californium-252 spontaneous fission and americium–beryllium (α, n) neutrons as well as monoenergetic neutrons, up to an energy range of 20 MeV, while weighing only 10.6 kg, which is 20% of conventional long counters.

3. Neutron counting in nuclear analysis of fissile materials and radioactive waste

Neutron counting tubes are also used in delayed neutron activation analysis. Some radionuclides follow a beta decay process; their beta emission is followed immediately by the emission of neutrons. Such nuclides are produced by fission of heavy elements. Therefore, this procedure can be used for the analysis of fissile materials. Using thermal neutrons for fission is a specific method for the determination of uranium-235 and plutonium-239. With fast neutrons, fission also occurs with uranium-238 and thorium-232.

Oxygen and calcium are interfering elements, creating nitrogen-17 and potassium-48 as activation products through fast neutron irradiation. However, since those radionuclides have short half-lives (nitrogen-17, 4.2 second;

potassium-48, 5.8 second) compared with the neutron-emitting products from uranium and thorium, the interference can be avoided by counting after a decay period of at least 20 seconds.

Delayed neutron activation analysis is carried out using a pneumatic transfer system at a neutron source of sufficient flux density, usually a reactor. The samples are first positioned near the reactor core by the transfer system, and after a suitable irradiation period (~ 60 seconds) and decay period (~ 20 second), samples are counted (~ 60 second) at a neutron detector assembly. At the NIST research reactor at Gaithersburg, United States, the detection limit for natural uranium is in the range of 20 ng natural U, which corresponds to ca. 200 pg of ^{235}U (Eriksson et al., 2013). Kapsimalis et al. (2013) studied the simultaneous determination of both fissile nuclides uranium-235 and plutonium-239, which is possible by studying the different neutron emission spectra of both nuclides. The analysis, according to the authors, was successful within a precision of ca. 5%–10%.

Thorium interference due to fast neutron-induced fission is overcome by irradiation with and without cadmium shielding. Cadmium-113 has a large cross section for the capture of thermal (only) neutrons, whereas epithermal and fast neutrons will penetrate the cadmium shield. The delayed neutron activation analysis is used mainly for the determination of uranium and thorium at trace levels in minerals and for forensic and nonproliferation studies. Fully automatic systems are available, with detection limits in the range of 0.01 $\mu\text{g/g}$ for uranium and 1 $\mu\text{g/g}$ for thorium.

Neutron counters have been applied also to the determination of transuranium elements. A high-sensitivity

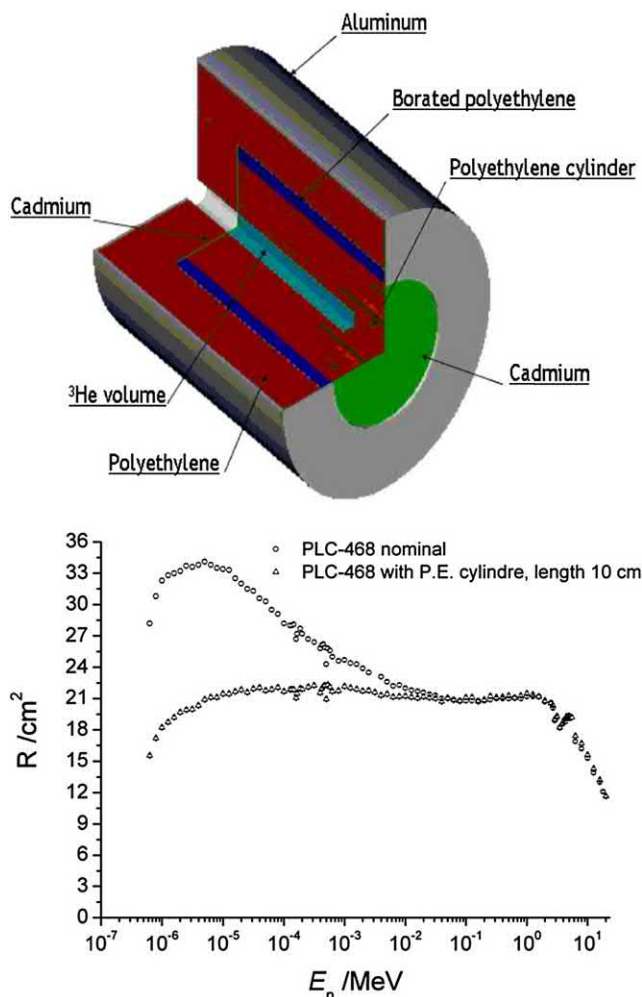

FIGURE 2.37 (Upper) PLC-468 long counter modeled with MCNPX. (Lower) Fluence response energy distributions of the PLC-468 long counter with and without a 10-cm-long cylinder of polyethylene inserted in front of the detector. The additional polyethylene cylinder decreases the sensitivity of the detector to the low-energy neutrons without affecting the detector response in the higher energy range. For the color version of the figure, the reader is referred to the online version of the book. From Lacoste (2010), reprinted with permission from Elsevier © 2010.

FIGURE 2.38 Structure of the compact flatresponse neutron detector (Harano et al., 2011). Reprinted with permission from © 2011 IEEE.

neutron counting tube arrangement was used successfully for the determination of plutonium in radioactive waste drums at Lawrence Livermore National Laboratory (Hankins and Thorngate, 1993a, 1993b). It was reported that the sensitivity of this equipment is about 10 times better than the sensitivity of X-ray and gamma-ray instruments that are normally used. Helium-3 counting tubes are arranged outside the waste package. These ^3He counters are covered with paraffin with an outside lining of cadmium. Fission neutrons passing the cadmium barrier are thermalized in the paraffin layer and detected by the ^3He tubes.

Another system uses a pulsed electron beam from a linear accelerator to produce high-energy photon bursts from a metallic converter. The photons induce fission in transuranium elements. When fission is induced in such material, delayed neutrons can be detected by a sensitive neutron counting system (Lyoussi et al., 1996).

A nanoparticle-doped micro-Geiger counter was designed to enable multispecies radiation detection, which is important for the detection of fissionable bomb-making materials (Whitney et al., 2009). In this forensic application, incoming radiation interacts with tailored nanoparticles, which release secondary charged particles into the fill gas. An array of multichanneled micro-GM tubes is formed to a counter platform. Each tube is doped with a nanoparticle from which the authors underscore the possibility of discriminating between alpha, beta, gamma/X-ray, and neutron radiation. Tungsten oxide nanoparticles convert beta particles to several electrons of lower energy; glass nanoparticles convert alphas to electrons; boron-10 converts neutrons to alphas; and lead oxide nanoparticles convert gammas/X-rays to photoelectrons. By analyzing the height of the resulting pulses of each individual channel under the same radioactive source, the type, location, and energy of the incoming radiation can be determined (Whitney et al., 2009).

Not only transuranium elements are determined in waste using neutron counting, but moisture measurements of the radioactive waste are also carried out. The thermalization of neutrons from an isotopic neutron source is detected by a proportional neutron counting tube. The moisture content of the waste is an important parameter that determines the combustibility of waste materials (Lentsch et al., 1996).

4. Moisture measurements

Moisture measurements are based on the principle of neutron moderation by hydrogen atoms. While various other methods have become available, the neutron-based moisture measurement in soil (neutron probe) is still regarded as one of the most accurate methods for the determination of moisture in soil (Fred Zhang, 2017). The method can even be used to analyze (significant)

contaminations with hydrocarbons (in the percent range) in soil, provided a correction for moisture is being conducted (Naqvi et al., 2018).

In neutron water gauges, neutrons are most frequently produced through (α, n) reactions, for example, $^9\text{Be}(\alpha, n)^{12}\text{C}$. These neutrons have a spectrum of energies from 0 to about 10 MeV. The neutrons of high energies are moderated (slowed down) by elastic scattering with hydrogen atoms from water. These slow neutrons are detected by a counting device, which is only sensitive for slow neutrons, for example, a BF_3 counter. Modeling of the interactions of slow neutrons with different media, such as soils, is not easy, and therefore, a calibration is needed to convert the slow neutron counts to water content. Usually, a neutron moisture meter (NMM) device is combined with a density gauge.

Neutron moisture gauges are well-proven devices for soil water determination, or other difficult, bulky matrices such as asphalt (Huang et al., 2013). Tolk and Evett (2009) compared the performance of an NMM and a lysimeter with respect to evapotranspiration determination of soil. They found a deviation of not more than 4% when comparing both methods. Although the NMM has served the need for this purpose, increasing regulatory burdens, including the requirement that the NMM not be left unattended, limit the usefulness of the method. Newer methods, which respond to soil electromagnetic (EM) properties, typically allow data logging and unattended operation, but with uncertain precision, accuracy, and volume of sensitivity. One major advantage of the NMM over EM devices is its insensitivity to temperature (Evett et al., 2006). In a later study on the same problem, Evett et al. (2009) conclude that the EM methods poorly reproduced the spatial and temporal behavior of NMM and gravimetric sampling and implied spatial variability of profile water content that was not evident in either the NMM or gravimetric data. The authors conclude that EM sensors were influenced not only by the mean water content in the sampling volume but also by the smaller-scale structure of soil electrical properties.

The theory and practice of measuring the water content in large volumes of material by neutron thermalization and the measurement of thermal neutrons with BF_3 or ^3He detectors are reviewed by Nielsen and Cassel (1984) and Bacchi et al. (2002).

B. Multiple sample reading systems

In radioassay methods in biochemistry and medicine, a high sample number throughput is frequently essential. Radioactivity quantitation on solid supports, and radio-immune, dot blot, cell proliferation, and receptor binding assays require systems for counting a rather high number of samples in a given time. Simultaneous counting methods

for a large number of samples are desirable. For these applications, multiple sample reading systems have been designed. Bateman (1994) has constructed a multipin detector. The pins are centered in holes in a metallic collimator system, and 60 beta-sensitive positions are obtained.

A system with 96 individual detectors working in the GM region has also been manufactured (Roessler et al., 1993; Hillman et al., 1993a). A high sample throughput is achieved, and the counting procedure is about 40 times faster than single-detector assay procedures. Of course, the counting efficiency for tritium is much lower than that achieved with liquid scintillation counting, but the background is reduced because the GM detectors are very small.

Roessler et al. (1993) compared several methods for receptor binding assays and compared the sample throughputs. Hillman et al. (1993b) applied the 96-sample measurement system for chromium-51 retention assays. Several other application examples can be found in the literature (Alteri, 1992; Hutchins, 1992).

Microplate assays related to investigations using radioactive tracers have attracted great interest during the past decade. For microplate assays, radioactivity has to be measured from samples on a solid support that may hold 96 samples in an area of 8×12 cm. Cells or tissues are incubated in the presence of a radiolabeled substrate simultaneously in all positions of such a microplate. After the incubation, the nonincorporated components must be separated from the incorporated radioactive substrate at each position of the microplate. Applying conventional techniques, this was usually done by filtration and washing one sample after the other. The radioactive residue on the filters was counted using liquid scintillation counting (LSC) techniques. All this was a rather time-consuming and expensive procedure. Great progress was achieved by developing a sample harvester that could harvest and wash 96 samples simultaneously, saving a great deal of time and work. This harvesting and washing procedure can be performed by a specially constructed fully automatic cell harvester from conventional microplates, or special filter bottom foils for these plates can be used. The application of a radioactivity reading system that can analyze 96 samples simultaneously greatly simplifies the microplate radioassay techniques.

Two different types of microplates can be chosen, those with and those without a removable bottom. The removable bottom consists of a membrane filter material that can be easily stripped from the bottom of the microplate.

These solid support samples can now be measured using either liquid scintillation counting (standard LSC or multidetector LSC) or ionization detector techniques, such as proportional ionization detector counting, PSPC scanning, or multidetector avalanche gas ionization detector quantitation. See Chapters 6 and 9 of Volume 1 for a detailed description of scintillation analysis in the microplate sample format.

FIGURE 2.39 Schematic diagram of a self-powered neutron detector. From *Alex and Ghodgaonkar (2007)*, reprinted with permission from Elsevier © 2007.

For PSPC scanning, systems similar to those used for scanning thin-layer chromatograms (TLCs) or paper chromatograms are used. With a position-sensitive wire detector, 12 samples in a single row can be counted simultaneously. This method suffers from some disadvantages. This type of detector has a very low counting efficiency for low-energy beta emitters, and it is subject to high amounts of cross talk when high-energy beta-emitting radionuclides such as phosphorus-32 are analyzed. Also, the efficiency is not uniform across the entire length of the wire. It seems that this technique is rather unsuitable for quantitative simultaneous multicounting applications. Therefore, systems with individual detectors in the format of the microplate were designed and manufactured. Open-end gas avalanche detectors are used, and the systems are capable of quantitating tritium, carbon-14, phosphorus-32, sulfur-35, iodine-125, and many other beta emitters. Of course, the filter mat must be dry, but there is no addition of cocktail. The filter is not destroyed and can be used for further investigations. Also, the amount of waste is minimized.

A detailed description and examples of applications are given by [Kessler \(1991\)](#). This technique can be applied to the radioassay of dot blots and labeled cell proliferation assays. With conventional autoradiography and densitometry, the range of radioactivity measurements is much smaller than with a multidetector system, because an X-ray film shows a saturation effect in blackening. Also, the exposure time for X-ray films is much longer than the measurement time for ionization detectors. Other more quantitative imaging methods are described in Chapter 9, Volume 2. The ionization multidetector arrangement seems to be comparable to a liquid scintillation multidetector system ([Kessler, 1991](#)). However, commercially available high-sample-throughput multidetector microplate scintillation analyzers described in Chapters 6 and 9, Volume 1 provide higher counting efficiencies and higher sample throughput.

C. Self-powered detectors

Self-powered neutron detectors are fabricated with a material incorporated in the detector volume that has a high cross section for neutrons, for example, rhodium ([Zhang et al., 2018](#)), vanadium, cobalt, or silver ([Khoshahval et al.,](#)

[2018; Kong et al., 2017](#)). By neutron capture, a beta-emitting radionuclide is formed. The detector operates by directly measuring the flow of current produced by the beta particles. No external bias voltage is needed. Other types of self-powered detectors (SPDs) for neutron counting are operated by the current that is produced by ionization due to gamma emission related to neutron capture during fission. The main advantages of these self-powered neutron detectors are their small size and the simple electronics necessary for this type of detector ([Alex et al., 2004; Miller et al., 2004; Alex and Ghodgaonkar, 2007](#)).

The basic design of the SPD is illustrated in [Fig. 2.39](#). The detector (emitter, [Fig. 2.39](#)) measures only 2 mm in diameter and 21 cm in length. The emitter is housed in a high purity alumina ceramic tube (2.2 mm ID \times 2.8 mm OD) and enclosed in a 3 mm ID and 3.5 mm OD Inconel 600 tube. One end of the emitter is coupled to a 2-mm-diameter twin core mineral insulated cable with a length up to 12 m. The long cable permitted in-core neutron monitoring. The small size of the self-powered neutron detector allows for applications in nuclear medicine such as the implanting of the detector into patients for the online measurement of neutron flux during neutron capture therapy ([Miller et al., 2004](#)). Examples of some emitters, which can be used in SPDs, their neutron and/or gamma response, and applications, are listed in [Table 2.1](#). From the table, it can be seen that not all SPDs are responsive to neutrons. For example, bismuth ($Z = 83$) has a neutron absorption cross section of 0.014 b exhibiting a negligible response to neutron flux, and it is essentially a pure gamma detector ([Alex et al., 2004](#)). Other emitters such as Pt yield nearly equal current contributions from neutrons and gamma rays.

Disadvantages are the low levels of the output signals, a slow response time, and sensitivity of the response to the neutron spectrum. SPDs have to be operated in the current mode, because the signal created by a neutron can be only a single electron.

D. Self-quenched streamer

Traditionally, gas ionization detectors are categorized as ion chambers, proportional counters, and GM tubes. A high-current gas-amplification mode in cylindrical detectors is considered as a time sequence of three amplification modes: a proportional mode, a mode of limited

TABLE 2.1 Response characteristics of self-powered detectors^a.

Emitter	Neutron response	Gamma response (γ , e)	Application
$^{103}_{45}\text{Rh}$	(n, β) (delayed)	Positive current	Flux mapping

proportionality, and an SQS (or limited streamer) mode (Akopdzhanov, 2008). The latter is a type of gas multiplication detector that is used in position-sensitive multiwire detector systems. In conventional proportional and GM counters, UV photons play a significant role in the propagation of an ion avalanche. If the propagation of the avalanche is kept small by the field strength or by absorption of UV, the system works in the proportional mode. If UV photons are able to create additional avalanches that may spread through the entire length of the anode wire and the whole process is terminated only by the creation of a space charge around the anode, the system works in the GM mode and the output signal does not depend on the original ionization effect (e.g., on the number of primary ions produced by the radiation event). In the SQS mode, the ion avalanches are controlled in a special way. The counting tube is filled with a gas mixture that absorbs UV photons. Therefore, no additional avalanches far from the original avalanche pathway can be created through excitation by photon absorption. Avalanches, therefore, grow and propagate in the shape of a streamer. The streamers have a diameter of about 200 μm and extend a few millimeters from the anode. They terminate at low field strength at larger radii of the detector.

If the voltage is high enough, a single electron can create a streamer. The streamers have a final length that depends on the voltage applied. The formation of such streamers is supported by anode wires with relatively large diameters (0.1 mm).

SQS detectors have some properties of both proportional and GM detectors. The rather high internal gas amplification is useful for position-sensitive detectors. Position-sensitive detectors operating in the proportional region have much smaller signal amplitudes. However, as in the case of GM tubes, the signal amplitudes in SQS detectors no longer provide information about the energy of the primary radiation event. Spreading of the avalanche along the total length of the anode wire is prevented. Thus, the resolving time is much shorter than with GM tubes (Knoll, 1989).

E. Long-range alpha detectors

Traditional alpha detectors suffer from limitations related to the very short range of alpha particles in air. If sample and detector together are kept in a vacuum or sample and detector are operated in close proximity, reasonable efficiency is achieved. An alpha particle produces about 30,000 ions per 1 MeV of its particle energy (see Chapter 1, Volume 1). These ions can be transported over significant distances by a moving stream of air to a detector. For that purpose, a current of air can be generated by a small fan and the ions can be transported over a distance of several meters. The current of air is finally monitored by an ion chamber (Garner et al., 1994). By using air as the detector gas, alpha contamination on any complicated surface can be measured (MacArthur et al., 1992, 1993; Allander et al., 1994; Vu et al., 1994). Fig. 2.40 illustrates the principle of a long-range alpha detector (LRAD). It is shown that the detector is sensitive to the ionized air molecules produced by the passage of an alpha particle rather than to the alpha particle itself. The detector consists mainly of two grids (see Fig. 2.41) across which an electric field is applied. One type of ion is attracted by the high-voltage (HV) grid, the other by the sense grid. Both possible polarities for the grids have

FIGURE 2.40 Principle of a long-range alpha detector operation. Ions created by alpha particles are transported to the detector by air flow. From MacArthur et al. (1992). With permission © 1992 IEEE.

FIGURE 2.41 Construction detail of a long-range alpha detector. An electric field is applied across the grids. One type of ion is attracted by the high-voltage (HV) grid, the other one by the sense grid. From *After MacArthur et al. (1992)*. With permission © 1992 IEEE.

been applied with equal sensitivity. The charge collected at the sense grid is measured by a suitable electronic circuit and used to determine the ionization, the number of alpha particles.

Instead of using air flow, the ions produced by alpha particles can be transported to the detector by an electrostatic field. At the Los Alamos National Laboratory, LRADs have been built for several applications, such as monitoring of soil surface and liquid effluents. A hand monitor has also been constructed. The method was applied to radon measurements (Bolton, 1994). Some effort has been made to use the long-range detectors for the measurement of beta contamination (Johnson et al., 1994a).

Real-time alpha activity monitoring is one of the applications for which the ionization detectors show several advantages. A monitoring system for real-time alpha monitoring was developed at Los Alamos and tested at the Radioactive Liquid Waste Treatment Facility as a means for real-time monitoring of liquid waste influent (Whitley et al., 1996). This system determines the alpha activity of

the wastewater by measuring the ionization of ambient air above the surface at a rather long distance. The distance to the surface of the liquid described by Whitley et al. (1996) was about 4 in. Sometimes this type of design causes problems because of changing levels of the surface to be monitored, for example, with liquids.

The ionization counting system consists of a metal enclosure and a signal plate that is maintained at 300 V DC. The box is maintained at ground potential. A highly sensitive electronic circuit is used to detect changes in current to the plate. Changes in alpha activity in the contaminated liquid at the 370 Bq/L level could be detected.

The authors claim that this kind of measurement equipment can be useful for monitoring low-level liquid streams before discharge into the environment. However, a more sensitive design will be necessary to ensure regulatory compliance and offer the opportunity for field application.

LRADs are useful when a contamination is suspected in areas that are not easily accessible. Wu et al. (2013) showed that this measurement principle can be useful in the decommissioning of nuclear facilities, when the inside of a pipe needs to be checked for α -emitters. In their detection system, the screened pipe is placed inside a chamber, and a fan sucks air through the pipe (see Fig. 2.42). The authors showed that the time between switching on the fan and the detection of ions in the ion chamber is a decent indicator of the position of the contamination inside the pipe.

Ionization monitoring by LRAD also has a great advantage in simultaneous measurement of the entire body of a person. Air currents that are created by high capacity fans can be drawn from all surfaces of the body of a person who is positioned in a monitoring chamber (size 91 cm \times 91 cm \times 213 cm). High air flow rate is essential because of the rather short "ion lifetime." Koster et al. (1998) describe a contamination measurement facility for alpha particle radionuclides, which is used at the Los Alamos National Laboratory for test experiments.

In practical application, LRADs have been shown useful in monitoring swipe tests for rapid contamination control in the field (Johnson et al., 1994b). In their design, two electrometers are used to instantly subtract background radiation from radon buildup inside the chamber. Another example of this application was an LRAD-based portable swipe monitor, presented by Whitley et al., 1998. This

TABLE 2.2 Comparison of instruments for the detection of alpha radiation ([Gurkovskiy et al., 2015](#)).

Parameter	Device proposed by Gurkovskiy et al. (2015)	Long-range alpha detector	Remote optical detection	Silicon ion—implanted alpha detector	ZnS alpha scintillation detector	Thin-window proportional counter	Thin-window Geiger—Müller counter
Principle of detection	Remote	Remote	Remote	Direct	Direct	Direct	Direct
Distance	40 cm and more	40 cm and more	40 cm ^a	<4 cm	<4 cm	<4 cm	<4 cm
Selectivity (β or γ)	Good (counting mode)	Bad (counting mode)	Good	Good	Good	Good	Bad
Problems	Power consumption (fan)	Power consumption (fan)	Discriminate the weak fluorescence signal from the background lighting	Direct detection	Direct detection, restricted area	Direct detection	Direct detection
Lower threshold of particle energy	~0.2 MeV			~0.02 MeV	~3 MeV	~3 MeV	~3 MeV
Power consumption	High	High	High	Low	Low	Low	Low

^aLiterature suggests higher distances than given by [Gurkovskiy et al. \(2015\)](#) in this table, up to 30 m ([Baschenko, 2004](#)).
With permission © 2015 Elsevier.

facility consists of two independent detection chambers. The swipe is placed in one chamber for the detection of the alpha contamination, and the other chamber records signals due to the presence of radon or other background radionuclides. The response to beta contamination is about 100 times weaker compared with the same activity of alpha-emitting radionuclides. A unit applicable to rapid field measurements is available with dimensions of 28 cm \times 13 cm \times 14 cm and weight of 5 kg.

An unusual detector principle is based on alpha radiation-induced luminescence, which shall be discussed here briefly, although it is not based on gas ionization detectors. [Baschenko \(2004\)](#) reported that 95% of the intensity falls in the narrow range between 310 and 400 nm and that the spectrum corresponds to a number of narrow (2–3 nm) and broad bands, which are due to the transitions of ionized and excited nitrogen molecules. Each alpha disintegration is accompanied with an average of ca. 30 UV photons, which may be detected optically. This method may be useful for the remote detection of radiation sources, which has sparked some research in recent years, primarily in forensic ([Kerst et al., 2018; Sand et al., 2015](#)) and environmental sciences ([Sand et al., 2016; Yamamoto et al., 2016, 2018](#)), as well as in decommissioning of nuclear facilities ([Crompton et al., 2017, 2018a, 2018b; Lamadie et al., 2005; Suran et al., 2018](#)).

[Gurkovskiy et al. \(2015\)](#) proposed a device for long-distance detection of alpha radiation, by detecting negatively charged ions from the alpha particle tracks by a discharge wire counter open to the air. Ion clusters in this device are transferred from the particle tracks to the detector volume by an air flux. A comparison of LRAD detectors and other detection systems is given in [Table 2.2 \(Gurkovskiy et al., 2015\)](#).

F. Liquid ionization and proportional detectors

Detector materials of high density offer some advantages, particularly for the detection of radiation with low LET and high energy. Radiation spectroscopy in many cases can be carried out much more reliably using detector materials of higher density. Consequently, research related to liquid and solid-state ionization detectors is carried out. Noble gases in the liquid or solid phase are dielectric materials where created electrons remain free once all electronegative impurities have been removed.

Among the noble gases, xenon has attracted much interest as a filling medium for ionization-type detectors ([Incicchitti et al., 1990](#)), such as ion chambers and PC systems. The start of the ion multiplication phenomenon is observed at a field strength of 10^8 V/m. At 10^5 V/m, the electron drift velocity is about 3×10^3 m/s. Main obstacles to the construction of such detectors are the requirements for operation at a low temperature and for extensive

purification of the detector medium. Liquid xenon ionization chambers compared with sodium iodide (NaI) detectors have a similar gamma efficiency and a higher energy resolution ([L'Annunziata, 1987](#)). Of course, the energy resolution of semiconductor gamma detectors is still better.

The size of useful liquid or solid noble gas ionization detectors depends on the purity of the filling material. Position sensing by large detectors can be carried out by measuring the electron drift time. Gridded versions of such ion chamber detectors have also been reported.

Liquid ionization chambers (He, Ar, Xe) are frequently used in basic nuclear physics, for example, for the search for weakly interacting massive particles, such as the neutrinos predicted by supersymmetric theories ([Ovchinnikov and Parusov, 1999; Masaoka et al., 2000](#)).

Liquid xenon is also used in proportional scintillation detectors ([Aprile et al., 2014](#)), which finds application in the search for dark matter. [Arazi et al. \(2013\)](#) observed proportional luminescence (secondary scintillation) in the holes of a THGEM immersed in liquid xenon, when bombarded with 662 keV gamma photons or 4 MeV alpha particles. This luminescence was found to be nearly linear to the applied voltage. The observation may result in novel detector systems.

Little information is available related to nonpolar liquids as ionization detectors at room temperature. Here, the purity that can be achieved and maintained for the applied material is extremely important. Research has been carried out using, for example, tetramethylsilane. This material was used for ion chambers working in pulse and current mode ([Knoll, 1989](#)).

Prof. Dr. Georg Steinhauser

Prof. Dr. Georg Steinhauser is alumnus of the University of Vienna (MSc in chemistry 2003) and the Vienna University of Technology (Atominstut; PhD in radiochemistry 2005). After 10 years of research using the Atominstut's TRIGA reactor, he joined Colorado State University's Health Physics Section in the Department of Environmental and Radiological Health Sciences in 2013 as an assistant professor of Radiochemistry. Since 2013, Prof. Steinhauser has been a member of the Radiation Protection Advisory Board of the Austrian Federal Ministry of Health. In October 2015, he was hired by Leibniz University Hannover (Institute of Radioecology and Radiation Protection) as a professor of Physical Radioecology. His main research focus is on environmental radioactivity studies in Chernobyl, Fukushima, and other release scenarios and environmental nuclear forensics as well as accident preparedness and response. He has (co) authored more than 100 publications. Since 2016, Prof. Steinhauser has been an editor of the Springer Nature Journal *Environmental Science and Pollution Research*.

Prof. Dr. Karl A. Buchtela

Prof. Dr. Karl A. Buchtela, born 1932, was the head of the Radiochemistry Unit at the Atominstut of Vienna University of Technology from 1975 to 2000. Since then, he continued his participation in teaching and research projects as Professor emeritus at the University, as freelance collaborator and advisor. Prof. Buchtela received his scientific education in chemistry, physics, and economy at the Austrian universities, followed by professional scientific research and teaching positions at the universities, in collaboration with national and international organizations in the framework of planning and design of facilities for the production, application, and analysis of radioactive materials. He was hired as an expert by the International Atomic Energy Agency for special tasks in various member states. Prof. Buchtela has authored and coauthored about 150 scientific papers and chapters in books and has served in cooperation with editorial and peer-reviewing teams globally.

Solid-state nuclear track detectors

Chapter outline

Part 1: Elements	309		
I. Introduction	309		
II. Detector materials and classification of solid-state nuclear track detectors	310		
A. Crystalline solids	311		
1. Muscovite mica	311		
2. Apatite	313		
3. Zircon	314		
4. Sphene	314		
5. Olivine	314		
6. Pyroxene	315		
7. Whitlockite	315		
8. Other crystalline solids	316		
B. Glasses	316		
1. Man-made glasses	316		
2. Natural glasses	317		
C. Plastics	318		
1. CR-39 (polyallyldiglycol carbonate, PADC, PM-355, PM-500, PM-600)	318		
2. Polycarbonate (PC, Lexan, Makrofol, Taffak)	319		
3. Cellulose nitrate (CN, LR-115, Daicell)	321		
4. Polyethylene terephthalate (PET, Mylar, Cronar, Melinex, Lavsan, Terphane, Hostphan)	322		
5. CR-39–DAP series	322		
6. Polyimide (PI, Kapton, Upilex)	323		
7. Other new track detector materials	324		
III. Recordable particles with solid state nuclear track detectors	325		
A. Protons	325		
1. Suitable detectors for proton detection	325		
2. Proton intensity measurements	326		
3. Proton energy measurements	326		
4. Obtaining mono-energetic proton beam for track detector calibration	327		
5. Proton spatial distribution measurements	328		
6. Applications of proton detection	328		
B. Alpha particles	329		
1. Suitable detectors for alpha-particle detection	329		
2. Alpha-particle intensity measurements	329		
		3. α -particle energy measurements	331
		4. α -particle spatial distribution measurements	332
		5. Applications of α -particle detection	332
		C. Fission fragments	333
		1. Suitable detectors for fission fragments	333
		2. Fission rate determination	336
		3. Determination of detection efficiency of fission fragments	337
		4. Statistical counting method for determination of detection efficiency	337
		5. Critical angle method	339
		6. Twin fragment method for determination of detection efficiency	339
		7. Projected track-length method for determination of detection efficiency	343
		8. Backscattering effect of fission fragments from substrate and fission source	345
		9. Spatial distribution of fission and angular distribution of fission fragments	345
		10. Application of fission detection	345
		D. Heavy ions ($Z \geq 3$)	346
		1. Suitable detectors for heavy ions $Z \geq 3$	346
		2. Identification of charge Z	346
		3. Identification of mass A of isotopes	346
		4. Heavy-ion energy determination	346
		5. Applications of heavy-ion detection	346
		E. Neutrons	347
		1. Principles of neutron detection	347
		2. Suitable detectors for neutron detection	347
		3. Neutron intensity measurements	348
		4. Neutron energy measurements	348
		5. Neutron dosimetry	348
		6. Applications of neutron detection	349
		F. Exotic particle detection	349
		1. Suitable detectors for exotic particle detection	349
		2. Magnetic monopole detection	349
		3. Dark matter particle detection	350
		IV. Track formation mechanisms and criterions	350
		A. Introduction	350

B. Track formation mechanisms	350	3. Apparent fission track age and its corrections	369
1. Ion explosion spike for inorganic solids	350	4. Geothermal chronology	369
2. Chain breaking mechanism in high polymers	351	VIII. Instrumentation	369
C. Criteria of track formation	351	A. Size of latent tracks and etched tracks	369
1. Primary ionization rate criterion	351	B. Optical microscope	370
2. Restricted energy loss for plastic track detectors	352	C. Track image analyser	370
3. Energy deposition model (e_v)	352	D. Electron microscope	370
D. Extended and transitional criterions	353	E. Scanning tunneling microscope (STM) and atomic force microscope	370
1. Z_{eff}/β	353	F. Spark counter	371
2. dE/dx transitional parameter	354	Part 2: Applications	371
E. Incapability of the former adopted criteria	354	I. Introduction	371
1. Incapability to estimate the threshold values of existing track detectors	354	II. Physical sciences and nuclear technology	371
2. Incapability to design a new material possessing the expected threshold value	354	A. Cluster radioactivities	371
F. Conflict between track formation criteria and chain breaking mechanism	355	B. Heavy ion interactions	372
G. Latent track structures	355	1. Relativistic projectile fragmentation	372
1. IR absorption spectrometry for polymer track detectors	355	2. Sequential fission after inelastic collisions	372
2. Cross-section of bond breaking by heavy ions	355	C. Nuclear fission and neutron physics	372
3. Effective track core radius	356	1. Nuclear fission	372
4. Layered structure of latent tracks	357	2. Neutron physics	374
5. Chemical etching and OH groups in polymers	357	D. Plasma physics	374
6. Radial Electron Fluence around ion tracks	358	1. Laser acceleration	374
V. Track revelation	359	2. Inertial confinement fusion	375
A. Chemical etching	359	E. Astrophysics and cosmic rays	375
1. Etching condition	359	F. Nuclear technology	376
2. Track etching geometry	360	1. Nuclear reactor physics	376
3. Critical angle of etching	360	2. Accelerator-driven subcritical reactors	377
4. Techniques of critical angle measurements	360	3. Nuclear forensic analysis and nuclear safeguards	377
5. Track etching geometry	361	G. Elemental analysis and mapping	380
6. Progress in track etching geometry	361	III. Earth and planetary sciences	381
B. Electrochemical etching	362	A. Fission track dating	381
C. Track etching kinetics	362	1. Absolute approach	381
1. Objectives and required parameters	362	2. Zeta approach	383
2. Forward calculation	363	3. LA-ICP-MS-based fission track dating	384
3. Inverse calculation	364	4. Continental drift and ocean-bottom spreading	385
VI. Particle identification	364	5. Archeology and anthropology	385
A. Maximum track length method	364	6. Tectonic up-Lift rate determination	386
B. Track etch rate versus radiation damage density method	364	B. Geothermal chronology	387
C. Track etch rate versus residual range method	364	C. Uranium and oil exploration and earthquake prediction	388
D. Track diameter method for identification of charge Z at high and relativistic energy	365	IV. Life and environmental sciences	389
E. Track length method for identification of charge Z at high and relativistic energy	367	A. Radiation protection dosimetry	389
VII. Track fading and annealing	367	1. Radon and thoron monitoring and dosimetry	389
A. Track fading and annealing	368	2. Neutron dosimetry	389

Part 1: Elements

I. Introduction

Solid-state nuclear track detector (SSNTD) is a special type of radiation detector, which records tracks of heavy charged particles ($Z \geq 1$) in insulating or dielectric solids.

In a broad sense, nuclear emulsions (Barkas, 1963), a special type of bubble detectors (BDs), etch track detectors, and fluorescent nuclear track detectors (FNTDs) (Akselrod et al., 2006) are all included in SSNTDs because these detector materials are all solid substances and the recorded signals are trajectories (or visible tracks) of charged particles. In this handbook, SSNTD refers to etch track detectors or dielectric track detectors. Track etching is the basic technique used to develop tracks in this type of track detector.

There are some other types of nuclear track detectors, such as cloud chamber, bubble chamber, and spark chamber (Wilson, 1951; Shutt, 1967). Their detector materials are saturated vapors, superheated liquids, and ionizable gases, respectively. These mediums are not solid substances. They do not belong to SSNTDs, even though they can record nuclear particle tracks. A special type of BD is able to record tracks of high-energy heavy ions in the whole Periodic Table of Elements ($Z \geq 1$) (Guo et al., 2003, 2005, 2015). However, its principle for development of tracks is formation of bubbles from superheated droplets, not track etching. Therefore, it will be excluded from this handbook.

The historic stories of track etching to develop tracks in solid can be retraced to a very early time. H. Baumhauer in 1894 etched apatite with diluted sulfuric acid and saw etched figures (fission fragment tracks); but he did not know what they were because radioactivity was not discovered until two years later by Becquerel (1896a,b) and nuclear fission was discovered many years later (Hahn and Strassmann, 1939a,b; Meitner and Frisch, 1939). In recent books, L'Annunziata (2007, 2016) provides a detailed historical account of the discoveries and research into nuclear radiation. Baumhauer (1894) published his results in a treatise on etch methods. Since the end of the 19th century, etching techniques had become a traditional method to display dislocation in minerals. A. P. Hones in 1927, A. R. Patel, and S. Tolansky in 1957 and L. C. Lovell in 1958 also showed etched figures (tracks) in minerals. None of them recognized the etchings as tracks (Fleischer, 1998). D. A. Young was the first scientist who intentionally revealed fission fragment tracks in lithium fluoride (LiF) by etching in 1958 (Young, 1958). His discovery showed that radiation damage by heavy charged particles (fission fragments) could form tracks in crystal. After his early success he discontinued research in this field. E. C. H. Silk and R. S. Barnes in 1959 observed fission fragment tracks in

muscovite mica with a transmission electron microscope (TEM) (Silk and Barnes, 1959). This was the first direct observation of straight latent (un-etched) tracks of fission fragments in mica. They also noticed that latent fission fragment tracks in muscovite mica disappeared (track fading) after a few seconds due to heating by the intensive electron beam of the microscope.

P. B. Price and R. M. Walker in 1961 found a way to circumvent the problem of the rapid fading of tracks in muscovite mica under the electron microscope. They stabilized and fixed the tracks by chemical etching (CE). They also discovered that CE could enlarge fission fragment tracks continuously and the enlarged tracks could be visible under the ordinary optical microscope when the diameter of tracks was enlarged to micrometers (Price and Walker, 1962a, 1962b; 1962c). Their discoveries made fission fragment tracks become sustainable records for continuous research, overcame the limitation of the electron microscope to survey only tiny volumes of solids, and made it possible for many difficult scientific problems to be easily tackled by very simple and popular instruments such as ordinary optical microscopes. Based on these discoveries, "a new track detector" was announced in 1962 by Price and Walker (Price and Walker, 1962d) and later was named the solid-state (nuclear) track detector (Walker, 1963; Fleischer et al., 1965a), which was similar to the cloud chamber, bubble chamber, and spark chamber, and superior to conventional nuclear emulsions in simplicity and ruggedness. At the same time, Price and Walker discovered fossil tracks in mica and invented fission track dating (FTD) (Price and Walker, 1962d, 1963a). They designed a low uranium determination technique (Price and Walker, 1963b) and suggested the idea to make nuclear track membrane (NTM).

R. L. Fleischer joined Price and Walker in 1962. By close cooperation they discovered that polymers and glasses could also record etchable tracks of heavy charged particles (Fleischer and Price, 1963a, 1963b). They extended nuclear track applications into nuclear physics (Price et al., 1963; Fleischer et al., 1964b), neutron detection (Walker et al., 1963), astrophysics (Price et al., 1968a, 1968b), meteorite (Fleischer et al., 1967c), cosmic rays (Price et al., 1967, 1968a, 1968b; Fleischer et al., 1967a), tektites (Fleischer and Price, 1964), archeology (Fleischer et al., 1965d), continental drift and ocean bottom spreading (Fleischer et al., 1968), Quaternary geology (Fleischer et al., 1969b), Crater dating (Fleischer et al., 1969e), dating of mechanical events and underground nuclear explosions (Fleischer et al., 1972, 1974), Lunar science (Fleischer and Hart, 1973), planetary science (Fleischer et al., 1965b), anthropology (Fleischer et al., 1965c, 1965d), search for magnetic monopoles (MMs) (Fleischer et al., 1969a, 1969c), mapping of uranium (Fleischer, 1966), and radon monitoring (Alter and Price, 1968). They made the first

practical polymer track membrane (Fleischer et al., 1964a, 1964b).

Before 1967, etch track applications were basically limited to track counting. In 1967, P. B. Price and co-workers discovered a method of identification of charge (Z) of nuclear particles by measuring the etch rate along the trajectory of the particles. They found that track etch rate along the trajectory of the particles is a function of radiation damage density for a specific track detector. By measuring residual range and track etch rate one could determine the charge of the particle creating the track (Price et al., 1967; Price and Fleischer, 1971). This discovery greatly opened new fields of modern applications of SSNTDs to high energy physics, astrophysics, cosmic ray physics, nuclear fragmentation, exotic particles, and many other fields. These applications are discussed further on in this chapter.

Discovery of CR-39 as a track detector in 1978 was another important event (Cartwright et al., 1978). Up to now, CR-39 has been the most useful detector material compared with others.

Electrochemical etching was first reported by L. Tommasino in 1970, which is an alternative way to develop tracks and is used widely in radiation dosimetry (Tommasino, 1970). The nuclear track spark counter was first devised by W. G. Cross and L. Tommasino in 1970 (Cross and Tommasino, 1970), which is an often-used technique for rapid counting of nuclear tracks.

For track formation mechanism, Fleischer et al. (1964a, 1964b) first suggested total energy loss rate as a criterion to judge whether a particle could be recorded by a specific detector material, but soon they found that this criterion could not fit the experimental data and they suggested another: primary ionization rate criterion (Fleischer et al., 1967b, 1967d). Benton and Nix in 1969 suggested restricted energy loss criterion (Benton and Nix, 1969). Katz and Kobetich in 1968 suggested total energy deposition criterion to judge the formation of tracks (Katz and Kobetich, 1968). The last three criteria were almost satisfied by track research, but none of them are perfect theoretically and experimentally. The most often-used criteria are primary ionization rate and restricted energy loss rate. The calculation of total energy deposition criterion is more complicated, and fewer researchers used it in practice.

Due to the obvious advantage of etch track detectors, many researchers joined in the study of etch track detectors; especially many nuclear emulsion scientists fully or partially turned to etch track detectors. This new interest was reflected in the name and topics of the international conferences on nuclear track detectors. At first, the name of the series of the conferences was on nuclear emulsions (“Corpuscular Photography”, “Nuclear

Photography”) from 1957 (the first international conference in Strasbourg) when the SSNTD was yet to be created. Since 1976 (the 9th international conference in Munchen), the name changed to “Solid State Nuclear Track Detector”. This change reflected the rapid growth of the team of etch track detectors and the shift of scientific interest from emulsions to etch track detectors. Since 1992 (the 16th international conference in Beijing), the name changed to “Nuclear Tracks in Solids” for the reason that nuclear tracks can be used not only as nuclear particle detectors, but also as nano- and microstructures applied to nanotechnology.

The split-off of the FTD workshop from the international conference on SSNTDs also showed the rapid expansion of the field of etch track detectors. A group of scientists who paid more attention to dating (including measurements of reactor neutrons, induced fission in nuclear reactors and ancient spontaneous fission events) preferred to participate in FTD workshops.

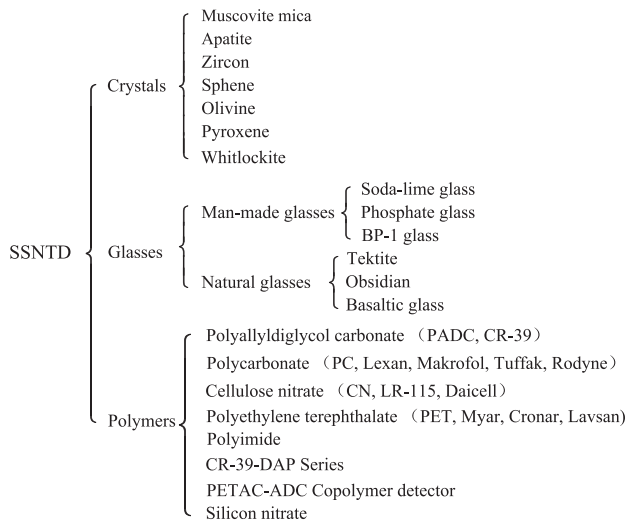

Since 1978, a special journal entitled: “*Nuclear Track Detection*” and later “*Nuclear Tracks and Radiation Measurements*” and now “*Radiation Measurements*” was established to publish research papers on SSNTDs under the auspices of Elsevier Science publishers. All of the international conference proceedings on SSNTDs were published in the above journals or separately in the early years (1976, 1979, 1981) by Pergamon Press. The treatise works such as “Nuclear Tracks in Solids, Principles and Applications” by Fleischer et al. (1975), “Solid State Nuclear Track Detection” by Durrani and Bull (1987), “Ion Tracks and Microtechnology, Basic Principles and Applications” by Spohr (1990), “Fission Track Dating” by Wagner and Van den haute (1992), “Radon Measurements by Etch Track Detectors; Applications to Radiation Protection, Earth Sciences and Environment” by Durrani and Ilic (1997) and “Nuclear Track Detectors: Design, Methods and Applications” edited by Sidorov and Ivanov (2009) had given systematic details or specialized explanations on etch track detectors. The reader is referred to these reference books for additional information on nuclear track detectors.

II. Detector materials and classification of solid-state nuclear track detectors

Nearly all kinds of transparent insulating solids can be used as SSNTDs. These materials can be classified into natural and man-made solids. Natural solids include terrestrial and extraterrestrial ones. Terrestrial solids include all kinds of natural crystalline minerals and amorphous natural glasses. Tektites, obsidian, volcanic glasses, and impact glassed are examples of natural glasses. Extraterrestrial solids include

meteorites and lunar rock. Most meteorites come from the asteroid belt between the orbits of Mars and Jupiter. Astronomers conjectured that there existed originally a planet in the asteroid belt. The planet broke at early time into many pieces or fragments. The fragments revolve round the sun on the original orbit of the planet but with some deviation. Some of the biased orbits intersect with the orbit of the earth. The fragments collide with the earth, forming meteorites. The lunar rocks were collected from the moon by astronauts of the United States in the early 1970s. Scientists from many countries participated in the research on lunar rocks with nuclear track techniques. The track lengths or diameters visible after etching under the optical microscope are usually several micrometers. Therefore, the lower limit of the sizes of the minerals or glasses for nuclear track studies is about $10\text{ }\mu\text{m}$ (μm). Very large areas of natural muscovite mica up to $10 \times 10\text{ cm}^2$ can be found and applied to nuclear physics studies. Man-made solids applied to as SSNTDs include man-made crystals (such as synthesized fluoro-phlogopite mica), man-made glasses (such as soda-lime glass and phosphate glass) and plastics (such as cellulose nitrate (CN), polycarbonate, and polyallyldiglycol carbonate (CR-39)). Usually, man-made materials can be made very large for use as track detectors, especially in recording rare events such as cosmic ray particles.

According to track formation mechanisms and etching behaviors, etch track detectors are usually classified as follows with the inclusion of some examples of commonly used detector materials and newly developed materials:

In the following subsections, some basic knowledge on each detector material listed above will be given. For information about additional materials, the readers are referred to the monographs written by [Fleischer et al. \(1975\)](#), [Durrani and Bull \(1987\)](#) and [Wagner and Van den haute \(1992\)](#).

A. Crystalline solids

Most of the transparent natural and man-made crystalline solids can be used as solid-state nuclear track detectors. Crystalline solids widely exist in the earth crust as mineral compositions of rocks, soils and dust. Large-sized muscovite mica and quartz are examples of pure track detectors. The main compositions of granite are mica, feldspar, and quartz. All of them are transparent crystalline minerals and can be used as nuclear track detector materials. Many kinds of accessory minerals, such as apatite, zircon, and sphene are also contained in granite. They are also transparent crystals with small sizes from about tens to hundreds of micrometers. They constitute about several percent of the total weight of the granite. These accessory minerals are very useful track detectors for FTD. After separation from the main compositions of the granite, each single grain of the accessory minerals can be used as track detectors. In many other types of rocks on the earth's crust, similar situations exist, but the main and accessory minerals differ from rock to rock. One can select one or more special types of main minerals or accessory minerals as track detectors.

Each crystalline solid has a special crystal structure. The etch rates in different directions of the crystal usually vary. Therefore, etching proceeds anisotropically in crystals. The detection efficiencies of crystalline solid for charged particles (the ratio of recorded to incident particles) on different surfaces are usually diverse.

The most commonly applied crystalline solids and their properties are described below.

1. Muscovite mica

Muscovite mica is a natural resource excavated from a mica mine. Large slabs of muscovite mica are found in pegmatite. It can be easily cleaved into thin flat pieces by a sharp needle or knife. The atomic composition of muscovite mica is $\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$, density is $2.76\text{--}3.10\text{ g/cm}^3$ (the commonly quoted density is 2.8 g/cm^3). It has three refractive indices $n_a = 1.560$, $n_b = 1.594$ and $n_c = 1.598$ in three directions, respectively. In track depth measurements under the optical microscope, the refractive index is taken as $n = 1.598$, that is n_c . Usually, the concentration of uranium in muscovite mica is very low ($\sim 10^{-9}\text{ g/g}$). It is about three orders of magnitude lower than that of the materials in the earth's crust ($\sim 2.7 \times 10^{-6}\text{ g/g}$). Therefore, muscovite mica is a good detector material with low concentration of uranium. It is suitable as a track detector for the determination of low uranium concentrations. The uranium concentration in muscovite mica varies. One must determine its uranium concentration before using it as a detector to determine the uranium concentration of other materials.

Muscovite mica is usually etched in hydrofluoric acid. For special purposes it can also be etched in hot concentrated NaOH solution (Khan et al., 1981; Guo et al., 1986). The etching condition of fission fragment tracks for optical microscope observation is listed in Table 3.1.

Fig. 3.1A shows a microphotograph of fission fragment tracks in muscovite mica taken with the ordinary optical microscope.

The etching condition is in 40% HF at 25°C for 500 minutes (Guo et al., 1982). Such an etching condition for muscovite mica was selected in order that the tracks

were easily visible under optical microscope and the observed number of tracks was at the middle point of the flat response with respect to the change of etching time. Under this etching condition, the detection efficiency of muscovite mica for fission fragments from thermal neutron induced fission of ^{235}U in 2π geometry is $(93.6 \pm 0.3)\%$, critical angle is $3^\circ 41'$ (Guo et al., 1982). Muscovite mica has been widely applied to fission rate measurements (Li et al., 2001), neutron dose and energy-spectrum determination (Walker et al., 1963), FTD as external detectors (Fleischer et al., 1975; Durrani and Bull, 1987; Wagner and

TABLE 3.1 Etching conditions of common nuclear track detectors for optical microscope observation.

Material	Etching condition	Reference
1. Crystalline solids		
Muscovite mica	48% HF, 23°C, 100 minutes–2 hours	Price and Walker (1962c)
Apatite	0.1–5% HNO ₃ , 20–25°C, 30 seconds–3 minutes	Fleischer and Price (1964)
Zircon	20 g NaOH + 5 g H ₂ O, 220°C, 15 minutes–4 hours	Wagner and Van den haute (1992)
Sphene	37% HCl, 80°C, 80 minutes	Guo et al. (1980)
Olivine	WN solution, boiling point, 5 hours (1 g H ₂ C ₂ O ₄ ·2H ₂ O + 1 mL H ₃ PO ₄ + 40 g Na ₂ EDTA + 100 mL H ₂ O, + NaOH until pH = 8.0 ± 0.3)	Liu et al. (1979)
Pyroxene	60% NaOH, boiling point, 80 minutes	Liu et al. (1979)
Whitlockite	0.25% HNO ₃ , room temperature, 60 seconds	Liu et al. (1979)
2. Glasses		
Soda-lime glass	48% HF, 20–25°C, 5–10 seconds	Fleischer and Price (1963b)
Phosphate glass	48% HF, 20–25°C, 5–20 seconds	Fleischer and Price (1963b)
BP-1 glass	49% HBF ₄ , 50°C, 58–100 hours	Wang et al. (1988)
Tektite	48% HF, 20–25°C, 30 seconds	Fleischer and Price (1964)
Obsidian	48% HF, 23°C, 60 seconds	Fleischer and Price (1964)
Basaltic glass	5–20% HF, 23°C, 1–5 minutes	Fleischer et al. (1969)
3. Plastics (high polymers)		
CR-39	6.25N NaOH, 75°C, 6 hours	Cartwright et al. (1978).
Polycarbonate (Lexan, Makrofol)	6.25N NaOH, 50°C, 20 minutes	Fleischer and Price (1963a)
Cellulose nitrate (LR-115)	6.25N NaOH, 23°C, 2–4 hours	Fleischer et al. (1975)
Polyethylene terephthalate	6.25N NaOH, 70°C, 10 minutes	Fleischer and Price (1963a)
Polyimide (PI, Kapton, Upilex)	5–15% NaClO, 5–70°C, 3–25 hours	Vater et al., 1988
4. New detector materials		
CR-39-DAP Series	7N NaOH, 70–90°C, 1–18 hours	Kodairo et al. (2008)
PETAC-ADC Copolymer	6N NaOH, 70°C, 60 minutes (α) 30 minutes (FT)	Manderekar et al. (2010)
Silicon nitrate (Si ₃ N ₄)	HF	Vlasukova et al. (2010)

FIG. 3.1 Microphotographs of fission-fragment tracks in (A) muscovite mica, (B) phosphate glass, (C) soda-lime glass, (D) polycarbonate, (E) quartz, and (F) polyester taken under an ordinary optical microscope. The etching conditions were selected such that the tracks were most clear and easy to observe under the optical microscope and the number of tracks was at the middle point of the constant part of the response curve for each type of detector. For the color version of the figure, the reader is referred to the online version of the book.

Van den haute, 1992), uranium and plutonium concentration determinations (Price and Walker, 1963b), and multi-prong sequential fission studies of heavy targets with heavy projectiles (Brandt, 1980; Vater et al., 1977, 1986; Gottschalk et al., 1983; Khan et al., 1987, 2001; Qureshi et al., 2005; Shahzad, 1995; Shahzad et al., 1999; Nasir et al., 2008; Baluch et al., 2006).

2. Apatite

Apatite is a sort of widespread accessory mineral, which exists ubiquitously in various rocks, such as plutonic-, volcanic-, metamorphic-, and sedimentary rocks. It is the most frequently used mineral in FTD and geothermal chronology. Its atomic composition is $\text{Ca}_5(\text{F,Cl})(\text{PO}_4)_3$, density 3.16–3.22 (usually 3.18) g/cm^3 , refractive index $n_0 = 1.629\text{--}1.667$ in the direction of axis with average 1.648, $n_e = 1.624\text{--}1.666$ in the direction perpendicular to

the axis with average 1.645. Its hardness is five (5), quite easy to be ground and polished.

The track-etching of apatite is very easy at room temperature and very fast (several seconds to several minutes) in concentrated or diluted nitric acid (See Table 3.1). Track etch rate V_T , bulk etch rate V_B , and detection efficiency for fission fragment tracks vary according to the orientation of apatite surfaces. The average detection efficiency of apatite for fission fragments of ^{252}Cf in 2π geometry is $(87.8 \pm 5.2)\%$ (Surinder Singh et al., 1986).

The uranium concentration in apatite is usually very high from about 1 to 100 ppm (parts per million = 10^{-6} g/g) (For comparison, the average concentration of uranium in the earth's crust is about 2.7 ppm).

Apatite has a relatively low thermal stability of fission tracks. Its partial annealing zone (PAZ) of fission tracks is in the range of about 60–125°C (Gleadow and Duddy, 1981). The lower limit of temperature about 60°C means that

fission tracks in apatite can be treated as stable at temperature lower than 60°C during the geologic time. Over the upper limit of the PAZ about 125°C, fission tracks will disappear after geological time. The closure temperature is $(100 \pm 20)^\circ\text{C}$ (Harrison et al., 1979). The relatively low PAZ, which is almost consistent with the formation window of petroleum (hydrocarbon) 60–130°C, makes apatite an important detector for the exploration of petroleum formation (Gleadow et al., 1983; Naeser and McCulloh, 1989; Green et al., 1989; Kang and Wang, 1991).

All the above advantages make apatite one of most useful mineral materials in FTD and geothermal chronology.

3. Zircon

Zircon, similar to apatite, as an accessory mineral, exists ubiquitously in most types of rocks; and it is rich enough in uranium to permit age determinations down to million years or so. Its atomic composition is ZrSiO_4 , molecular weight is 183.304 g/mol, $A/Z = 2.128$, and ionization potential is $I = 209.5$ eV. The colorless zircon has a density of 4.6–4.8 (usually 4.7) g/cm³, refractive index of 1.925–1.984, and hardness of 7–7.5. The green or dark brown zircon has a density of 3.9–4.1 g/cm³, refractive index of 1.78–1.815, and hardness of 6. Zircon can be etched by H_3PO_4 , or NaOH, KOH, and their mixture at high temperature. The etching condition 20 g NaOH:5 g H_2O (≈ 100 N) at 220°C for 15 min to 4 h (See Table 3.1) is often adopted. For zircon etching, the grains of zircon are mounted on one surface of polyvinylidene fluoride (PVDF) sheet by pressing with a glass plate at high temperature. The grains of zircon will be adhered and fixed onto the PVDF sheet. After grinding and polishing, the adhered zircon is etched in a tightly closed container made of Teflon. The Teflon container is held by a steel container, which is placed in an electric oven for heating to 220°C.

The uranium concentration of zircon is generally very high, between 300 and 600 ppm (Wagner and Van den haute, 1992), which is well-suited for FTD and even for archeological dating. The latent fission tracks in zircon are more thermal resistant than that in apatite. The track retention temperature of zircon is $210 \pm 40^\circ\text{C}$ (Wagner and Van den haute, 1992).

Zircon and apatite often exist in the same geological body. The apparent age (age calculated by the simple age equation without taking track fading into account, See Section III.A.1 of Part 2) of zircon and apatite reflect the years the geological body passed through their closure temperatures, respectively. From the depth–temperature relationship in the earth and the age difference between zircon and apatite, the uplift rate of the geological body can be derived. This technique of uplift rate determination is referred to as the mineral pair—closure temperature method

or simply mineral pair method. Zircon is the second most commonly used mineral in FTD and geothermal chronology.

4. Spheene

Spheene (titanite) widely exists as an accessory mineral in plutonic and metamorphic rocks; but it is less common in pegmatite and volcanic rocks. Its atomic composition is $\text{CaTiO}[\text{SiO}_4]$, molecular weight 196.04 g/mol, $A/Z = 2.042$, ionization potential $I = 144.4$ eV, density 3.4–3.6 (usually 3.54) g/cm³, hardness 5.0–5.5, and refractive index 1.888–2.054.

The etching of spheene is easy to carry out with concentrated HCl at 90°C for 30–90 minutes. The etching behavior of spheene exhibits a very strong anisotropic nature. The shapes of etched fission tracks are very different on different surfaces, depending on the orientation of the surfaces with respect to the crystal structure of the spheene and on the annealing before irradiation to fission fragments (Gleadow, 1978). The detection efficiency for fission tracks is also dependent on the orientation of the surface. The detection efficiency of annealed spheene can be down to one-half or even one-third compared with muscovite mica for spontaneous fission tracks. A calibration with annealed spheenes with random orientations showed that the ratio of detection efficiencies of the spheenes to muscovite mica is 0.516 ± 0.035 for fission fragments of ^{235}U fission induced by thermal neutrons (Guo et al., 1980, 1982a). This value is much less than 1. It means that the detection efficiency of annealed spheene for fission fragments is reduced.

Uranium concentration in spheene is usually rather high, between 100 and 1000 ppm. It is suitable for FTD and geothermal chronology. Thermal resistivity of fission tracks in spheene is higher than apatite and zircon. The effective track retention temperature (closure temperature) is $250 \pm 50^\circ\text{C}$ (Wagner and Van den haute, 1992). Its PAZ is 200–280°C (Harrison et al., 1979).

Spheene has provided much data on geological dating (Naeser, 1967; Wagner and Van den haute, 1992) and also archeological dating (Guo, 1982a; Guo et al., 1980, 1991).

5. Olivine

Olivine is a general composition of stone meteorites and stony-iron meteorites and exists in the earth's crust. It contains plenty of information about radiation in space. It is a space radiation detector. It has been recording heavy charged particle tracks since its formation billions of years ago. Fossil tracks in extraterrestrial minerals were first found in olivine in a stony-iron meteorite (Fleischer et al., 1975).

The atomic composition of olivine is $(\text{Mg,Fe})_2\text{SiO}_4$, in which the ratio of Mg to Fe can be any value. The molecular weight is 140.708 g/mol for Mg_2SiO_4 and

203.778 g/mol for Fe_2SiO_4 , the average value 172.2335 g/mol is usually taken. Its density increases with increasing Fe content from 3.3 to 3.5 g/cm³, usually 3.35 g/cm³ is taken. Its hardness is 6.5–7.0, and refractive index 1.654–1.690. The $A/Z = 2.050$, and its ionization potential $I = 158.9$ eV.

The etching condition used by many workers is the following:

1 mL H_3PO_4 :1 g oxalic acid: 40 g disodium salt of EDTA: 100 g H_2O : ~ 4.5 g NaOH, boiling temperature ($\sim 125^\circ\text{C}$) for 5 hour. Some amount of NaOH is added to make the pH value equal to 8.0 ± 0.3 of the etchant (Liu et al., 1979).

The uranium concentration of olivine is usually very low. It is $(0.046 \pm 0.004) \times 10^{-9}$ g/g in Jilin meteorite (Liu et al., 1979).

The tracks in olivine from meteorites or lunar rocks can provide information in the following fields:

1. Spontaneous fission of ^{238}U and ^{244}Pu . The latter nuclide is extinct in nature since its half life is 8.08×10^7 a (year), which is much less than the age of the earth $(4.6 \pm 0.1) \times 10^9$ a. It could exist only in the early era of the solar system. The tracks of spontaneous fission from both ^{238}U and ^{244}Pu in meteorites can provide information on the age of meteorites (Liu et al., 1979) as well as of lunar rocks.
2. Space radiation particles, including cosmic ray particles and possible magnetic monopoles.
3. Records of interactions of cosmic ray particles with nuclei in the meteorites and lunar rocks, such as high-energy spallation reactions and space neutron-induced fission.

From the above information, the origin of cosmic ray particles and the phenomena occurring in cosmic ray sources can be derived (Fleischer et al., 1975).

6. Pyroxene

Pyroxene is one of the main minerals in stone meteorites, stony-iron meteorites, and lunar rocks as well as in the earth's crust. Its atomic composition is $\text{R}_2[\text{Si}_2\text{O}_6]$, where R represents Mg, Fe or Ca; Mg and Fe are exchangeable. In some other pyroxenes, R represents Na, Li, Al, Fe, Ti, and the other elements. The basic structure of the above varieties of pyroxene are nearly the same, their properties are also very similar. For diopside $\text{CaMg}[\text{Si}_2\text{O}_6]$, its density is 3.28–3.40 (usually 3.29) g/cm³, refractive index 1.675–1.701, hardness 5.5–6, $A/Z = 2.000$, and ionization potential $I = 138.3$ eV. The etching condition for varieties of pyroxene (diopside, pigeonite, augite, enstatite, bronzite, hypersthene and ferrohypersthene) is 3 g NaOH: 2 g H_2O , boiling temperature, 35–90 minutes (Lal et al., 1968). The uranium concentration in pyroxene is usually very low, for

example, $(1.50 \pm 0.13) \times 10^{-9}$ g/g in Jilin meteorite (Liu et al., 1979), $(0.95\text{--}15.0) \times 10^{-9}$ g/g in lunar mare basaltic fragments 70017–291 (Hu et al., 1982).

Pyroxene, similar to olivine, is an important mineral detector for retrieving space radiation information as described in I.E of Part 2 and in the classic book by Fleischer et al. (1975).

7. Whitlockite

Whitlockite (or pyrophosphorite) is an accessory mineral in chondrite, achondrite, and aerosiderolite meteorites and a composition in enclosures of aerosiderite meteorites. It was formed in the early stage of condensation of nebula in the solar system. Whitlockite takes up to 0.31–0.57% by weight in chondritic meteorites (Ouyang, 1988). The sizes of the whitlockite crystalline grains are usually < 0.5 mm, among which the size from 0.1 to 0.4 mm are easy to be used as track detectors for FTD and determination of uranium concentration.

The atomic composition of whitlockite is $\text{Ca}_3(\text{PO}_4)_2$. Its molecular weight is 310.18 g/mol, and density 3.1 g/cm³. The structure of whitlockite belongs to trigonal system in crystallography. Fission tracks in whitlockites can be etched in 0.25% HNO_3 at room temperature for 60s. The annealing condition in the laboratory for erasing all fission tracks (100% annealing degree) is at 584°C for 1 hour. The annealing temperatures are 274°C and 212°C for 100% reduction of fission track density for 106 and 109a of geological time, respectively. The uranium concentration in crystalline whitlockite in meteorites is usually relatively high. For example, $(80 \pm 16) \times 10^{-9}$ g/g U is contained in whitlockites in the Jilin meteorite, which fell in Northeast part of China in 1976 (Liu et al., 1979); whereas, the coexisted essential minerals of olivine and pyroxene contain only $(0.046 \pm 0.004) \times 10^{-9}$ and $(1.50 \pm 0.13) \times 10^{-9}$ g/g U, respectively.

The fission tracks in whitlockite in meteorites may not only come from spontaneous fission of ^{238}U , but also from spontaneous fission of ^{244}Pu . The half-life of ^{244}Pu is $(8.26 \pm 0.09) \times 10^7$ a, which is much shorter than the age of chondritic meteorites 4.55×10^9 a (Ouyang, 1988). The percentage of ^{244}Pu atoms, survived now in chondrites, inferred from the decay law is only 2.6×10^{-17} , which actually is zero. Therefore, ^{244}Pu is an extinct element in the solar system, but it created a large number of spontaneous fission tracks in the early stage of formation of whitlockites in meteorites. For example, the density of ^{244}Pu spontaneous fission tracks is about $7.9 \times 10^5 \text{ cm}^{-2}$ on the internal surface of whitlockite, while the density of ^{238}U spontaneous fission tracks is about $3.6 \times 10^5 \text{ cm}^{-2}$. The ratio of ^{244}Pu to ^{238}U spontaneous fission is about 2.2. It means that there are more spontaneous fission tracks from ^{244}Pu than from ^{238}U in whitlockites in the Jilin meteorite. The tracks of extinct ^{244}Pu

in whitlockites are valuable historical remains of the early solar system contributing to our understanding of the history and evolution of the universe.

8. Other crystalline solids

Up to now, about 100 crystalline minerals have been successfully etched to show fission fragment tracks (Fleischer et al., 1975; Wagner and Van den haute, 1992). Besides the most commonly used minerals described above, quartz, feldspar, garnet and epidote are also used frequently.

Quartz is one of the crystalline detectors with low uranium concentration. By using quartz as a track detector and irradiating samples in nuclear reactors, an atomic concentration of uranium as low as 10^{-12} can be determined (Fleischer et al., 1965a).

Feldspar is one of the main mineral compositions in meteorites and lunar rocks. Feldspar has recorded a large number of tracks of space radiation particles, which should undergo further detailed research.

For more information about the etching and applications of all of the crystalline minerals, the readers are referred to the monographs by Fleischer et al. (1975) and by Wagner and Van den haute (1992).

B. Glasses

Glasses, as nuclear track detectors, are a type of amorphous noncrystalline (uncrystallized) inorganic solid. It can be divided into natural glasses and man-made glasses. Natural glasses include terrestrial glasses and extraterrestrial glasses. Terrestrial glasses are formed in volcanic eruption, rock-melts solidification, tectonic frictional fusion, and meteoritic impaction. In other words, in all geological events in which the temperature dropped rapidly, the fused substance could not form crystalline structures, resulting in the formation of glasses.

Volcanic glasses and tektites are examples of this type of glass. Extraterrestrial glasses exist in meteorites and lunar rocks. When the meteoritic or lunar substances underwent cooling, some kinds of main mineral crystals, such as olivine, pyroxene, and feldspar were first formed. The remaining substance with low crystallization temperature would form glassy substances by the rapid cooling process (Hu et al., 1982). Owing to the larger ionic radius of the uranium atom than that of other metallic ions, uranium atoms were pushed aside from the forming crystals into the gap substance, which were later formed in glassy interstitial materials. Therefore, glassy substance, distributed in the gaps of crystalline minerals, have a higher concentration of uranium than crystalline minerals.

Man-made glasses include different varieties. Such as soda-lime glass, phosphate glass, BP-1 glass, and others.

The common feature of glass track detectors is isotropic etching behavior. This feature results from the amorphous structure of glassy materials. Detailed explanation of etching of particle tracks in amorphous solids can be found in more recent publications (Nikezic and Kostic, 1997; Nikezic, 2000; Nikezic and Yu, 2003, 2004).

1. Man-made glasses

a. Soda-lime glass

The atomic compositions of most man-made glasses vary according to their manufacture from place to place. For example, the compositions of soda-lime glasses are $23\text{SiO}_2:5\text{Na}_2\text{O}:5\text{CaO}:\text{Al}_2\text{O}_3$ in the USA, (Fleischer et al., 1975), $67\text{SiO}_2:14\text{Na}_2\text{O}:14\text{CaO}:5\text{Al}_2\text{O}_3$ in the U. K (Durrani and Bull, 1987), and $71\text{SiO}_2:15\text{Na}_2\text{O}:9\text{CaO}:3\text{MgO}:2\text{Al}_2\text{O}_3$ in China (Guo et al., 1976b, 1982). All of these are commonly used as window glass, microscope slides, and cover slips, etc. It is very convenient to place a slip of window glass or microscope slide in the beam of particles ($Z \geq 10$) at an accelerator to make an exposure for a certain time. Then, by etching it in HF for a few seconds at room temperature and washing it immediately in water, the tracks of the particles as well as the flux and radial distribution of the particles from the accelerator can be determined easily. Similar determinations can be carried out within several minutes at nuclear reactors for flux and radial distributions of thermal neutron beams by folding a uranium foil with glass plate.

A microphotograph of fission fragment tracks in soda-lime glass is shown in Fig. 3.1C. The critical angle of soda-lime glass for detecting fission fragments of ^{235}U is $\theta_c = 37^\circ 21'$; and its detection efficiency in 2π geometry for isotropic emitted fission fragments from thin ^{235}U foil is $(39.3 \pm 0.4)\%$ (Guo et al., 1982).

The advantage of soda-lime glass as a track detector is insensitivity to particles lighter than or equal to C ($Z = 6$). It can overcome intense background of α -particles in fission studies and against intense accelerator beam particles in studies of nuclear reactions in the synthesis of transuranium elements (Flerov et al., 1964).

b. Phosphate glass

The composition of phosphate glasses is also varied. For example, $10\text{P}_2\text{O}_5:1.6\text{BaO}:\text{Ag}_2\text{O}:2\text{K}_2\text{O}:2\text{Al}_2\text{O}_3$ in the United States (Fleischer et al., 1975), $34\text{P}_2\text{O}_5:7\text{ZnO}:4\text{Al}_2\text{O}_3:4\text{BrO}_3:\text{SiO}_2$ in the United Kingdom (Durrani and Bull, 1987), and $50\text{LiPO}_3:50\text{Al}(\text{PO}_3)_3:7\text{AgPO}_3:3\text{B}_2\text{O}_3$ in China (Guo et al., 1976b, 1982).

The critical angle of Chinese phosphate glass for recording fission fragment tracks is $7^\circ 6'$ while the 2π detection efficiency for isotropic ^{235}U fission source is

$87.6 \pm 0.5\%$, which is higher than soda-lime glasses (Guo et al., 1976b, 1982).

BP-1 glass is a special type of phosphate glass, whose composition is 65wt% P_2O_5 , 25wt% BaO , 5wt% Na_2O , and 5wt% SiO_2 (Wang et al., 1988). BP-1 glass has been used in discoveries of several cluster radioactivities, studies of high-energy nuclear reactions, and measurements of isotopic compositions of manganese and nickel in galactic cosmic rays (GCRs). The latter measurements were carried out by using a stack of plates of BP-1 glass attached outside the Mir station for 5 years. The charge resolution was obtained being $\sigma_z = 0.08e$ for $Z = 69\text{--}79$, $E = 10.6$ AGeV for three individual measurements over three sheets of glass. The mass resolution is $\sigma_m = 0.43\text{--}0.58$ amu for $Z = 25\text{--}28$, $A = 53\text{--}62$, and $E = 150\text{--}400$ AMeV of GCRs. These are the highest charge and mass (isotope) resolutions yet obtained (Westphal et al., 1996).

c. BP-1 glass

BP-1 glass has been used in the identification of the emission of ^{23}F and ^{24}Na clusters from ^{231}Pa with branch ratios of 1×10^{-14} and 1.3×10^{-11} , respectively. In this study, BP-1 glass only recorded the emitted nuclei ^{23}F and ^{24}Na without recording α (background), whose intensity is 10^{14} or 10^{11} times higher than that of the emitted nuclei (Price et al., 1992a).

BP-1 glass has also been used in the measurement of the fragmentation cross section of 160 AGeV Pb. Charge resolution is ~ 0.14 charge unit for one single cone measurement. For successive 5 sheets of glass, the $\sigma_z = \sim 0.06e$. This charge resolution is more than adequate to identify fragments and hence to measure cross-sections for charge-changing interactions. BP-1 glass is expected to be able to detect magnetic monopoles (MMs) with charge $n = 2$ and $\beta > 0.2$. No tracks of MMs with $n = 2$ were found.

2. Natural glasses

Natural glasses were formed in the earth's crust or in meteorites or lunar rocks. Most important natural glasses are tektite and obsidian. Some other types are basaltic deep-sea glass and frictionite glass.

a. Tektite

Tektite is a special type of glassy object, which distributes in four restricted areas in the world: (1) South-East Asia and Australia (0.732 ± 0.039 Ma) (Guo et al., 1997), (2) Ivory Coast (1.08 ± 0.10 Ma) (Wagner, 1966), (3) Czech Republic and Slovakia (Moldova) (14.7 ± 0.4 Ma) (Wagner, 1966; Storz and Wagner, 1977), and (4) North America (34.6 ± 0.7 Ma) (Storz and Wagner, 1977). Many authors have dated the tektites and obtained results consistent with each other for each restricted area. The above ages in the

brackets are given in order to show the time of their formation. The most acceptable hypothesis of the origin of tektites is that they were formed by impacts of meteoroids on the earth. During impact, a large kinetic energy of the meteoroid was transferred to the substance in the earth's crust and subsequently melted and sputtered the impacted substance to the sky; then the substance cooled down quickly to form glassy objects in sizes from several centimeters to less than one millimeter. The glassy objects drop down to the earth, forming tektites or micro-tektites. The chemical compositions of tektites are similar to that of the earth's crust. For example, 74.63% SiO_2 , 12.19% Al_2O_3 , 4.16% FeO , 2.32% K_2O , 1.87% CaO , 1.82% MgO , 1.36% Na_2O , 0.77% TiO_2 , 0.54% Fe_2O_3 , 0.09% MnO (Li, 1982). The uranium concentration of tektites is also consistent with that of the average earth's crust, for example, 1.74 ± 0.18 and 1.39 ± 0.15 ppm in the tektites found in Hainan island, China (Collaboration Group of China Institute of Atomic Energy and Guiyang Institute of Geochemistry, 1976).

The density of tektites is $2.32\text{--}2.5$ g/cm³, and refractive index: 1.48–1.52. Tektite is a suitable detector for fission track registration. FTD of tektites can provide a variety of information in space research, stratigraphy, and paleoanthropology (Guo et al., 1997).

b. Obsidian

Obsidian is a special type of natural glassy detector to record fission fragment tracks. Obsidian was formed during the young volcanism. When magma on the earth's surface met with water in lakes or rivers, it rapidly cooled down at normal atmospheric pressure, forming obsidian glasses. Obsidian exists worldwide with volcanoes, such as around the Pacific and Mediterranean Oceans, west part of North and South America, New Zealand, Japan, Near East, East Africa, and Iceland. The sizes of obsidians are varied from several hundred meters to centimeters or even as tephra. The refractive index of obsidian is 1.48–1.52 (usually 1.49), density $2.33\text{--}2.41$ g/cm³; and hardness: 5–5.5; Its uranium concentration is 5–15 ppm, which is suitable for FTD. Obsidian was used as sharp tools by ancient man, such as stone knives, saws, and arrow heads. It was a sort of object for commercial trade. By fission track techniques, the following information may be obtained: age and geographic provenance of obsidian raw materials, age of heating for manufacture of obsidian artifacts, and the age and uranium concentration of the obsidian, which are specific for each source of obsidian. Both can be criterions for judging the source (Bigazzi et al., 1990).

c. Basaltic glass

Basaltic glass was formed during the extrusion of fresh lava from the upper mantle through a fracture of the earth's crust to deep-sea water and quenched by the cold seawater. The

substance of the extruded lava did not have enough time to differentiate to grow into crystalline minerals, forming an amorphous glassy substance—basaltic glass. According to the concept of seafloor spreading, basaltic glass may exist in the whole surface layer of the Mid-Atlantic Ocean floor, where lava has been extruding outward sequentially and the surface layer of lava was cooled by deep-sea water. Basaltic glass is suitable to record fission tracks for dating of geological events.

Due to the fact that basaltic glass was formed directly from mantle lava, the uranium concentration in basaltic glass would be lower than that of zircon, apatite, and sphene, which are accessory minerals enriched with uranium. The uranium concentration in basaltic glass is $(0.1\text{--}0.3) \times 10^{-6}$ g/g. Two special techniques have been adopted to locate an adequate number of spontaneous fission tracks in the low uranium samples. The first technique is that following the original scan of spontaneous fission tracks, the glass is re-etched (removing a 20 μm layer on the surface of the glass) to reveal tracks at a different depth, then to scan, re-etch, scan, re-etch, until enough spontaneous fission tracks were found. Finally, the piece of glass was irradiated in a nuclear reactor for exposure to thermal neutrons for the determination of uranium concentration in the glass and dating of the glass (Fleischer et al., 1975). Another technique used to increase the scanning area of spontaneous fission tracks, one can repeat re-grinding ($>20 \mu\text{m}$ off), re-polishing and re-etching of the sample, until one can count a large enough number of spontaneous fission tracks. Then, one undertakes an irradiation of the sample in a nuclear reactor for the determination of uranium concentration and dating (Wagner and Van den haute, 1992). The etching condition of basaltic glass is 5–20% HF, 23°C, 1–5 m.

Fading of spontaneous fission tracks in basaltic glass for a geological time cannot be ignored even in deep-sea water temperature (4°C). A correction for track fading in basaltic glass must be carried out (Selo and Storzer, 1981). The activation energy for total fading of fission tracks in basaltic glass is 1.9 eV and for start of fading is 1.3 eV. The 1-hour annealing temperature in the laboratory for total fading is 240°C and for start of track loss is 190°C (MacDougall, 1973; Fleischer et al., 1975; Wagner and Van den haute, 1992).

Basaltic glass had been used to provide a strong proof for seafloor spreading hypothesis by FTD of Mid-Atlantic Ridge, combined with KAr dating (Fleischer et al., 1968, 1975).

Other natural glasses, such as frictional glasses formed during fault displacement, impact glasses formed during the formation of a crater by meteorite bombardment, are all useful for fission track measurements for many different purposes (Fleischer et al., 1975; Wagner and Van den haute, 1992).

C. Plastics

Since the discovery that polymers (plastics) can record etchable tracks of heavy charged particles (Fleischer and Price, 1963a), more than 30 types of polymer detectors have been successfully etched to reveal tracks. Compared with inorganic crystalline solids and glasses, plastic track detectors are more sensitive to heavy charged particles, such as the charge as low as $Z = 1$ (proton). The sensitivities of different polymers are different. CR-39 (polyallyldiglycol carbonate, PADC for short) is the most sensitive detector in common use (the recordable charge $Z \geq 1$); amber is the most insensitive plastic detector (the lowest recordable charge is fission fragments, $Z > 30$).

1. CR-39 (polyallyldiglycol carbonate, PADC, PM-355, PM-500, PM-600)

CR-39, as a unique sensitivity and high-charge resolution detector, was discovered by Cartwright et al. (1978). CR-39 is the trade name of allyl diglycol carbonate. CR stands for “Columbia Resin”. CR-39 plate (sheet) is produced by casting CR-39 monomer with some kinds of initiators in a frame. Kinoshita and Price (1980) found that IPP (diisopropyl peroxydicarbonate) as initiator could produce a smoother surface than the other initiators. Tarle et al. (1981) found that adding DOP (dioctyl phthalate) as plasticizer into the monomer before casting could reduce roughness after long etching. In order to meet the need of scientific research, many firms have made CR-39 sheets with special care. The most successful firms include: Intercast Europe in Italy,¹ Page Molding in the United Kingdom,² American Acrylic and Plastics in the United States,³ Fukuvi Chemical Industry in Japan,⁴ Tastrak in the United Kingdom,⁵ and others (Pang and Ma, 1988).

The Chemical composition of the monomer of CR-39 is $\text{C}_{12}\text{H}_{18}\text{O}_7$, with its molecular weight being 274.2707 g/mol. Its molecular structure is:

1. Intercast Europe Srl., 10/A Via G. Natta, Area SPIP, 43,122 Parma, Italy. Tel: (+39) (0)521 607555; Fax: (+39)(0)521 607924. Web: <http://www.intercast.it>. E-mail: intercast@intercast.it

2. Pershore Mouldings Limited, Trade Estate, Poreshore, Worcestershire, WR10 2DH, England, Tel.: (+44)(0)386 553425.

3. American Acrylics and Plastics, Stratford, CT, USA.

4. BARYOTRAK, Fukuvi Chemical Industry, Tokyo, Japan.

5. Tastrak, Track Analysis Systems Ltd., c/o H. H. Wills Physics Laboratory, Bristol, UK.

It has a chain-like structure. In the polymerization of CR-39 monomers, the double bonds of allyl groups ($\text{CH}_2\text{CH}=\text{CH}_2$) in the structure of the monomers open and form a cross-linked net structure in three dimensional directions with other molecules, forming polyallyldiglycol carbonate (PADC).

The chemical structure of polyallyldiglycol carbonate (PADC) is shown below:

In general, chain-like structures are more sensitive to radiation than the other structures, such as a benzene ring in polycarbonate. It is thus understandable why CR-39 is more sensitive than polycarbonate (Tsuruta et al., 2008).

The density of CR-39 is 1.32 g/cm^3 , refractive index is $n = 1.504$, $A/Z = 1.877$, and its mean ionization potential $I = 70.2 \text{ eV}$ (Durrani and Bull, 1987). CR-39 track detectors can be etched with NaOH and KOH solutions. The recordable minimum ionizing particle is a 20 keV proton by etching with NaOH solution (Duan et al., 2009, 2010). The etched tracks of protons from 20 keV to 1.02 MeV are shown in Fig. 3.2 (Duan et al., 2010).

The infrared (IR) absorption spectrum of virgin CR-39 is shown in Fig. 3.3. Every peak in the spectrum corresponds to a chemical group in the CR-39 structure and its type of vibration.

The major infrared absorption frequencies (wave-number, cm^{-1}) measured with Fourier transform infrared absorption spectroscopy (FT-IR) in virgin CR-39 and irradiated one with 22.5 MeV protons are listed in Table 3.2 (Lounis-Mokrani et al., 2003).

The CR-39 detector can not only record track number N , positions (X, Y, Z), directions (zenith angle θ , azimuth angle ψ), but also it can derive particle charge Z , mass M , and energy E from the track parameters. It is the most widely used SSNTD.

2. Polycarbonate (PC, Lexan, Makrofol, Taffak)

Before the discovery of the CR-39 track detector in 1978, polycarbonate (PC) was the most commonly used track detector. Since CR-39 is more sensitive than polycarbonate, many of the measurements previously carried out with polycarbonate have been replaced by CR-39. But polycarbonate is still used frequently when proton tracks may be a strong background. For example, during nuclear reactor irradiation fast neutrons will produce background

tracks of recoil protons in CR-39, but in polycarbonate the recoil protons will not be recorded as background tracks. In this case, polycarbonate is better than CR-39. Up to now, polycarbonate is preferred as an external detector in FTD. The flux of protons in cosmic rays at the top of the atmosphere is over 10^2 times more than the sum of the other nuclei, as described in Chapter 1, Volume 1 of this book. Protons will produce a large background in CR-39, but will have no effect on polycarbonate. Therefore, polycarbonate is still used in satellites and balloons to collect data on heavy cosmic rays.

The composition of polycarbonate is $\text{C}_{16}\text{H}_{14}\text{O}_3$, molecular weight 254.2855 g/mol , and its molecular structure is

The benzene ring in the structure of polycarbonate has a tendency to absorb more radiation energy than the chain structure of CR-39 (Tsuruta et al., 2008; Chadderton et al., 1993). Therefore, polycarbonate is less sensitive to recording tracks than CR-39. The minimum recordable charge (atomic number) Z of particles by polycarbonate is 2 (α -particle). The ionization potential $I = 69.5 \text{ eV}$, $A/Z = 1.896$, refractive index, $n = 1.586$, and density $= 1.29 \text{ g/cm}^3$. Lexan is a commercial name of the product of Bisphenol-A polycarbonate foil made by General Electric Company. Lexan is one of the most widely used detectors in the polycarbonate series. Makrofol is a commercial name of Bisphenol-A polycarbonate foil produced by Bayer AG, Germany (Note: Bayer AG has stopped the production of Makrofol foil).

The properties of polycarbonate foils, produced by different firms, are similar but with noticeable differences. For example, the detection efficiency of polycarbonate foil produced in China for fission fragments of ^{235}U in 2π geometry is $(95.5 \pm 0.4)\%$, the critical angle is $2^\circ 24'$; while the detection efficiency of Makrofol K from Bayer AG for the same source of fission fragments is $(93.6 \pm 0.7)\%$, the critical angle is $3^\circ 40'$ (Guo et al., 1976b, 1982). The two results are close to each other, but not within statistical uncertainties. Similar situations happen for other types of plastic track detectors. For this reason, the parameters calibrated for a particular type of detector material cannot be used for another type of the detector when very precise results are required.

Experiences also show that the properties of different batches of the detector materials produced by the same firm

FIG. 3.2 Microphotographs of tracks of monoenergetic protons of (A) 20, (B) 40, (C) 60, (D) 80, (E) 100, (F) 220, (G) 320, (H) 420, (I) 520, (J) 620, (K) 820 keV and (L) 1.2 MeV, respectively, etched in 6 mol/L NaOH at 70°C for 9 h. The minimum detectable energy of protons with CR-39 is ~ 20 keV. From [Duan et al. \(2010\)](#). Reprinted with kind permission from *Acta Physica Sinica* © 2010.

with the same raw material are usually different. One must calibrate each batch of detectors before use. It does not mean one cannot use the results obtained by other workers. We just want to note that the best way to get reliable results is to calibrate the detector for every batch and for each situation, if one needs high precision.

Tuffak is a commercial name of the polycarbonate foil produced by Rohm & Haas Company, USA. The density of

Tuffak polycarbonate is 1.249 g/cm^3 , refractive index is 1.586. The smoothness of the surface of Tuffak is much better than that of Lexan. A comparative study between Lexan and Tuffak showed that σ_D/\bar{D} are 0.015 and 0.0034 for Lexan and Tuffak, respectively, for 955 MeV/u U tracks. \bar{D} is the average diameter of U tracks in Lexan or Tuffak; and σ_D is the standard deviation of the track diameters. The value $\sigma_D/\bar{D} = 0.0034$ infers that by

FIG. 3.3 Infrared (IR) spectrum of virgin CR-39 (PADC). From *Lounis-Mokrani et al. (2003)*. Reprinted with kind permission from Elsevier © 2003.

measuring a single track diameter, one can determine the charge Z with an uncertainty $\sigma_Z = 0.9e$ near the charge Z around 92 (U). In other words, by measuring the diameter of a single cone of the track in Tuffak, one can resolve an uranium ion from the neighboring elements (*O'Sullivan and Thomson, 1982; Ahlen et al., 1984; Salamon et al., 1985; Guo et al., 1984a*).

The peaks of the infrared absorption spectrum of polycarbonate (PC) foil, the corresponding chemical functional groups for the peaks, the rules of the changes of the absorption as a function of the fluence, and energy of the heavy ions irradiated to the foils have been studied by many authors. Interested readers may refer to the following articles: *Barillon et al. (2013); Dehaye et al. (2003); Gagnadre et al. (1993); and Yamauchi et al. (2010)*.

Polycarbonate track detectors have been used extensively in α radiography, neutron physics, heavy ion studies, cosmic ray research, and NTM production (*Fleischer et al., 1975; Durrani and Bull, 1987*).

3. Cellulose nitrate (CN, LR-115, Daicell)

CN is one of the most sensitive nuclear track detector materials. Its sensitivity is just less than CR-39. The least ionizing ion is 0.55 MeV protons (Daicell). *Fleischer (1981)* showed that the least ionizing ion seen was 1.2 MeV protons for CN (VEB Eilenburg). In this case, the CN is more sensitive than CR-39.

CN is made from absorbent cotton (cellulose) reacted with concentrated nitric acid. The three $-OH$ groups in the molecular structure of cellulose partly (1, 2, or all the 3 $-OH$ groups) are replaced by $-O-NO_2$ groups in the reaction.

TABLE 3.2 Absorption bands of CR-39 in the infrared (IR) region measured by FT-IR spectrometer and the corresponding chemical bonds and vibration types for the absorption bands.

Chemical bond	Absorption band		Vibration type
	Wavenumber, cm^{-1}	λ , μm	
CH_3	2951	3.389	C—H stretching
CH_2	2924	3.420	Doublet H stretching
	2853	3.505	
$> C=O$	1734	5.767	Carbonate stretching
CH_3, CH_2	1452	6.887	Bending vibration
	1398	7.153	
$-C-O-C-$	1226	8.157	Ether bond vibration
	1133	8.826	Ether bond stretching
	1090	9.174	
	1022	9.785	
$-CH=CH-$	963	10.784	
C—H	871	11.481	Double bond wagging vibration
	784	12.755	CH rocking out-of-plane

More information about the IR absorption peaks and their changes after irradiation by heavy charged particles could be found in the following publications: *Barillon et al., (2013, 2015); Hassan et al. (2013); Kusumoto (2017); Kusumoto et al. (2015, 2016, 2018); Lounis-Mokrani et al. (2003); Mori et al. (2009, 2011, 2012, 2013); Yamauchi et al. (2003, 2008, 2010, 2012)*.

The structure of CN formed with 2 $-\text{O}-\text{NO}_2$ groups is the following:

with formula $[\text{C}_6\text{H}_8\text{O}_9\text{N}_2]_n$ or $\text{C}_6\text{H}_8\text{O}_9\text{N}_2$ for short.

The density of CN is 1.4 g/cm^3 , $A/Z = 1.939$, and ionization potential $I = 81.1 \text{ eV}$.

LR-115 is a commercial name of CN detector made by Kodak-Pathe, or DOSIRAD, France. LR-115 type-II has an active layer of $12 \mu\text{m}$ red-dyed CN film coated on inert polyester base of $100 \mu\text{m}$ thickness. The thickness of $12 \mu\text{m}$ is designed for spark counting of α -particle tracks recorded in the film. LR-115 type-II is welcomed by radon scientists for the reason that α -particles emitted from radon progenies attached onto the surface of the detector cannot be developed by CE for short etching times. The energies of the α -particles from the short-lived progenies are all higher than 6.0 MeV , which are beyond the energy window $0.06\text{--}6 \text{ MeV}$ of LR-115. In contrast, all the α -particles from the progenies can form etchable tracks in CR-39 by a short etching time. This is an advantage of LR-115 over CR-39 (Eappan and Mayya, 2004; Nikolaev and Ilic, 1999; Barillon, 2005; Yamauchi et al., 2008a, 2008b, 2008c; Durrani and Bull, 1987; Durrani and Ilic, 1997; Narula et al., 2009a, 2009b; Nikezic et al., 2009; Sajo-Bohus et al., 2008, 2009; Bochicchio et al., 2003, 2009).

The peaks of the infrared absorption spectrum of CN foil, the corresponding chemical functional groups for the peaks, the rules of the changes of the absorption as a function of the fluence, and the energy of the heavy ions irradiated to the foils have been studied. Interested readers may refer to the following articles: Barillon et al. (2002); Barillon and Katz (2000); and Kovalenko et al. (1993).

4. Polyethylene terephthalate (PET, Mylar, Cronar, Melinex, Lavsan, Terphane, Hostphan)

Polyethylene terephthalate (PET) is another commonly used track detector. Its molecular structure is:

The molecular formula is: $(\text{C}_{10}\text{H}_8\text{O}_4)_n$ or $\text{C}_{10}\text{H}_8\text{O}_4$ for short.

The density of PET is 1.397 g/cm^3 , refractive index $n = 1.640$, $A/Z = 1.915$, and ionization potential $I = 73.2 \text{ eV}$. The most commonly used etching condition is 6.25 N NaOH , 70°C , $10\text{--}40 \text{ min}$ for fission fragment tracks.

PET is less sensitive than polycarbonate: PET cannot record tracks of α -particles. Therefore, PET is often used to selectively record heavy ion tracks in the environments where intensive α -particles exist. Its charge and mass resolutions for several MeV/amu Ne ($Z = 10$) to Si ($Z = 14$) ions are good enough for the measurement of track parameters; thus, it was one of the detectors used in the discovery of cluster radioactivity (Barwick et al., 1985; Price, 1987; Tretyakova et al., 1985). See also Chapter 1, Volume 1 of this book for a more detailed treatment of cluster radioactivity.

The peaks of the infrared absorption spectrum of polyethylene terephthalate (PET) foil, the corresponding chemical functional groups for the peaks, the rules of the changes of the absorption as a function of the fluence, and energy of the heavy ions irradiated to the foils have been studied. Interested readers may refer to the following articles: Yamauchi et al. (2012, 2018); Barillon et al. (2013).

PET track detectors have also been used widely in many fields, such as:

- heavy cosmic ray analyses (Drach et al., 1987; Price and Drach, 1987),
- NTMs (Apel et al., 2008; Husaini et al., 2008; Zhu et al., 2004; Guo et al., 2008; Cao and Wang, 2009; Gomez Alvarez-Arenas et al., 2009),
- nano- and micro-structure device manufacture (Spohr, 1990, 2008; Fink et al., 2008; Chakravarti, 2009; Wang et al., 2009; Zagorskiy et al., 2009) and
- anti-counterfeiting techniques (Wang et al., 2008).

5. CR-39–DAP series

Tsuruta (1999, 2000) found that the mixture of monomers of CR-39 and diallyl phthalate (DAP) can be copolymerized into a new type of track detector CR-39–DAP, whose property is in between that of CR-39 and DAP.

The structure of DAP monomer is:

For comparison, the structure of CR-39 monomer is copied here:

Similar to the CR-39 monomer, DAP monomer has also two allyl groups ($-\text{CH}_2\text{CH}=\text{CH}_2$), each of which has a double bond. When copolymerization starts, the double bond opens and connects with the opened bonds of CR-39 to form a three-dimensional structured copolymer CR-39–DAP.

In the DAP monomer there is a benzene ring, which has a tendency to adsorb radiation energy. For this reason, CR-39–DAP and DAP has a higher threshold than CR-39. Tsuruta et al. (2008) showed that the detection threshold of CR-39–DAP is lower than that of DAP and higher than CR-39, and the threshold increases as the percentage of DAP increases as follows:

2 keV/ μm (water) (CR-39, DAP:CR-39 = 0:100), 40 keV/ μm (50:50), 88 keV/ μm (60:40), 108 keV/ μm (70:30), 125 keV/ μm (80:20), and \sim 250 keV/ μm (DAP 100:0). They express the threshold as the total rate of energy loss in water on the right-hand side of the Bragg peak of the dE/dX curve. By the same expression, the thresholds of CN and polycarbonate (Lexan) are 110 and 330 keV/ μm (water), respectively. This means that the sensitivity of CR-39–DAP is higher than Lexan and lower than CR-39; CN is nearly equal to the copolymer (70:30). These thresholds rank up as 2, 40, 88, 108, 125 and 250 keV/ μm (water), which look like a spectrum of thresholds. This study opens up a new road to the development of nuclear track detectors, that is, to make a series of detectors with a rank of thresholds.

Doke (2008), Kodaira et al. (2008) and Ogura et al. (2006) confirmed the above development and suggested the application of these new types of detectors to the study of trans-iron nuclei in GCRs at a space station or on long-duration balloon experiments.

6. Polyimide (PI, Kapton, Upilex)

Polyimide (PI) has been used to make NTMs and as track template to synthesize nanostructures. During recent years, it has also been used to study track formation mechanisms. Polyimide has excellent temperature resistivity of 310°C for short exposures. It can be used at lower temperature down to -269°C . Kapton is a trade name of polyimide film produced by Du Pont, USA. It is also produced by Nilaco Corporation in Japan (Yamauchi et al., 2013). Upilex is a

trade name of polyimide film produced by Ube Industries Ltd., Japan.

The molecular formula of polyimide is $[\text{C}_{22}\text{H}_{10}\text{O}_5\text{N}_2]_n$, or $\text{C}_{22}\text{H}_{10}\text{O}_5\text{N}_2$ for short. Its molecular structure is

Its molecular weight (a repeat unit in the brackets) is 382.3321 g/mol. Its density is 1.40 g/cm³.

The tracks in polyimide can be etched in KMnO_4 in water (Monnin and Isabelle, 1970). More authors used sodium hypochlorite solution NaClO with various concentrations 5–15% of free chlorine as etchant at temperature 50–70°C for 3–25 hours (Vater 1988; Zhu et al., 1988; Guo et al., 1990; Chakarvarti and Mahna, 1992; Vonderau et al., 1995; Ensinger et al., 2003; Yamauchi et al., 2013a, 2013b).

Gas separation has been tested by using Upilex nuclear track microfilters aimed at the separation of tritium from deuterium for fusion energy generation. The earlier stage of research was carried out by the separation of nonradioactive carbon monoxide CO from carbon dioxide CO_2 . The thickness of Upilex microfilter was 40 μm , the pores are cylindrical in diameter in the range of 100 nm. A pressure pushed a gas mixture of CO + CO_2 to pass through the pores with an aspect ratio of 400 (length/diameter). It shows that the light molecules CO pass through the microfilter faster than the heavy molecules CO_2 , the Upilex microfilter can be used to separate CO from CO_2 . Considering that tritium gas has a high β radioactivity, a test was carried out to show the resistivity of Upilex microfilter to β radioactivity. The test demonstrated that the microfilter turned out to be resistant (Enginger et al., 2003). For fusion energy generation, a practical tritium/deuterium separation with nuclear track microfilters would be of vital need in the future.

Fourier transform infrared absorption spectroscopy (FT-IR) and other instruments can be adopted to analyze the molecular structures of track detecting materials and reveal the damages in the detectors.

Fig. 3.4 shows the absorption spectra of a Kapton film with thickness of 12 μm before and after the exposure to 5.4 MeV/u Mo ions with a fluence of 2×10^{12} ions/cm² (Severin et al., 2005). The broken curve indicates the spectrum of the pristine film; the solid curve is that of irradiated film.

The assignment of each peak in Fig. 3.4 has been well investigated (Guenther et al., 2001; Mishra et al., 2003; Sun et al., 2004; Severin et al., 2005). The absorption bands in

FIG. 3.4 FTIR spectra of 12 μm thick Kapton foils, before and after irradiation with Mo ions (5.4 MeV/u, mean $dE/dX = 8.4$ keV/nm, 2×10^{12} ions/cm 2 , 1.9×10^7 MGy). From [Severin et al. \(2005\)](#). Reprinted with kind permission from Elsevier © 2005.

polyimide at some selected frequencies are listed in [Table 3.3](#).

The sensitivity of polyimide for the registration of heavy charged particles is relatively low compared with CR-39, CN and polycarbonate (PC). In other words, the threshold of polyimide is relatively high. [Fleischer \(1981\)](#) showed that the least ionizing ion for forming etchable track in polyimide is 36 MeV ^{16}O ; but recently [Yamauchi et al. \(2013a, 2013b\)](#) did not see any etched tracks of ^{20}Ne

with energy from very low energy to 79 MeV. The damage density of ^{20}Ne ions in polyimide at the Bragg peak should be higher than that of ^{16}O ions. If ^{16}O can be recorded by polyimide, the ^{20}Ne should be easier than ^{16}O to be recorded in polyimide. One needs to do more work to clarify the true value of threshold of polyimide.

7. Other new track detector materials

One of the important tasks of nuclear track studies is to look for or synthesize new detector materials which have specific properties, such as a sensitivity higher than CR-39, or a threshold higher than that of the existing detector materials, or anti-annealing temperature of tracks higher than 1000°C for days.

a. PETAC-ADC copolymer detector

[Mandrekar et al. \(2010\)](#) claimed that a copolymer of pentaerythritol tetrakis (allyl carbonate) (PETAC) and allyl diglycol carbonate (ADC) in weight percent 4:6 shows that its maximum alpha sensitivity is almost double that of CR-39 under identical experimental conditions. The polymers can be conveniently etched by aqueous sodium hydroxide. In order to further verify the above conclusion, one should irradiate the copolymer and CR-39 sheets with heavy ions from accelerators to see at which energy the heavy ions can be recorded as tracks in each of the detectors.

TABLE 3.3 Chemical function groups, IR absorption bands and their corresponding wavelengths, and the vibration types of the bonds in polyimide.

Chemical bond	Absorption band		Vibration type
	Wavenumber, cm $^{-1}$	λ , μm	
C=O	1777	5.627	Stretching vibration of carbonyl group
	1732	5.774	
	1725	5.797	
C—C	1598	6.258	Skeletal in-plane phenyl ring vibration (C—C stretching of phenyl rings)
	1504	6.649	
C—N—C	1383	7.231	C—N—C asymmetric stretching
C—O—C	1289	7.758	C—O—C group vibration between two aromatic cycles
	1250	8.000	Diphenyl ether symmetric stretching
	1169	8.554	
	1118	8.945	
	1094	9.141	
	883	11.325	C—H deformation of phenyl ring
C—H	823	12.151	

b. Silicon nitride (Si_3N_4) as track detector

Vlasukova et al. (2010) found that amorphous silicon nitride Si_3N_4 can record discontinuous tracks of W ($Z = 74$) with electron energy loss of 20.4 keVnm^{-1} being maximum with etchant HF solution; Fe ($Z = 26$) and Kr ($Z = 36$) ions in the electron energy loss regime cannot form tracks in it. From the above results one can see that the threshold of Si_3N_4 is quite high, but it is difficult to be used as a track detector at this stage due to its discontinuous tracks.

III. Recordable particles with solid state nuclear track detectors

When a heavy charged particle enters an insulating solid, it produces radiation damage to materials in the solid along the trajectory of the particle. If the density of the damaged materials is high enough, the damaged materials can be selectively etched by a chemical reagent resulting in an etched channel (hole) along the trajectory. The chemical reagent will continue to attack the bulk material of the solid in all directions. The inner diameter of the channel (hole) will increase in size. When the diameter of the channel increases to the size comparable with the wavelength of light, the channel becomes visible with an optical microscope. The visible channel is called an etched track of the particle. The original radiation damage region along the trajectory before etching is called the latent track of the particle. In some types of very thin solid layers, latent tracks of particles have been observed under transition electron microscopes (TEMs), such as muscovite mica. The diameter of latent tracks of fission fragments is several nanometers. If the radiation damaged materials are not dense enough, the damaged materials cannot be etched to form an etched track. In this case, the solid is not sensitive to the particle. The particle cannot be recorded by the solid. Conversely, when the solid is sensitive to the particle, it is recordable with the solid.

The density of radiation damaged materials is related not only to the species of particles (Z), but also to the velocity V (or energy E) of the particles. When the velocity (or energy) of a particle is very high, the time of interaction between the particle and the atomic electrons of the atom in the solid is very short. The energy transferred from the particle to the electrons is very little. In such a case, the resultant radiation damage is very low. The radiation damaged region cannot be etched to become a track. As the velocity of the particle slows down, the interaction time increases gradually as described in Chapter 1, Volume 1 of this book. The density of the radiation damaged materials increases. Up to a certain density, the damaged materials become etchable to form a continuous track. As the charged particle is further slowed down, the particle will catch more

and more electrons from the solid. The effective charge (Z_{eff}) of the particle gradually reduces. Its ability to produce damage also reduces. At some velocity, the density of damaged materials drops down to the least value required for etching. Afterward, the charged particle cannot produce an etchable track. The charged particle can produce an etchable track only in a limited region of velocity or energy. Above or below this region, the particle cannot leave etchable tracks in the solid. Here, we conclude that as long as the radiation damage density, even in a small region, can reach the etchable level, we consider the charged particle recordable with the solid (SSNTD).

Generally speaking, selecting appropriate detector materials, SSNTDs can record tracks of protons, α -particles, fission fragments, heavy ions, neutrons via its charged reaction-products, α -recoil particles, exotic particles such as MMs, dark matter, and fractional charge particles if they exist. In contrast, γ -rays, β -rays and X-rays cannot be recorded by any kind of SSNTDs.

A. Protons

Proton measurements with SSNTDs has suddenly become an urgent need since the advent of laser acceleration and the latest advances in the study of laser inertial confinement fusion (ICF). In these studies, the duration of a proton burst is about 10^{-12} seconds or less for laser acceleration and about 10^{-9} seconds for a particle blast in laser fusion. In these cases, electronic detectors are blocked by dead time, but solid-state track detectors are superior in light of their advantages, which are the following: no dead time limitation, high detection efficiency, large dynamic range, good spatial-, charge-, mass- and energy resolutions, insensitivity to background radiation (neutrons, X- and γ rays), and insensitivity to electromagnetic disturbances. Therefore, CR-39 has become the key material for the detection of protons and other light nuclei produced in these studies (Duan et al., 2009, 2010; Szydlowski et al., 1999; Seguin et al., 2003).

The sources of protons, which are currently studied with SSNTDs include:

- (1) Proton beams from laser acceleration;
- (2) Protons produced from an ICF assembly and other plasma facilities;
- (3) Proton beams from particle accelerators;
- (4) Recoil protons from foil-radiators for neutron spectrometry and dosimetry;
- (5) Recoil protons in hydrogen-containing plastic track detectors (CR-39); and
- (6) Protons from other nuclear reactions.

1. Suitable detectors for proton detection

CR-39 is the most sensitive detector material in SSNTDs. It is the most suitable detector for recording proton tracks

(Baiocchi et al., 1995; Bernardi et al., 1991; Cross, 1986; Cross et al., 1986; Jager et al., 1985; Sadowski et al., 1994; Szydłowski et al., 1999; Wang et al., 2002). The lowest recordable energy of protons in CR-39 is ~ 20 keV (Duan et al., 2009, 2010). The upper limit of energy of protons is ~ 6 MeV (Seguin et al., 2003). The tracks of protons from 20 keV to 1.020 MeV in CR-39 are shown in Fig. 3.2.

CN detector is less sensitive than CR-39. It can also record proton tracks. The minimum energy of protons recordable in Daicell (CN) is 0.55 MeV (Fleischer et al., 1980).

2. Proton intensity measurements

Intensity usually refers to the number of specific particles that are produced from a source in unit time (second). To measure the intensity of a source, one needs to record the time (t) and to count the number of the particles (N) emitted from the source. The intensity is N/t . For proton intensity measurements with a SSNTD, one needs to record the time t , count the tracks N in a small area S of the detector, measure the distance X from the proton source to the detector, measure the angle θ between the proton direction and the normal of the detector, know the detection efficiency ε of the detector to protons and the anisotropy $\Phi(\varphi)$ of the source. The proton intensity can be calculated according to following equation:

$$I = \frac{4\pi X^2 N}{S \cos \theta \Phi(\varphi) \varepsilon t} \quad (3.1)$$

where φ is the angle of the detector position with respect to the proton source. For an isotropic source, $\Phi(\varphi) = 1$.

If particles (protons) from a source are collimated by apertures to become a beam such as that from particle accelerators, the particle (proton) intensity in these cases means particle flux, that is, the number of particles passed through a unit area (cm^2) in unit time (second), also referred to as beam intensity.

Proton sources may be a point source, or an extended source. Any particle source has a definite size (extended source). A so-called point source is a simple approximation, that the size of the source is negligible. Eq. (3.1) is derived by an assumption that the particle source is a point source.

Placing a CR-39 sheet in the path of the protons and after counting the proton tracks, one can easily measure the intensity of the proton source or proton beam flux.

3. Proton energy measurements

a. Track diameter method

In order to determine proton energy with a CR-39 or LR-115 detector, one must first calibrate the detector with mono-energetic protons. A detailed explanation of the

calibration techniques with real monoenergetic protons (not by scattered protons through foil) can be found in the paper of Duan et al. (2009, 2010).

Fig. 3.5 illustrates the results of a typical calibration with proton energies of 20, 40, 60, 80, and 100 keV:

In this energy region, it shows that the diameter of proton tracks increases monotonically with increasing proton energy in a defined etching condition. By measuring the track diameter of protons of unknown energy, one can immediately find the energy E_p of the protons from the calibration curve as illustrated in Fig. 3.5. The uncertainty $\sigma(E_p)$ can be calculated from the following formula:

$$\sigma(E_p) = \frac{\sigma(D)}{\Delta D / \Delta E_p} \quad (3.2)$$

where $\sigma(D)$ is the statistical deviation of the measurements of the track diameter, and $\Delta(D)/\Delta E_p$ is the slope of D versus E_p curve at the point of track diameter D .

b. Track contrast (gray level) method

Fig. 3.6 illustrates the variation of track diameter D versus proton energy E_p in an extended range of energy.

There are two proton energies corresponding to a given track diameter. In this case, the two proton energies can be distinguished by the track contrast or track gray levels. The tracks of the lower energy protons are generally shallower and less dark due to the shallow and blunt etch pits. The tracks of the higher energy protons are deeper and darker due to the deep and sharp etch pits. This method of energy measurement of protons is practical with the use of the optical microscope and track image analyzers (Duan et al., 2009, 2010; Seguin et al., 2003; Nikezic and Yu, 2009).

FIG. 3.5 Relation between track diameter and proton energy in CR-39 etched in 6N NaOH, 70°C for 3, 6 and 9 hours. From Duan et al. (2009); printed with permission from Elsevier © 2009.

FIG. 3.6 Relation between track diameter and energy of protons in CR-39 etched in 6N NaOH at 70°C for 3, 6 and 9 h for proton energies from 20 keV to 1.2 MeV (Duan et al., 2009). Each track diameter corresponds to two proton energies. Track contrast or track gray level must be adopted in order to distinguish the energies of the protons. From Duan et al. (2009). Reprinted with permission from Elsevier © 2009.

c. Step filter method

The energy and energy spectrum of protons can be retrieved by the step filter method. If we let the protons pass through a plate of stopping material (filter of Al, Cu, or plastic sheet) and allow the protons to reach a CR-39 detector; and if the energy of the protons is in the energy window of the CR-39 registration (~ 20 keV–6 MeV), the protons will be recorded as tracks in the CR-39. The energy of protons on reaching the CR-39 can be obtained by measurement of track diameters. From the thickness of the stopping material (the filter) and the range–energy relation of protons in the material, one can further derive the energy of the protons arriving at the front surface of the filter. On the other hand, if a wedge-shaped filter is used to replace the plate filter, a wedge-range-filter (WRF) spectrometer is composed. This kind of filter can provide information of the proton energy spectrum of the source. Fig. 3.7 is a schematic illustration of a wedge-filter spectrometer used for measuring the proton energy spectrum.

The wedge can be composed of a series of films overlapping partly together. Different thicknesses of stopping material in the composed areas can be obtained. The wedge looks like a terraced field. The thickness of each part of the stopping material can be known precisely. This is the reason it is called a “step filter”.

FIG. 3.7 Schematic illustration of a wedge-shaped-filter spectrometer. In front of a CR-39 there is a wedge filter (Al). The thickness of the wedge changes gradually. Some of the protons incident on the filter are energetic enough to pass through it, and they impinge on the CR-39, forming tracks within the CR-39. The energy of the protons can be determined by the diameters of the tracks and the thickness of the filter at the track positions. A two-dimension histogram of track number versus track diameter and versus the thickness of the filter can be converted to a histogram of proton number versus energy of the protons. Seguin et al. (2003). Reprinted with permission from American Institute of Physics © 2003.

4. Obtaining mono-energetic proton beam for track detector calibration

a. Defocusing proton beam

Defocusing of heavy ion beams including protons for irradiation of nuclear track detectors is a special requirement. Most of the nuclear physics researches require very well-focused strong beams of heavy ions. On the contrary, nuclear a track detector as a tool of nuclear physics research needs a reduced and defocused beam of heavy ions. The reason for the special requirement is that nuclear track analysis needs to separate each track from the others. The track density usually should be less than about 10^4 – 10^5 cm $^{-2}$ and should be kept mono-energetically. Therefore, one needs a specially designed defocusing beam facility to reduce the intensity of the beam. Usually the beam should be uniform in a quite large area perpendicular to the beam direction.

b. Deflection by high voltage electric pulse

If the particle accelerator cannot defocus to the required level, a deflection high voltage electric pulse may be used to deflect the beam in very short time. Fig. 3.8 shows a sketch of a high voltage pulse generator system to deflect

FIG. 3.8 Sketch of the calibration system. From Duan et al. (2009). Reprinted with kind permission from Elsevier © 2009.

the proton beam at an accelerator for proton energy calibration in the studies of laser acceleration.

The output of the high voltage waveform of the high-voltage pulse generator is shown in Fig. 3.9.

In this method of irradiation with protons, two requirements need to be satisfied. First, the pulse duration should be set according to the requirement of the heavy ion energy. The adjustable duration of the pulse of the generator is from 0 to larger than 100 ns. Second, the magnitude of the voltage must be high enough to ensure enough deflection of the beam direction. The adjustable magnitude of the generator ranges from 0 to 5000 V (Duan et al., 2009). The track detector CR-39 sheet is placed at the angle where the beam of protons is to be deflected. By counting the pulse, one can obtain the required number of proton tracks.

c. High-speed rotation wheel

A reduced density of tracks of mono-energetic protons in CR-39 sheet for calibration purposes can be irradiated at an accelerator by using a high-speed rotation wheel. CR-39 sheets are fixed on a wheel with a certain distance r from the center of the wheel. The wheel is then arranged in the

FIG. 3.9 Output voltage waveform of the high-voltage pulse generator. The abscissa is the duration of high-voltage pulse in nanoseconds (ns). The ordinate is the magnitude of the pulse in voltage (V). From Duan et al. (2009). Printed with kind permission from Elsevier © 2009.

target chamber and the chamber is pumped to vacuum. The CR-39 sheets will be faced toward the beam of protons. High-speed rotation of the wheel brings the CR-39 sheets to the beam, and the CR-39 sheets are exposed to the beam and left without stopping; but the wheel stops immediately after the exposure. Duan et al. (2009) made proton irradiation successfully at the accelerator in Beijing Normal University for calibration of CR-39 used in laser acceleration.

All the above techniques are able to obtain mono-energetic protons for calibration of track detectors.

5. Proton spatial distribution measurements

The SSNTD is a type of position sensitive detector. Its track diameter after etching is about several micrometers. Therefore, its spatial resolution is in the same range (several micrometers).

In some cases, the information of emission angles of protons is essential. For example, recoil protons from a thin hydrogen-containing foil, such as polyethylene $(CH)_n$, produced by elastic scattering of fast neutrons, can be recorded by a flat or curved CR-39 detector. The track coordinate on the detector reflects the recoil angle θ with respect to the direction of the incident neutron. The diameter of the track reflects the energy of the proton E_p (See Section III.A.3). The energy of the incident fast neutron can be calculated by the equation:

$$E_n = E_p / \cos^2 \theta \quad (3.3)$$

This technique is often called the recoil proton method for neutron spectrum determination (Wan et al., 2003).

Another example of the measurement of proton spatial distribution is in laser acceleration. In order to determine the energy spectrum of protons accelerated in laser-plasma interaction, an electromagnetic spectrometer (Thomson spectrometer) is used to deflect the energetic protons produced in the interaction. Different energies of protons will be deflected to different angles. A flat or curved CR-39 sheet is placed behind the spectrometer to record the protons at different angles. Counting the proton tracks at different angles provides the energy spectrum of the protons after acceleration (Lan, 2009).

6. Applications of proton detection

The SSNTD is a kind of passive detector. It exists simultaneously with active detectors such as electronic types of detectors. Electronic types of detectors can instantaneously acquire data of measurements; but suffers from their dead time, which is in the level of ns (10^{-9} s). If there are many particles incident to the electronic type of detector at the same time, only one particle can be recorded, the other particles will be lost. More over, the signal of the first

recorded particle will be distorted. Under these circumstances, electronic types of detectors are incompetent; but the SSNTD is almost unique.

a. Laser acceleration

Proton registration has become a budding and expanding field since the advent of laser acceleration. When an ultrashort and ultraintense laser hits on a target, the target substances become plasma. The electrons with much higher speed in the plasma fly out toward the direction nearly perpendicularly to the original target substances and forming a shell (sheath). In the gap of the high-speed shell of electrons and the positive ions forms a very strong electric field, which accelerates hydrogen nuclei (protons) contained in this region to very high velocity. This process accelerates the protons to very high energy (up to now about 100 MeV). This is the so-called laser acceleration. Large numbers of protons are produced and accelerated within a very short time, which is in the range of about pico-second (ps, 10^{-12} s) to femto-second (fs, 10^{-15} s). Electronic types of detectors cannot record and analyze the protons, but SSNTD can. Therefore, SSNTD is an indispensable tool in laser acceleration studies (Kanasaki et al., 2013; Yogo et al., 2011).

b. Laser confinement fusion

Laser confinement fusion is also a process produced within a short time from $\sim 10^{-12}$ to 10^{-15} s by laser on bullet target of fuel of deuterium and tritium. At this stage, CR-39, polycarbonate (PC) and the other SSNTD play important roles in these studies.

The application of proton detection in these fields will be described in more detail in Section II.D.1 and II D.2 of Part 2 of this chapter. See also Chapter 1, Volume 1 of this book for a description of current studies on laser and inertial electrostatic confinement fusion.

B. Alpha particles

Alpha particles (α -particle) are equivalent to a helium (He) nucleus with kinetic energy. The following sources of alpha particles are usually analyzed with SSNTDs:

- (1) Alpha particle sources used in laboratories for calibration purposes;
- (2) U-bearing aerosol particles for nuclear safeguards;
- (3) Hot particles and fallout from nuclear accidents;
- (4) Radon (Rn) and thoron dosimetry in dwellings, mines, and environments;
- (5) Radon (Rn) monitoring for exploration of uranium (U) and petroleum (oil), and prediction of earthquake and landslide;
- (6) $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ reaction α -particle mapping for boron determination in metallurgy, agriculture, and cancer therapy (BNCT).

α -Particle registration is the most popular work in developing countries because it does not require expensive equipment, such as nuclear reactors and particle accelerators. One needs only CR-39, LR-115, an optical microscope, etching bath, and chemicals; and it provides valuable research results for natural resources, human health, and scientific training.

1. Suitable detectors for alpha-particle detection

CR-39 (Polyallyldiglycol carbonate, PADC), LR-115 (CN) and Lexan or Makrofol (Polycarbonate, PC) are suitable detectors for recording α -particles.

a. CR-39

CR-39 is the most sensitive and popular detector for recording α -particles. Its energy window for recording α -particles is from ~ 0.1 to > 20 MeV, or approximately from 0 to infinite (Durrani and Bull, 1987). This means that no matter what is the medium between the source and the detector (CR-39), gas, liquid, or solid, the α -particles will create tracks in the detector as long as the α -particle can reach the detector, with the exception of the limitation of critical angle θ_c (See Section V.A.3).

b. LR-115

The sensitivity of CN LR-115 is less than CR-39. Its energy window for α -particles is about 1.2–3.9 MeV (Yu and Nikezic, 2009; Benton, 1968; Eappan and Mayya, 2004; Ilic and Durrani, 2003).

c. Lexan or Makrofol

Polycarbonate (Lexan, Makrofol and Tuffak) is less sensitive than CN for recording α -particle tracks. In order to reveal α -particles clearly, it is better to irradiate the detector with ultraviolet light before etching (Stern and Price, 1972; Benton and Henke, 1969a; Crawford et al., 1968; DeSorbo and Humphrey, 1970; DeSorbo, 1979; Fleischer et al., 1975; Durrani and Bull, 1987). The energy window of polycarbonate for recording α -particles is in between ~ 0.2 and 3 MeV (Durrani and Bull, 1987).

2. Alpha-particle intensity measurements

α -Particle sources mainly have three states: solid, liquid, and gaseous. Solid α -sources are prepared on smooth plane surfaces of metals, such as stainless steel, or aluminum. The plane sources can be divided into thin sources and thick sources. If the thicknesses of α -emitting material on the surfaces are less than about $100 \mu\text{g}/\text{cm}^2$, the sources may be considered thin sources. Because the ranges of α -particles of natural radioactivities in the source materials are in the range of about several to over ten mg/cm^2 (see Chapter 1, Volume 1), the absorption loss or energy losses of

α -particles in the thin source are negligible. Conversely, if the thicknesses are over $\sim 100 \mu\text{g}/\text{cm}^2$, the absorption losses or energy losses cannot be ignored.

Some α -emitting materials are dissolved or suspended in water or other solutions. Determination of α -concentration in the liquids is often required. Radon in air is an example of gaseous α -source.

a. Determination techniques of α -particle intensity on plane surfaces

α Intensity is defined as the number of α particles emitted from a source in unit time (s^{-1}). Two types of techniques can be used in the determination of α intensity of plane sources: small sterad technique and 2π geometrical measurement.

Small Sterad Technique. The small sterad technique can give the most accurate and absolute determination of the intensity of α -particle sources. The α -plane source to be determined and a CR-39 sheet are put face to face, in a vacuum chamber with a distance 10–30 cm from each other, both surfaces being parallel with common axis. After pumping to remove air from the vacuum chamber, a shutter between the source and CR-39 sheet is opened, and α recording starts. After some time, the shutter is closed, and α recording stops. The α tracks on the CR-39 sheet are etched in NaOH solution and counted with a microscope. The α intensity I of the α -plane source can be calculated by the equations

$$I = \frac{N_T}{g \epsilon t} \quad (3.4)$$

and

$$g = \frac{1}{2} \left[1 - \frac{h}{\sqrt{h^2 + r^2}} \right] \left\{ 1 - \frac{3}{8} R^2 \left[\frac{h(h + \sqrt{h^2 + r^2})}{(h^2 + r^2)} \right] \right\}, \quad (3.5)$$

$(R \ll h, r \ll h)$

where N_T is the number of α -tracks on the CR-39 sheet, t is the α recording time in seconds (s), g is the geometric factor for recording α particles with CR-39 sheet, h is the distance between the α source and CR-39 detector (cm), R is the radius of the α source (cm), r is the radius of the CR-39 detector (cm), and ϵ is the revealing efficiency of the α -particles in the CR-39 sheet.

If the CR-39 is shaped as a square with side a and all the tracks are counted as N_T , then r^2 in Eq. (3.5) should be replaced by a^2/π .

If one counts only a part of tracks in a small area S of CR-39 sheet, such as in several fields of view, one should replace r^2 in Eq. (3.5) by S/π . If the energy of the α particles is in the energy window of the detector, $\epsilon = 1$. Otherwise, $\epsilon = 0$. If the energy of the α particles is higher than the energy window of the detector, one can put a thin

degrader foil in front of the detector to degrade the α energy. The thickness of the degrader can be calculated by an empirical Bragg–Kleeman formula (L'Annunziata, 2003; Eappen and Mayya, 2004):

$$R_s(\text{cm}) = 3.2 \times 10^{-4} R_a A^{1/2} / \rho \quad (3.6)$$

where A is the mean atomic weight of the solid (g), ρ is density of the solid in g/cm^3 , R_s is the range of α particle in a given solid (the degrader foil), and R_a is the range of the α particle in air at an ambient temperature of 15°C under pressure of 760 mm Hg. R_a may be estimated through the relation:

$$R_a(\text{cm}) = 0.324 E^{3/2} \quad (3.7)$$

where E is the energy of the α particle (MeV). The above equations for the calculation of α particle ranges are the same as Eqs. (1.166) and (1.167) in Chapter 1, Volume 1, where example calculations are provided.

When one has calculated the α particle range, one can select a thickness of the degrader foil, which is thinner than the calculated range. The selected foil can be used as degrader. The thickness of α sources for small sterad measurement should be thin, that is, at least less than half of the range of the α particles in the source material to ensure the accuracy of the measurement. In measurements utilizing the small sterad technique, other detectors can also be used, such as a surface barrier silicon detector or a scintillation detector. The advantage of the SSNTD (CR-39) is that it does not need the complicated electronic instrumentation.

2π geometrical measurement. The 2π geometrical measurement is a simple technique for determining the intensity of an α plane source. In this measurement, it is best that it be carried out as a relative measurement.

First, one should make a thin plane source of α particles as a standard source, determine its intensity I_s by using other techniques, such as small sterad, surface barrier detector, ionization chamber, or chemical analysis. Then the standard source is covered with a CR-39 detector (2π geometry), for a time t_s . After etching the CR-39 in NaOH solution, the α tracks are counted with an optical microscope (N_{Ts}). Afterward, an unknown α source is covered with another CR-39 sheet of the same batch as that used for the standard source for a time t . The tracks are etched and counted (N_T) in the same manner, as above. An approximation of the intensity I of the unknown source can be calculated by the following equation:

$$I = \frac{N_T}{N_{Ts}} \frac{t_s}{t} I_s \quad (3.8)$$

In Eq. (3.8), the difference of detection efficiencies for the standard and unknown sources due to possible difference in thicknesses of the sources are ignored.

From Eq. (3.8) one can see that the intensity of the unknown source I can be calculated from the measured data N_T , N_{Ts} , t , t_s and the known intensity I_s . The advantage of this relative measurement for plane sources is that one does not need to calibrate the detection efficiency of the CR-39 detector for the α particles produced in the sources.

b. Determination technique of α -particle intensity in liquids

In the process of uranium production and nuclear disposal as well as in laboratories, various liquids having α radioactivity have to be managed. The α radioactivities in these liquids can be easily determined by using SSNTDs (CR-39 or LR-115) through the relative measurement. Here, we will give an example to illustrate how to determine the α intensity of uranium in liquids. Firstly, some amount of uranium nitrate of natural uranium is dissolved in water. The uranium concentration in the solution can be calculated from the formula of uranium nitrate. The α intensity I_s in a unit volume of solution is obtained by the isotopic ratio of ^{238}U (99.2745%), ^{235}U (0.720%) and ^{234}U (0.0055%) and the half-life of ^{238}U (4.468×10^9 a), ^{235}U (7.038×10^8 a) and ^{234}U (2.455×10^5 a). This solution can be used as a standard solution for the α intensity determination. A piece of SSNTD, such as CR-39 is immersed into the solution for a certain time t_s . The CR-39 sheet can be cleaned by water. After etching the CR-39 sheet in NaOH solution (see Table 3.1), the track density N_{Ts} of α particles is measured with an optical microscope. Afterward, another sheet of CR-39 of the same batch is immersed in the solution of unknown α intensity for a time duration t_x . The track density N_{Tx} is measured. The α intensity I_x in the unknown solution can be calculated by the equation

$$I_x = \frac{N_{Tx}}{N_{Ts}} \frac{t_s}{t_x} I_s \quad (3.9)$$

Eq. (3.9) is strictly valid only in the case when the composition and concentrations of the chemicals and α energy are the same for the standard and unknown solutions. The variation of concentration will not affect the calculated value of I_x very seriously. The effect of α energy can be corrected as inversely proportional to the range of the α particles, that is,

$$I_x(\text{corrected}) = I_x \frac{R_s}{R_x} \quad (3.10)$$

The calibration result of CR-39 with standard solution can be treated as a constant c where

$$c = \frac{I_s t_s}{N_{Ts}} \quad (3.11)$$

Once the constant c is obtained, it can be used for follow-up determinations of unknown solutions with the same batch of detector.

The advantage of this relative determination of α intensity in liquids is that one does not need to worry about the critical angles of α particles in the CR-39. The effect of the critical angles will be canceled in the calculation. The distribution of tracks on the surface of the CR-39 is homogeneous in the case of a liquid source. One can select any place on the detector surface to measure the density of tracks and derive the α intensity of the liquid source.

c. Determination of α -particle intensity in air (gaseous substances)

The determination of the activities of radon (^{222}Rn), thoron (^{220}Rn), and ^{219}Rn in air is a typical example for α intensity measurement in gaseous substances. This subject is important in earth science, environmental studies, health physics, and resource prospecting. LR-115 and CR-35 are traditionally used to carry out the research. It has become a special field of Radon (Rn) monitoring (Jonsson, 1995; Ilic, 2005; Monnin et al., 1993; Segovia et al., 2005; Virk and Valia, 2001; Saad, 2008; Dwivedi et al., 2005; Mishra et al., 2005; Font, 2009; Font et al., 2008; Baixeras et al., 2005). More detailed explanation can be found in the Subsection Radon Measurement (Section IV.A.1 in Part 2 of this chapter).

3. α -particle energy measurements

Three methods can be adopted in α particle energy determinations, namely, the track diameter method, the residual range method, and the stopping-foil method.

a. Track diameter method

The experimental determination of energy of α particles with a SSNTD by the track diameter method includes two steps. The first step is to calibrate the detector, such as CR-39 with mono-energetic α particles from a particle accelerator or from an α source, such as an ^{241}Am thin source (5.486 MeV (85.2%), 5.443 MeV (12.8%), other α energies are negligible). The energy of α particles may be degraded by air or foils of various thicknesses. The α particles impinge on the CR-39 detector perpendicularly. After etching of the CR-39 under certain etching conditions, the diameter of the α tracks are measured with an optical microscope. A calibration curve will be obtained, which is the relationship between track diameter and the energy of the α particles. The calibration curve is similar to that of protons (Figs. 3.5 and 3.6). The second step is to record the α particles of unknown energy in normal incidence with the calibrated CR-39 detector (the detector produced in the

same batch if possible). After etching under the same etching conditions, the track diameter is measured. By comparison of the track diameter with the calibration curve, one can obtain the energy of the α particles. On the calibration curve, one diameter may correspond to two energies of α particles (Similar to Fig. 3.6). In this case, the gray level and the depth of track can be used to distinguish which energy is correct (See Section III.A.3, Proton Energy Measurements); on the low-energy side, the track is shallower and the gray level is lower than that on the high-energy side.

b. Residual range method

The residual range method makes use of the range–energy relation (R – E relation) of α particles in the detector materials. Measuring the residual range (R_0) allows one to retrieve the energy (E) of the particles. The range–energy relation can be calculated by the empirical Bragg–Kleeman formula, or by theoretical formulas (Bethe, 1930; Fano, 1964; Ahlen, 1980; Barkas and Berger, 1964; Benton and Henke, 1969b; Weaver, 2001; Henke and Benton, 1966), or by more popular computational codes SRIM (Ziegler and Biersack, 2003; Ziegler et al., 1985). The residual range of a particle is the distance from the point considered to the end point of the range. The coordinates of the end point of the range can be obtained by etching the track to a round blunt tip. The actual end point is at the point with a distance r to the etched tip where r is the radius of the blunt tip. When the residual range R_0 is measured, one can immediately obtain the energy from the range–energy relation (Fews and Henshaw, 1982; Seguin et al., 2003).

c. Stopping-foil or range-filter method

A flat foil or wedge-like stopping material (range filter) and a CR-39 detector are used in this method, which is based on the range–energy relation of α particles in stopping material (Range filter) to determine the energy of the α particles. Only the α particles whose range is larger than the thickness of the range filter can be recorded as etchable tracks in the CR-39 detector behind the filter. The track diameter on the CR-39 sheet can give the energy of α particles. From this energy and the thickness of the filter one can derive the incident energy of the α particle to the filter.

If one uses several filters of different thicknesses and CR-39 sheet, a series of energies (energy spectrum) can be obtained. If one uses a WRF of appropriate thickness intervals, an accurate energy spectrum of α particles may be obtained (Seguin et al., 2003; Kacénjar et al., 1982).

4. α -particle spatial distribution measurements

The SSNTD is a position sensitive detector. Its spatial resolution is normally about several micrometers for α particles. α spatial distribution measurements have two meanings. The first meaning relates to the measurement of the distribution of α emitting nuclei on a surface or in a volume. This is a homogeneity measurement of an α source. The second meaning relates to the measurement of the directions of an α emission from a source. This is the angular distribution measurement of an α source. For the first measurement, one needs to put a CR-39 or LR-115 sheet on the area or in the volume of the α source for a certain time to allow enough numbers of α particles to bombard the detector sheet. Afterward, the detector is etched, whereby one can see the distribution of tracks produced by the α particles. Subsequently, one will be aware of the distribution of the source nuclei. The following measurements belong to the first type of measurements: distribution of α contaminations on surface of working places; the distribution of α emitting nuclei, such as ^{239}Pu , ^{235}U , and ^{237}Np in organs of animals and human bodies; distributions of α hot particles in the environments; uranium distribution in minerals; boron distribution measurements in steels, leaves, and soils through (n, α) reaction-produced α particles.

For the second type of spatial distribution measurement, one needs to deploy CR-39 or LR-115 sheets around the α source in different directions. In laser ICF studies, the CR-39 detector is the most useful detector to determine the yield and spatial distribution of α particles from $\text{D} + \text{T}$, $\text{T} + \text{T}$, $\text{D} + ^3\text{He}$, and $\text{T} + ^3\text{He}$ reactions (Seguin et al., 2003). By counting the tracks in unit area on the detectors in different directions, one will know the spatial distribution of the α particles.

5. Applications of α -particle detection

α -particle detection is one of the commonly applied domains of SSNTDs. Nearly all the fields where α particles are produced can be studied by the track detectors. The particular fields requiring α detection and where SSNTDs are particularly useful are as follows:

- a. Long-term radon and thoron monitoring,
- b. Nuclear fallout and hot particles,
- c. Nuclear contamination around nuclear plants,
- d. Neutron spectrometry and dosimetry,
- e. Laser and plasma interactions,
- f. Uranium and petroleum exploration and earthquake prediction,

- g. Agriculture and metallurgy, and
- h. α -particle radiograph (Somogyi and Srivastava, 1970, 1971; Su, 1992, 1993).

The details of applications in these fields will be explained in the related subsections in Part 2 of this Chapter.

C. Fission fragments

A heavy nucleus can split into two nuclei, which is called nuclear fission. This process may occur automatically by the nucleus itself without any disturbance by other particles. This fission is called spontaneous fission. For example, the ^{238}U nucleus can split into two nuclei (the two new nuclei are called fission fragments, nuclear fission into three or more fission fragments is very rare (See Chapter 1, Volume 1 for a detailed treatment of nuclear fission). The two fission fragments have different masses. The masses of light fragments of ^{238}U spontaneous fission range from $A = 85\text{--}105$ with an average $A = 97$. The heavy fragments have masses $A = 130\text{--}150$ with an average $A = 139$. The light fragments have an average kinetic energy of 97.6 ± 0.7 MeV. The heavy fragments have an average kinetic energy of 67.0 ± 1.2 MeV. The total kinetic energy is 164.6 MeV (Kase et al., 1978).

The rate of spontaneous fission of heavy nuclei is expressed by the spontaneous fission decay constant λ_f . For ^{238}U spontaneous fission, one value of the decay constant $\lambda_f = 7.03 \times 10^{-17} \text{ a}^{-1}$ (Roberts et al., 1968) may be recommended. This value corresponds to the half life of ^{238}U spontaneous fission $T_{1/2} = 9.86 \times 10^{15} \text{ a}$ ($T_{1/2} = \ln 2 / \lambda_f \approx 0.693 / \lambda_f$).

It should be noted that more than 30 measurements on the decay constant of spontaneous fission of ^{238}U have been published (See the review articles: Bigazzi, 1981; Durrani and Bull, 1987; Wagner and Van den haute, 1992; Holden and Hoffman, 2000). A wide spread of the results is apparent (λ_f from $1.7 \times 10^{-17} \text{ a}^{-1}$ to $11.8 \times 10^{-17} \text{ a}^{-1}$) from different measuring techniques. Most of the results are gathered into two groups. The largest group is peaked around $7 \times 10^{-17} \text{ a}^{-1}$, all of them were measured by SSNTDs. Another group is peaked around $8.46 \times 10^{-17} \text{ a}^{-1}$, which are measured mostly by the other techniques. A technical report on spontaneous fission half-lives for ground-state nuclides was published in 2000 by the International Union of Pure and Applied Chemistry, Analytical Chemistry Division, Commission on Radiochemistry and Nuclear Techniques (Holden and Hoffman, 2000), in which a value of ^{238}U spontaneous fission half-life $T_{1/2} = (8.2 \pm 0.1) \times 10^{15} \text{ a}$ was recommended, which corresponds to $\lambda_f = 8.45 \times 10^{-17} \text{ a}^{-1}$.

To obtain the recommended value, all the data of λ_f measured by SSNTDs were ruled out (16 out of 26 data in total). The reasons for ruling out the track data were explained in detail in the report. The basic reason is that most of the results of the λ_f measured by etch track detectors are lower than those by other detectors. The simplest way to get an average value is to throw away all the data from etch track measurements. The true reason for causing the large differences of λ_f values determined by different detectors might not have been exposed. Durrani and Bull (1987) suggested that if λ_f of ^{238}U spontaneous fission has been explicitly used in FTD, the value λ_f assumed must be stated in reporting results, so that valid comparisons can be made with other age determinations.

In addition to spontaneous fission, a heavy nucleus can split into two fission fragments upon bombardment with an incident particle, such as neutron, proton, heavy ion, γ -ray photon, and other elementary particle. For example, the ^{235}U nucleus bombarded by a thermal neutron will split into two fission fragments. This type of nuclear fission is called induced fission, as described in Chapter 1, Volume 1.

The mass distributions of ^{235}U fission induced by thermal neutrons are similar to those in ^{238}U spontaneous fission. The masses of light fragments are in the range of $A = 78\text{--}107$, with a peak value at $A = 95$. The heavy fragments are in the range of $A = 118\text{--}146$, with an average value $A = 140$ and a peak value $A = 134$. The charges of the light fragments are in the range $Z = 31\text{--}43$ with a peak value at $Z = 38$. The charges of the heavy fragments are $Z = 47\text{--}57$ with a peak at $Z = 52$. The charge Z and mass A of the fission fragments are in the range suitable for detection with SSNTDs.

The probability of nuclear reaction between a target nucleus and incident particle is described by the quantity reaction cross section. For example, the fission cross section σ_f of ^{235}U by thermal neutrons ($v = 2200 \text{ m/s}$, $E_n = 0.0253 \text{ eV}$) is 582 b ($1 \text{ b} = 10^{-24} \text{ cm}^2$). The fission cross section of ^{239}Pu by thermal neutrons is 738 b (Garber and Kinsey, 1976a,b). The fission cross section of ^{239}Pu is larger than that of ^{235}U for thermal neutrons. Both spontaneous and induced fission of heavy nuclei are important fields of research and application of SSNTDs.

1. Suitable detectors for fission fragments

The energies of fission fragments of ^{235}U induced fission are about 1 and 0.5 MeV/amu for light and heavy fragments, respectively (MeV/amu = energy per atomic mass unit, nearly equal to energy per nucleon). These energies are around the peak regions of energy-loss rate (dE/dx), or restricted energy-loss rate (REL) or primary ionization (J) of nuclear particles in solids. Therefore, fission fragments

are very easily recorded by SSNTDs. Even the most insensitive track detector of meteoritic minerals can record tracks of fission fragments. In other words, all of the known etch track detectors can be used to record tracks of fission fragments.

The track detectors for recording fission fragments can be classified into natural and man-made detectors. The most often used natural detectors include minerals (such as muscovite mica, apatite, zircon, sphene, olivine, pyroxene, whitlockite) and natural glasses (such as tektite and obsidian). These detectors not only can record currently produced fission fragments, but also have retained large number of fission fragment tracks recorded since the formation of the detectors millions or billions of years ago. These detectors have been used in FTD, geothermal history and paleoanthropology studies. If one wants to use these detectors to record newly produced particles in the laboratory, one should first anneal out the fossil tracks of fission fragments and other tracks to produce clean detectors (free from the backgrounds of the fossil tracks). If the annealing process had been made by ancient mankind by making fires, the newly recorded fission fragment tracks after firing can provide the information of the age of the ancient man.

Man-made detectors for fission fragments can be classified into inorganic detectors and organic detectors. Inorganic detectors include synthetic mineral (such as synthetic phlogopite) and man-made glasses (such as soda-lime glass or window glass and phosphate glass). The advantage of these detectors is that these are free from background tracks. Organic detectors include polycarbonate, polyethylene terephthalate, CR-39 and cellulose nitrate (LR-115).

a. Muscovite mica

Muscovite mica is an ideal track detector for the study of nuclear fission at the low-energy region. It can be cleaved into suitable thickness with a perfect smooth surface and cut to the required area. The lowest atomic number Z of particles recordable by muscovite mica is 10 (Ne). α particles emitted from fission sources cannot be recorded as background tracks in mica. During irradiation with neutrons in nuclear reactors, the recoil nuclei and most of nuclear reaction products from the compositions of mica and from other materials cannot form background tracks in mica. Therefore, muscovite mica is a clean detector for the study of nuclear fission. In this respect, muscovite mica is much better than plastic track detectors, such as polycarbonate, CN, cellulose acetate, polyethylene terephthalate, and CR-39.

In nuclear fission rate measurements, 2π geometry is often used. An amount of fissile material such as natural uranium (99.2745% ^{238}U , 0.720% ^{235}U and 0.0055% ^{234}U) is electrodeposited onto a stainless-steel plate. A sheet of

muscovite mica overlaps on it, constituting a 2π geometry. If one places this combination on the beam of thermal neutrons from a nuclear reactor channel, one can record fission fragment tracks with the muscovite mica. Because the angular distribution of fission fragments is isotropic in thermal neutron induced fission and every fission event releases two fission fragments in opposite directions, the detection efficiency of the muscovite mica for the fission fragments can be written as follows (Guo et al., 1976b, 1982).

$$\varepsilon = \begin{cases} 1 - \sin \theta_c & 0 \leq t \leq t_c \\ 1 - \sin \theta_c - \frac{(t - R \sin \theta_c)^2}{2Rt} & t_c \leq t \leq R \\ \frac{R}{2t} \cos^2 \theta_c & t \geq R \end{cases} \quad (3.12)$$

where ε is the detection efficiency of muscovite mica for fission fragments, θ_c is the critical angle of track etching of fission fragments in the detector (See Section V.A.2), R is the average range of fission fragments in the fission source (mg/cm^2), t is the thickness of the fission source (mg/cm^2), and t_c is the critical thickness of the fissile material, $t_c = R \sin \theta_c$.

For other track detectors and isotropic distribution of fission fragments, Eq. (3.12) can also be useful.

Many authors have determined the detection efficiency ε and the critical angle θ_c of muscovite mica for fission fragments. For example, $\varepsilon = (93.6 \pm 0.3)\%$ and $\theta_c = 3^\circ 41'$ for fission fragments of ^{235}U fission induced by thermal neutrons (Guo et al., 1976b, 1982), $\varepsilon = 91.8\%$ and $\theta_c = 4^\circ 31'$ for fission fragments of ^{252}Cf spontaneous fission (Khan and Durrani, 1972), and $\varepsilon = (94.8 \pm 0.53)\%$ for ^{244}Cm spontaneous fission (Gold et al., 1968).

In fission rate measurements with SSNTDs in 2π geometry, the backscattering effect of fission fragments from the substrate of fission source must be taken into consideration. For a thin fissile source attached to the surface of the detector, one fission fragment from each fission event will reach the surface of the detector; another fission fragment will go in the opposite direction and hit the substrate of the source. But there is a possibility that the fission fragment undergoes elastic scattering on the atoms in the substrate and changes its direction and enters into the detector. This fragment may also create a track in the detector. For this reason, one fission event may create two fission fragment tracks in the detector. In other words, the number of tracks recorded in the detector is more than expected from the 2π geometry. For an accurate determination of fission rate, one must make a backscattering correction for the number of tracks recorded by track detectors. A careful calibration showed that for gold-silicon substrate (Au-Si surface barrier detector), 2.1% more tracks will be recorded

by muscovite mica detectors and 2.1–2.7% more tracks will be recorded by polycarbonate track detectors (Guo et al., 1976b, 1982).

Muscovite mica has been used in measurements of fission cross sections, angular distribution of fission fragments, neutron spectrometry and dosimetry, fission and neutron distribution in nuclear reactors, sequential fission in medium energy nuclear interaction and FTD as external detectors. More details will be explained in Part 2 of this chapter.

b. Polycarbonate (Lexan, Makrofol, Tuffak)

The polycarbonate track detector is more sensitive than muscovite mica for fission fragments. Its least recordable particle is helium ($Z = 2$). However, it does not mean that full energy α -particles emitted from uranium and plutonium can be recorded by polycarbonate. The α particles can be recorded by polycarbonate detector only when the α particles are slowed down within the detector to a very low energy (≤ 0.75 MeV/u) (Fleischer et al., 1975; Fleischer, 1981). In other words, by short etching, polycarbonate cannot show tracks of α particles from natural α radioactivity of uranium and plutonium and more heavier elements. For this reason, polycarbonate is also a clean detector in fission track measurements. It is comparable with muscovite mica. Therefore, the polycarbonate track detector is used wherever muscovite mica can be applied except for fossil tracks, or at high temperature. In addition, polycarbonate is much cheaper (~ 100 times) than muscovite mica, is more flexible, and has a higher charge resolution.

Currently, polycarbonate is more popular than muscovite mica in fission track recording.

c. Polyethylene terephthalate (PET for short; Mylar, Chronar, Melinex, Terphane, Lavsan)

The sensitivity of polyethylene terephthalate is less than polycarbonate. The lowest recordable particles vary from Li ($Z = 3$) to B ($Z = 5$). α particles and protons cannot be recorded as tracks in this detector. Therefore, PET is a clean detector for recording fission fragments of ^{235}U and ^{239}Pu .

d. CR-39

Even though CR-39 is sensitive to low Z heavy charged particles, it can be used safely to detect fission fragments induced by high-energy projectiles. At very high energies over several hundreds of MeV/amu, CR-39 can identify the charges of projectiles and distinguish the tracks of projectiles and fission fragments.

By measuring track diameters or track etched lengths, the charge resolution achieves the separation of each

element in the periodic table of elements. Therefore, CR-39 is one of the best detectors in studies of relativistic projectile fission and fragmentations.

e. Glasses

One of the advantages of glass track detectors is their short etching time for fission fragment tracks. For example, several seconds to minutes are enough to develop fission fragment tracks in soda lime glass (e.g., window glass, microscope slide, or cover glass) with 48% HF at room temperature. This advantage makes glass a convenient detector for the rapid testing of whether or not a fission source, such as ^{252}Cf meets, the requirements. For this purpose, one needs to put a piece of glass over the source at a distance for a certain time period, then etch the glass in HF for several seconds, wash it in water, dry it in air, and scan it with microscope, after which one will know the intensity of the fission source. In total, one needs less than 10 minutes for the test. If one wants to judge the flux or shape or distribution of neutrons in a beam, one needs to cover a plane of natural-uranium source with a glass plate and put the uranium-glass combination in the beam to irradiate it for a certain time. The track of fission fragments of ^{235}U induced by thermal neutrons will be recorded in the glass. Then the glass detector plate is etched, washed, dried, and scanned, after which one will see the shape of the neutron beam, the distribution of beam neutrons, and possibly measure the flux of neutrons from the nuclear reactor.

The detection efficiency of soda lime glass ($71\text{SiO}_2:15\text{Na}_2\text{O}:9\text{CaO}:3\text{MgO}:2\text{Al}_2\text{O}_3$) in 2π geometry for fission fragments from a thin layer of uranium source is $(39.3 \pm 0.4)\%$, which is less than that of muscovite mica and polycarbonate detectors (Guo et al., 1976b, 1982).

f. Geological minerals

The substances which can be used as SSNTD to record fission fragments not only include large pieces of plastics, such as CR-39, polycarbonate (PC), polyethylene terephthalate (PET), cellulose nitrate (CN, LR-115), and glasses, but also include many unusual substances, such as stones, meteorites, tektites, lunar rocks, and lunar soils. The latter substances include essential (main) minerals and accessory minerals. For example, in granite, the essential minerals are quartz, feldspar and mica, which are composed of the main compositions of granite and with large sizes, such as in mm size or larger sizes. The accessory minerals in granite are apatite, zircon and some other minerals, which are contained in very small amount and very small grain size, such as several to hundreds of micrometers (μm). All these minerals (essential and accessory) can be

used as a SSNTD. One can use any one of the minerals as your track detector for fission fragment studies. Up to now, more than 100 kinds of minerals contained in various stones or geological substances have been tested and shown that they are candidates for selection to be track detectors to study fission fragments. The recorded fission tracks can provide information about the age and thermal history of the geological objects. For more details, the readers are referred to the monographs written by [Fleischer et al. \(1975\)](#), [Durrani and Bull \(1987\)](#) and [Wagner and Van den haute \(1992\)](#).

g. Space minerals

Space objects such as various types of meteorites, lunar rocks, and lunar soils are composed of various kinds of minerals similar to the geological substances. The main compositions are olivine and pyroxene that depend on the real substances. These minerals have recorded tracks of heavy charged particles from space in their history and fission fragments from ^{238}U and ^{244}Pu spontaneous fission. These tracks can provide information of the history and evolution of the objects.

2. Fission rate determination

a. Thin, thick, and asymptotic fission sources

The SSNTD is a convenient detector for the determination of fission rates in a fission source. Fission sources can be classified into solid sources and liquid sources. Solid sources include plane sources and point sources. Plane sources include thin sources, thick sources, and infinite-thickness sources (i.e., asymptotic sources). A plane (fission) source exposes a plane surface, which can be covered with a sheet of track detector.

Thin, thick, and infinite-thickness sources are differentiated by the critical thickness t_c of the source and the average range R of fission fragments in the source material. t_c is a constant for a given fissile material, where $t_c = R \sin \theta_c$ ([Guo et al., 1976b, 1982](#)). If $0 \leq t \leq t_c$, the detection efficiency ε of the detector exposed or placed in contact with the fissile material will be equal to $1 - \sin \theta_c$, independent of the thickness t of the source. In other words, the detection efficiency is a constant, which is equal to that of a zero-thickness source. Therefore, the source with thickness less than t_c is referred to as a thin source. If $t_c \leq t \leq R$, some fission fragments will stop in the fissile material, so that they cannot reach the detector. The detection efficiency changes as the thickness changes. The source in this thickness interval is referred to as a thick source. If $t \geq R$, only the fission fragments originating from the surface layer of the source material have the possibility of reaching the detector. Beyond the thickness R , no fission fragments can reach the detector. In this case, the thickness

has reached an infinite thickness, or so-called asymptotic thickness. If one uses muscovite mica as fission detector for ^{235}U foil source, $\theta_c = 3^\circ 41'$. If the fission source material is uranium, $R \approx 7.5 \text{ mg/cm}^2$, then $t_c \approx 482 \text{ }\mu\text{g/cm}^2$.² This means that the uranium fission source with thickness less than about $482 \text{ }\mu\text{g/cm}^2$ is a thin source. The source with a thickness ranging from about $482 \text{ }\mu\text{g/cm}^2$ to about 7.5 mg/cm^2 is a thick source. The source with thickness larger than about 7.5 mg/cm^2 is an asymptotic source.

b. Point fission source

A point source is defined as a source whereby the size of the source in all directions is smaller than the range of fission fragments in the source material. In this case, all the fission fragments emitted toward the detector in a 2π geometry can reach the detector, and no self absorption loss occurs in such source material. Fine dust such as aerosol particles bearing uranium or plutonium are examples of point sources.

c. Liquid fission source

A liquid fission source is a source material in which the fissile material is dissolved or dispersed in a liquid. The rate of spontaneous or induced fission events are calculated according to the equation

$$A_f = \frac{N_T}{t\varepsilon} \quad (3.13)$$

where A_f is the number of spontaneous or induced fission events that have occurred in unit time (s), N_T is the number of tracks recorded by the detector, ε is the detection efficiency of the detector for fission fragments (see [Eq. 3.12](#)), and t is the time of irradiation of the detector to the fission fragments.

For a liquid fission source, a strip of track detector is immersed into the liquid to record the tracks of fission fragments during irradiation. The fission rate can be calculated by [Eq. \(3.13\)](#). In this case, the thickness of the fission source represented by “ t ” in [Eq. \(3.12\)](#) is unit thickness (1 cm). Compared with the average range of fission fragments in liquid ($R = 15.6 \text{ }\mu\text{m}$ in water), the thickness “ t ” is larger than the range of fission fragments (R). Therefore, $\varepsilon = \frac{R}{2t} \cos^2 \theta_c$ with $t = 1 \text{ cm}$. The distribution of fission tracks on the surface of the detector is uniform. One does not need to count all the tracks on the detector. N_T should be considered as track density (number of tracks in unit area of the detector, cm^{-2}). The meaning of fission rate in a liquid is the fission number occurring in unit volume of the liquid (cm^{-3}).

For point fission sources, such as dusts or aerosol particles, or particles on swipes, one can move them to the surface of a track detector by micromanipulator or other means and stick them with diluted glue and cover them

with another track detector for recording fission fragments from the source particles. The fission tracks gather like stars. If the tracks are not too crowded together, one can count the total tracks to know the number of fissions that had occurred.

3. Determination of detection efficiency of fission fragments

The definition and significance of detection efficiency of fission fragments are as follows:

The detection efficiency ε of SSNTDs for fission fragments is defined as the ratio of the number of tracks N_T recorded on SSNTD to the number of nuclear fission N_f occurred in the fission source:

$$\varepsilon = \frac{N_T}{N_f} \quad (3.14)$$

The significance of the determination of the detection efficiency of a SSNTD for fission fragments is exemplified in the following cases:

a. Determination of the number of atoms of ^{235}U , ^{238}U , ^{239}Pu , and ^{233}U

For the quantitative determination of the number of atoms of ^{235}U , ^{238}U , ^{239}Pu , ^{233}U , as well as the other fissile nuclides in a sample, one needs to know the detection efficiencies ε . The easiest way to determine the number of the atoms (or nuclei) in the sample is to irradiate the sample to neutrons at nuclear reactors or accelerators. As long as one counts the number of tracks of fission fragments N_T recorded by the SSNTD, knowing the neutron energy E_n , the fluence of neutrons F_n , the fission cross section σ_f and the detection efficiency ε_T , one can immediately calculate the number of the atoms N in the sample by the following equation:

$$N = \frac{N_T}{F_n \sigma_f \varepsilon_T} \quad (3.15)$$

This is a type of traditional work carried out in nuclear research.

b. Determination of neutron number, fluence, and energy spectrum

The SSNTD is often used to determine the number N_n , fluence F_n and energy spectrum $N_n(E_n)$ of neutrons from nuclear reactors or accelerators. Fission foils (^{235}U , ^{237}Np , ^{238}U , and/or ^{232}Th) overlapped with muscovite mica are placed at certain distances and in ε_T certain directions from the source of neutrons. The number, fluence, and energy spectrum of neutrons irradiated to the samples can be determined by the SSNTD. These types of determinations are widely applied in neutron physics and neutron

dosimetry. In these determinations, the detection efficiency of the SSNTD for fission fragments ε_T is required.

c. Fission cross-section σ_f measurements

For systematic study of fission cross-sections σ_f of heavy nuclei induced by neutrons, heavy ions, γ -rays, elementary particles such as the pion (π), or other particles, one needs to know the detection efficiencies of the recording SSNTD for fission fragments.

High precision of fission cross-sections σ_f of ^{235}U , ^{238}U , ^{239}Pu , as well as the other fissile nuclides is of vital importance in the designing of any fission energy facilities. Therefore, one needs a high precision of detection efficiencies, especially for determination of σ_f of the nuclei with high α -ray radioactivity. For samples with high α -ray radioactivity, electronic types of detectors cannot record fission events accurately due to the existence of dead time ($\sim \mu\text{s}$ to ns) of the detectors, or due to pileup of two or more electric pulses of α particles into one pulse. Therefore, the N_f measured by electronic detectors will be less than that of the real fission events. On the contrary, the number of tracks recorded in SSNTD for short-time exposure is not affected by the high radioactivity of α particles.

From the above discussions, one can see that accurate determination of the detection efficiency ε_T of SSNTD for fission fragments is very important in nuclear science.

Several methods have been devised for determination of detection efficiencies of SSNTD for fission fragments. They are: statistical counting method, critical angle method, twin fragment method, and horizontal projected confined track-length method, which are discussed in the following paragraphs.

4. Statistical counting method for determination of detection efficiency

The statistical counting method can be classified into two types: The first type utilizes spontaneous fission sources; and the second type exploits induced fission sources.

a. Statistical counting method using spontaneous fission sources

Statistical counting method by using spontaneous fission sources for determination of detection efficiency of SSNTD for fission fragments is carried out as follows: Spontaneous fission sources, such as ^{244}Cm or ^{252}Cf evaporated or electrodeposited on stainless steel plates can be used to determine the detection efficiencies of various track detectors. The sheet of track detector such as muscovite mica is put over the surface of the fission source for a period of time. The spontaneous fission fragments from the fission source hit on the detector and form tracks in the detector. The detector is taken away from the source. Then, the detector is etched and the tracks are counted. One can

immediately obtain the detection efficiency ε of the detector for fission fragments (Gold et al., 1968), which is the ratio of the number of tracks N_T recorded in the detector to the number of fission fragments N_f hit on the detector. In this determination, the number of spontaneous fission fragments N_f hit on the detector and the number of tracks N_T recorded in the detector both occur statistically.

b. Statistical counting method using induced fission sources

At nuclear reactors or accelerators, one can use induced fission fragments to determine the detection efficiency of a SSNTD for fission fragments. The simple way to carry out this determination is to use a fission chamber and a SSNTD sandwich. In the fission chamber, a natural U source deposited on a stainless steel or Al foil is used as cathode attached to the bottom surface inside the chamber. Outside the chamber, the sandwich of SSNTD and another natural U source is attached to the opposite surface of the U foil inside the chamber. The two U foils are set back to back to each other, but between the two backs of the U foils, there is only a thin window of the chamber. One is often called the measurement as back-to-back calibration of the detection efficiency of SSNTD for fission fragments. The detailed procedures are as follows:

- (a) Preparing two layers of natural U ($\leq 482 \mu\text{g}/\text{cm}^2$, thin sources, defined as in Section I.C.2.a) on two thin plates of substrates (aluminum $< 0.3 \text{ mm}$, or stainless steel, $0.1\text{--}0.2 \text{ mm}$ in thickness) by vacuum evaporation, or electric deposition, or electrochemical deposition.
- (b) A cylindrical fission chamber is prepared. The bottom outer surface of the chamber is machined from outside to form a depressed trough with wall being very thin ($< 1 \text{ mm}$ in thickness). The diameter of the trough is about 3 cm . One can use the thin circular depressed part as the window of the chamber. On the inner surface of the window, a circle is drawn just opposite to the depression (the trough) to show the correct position of the U foil to be placed. A parallel metal plate is arranged in the chamber to act as anode of the fission chamber. After filling in argon (Ar) gas and plugging in the direct current, the fission chamber can give pulses of α particles. One should select a proper threshold value of the electronic circuit system to discriminate (against) the α particles produced from the U foil; only allow the pulses of fission fragments to be recorded. When one has selected the threshold value, one can obtain the detection efficiency ε_c of the fission chamber for fission fragments. This detection efficiency must be used to correct the number of the fission fragments N_C recorded by the fission chamber.

- (c) In the trough outside the chamber, another U foil is attached to the window of the chamber. A SSNTD sheet is overlapped to the U foil to form a sandwich U foil + SSNTD.
- (d) The fission chamber is again placed on the neutron beam at a nuclear reactor or accelerator (with moderating substances usually paraffin). The thermal neutrons induce fission of ^{235}U in the two foils. The fission fragments from the foil inside the chamber are recorded by the fission Chamber. The fission fragments from the foil outside the chamber are recorded by the SSNTD. The detection efficiency of fission chamber ε_c is determined by the method mentioned above. The detection efficiency of SSNTD, ε_T , for fission fragments is calculated from the following equation

$$\varepsilon_T = \frac{N_T}{N_C} \frac{N_{UI}}{N_{UO}} \varepsilon_c \quad (3.16)$$

where N_T is the number of tracks of fission fragments recorded in the SSNTD, N_C is the number of pulses recorded by the fission chamber, N_{UI} and N_{UO} are the numbers of ^{235}U nuclei on the foils of U placed inside and outside of the chamber, respectively.

- (e) In order to compensate for the difference in the numbers of thermal neutrons penetrating through the two U foils, which is caused by the absorption of the window and the substrates of the U foils for neutrons, the fission chamber with the sandwich (a composite) must be turned over (the front end of the composite turns to the back end of the composite) to have the neutrons first penetrating through the U foil with SSNTD to first penetrating through the U foil in the chamber. Counting the electron pulses of fission fragments from the chamber to the same number as that counted before turning the fission chamber. The total number of electron pulses before and after turning the chamber must be used in Eq. (3.14) to calculate the detection efficiency of the SSNTD for fission fragments. The total number of tracks N_T of fission fragments are counted after irradiation in two directions of the composite.
- (f) The fission chamber can be replaced by a surface barrier Si detector (Au—Si detector) for the determination of the detection efficiency of the SSNTD for fission fragments. But comparatively, a fission chamber is more convenient than a surface barrier Si detector.
- (g) The angular distribution of fission fragments emitted from the fission of ^{235}U induced by thermal neutrons is isotropic. The above determination of detection efficiency of a SSNTD in 2π geometry is based on the isotropic distribution of fission fragments. Anisotropic distribution of fission fragments may occur in fissions

induced by high energy particle (fast neutrons, high-energy heavy ions and so on). In these cases, Eq. (3.14) may give the wrong detection efficiencies for fission fragments.

The statistical counting method is simple to carry out, but generates many sources of uncertainties: such as the uncertainties from N_T , N_C , N_{UL} , N_{UO} , and ε_c . All the uncertainties add together to form the uncertainty of ε_T , which are reducible by adopting other methods of calibration of detection efficiency. For this reason, several other methods for the determination of detection efficiency of SSNTD for fission fragments have been proposed and used (see below).

5. Critical angle method

The dominant factor for track etching is the threshold property of SSNTDs. Only when the damage density created by heavy charged particles in the detector is higher than a certain value (threshold value) can the damaged tracks be etched. However, not all latent tracks formed in the detector, whose damage density is higher than the threshold, can be etched to form visible tracks. The second factor to influence the appearance of tracks is the critical angle of etching. If the angle θ between the direction of incident particle and the surface of the detector is less than a certain value θ_c , the latent track created by the particle cannot be etched to form a visible track. Only when the incident angle θ is larger than the value θ_c , that is $\theta > \theta_c$, can the track be etched to form an observable track. The specific value θ_c of incident angle is one of the critical conditions to show the etched track. The angle θ_c is called the critical value for etching the track (see Section V.A.3).

The relationship between detection efficiency ε and critical angle θ_c is as follows:

$$\varepsilon = 1 - \sin \theta_c \quad (3.17)$$

From the determination of the critical angle θ_c , one can derive the detection efficiencies ε of a SSNTD for the particle, or in this case, for fission fragments.

Khan and Durrani (1972) developed a technique to determine the detection efficiencies of a SSNTD for fission fragments. They used a beam of fission fragments from a ^{252}Cf spontaneous fission source to irradiate a SSNTD at different angles (θ) to find the critical angle θ_c ; less than or equal to θ_c , no tracks can be seen on the surface of the detector.

This method converts the measurements of track numbers into observation of the occurrence of tracks.

This method is not concerned with the number N_T of tracks recorded in the detector as well as their statistics.

However, the uncertainty of angle measurements arises, and its absolute value is relatively large compared to the other methods.

6. Twin fragment method for determination of detection efficiency

a. Principle of twin fragment method

Usually, each fission event of ^{235}U or ^{239}Pu induced by thermal neutrons produces only two fission fragments (binary fission). Scientists have found that some fission events may release three or more fission fragments with about the same masses or relatively large fragments, but the ratio of this type of fission to binary fission is only about 10^{-5} to 10^{-6} . Therefore, in the discussion of detection efficiency of a SSNTD for fission fragments, one can consider that every fission event produces only two fission fragments (twin fragments).

In order to achieve higher accuracy in the determination of detection efficiency of fission fragments, the twin fragment method was suggested and adopted (Guo et al., 1976a,b, 1982). The principle of twin fragment method in the determination of the detection efficiency is that one records the twin fragments from the same event with two types of detectors, such as a Au-Si surface barrier detector and a SSNTD. The fission source (^{235}U) is prepared on the surface of one of the detectors, such as the Au-Si detector, and the source is very thin ($<10 \mu\text{g}/\text{cm}^2$) and uniform, so that the thickness of the source is negligible. Another detector such as a SSNTD is overlapped onto the surface of the Au-Si detector, forming a sandwich Au-Si detector-fission source-SSNTD.

Fission fragments of ^{235}U induced by thermal neutrons are recorded by the SSNTD and Au-Si surface barrier detector. Since the two correlated fission fragments from one event are emitted in opposite directions, each of the two fragments should be emitted into one of the detectors, respectively. Therefore, the number of fission fragments entering the SSNTD should be the same as that entering the Au-Si detector. However, the number of recorded tracks N_T of fission fragments is less than the number of fission fragments N_S entering into the Au-Si detector. The reasons for $N_T < N_S$ are: (A) the SSNTD has a critical angle θ_c in track etching. For the fission fragments with incident angle $\theta < \theta_c$, the tracks are removed out from the surface of the SSNTD. (B) Eyesight is limited. For very shallow etch pits of tracks, the eyes of mankind even with the help of a microscope, cannot see them clearly. Finally, they are lost in counting tracks. In the determination of detection efficiency of a SSNTD, one cannot eliminate these two types of losses. It should be noted that for determining N_S with Au-Si detector, one must take into account the loss by the thickness of the Au layer (dead layer) on the surface of Au-Si detector (Guo et al., 1976a,b; 1982).

b. Statistical uncertainty of tracks in the twin fragment method

The aim of adopting the twin fragment method is to reduce statistical uncertainty in counting the number of tracks (N_T). Even though the numbers of fission fragments emitted to the Au–Si detector and SSNTD are both N_S , the number of tracks N_T on SSNTDs may not be equal to N_S . In other words, the number of tracks on the surface of SSNTDs should follow the rule of statistical fluctuation. In the twin fragment method, the way of statistical fluctuation takes place as follows: due to the negligible thickness of the fission source t ($t \ll R$), when N_S of fragments travel to the Au–Si detector, the same number N_S of fragments in the opposite direction will be certain to travel to the SSNTD. However, the latter fragments will enter into two regions due to the existence of a critical angle of the SSNTD. A part of fragments enter into a region where $\theta > \theta_c$, the tracks of these fragments can be etched visibly. Another part of fragments falls into the region $\theta \leq \theta_c$, their tracks disappeared after etching. The Au–Si detector records only a total number of fragments N_S , but cannot indicate which fragment enters into the region of $\theta > \theta_c$, or which one enters into the region of $\theta \leq \theta_c$. Therefore, the probability for a fragment to fall into the region $\theta > \theta_c$ and form a visible track should follow a binomial distribution. Supposing that the detection efficiency of a SSNTD for fission fragments in 2π geometry is ε , then, the probability for entered N_S fragments to form N_T tracks in SSNTDs can be written as:

$$P(N_T) = \frac{N_S!}{N_T!(N_S - N_T)!} \varepsilon^{N_T} (1 - \varepsilon)^{N_S - N_T} \quad (3.18)$$

The standard uncertainty of N_T is

$$\sigma(N_T) = \sqrt{N_T(1 - \varepsilon)} \quad (3.19)$$

From Eq. (3.19) one can see that due to the fission fragments impinging on the SSNTD and Au–Si detector are corresponding to each other one by one, the statistical uncertainty $\sigma(N_T)$ of the number of tracks recorded on the SSNTD being $\sqrt{N_T(1 - \varepsilon)}$ is less than the uncertainty $\sqrt{N_T}$ of the total number of N_T formed on SSNTD by a statistical source. If the detection efficiency ε of the SSNTD is close to 1 (it is true for most of SSNTD), then the uncertainty $\sigma(N_T)$ for recording twin fragments with the aid of a Au–Si detector would be much less than that of recording statistical tracks of ^{235}U source:

$$\sqrt{N_T(1 - \varepsilon)} < \sqrt{N_T} \quad (3.20)$$

This is the advantage of the twin fragment method over the other methods for the determination of detection efficiency of SSNTDs for fission fragments.

Table 3.4 shows a comparison of the results between the twin fragment method and statistical counting method as well as critical angle method.

c. Effect of backscattering on detection efficiency of fission fragments

The fission fragments originally flying toward the substrate of the fission source may be scattered by the nuclei in the substrate and turn its direction to fly out of the substrate and finally enter into the detector as shown in Fig. 3.10.

Suppose a fission event occurs at point N in a thin fission source between a nuclear track detector and the substrate of the fission source (See Fig. 3.10). One of the fission fragments (fragment 1) impinges on the track detector directly and forms a track (the first track) in the detector. Another fission fragment (fragment 2) enters into the substrate and then is scattered at point B by a nucleus. Fragment 2 changes its direction and also enters into the track detector, creating a track (the second track) in the detector. Therefore, two tracks can be formed by one fission event due to backscattering of a fission fragment. This phenomenon may result in extra tracks in an SSNTD and make the detection efficiency of SSNTD look higher than its intrinsic value. Therefore, one must make a correction for the backscattering of fission fragments from the substrate. In the following section, an example will be shown on how backscattering occurs and how to correct it.

A thin layer of enriched uranium (U) was sprayed by high electric voltage onto the surface of a Au–Si surface barrier detector. An SSNTD detector sheet was put on the U layer. The composition of the two detectors was placed at the nuclear reactor for irradiation with thermal neutrons. The fission fragments were recorded by the two detectors. However, as mentioned above, the fragment entering the Au–Si detector (the substrate of the U layer) may be backscattered by a nucleus or nuclei and turn its direction to the SSNTD covering on the Au–Si detector. If the incident angle θ of the fragment to the surface of SSNTD is larger than the critical angle θ_c of the SSNTD, the backscattered fragment will create a visible track in the SSNTD. Therefore, one event of fission, that occurred in the thin layer of ^{235}U , may create two tracks in the SSNTD. The extra track will result in an erroneous (larger) value of detection efficiency of the SSNTD for fission fragments. Alternatively, the fragment entering the SSNTD may be backscattered by nuclei in the SSNTD and turn its direction into the Au–Si detector, whereby the two fragments that entered into Au–Si detector will produce only one electronic pulse in the Au–Si detector because the dead time of Au–Si detector ($\sim \text{ns}$) is much longer than the gap of time between the two fragments entering the Au–Si detector. Therefore,

TABLE 3.4 Comparison of detection efficiencies of muscovite mica and polycarbonate for fission fragments in 2π geometry determined by the twin fragment method, statistical counting method, and critical angle method.

^cCalculated from $\theta_c = 2^\circ 30' \pm 30'$ and $\epsilon = 1 - \sin\theta_c$ for polycarbonate (Lexan) (Khan and Durrani, 1972).

FIG. 3.10 Sketch of backscattering of a fission fragment by a nucleus in the substrate of fission source. A nuclear fission event occurs at point N in the fission source (U layer). A fission fragment (1) enters the SSNTD forming a track in the detector. The other fission fragment (2) flying to the opposite direction of fragment (1) is scattered by a nucleus at point B of the substrate causing the fragment to change its direction and create a second track in the SSNTD.

backscattering that occurs in the SSNTD will not increase the number of pulses of fission fragments in the Au–Si detector, but the backscattering that occurs in the substrate may increase the number of tracks in the SSNTD. For this reason, a correction of the track number recorded by the SSNTD must be made in a determination of the detection efficiency of SSNTDs for fission fragments.

A device for the determination of the value of backscattering is shown in Fig. 3.11 (Guo et al., 1976b; 1982).

A frame was made in a half circular shape by an Al plate with 1 mm in thickness and 20 mm in width as shown in Fig. 3.11A. The Au–Si detector which was used to determine the detection efficiency was placed at the center of the frame. The center of the U ($90\% \text{ } ^{235}\text{U}$) fission source

FIG. 3.11 Experimental device and measured curve of backscattering correction coefficient. (A) Experimental device (inset). (B) Number of tracks in unit area as a function of θ (lower curve). Φ — measured value. — Smoothed curve. - - - Average value measured is in the range from $\theta = 20^\circ$ to 90° .

was precisely coincident with the center of the frame. The normal line of the surface of the ^{235}U source through the center of the source was precisely penetrating through the midpoint of the Al plate. A polyester detector strip with the same width and same length as the Al plate was attached to the inner surface of the Al plate and used to record the tracks of fission fragments emitted to different angles from the fission source. The whole device was put inside a vacuum chamber with pressure 0.1 mm height of Hg column. The ^{235}U fission source was irradiated with thermal neutrons from a nuclear reactor. Thermal neutrons

induce fission of ^{235}U . The fission fragments from the source were recorded by the strip of polyester detector at different angles θ between the direction of the fission fragment and the surface of the source. The end point of the strip corresponds to $\theta = 0^\circ$. The midpoint of the strip corresponds to $\theta = 90^\circ$. The total number of ^{235}U fissions for the irradiation was 1.8×10^8 . After etching the polyester track detector, the numbers of fission fragment tracks N_θ in unit area at different angles θ on the polyester were measured with an optical microscope. The numbers of tracks at different angles are shown in Fig. 3.11B. From Fig. 3.11B one can see that in the interval of $\theta > 40^\circ$, N_θ is not changed at different angles, $N_\theta = N_D$, where N_D is the track density directly incident to the circular strip of polyester detector. In the interval of $\theta < 40^\circ$, $N_\theta > N_D$. The extra tracks of N_θ over N_D , that is $N_\theta - N_D$, are backscattered from the Au–Si detector and recorded by the polyester detector.

The backscattering coefficient b for the tracks N_T observed on the surface of SSNTD can be written as the following equation:

$$b = \frac{1}{1 + F} \quad (3.21)$$

where F is represented by the following equation:

$$F = \int_{\theta_c}^{\pi/2} \left[\frac{N_\theta}{N_D} - 1 \right] \cos \theta d\theta \quad (3.22)$$

The meaning of b is that for recorded N_T tracks on the surface of the SSNTD, one must multiply N_T by a faction b which is less than 1, that is bN_T being the corrected number of tracks of the direct fission fragments.

The backscattering coefficients b and backscattering ratio F from Au–Si detector to several SSNTDs are listed in Table 3.5.

From the above results one can see that the backscattering of fission fragments by the substrate (here Au and Si) of the Au–Si detector contributes 2.6% more tracks in the detector polycarbonate (PC, China). When one determines the detection efficiency of PC for fission fragments, one must deduct the 2.6% tracks from N_T recorded by the PC detector. Furthermore, when one counts the fission number, that occurred in a fission source prepared on a Au–Si detector, one must deduct 2.6% from the track number N_T . The true fission number, that occurred in the source, is $N_f = N_T (1 - 2.6\%) / \epsilon$.

The value of the backscattering coefficient b is related to the atomic compositions of the substrate of the fission source and the critical angle θ_c of the detector. Fortunately, by using a simple device similar to that in Fig. 3.11, one can easily determine the backscattering coefficient for the source and the detector.

From the result (Table 3.5) of the backscattering coefficient of muscovite mica one can see that the number of tracks N_T recorded on the surface of muscovite mica must be deducted (2.1%) from N_T . That is, the true number of fission event is $N_f = N_T (1 - 2.1\%) / \epsilon$.

Many authors did not take into account the backscattering phenomenon in determining the fission number and the detection efficiency. This omission will result in about 2.6% bias error for work with polycarbonate and about 2.1% error with muscovite mica.

The equation for the calculation of the detection efficiency ϵ of SSNTDs for fission fragments is as follows:

$$\epsilon = \frac{bN_T\epsilon_S}{N_S} \quad (3.23)$$

where N_S is the number of fission fragments counted by the Au–Si detector, ϵ_S is the detection efficiency of the Au–Si detector for fission fragments.

TABLE 3.5 Backscattering coefficients b and backscattering ratio F of fission fragments from a ^{235}U source on a Au–Si detector to several types of SSNTDs.^a

SSNTD	Backscattering coefficient, b	Backscattering ratio F
Polycarbonate (Chaoyang, China)	0.974 ± 0.002	2.6%
Polycarbonate (Makrofol K, Bayer, Germany)	0.979 ± 0.002	2.1%
Muscovite mica (Sichuan, China)	0.979 ± 0.002	2.1%
Polyester (Changzhou, China)	0.979 ± 0.002	2.1%
Phosphate glass (Beijing, China)	0.989 ± 0.002	1.1%
Quartz (China)	0.999 ± 0.002	0.1%
Silicate glass (China)	1.000 ± 0.000	0%

^a θ_c in Eq. (3.22) is derived from $\epsilon = 1 - \sin \theta_c$; ϵ is determined by twin-fragment method (Guo et al., 1976a,b, 1982).

The ε_S is determined with a fission chamber. The Au—Si detector was placed inside the fission chamber to record one of the twin fragments. Another fragment was recorded by the fission chamber with an Al plate as anode inside the chamber. The detection efficiency ε_S of the Au—Si detector for fission fragments can be obtained by equation:

$$\varepsilon_S = \frac{N_S'}{N_F'} \left(1 - \frac{t}{2R} \right) \quad (3.24)$$

where N_S' and N_F' are the numbers of fragments recorded for the twin fission fragments in the Au—Si detector and fission chamber, respectively; and $(1 - \frac{t}{2R})$ is the self-absorption factor for the detection efficiency of the fission chamber due to the thickness of the ^{235}U source. Here, t is the thickness of the ^{235}U source, and R is the range of fission fragments in the source. From Eqs. (3.23) and (3.24), one can see that by means of Au—Si detector and fission chamber, one can determine the detection efficiency ε of a SSNTD for fission fragments by the twin-fragment method.

7. Projected track-length method for determination of detection efficiency

The detection efficiency of internal and external surfaces of a mineral and external detector for fission fragments can be determined by the distribution of horizontal projected (confined) track lengths. Confined tracks are those that are entirely localized within a detector (usually mineral). The etchant for developing confined tracks comes through another track which intersects with the confined tracks and reaches the outer surface of the detector. The etchant first etches the outer track and reaches the confined tracks and etches them. The etched outer track is a man-made or natural tunnel for transporting etchant to the confined tracks. The etched confined tracks are called “track in track” or TINT. Confined tracks can also be etched by the etchant that passed through a crack or a cleavage of the detector, if the confined tracks penetrate through the crack or cleavage. The etched confined tracks by this way are called “track in cleavage” or TINCLE (Lal, 1969; Lal et al., 1968). For internal surface of a mineral, the maximum length of the confined tracks is the sum of the lengths of the two fission fragments from one fission event. For external detector, the maximum length of tracks is equal to the range of one fission fragment from the mineral. The “internal surface”, “external surface”, and “external detector” are technical terms for FTD. It means that each of them is a flat surface produced by cutting a mineral or on the attached track detector, and the boundary of the flat surface has a gap distance of one range of fission fragment to the outer edge of the mineral. The requirement of a gap distance from the edge of the mineral is to ensure that no fission

fragments from outside the mineral could reach the detecting surfaces. To further describe the definitions and uses of the technical terms, a sketch is shown in Fig. 3.12.

For the components illustrated in Fig. 3.12, the following explanations according to the numbering in the figure are given in more detail:

- 1 Mineral, including crystalline minerals and amorphous glassy substances.
- 2 Cutting plane. Large-sized crystalline minerals or glassy substances can be cut by various saws or cutting wheel with diamond. Small-sized minerals may be mounted in epoxy resin or EFP (Tetrafluoroethylene-hexafluoropropylene copolymer), and then ground by emery and polished.
- 3 Internal surface of mineral, which (1) may be used to record tracks of spontaneous fission occurred in the mineral before cutting and (2) may be used to record tracks of induced fission of ^{235}U in the mineral exposed to thermal neutrons after annealing and before cutting.
- 4 G , the gap distance from the border line of the internal surface to the outer surface of the mineral. $G \geq R$, where R is the range of a fission fragment.
- 5 External surface of mineral, which may be used to record tracks of (1) spontaneous fission or (2) of induced ^{235}U fission by thermal neutrons in the mineral (after or without annealing), that occurred in the mineral after cutting or grinding and polishing of the mineral.
- 6 External detector, free from uranium (U) or with very low concentration of U, which may be used to record tracks of (1) spontaneous fission occurred in the mineral after overlapping with the mineral and (2) induced fission of ^{235}U in the mineral by thermal neutrons.
- 7 External detector surface (same application as component 6 above).
- 8 G' , the gap distance from the border line of the external surface to the outer surface of the mineral. $G' \geq R$, where R is the range of a fission fragment.

FIG. 3.12 Definitions and uses of technical terms on internal surface and external surface of a mineral and an external detector in FTD.

A new technique was suggested by Jonckheere and Van den haute (1999, 2002) for calibration of the detection efficiency of a SSNTD for fission fragments. It measures the distribution of horizontal projected confined fission-track lengths intersected with the mineral internal surface or external surface or with the surface of external detector. This method can be used to measure the detection efficiency of internal surface of the mineral for spontaneous fission tracks in the mineral. It can also determine the detection efficiency of the external surface of the mineral for induced ^{235}U fission tracks in the mineral. By covering with an external detector, the detection efficiency of the external detector for induced fission in the mineral can also be determined. In this method, the number of tracks N can be counted in an area. The number of fission events N_f ($\varepsilon = N/N_f$), that occurred in the corresponding area in the mineral, can be obtained by integration of the area below a straight line from $p = 0$ to $p = 2R$, where p is the projected track length, $2R$ is the maximum length of the confined tracks, the straight line is a function of the number N of confined tracks versus the projected track length p as shown in Fig. 3.13.

In Fig. 3.13, the abscissa is the horizontal projected track length. The ordinate is the number of tracks in the unit track length. A straight line can be found from counting the tracks. The intercept on the ordinate by the straight line is the number of tracks with zero length. The intercept on the abscissa by the straight line is the mean length of the confined tracks. The observed number of spontaneous

fission tracks is $N = 2611$ in this specific example. The number of spontaneous fission N_f of ^{238}U , that occurred in the apatite was obtained by integration as mentioned above. The detection efficiency $\varepsilon = N/N_f$ being 0.91% was obtained with the apatite internal surface for spontaneous fission tracks that occurred in the apatite (Jonckheere and Van den haute, 2002).

From similar measurements, one can determine the detection efficiency of the external surface of a mineral for induced fission of ^{235}U in the mineral (The external surface of the mineral must be covered with a substance having very low U concentration such as muscovite mica). An example of this type of measurements is shown in Fig. 3.14.

One can also determine the detection efficiency of an external detector for fission events that occur in a mineral (apatite here). Fig. 3.15 shows an example.

From Fig. 3.15 one can determine the detection efficiency of the external detector (muscovite mica) for induced fission of ^{235}U in the apatite, which, in this example, was 0.91% as the result.

From the above discussion, one can see that this method does not require the measurement of the number of fission events N_f in the sample. The number N_f is derived from integration of the data in the measurements. This is the advantage of the projected track length method for the determination of detection efficiency of fission fragments.

8. Backscattering effect of fission fragments from substrate and fission source

As discussed in Section III.C.3.d, the phenomenon of backscattering of fission fragments from the substrate and from the fission source may result in an increase of more than 2% tracks in the number of real fission events. This bias is obviously not negligible in physics research. On the other hand, many workers are not concerned with the effect of backscattering in their measurements with track detectors. Their results of measurements must be given a correction before using them.

The backscattering coefficient (See Eqs. 3.21 and 3.22) is easily determined by a device similar to that shown in Fig. 3.11. One should make a correction measurement at the same time as one counts the number of fission fragments in the track detector with the same fission source.

9. Spatial distribution of fission and angular distribution of fission fragments

a. Spatial distribution of fission events

The SSNTD is a passive position sensitive detector. The spatial resolution is about several micrometers. It is suitable for the measurement of the distribution of fission events in a certain direction (one dimension) or on an area (two dimensions) or in a volume (three dimensions). The techniques of measurements are similar to that described in the previous subsections for protons. More detailed techniques and applications can be found in Section II.C of Part 2 of this chapter.

b. Angular distribution of fission fragments

The fission fragments released in thermal neutron induced fission of ^{233}U , ^{235}U , and ^{239}Pu are isotropically emitted to the 4π direction. On the contrary, the fragments emitted from fission induced by fast or high energy neutrons as well as by high-energy particles are anisotropic (*Vandenbosch and Huizenga, 1973; Zhou et al., 1981; Zhang et al., 1990a,b, 1994*). Therefore, the detection efficiencies for fission fragments determined in Section III.C.3 are correct only for thermal neutron induced fission or for spontaneous fission. They cannot be used for calculations of high-energy fission. However, it does not decrease the importance of thermal-energy fission because up to now, most of the work on nuclear energy is related to fission by thermal neutrons. On the other hand, one must be careful if one is working on high-energy fission. In this case, one must clarify the anisotropy of the fission fragments in one's study.

10. Application of fission detection

a. Nuclear fission study

Nuclear energy mainly has two sources: fission energy and fusion energy. The utilization of large amounts of fusion energy is now only in the promising stage, as described in Chapter 1, Volume 1. The application of fission energy is the main activity in the present era. Therefore, the detection and quantitative analysis of fission events are the main tasks of nuclear scientists and engineers.

SSNTDs are vastly used in fission studies. As far as fission reactions are concerned, the following measurements have been carried out:

- (1) Incident particles: n, p, γ , π , α , heavy ion;
- (2) Target nuclei: U, Pu, Th, Bi, Pb, Tl, Hg, Au, Ho;
- (3) Energy range: Spontaneous fission; Low-energy fission ($E < 50$ MeV); Medium-energy fission ($50 \text{ MeV} < E < 1000$ MeV); High and relativistic energy fission ($E > 1000$ MeV).

SSNTDs have the following advantages for studying fission:

- (1) they can withstand intense low ionizing beam particles,
- (2) they can undergo a long duration of irradiation without the need for a power supply,
- (3) they have a high efficiency for fission fragments,
- (4) they are position sensitive for fission events, and
- (5) they exhibit a high charge resolution at high energy.

A very broad range of research fields utilize track detectors. Among these research fields, several areas of fission detection have been developed, which belong to the most important branches of nuclear science and technology, such as:

- a. neutron physics and dosimetry,
- b. nuclear reactor physics,

- c. nuclear forensic analysis and safeguards,
- d. FTD and geothermal chronology, and
- e. uranium exploration.

For additional information, readers are referred to books by [Fleischer et al. \(1975\)](#); [Durrani and Bull \(1987\)](#); and [Wagner and Van den haute \(1992\)](#) and the related [Sections III.C, II.F.1, II.F.2, II.F.3, II.G, III.A, and III.B](#) in Part 2 of this chapter.

D. Heavy ions ($Z \geq 3$)

The origins of heavy ions are mainly the following:

- (1) Low-, medium- and high-energy nuclear-interaction products,
- (2) Cosmic ray nuclei,
- (3) Cluster radioactivity emissions, and
- (4) Heavy-ion accelerator beams.

1. Suitable detectors for heavy ions $Z \geq 3$

The following are suitable detectors for heavy ions with $Z \geq 3$:

- a. CR-39 (PADC)
- b. Cellulose nitrate (CN, LR-115)
- c. Polycarbonate (PC, Lexan, Makrofol)
- d. Polyethylene terephthalate (PET, Mylar, Lavsan, Melinex)
- e. Polyimide (PI, Kapton)
- f. BP-1 glass
- g. Phosphate glass

Some basic points on the selection of detectors are as follows:

- a. Plastic track detectors, such as CR-39, CN, PC, PET, and PI, are the most sensitive detectors for recording heavy ions ($Z \geq 3$).
- b. Glass detectors, such as BP-1 glass and phosphate, are the most resistant to high temperature and radiation.
- c. Muscovite mica is superior for the discrimination of less ionizing particles.
- d. The criterion to select the most suitable detector is the capability to discriminate against background—less ionizing particles, if they exist. Otherwise, the detector should have the best potential to identify the charge Z and mass A of the beam and product heavy ions.

2. Identification of charge Z

In the first several years after the discovery of SSNTDs, scientists were very disappointed that this type of detector could not distinguish particles of different charges (Z). In those early years, these track detectors were mainly used to count tracks of particles. It was [Price et al. \(1967\)](#), who first discovered that plastic track detectors could distinguish charge Z of particles. The principles of identification of charge Z is similar to that used for silicon surface-barrier

detectors. This discovery opened up very broad applications of etch track detectors.

The techniques of identification of charge Z by etch track detectors can be classified as: maximum etchable track-length (L_{\max}) method, track etch rate versus radiation damage density method, track etch rate versus residual range method, track diameter method for relativistic energy, and track length method for relativistic energy.

Detailed explanations of these methods will be provided in [Section VI](#) of Part 1 of this chapter.

3. Identification of mass A of isotopes

Isotope identification is an extension of identification of charge Z (atomic number). It is based on the fact that the residual range R_0 of nuclei in a uniform substance is related to their mass A if their charge Z and phase velocity β ($= v/c$) are the same. By measuring the etch rate V_t (or etch track length L) and residual range R_0 , drawing a figure $V_t - R_0$, one can separate nuclei with different A (isotopes). The reader can refer to the monographs on track detectors ([Fleischer et al., 1975](#); [Durrani and Bull, 1987](#)) for additional information on this subject.

4. Heavy-ion energy determination

Energy determination of heavy ions is based on charge identification and range-energy relation. In order to determine the energy of heavy ions, one must first identify what kind of nuclei (Z) created the tracks, then solve the problem about what energy the heavy ions possess.

The following techniques may be used in determination of energy of the heavy ions:

- a. Range-Energy Relation for Charge Z
- b. Track Diameter (D) versus Energy (E) Calibration Curve Method
- c. Etch Rate (V or S) versus Residual Range (R) Method
- d. Two Points Etch Rates versus Gap Distance Method.

The techniques used to identify charge Z of the heavy ions, which created the tracks, have been explained in [Section III.D.2](#). The range-energy relation of heavy ions in a nuclear track detector will be discussed in the following [Section IV.D.2](#). When one has obtained the value of charge Z of the heavy ion, one can find the energy value E on the curve of range-energy relation of the special ion in the given detector material based on the residual range R_0 measured in the process of identification of charge Z .

5. Applications of heavy-ion detection

Since the 1980s, great achievements have been made by using SSNTDs. The most important achievements are in the following two fields:

a. Heavy ion emission from heavy nuclei

Heavy nuclei can release not only α -, β -, γ -rays, but also heavy ions. Even though the first discovery of heavy ion emission, that is ^{14}C emission from the nucleus ^{223}Ra was achieved by a silicon $\Delta E - E$ detector by Rose and Jones (1984), the similar emission from other nuclei are not feasible to detect by the same detector, because of the more intense α -ray background. The solid-state track detector has taken the role of measuring the ions emitted from the other nuclei. Up to now, about 20 parent nuclei of heavy-ion emission have been discovered and measured (^{221}Fr , $^{221,222,223,224,226}\text{Ra}$, ^{225}Ac , $^{228,230,232}\text{Th}$, ^{231}Pa , $^{232,233,234,235}\text{U}$, ^{237}Np , $^{236,238}\text{Pu}$, ^{241}Am , ^{242}Cm , and ^{114}Ba) by nuclear track detectors. No other detectors can take the role in the subsequent discoveries. (See Chapter 1, Volume 1 for a more detailed treatment of cluster radioactivity).

b. Relativistic projectile fragmentations and their products

Since the first acceleration of heavy nuclei to relativistic energy at Bevalac at the Lawrence Berkeley National Laboratory in California in the early 1980s, the capability of charge resolution $\sigma_z < 1$ was achieved for heavy nuclei ($Z > 26$) with the use of a nuclear track detector and detector stacks. This capability made possible the charge determination of the products from relativistic fragmentation. A series of studies emerged, such as:

- Searching for fractional charge particles,
- Measurements of charge pickup cross sections in nuclear interactions,
- Projectile fission studies,
- Electron capture and stripping process studies of ions in matters,
- Charge-changing cross-section measurements of heavy ions in nuclear interactions,
- Measurements of the composition of ultraheavy cosmic rays,
- Laser Acceleration and Laser Confinement Fusion,
- Deep-Inelastic Collision and Multi-Fragment Sequential Fission

More detailed information can be found in the relevant sections in Part 2 of this chapter.

For other applications of heavy ion detection with track detectors, the readers are referred to the book of Fleischer et al. (1975); Durrani and Bull (1987); and Benton et al. (1973); Hashemi-Nezhad and Durrani (1986); Trautmann et al. (1998); Hou et al. (1990); and Dunlop et al. (2007).

E. Neutrons

1. Principles of neutron detection

The neutron is a neutral particle. It cannot directly produce ionization and excitation of atoms. Therefore, it cannot be

recorded directly by any kind of radiation detector including etch track detectors. Neutrons are recorded through their recoil nuclei and reaction products with the atoms in or in front of the detector materials. Recoil nuclei H, C, O in CR-39 ($\text{C}_{12}\text{H}_{18}\text{O}_7$) can be recorded directly in the detectors. Polycarbonate ($\text{C}_{16}\text{H}_{14}\text{O}_3$) sheet can only record recoil C and O in itself. Recoil nuclei may come from a radiator, such as a thin foil polyethylene (CH_2)_n. The downstream detector such as CR-39 will record the recoil protons and carbon nuclei. The energy E of recoil nuclei follows equation $E = \alpha E_n \cos^2 \phi$, where E_n is the energy of incident fast neutrons, ϕ is the angle of the recoil nucleus with respect to the direction of the incident neutrons in the laboratory system. $\alpha = 4A/(A+1)^2$, where A is the atomic number of the recoil nucleus. The nuclear reactions often used to record neutrons are (n, α) and (n,f) reactions, such as $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$, $^6\text{Li}(\text{n},\alpha)^3\text{H}$, $^{235}\text{U}(\text{n},\text{f})$, $^{237}\text{Np}(\text{n},\text{f})$, $^{238}\text{U}(\text{n},\text{f})$, and $^{232}\text{Th}(\text{n},\text{f})$. Their threshold energies are $E = 0$ (^{10}B , ^6Li , ^{235}U), 0.4 MeV (^{237}Np), 1.1 MeV (^{238}U), and 1.17 MeV (^{232}Th).

To record neutron reaction product α particles, usually CR-39 or LR-115 (CN) sheet is used. For recording neutron produced fission fragments, muscovite mica, Lexan or Makrofol polycarbonate foil is used.

2. Suitable detectors for neutron detection

a. CR-39

CR-39 is suitable for recording neutrons through (1) recoil nuclei, *i.e.*, p, C, O in its own compositions (CR-39 sheet is used as both radiator and detector); (2) recoil nuclei, *i.e.*, p and C from radiator polyethylene (CH_2)_n. In this case, CR-39 is used only as detector, but fast neutrons will produce nuclear recoils in the CR-39 as background; (3) neutron reaction products, namely, α -particles and ^7Li from the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ reaction; and α -particles and tritium from the $^6\text{Li}(\text{n},\alpha)^3\text{H}$ reaction.

b. LR-115

LR-115 CN is nearly the same as CR-39 in neutron detection, but it is less sensitive than CR-39.

c. Lexan, Makrofol (polycarbonate)

Polycarbonate detector can be used as a nuclear recoil detector without radiator for fast neutron detection. Bare polycarbonate sheets will record recoil nuclei of oxygen and nitrogen produced in air by neutrons. Usually, an aluminum plate is placed in contact and in front of the detector to shield off the recoil nuclei from the air; or alternatively, to treat air as a radiator.

Polycarbonate sheets sandwiched with fissile foils can record fission fragments (fission rate measurement) and consequently derive the neutron fluences and neutron spectrum.

d. Muscovite mica

Muscovite mica is the most ideal detector of neutrons with the help of fissile foils. It is insensitive to α particles and β - and γ -rays. It is suitable for the measurement of neutrons in mixed radiation fields, where neutrons coexist with γ -rays.

3. Neutron intensity measurements

The advantages of the SSNTD in neutron intensity measurements are (1) its small size and (2) insensitivity to β - and γ -rays and to less ionizing nuclear particles. It can be inserted into small gaps to measure neutron intensities in nuclear facilities. A modern example is the measurement of the neutron production yield, neutron spatial distribution, and neutron spectrum in the study of accelerator driven subcritical reactors (ADSs) for the disposal of long-lived radioactive wastes (Brandt et al., 2005, 2008; Zamani et al., 2008; Fragopoulou et al., 2008; Wan et al., 2001, 2003). A variety of fields of neutron applications and measurements have been studied with SSNTDs at different facilities (Zaki-Dizaji et al., 2008; Belafrites et al., 2008; Esposito et al., 2008; Bedogni et al., 2008; Al-Ghamdi et al., 2008; Al-Jarallah et al., 2002; Ohguchi et al., 2008; Abu-Jarad et al., 2002; Palfalvi, 2009; Guo et al., 1976a).

4. Neutron energy measurements

Early developments of neutron energy determination by track detectors have been reviewed and explained in books (Fleischer et al., 1975; Durrani and Bull, 1987). Here, only the basic techniques and new developments are pointed out.

a. Fission foil and track detector sandwich techniques

The commonly used fission foils are ^{235}U , ^{237}Np , ^{238}U , and ^{232}Th with muscovite mica and polycarbonate track detectors.

b. Recoil carbon and oxygen nuclei method

By measuring the etched track parameters: the mouth and depth, one can calculate the REL spectrum. By computer simulation with the composition of the detector, the reaction cross sections of carbon and oxygen with fast neutrons and the REL spectrum, one can obtain the neutron spectrum (Wang et al., 1998).

c. Radiator-Degrader-CR-39 method

The radiator is hydrogen containing material, such as polyethylene $(\text{CH}_2)_n$ thin foil. The degraders are Pb, Au, or Al in different thicknesses. CR-39 is the track detector to record the recoil protons with energy in the energy window

of CR-39 (Aslam et al., 1988; Durrani et al., 1988; Dajko, 1990; Wan et al., 2003; Oda et al., 2009).

d. Bonner sphere spectrometers

More detailed explanation about Bonner sphere spectrometers (BSSs) will be given in IV.A.2 of Part 2 of this chapter, and Chapter 9, Volume 1 of this book.

5. Neutron dosimetry

Neutron dosimeters are used in measurements of neutron dose. From the readings of neutron dosimeters, one can directly get the information of the dose received by a person. Accurate measurements of neutron dose are very difficult. Theoretically, the process of energy deposition of neutrons and its effects on the human body are very complicated. Recent renewal of the recommendations of the ICRP (International Commission on Radiological Protection) from publication 60 (1991) to Publication 103 (ICRP 103, 2007) reflects the progressive deepening of the understanding of neutron energy deposition and its effects on human health. Practically, ideal neutron dosimeters have not been found at the moment. All the existing neutron dosimeters cannot give accurate measurements of neutron dose owing to their intrinsic deficiencies.

The principle of neutron dose measurements includes two steps. The first step is to measure the fluence of neutrons Φ irradiated to the human body. The second step is to convert the neutron fluence Φ to dose equivalent $H(d)$ by using the documented conversion coefficients $H(d)/\Phi$ (ICRP Publication 74, 1996). New replacements for the ICRP 74 conversion coefficients will be published after having the ICRP recommendation 103. The procedure for the calibration of a neutron detector to become a neutron dosimeter is as follows: (1) the neutron detector is put in the field of neutrons of known energy E_n ; (2) the detector is irradiated with the neutrons to a certain fluence Φ ; and readings M_c of the detector and the fluence Φ of neutrons with their energy E_n are recorded. (3) Then, the response of neutrons M_c/Φ is obtained at the energy E_n of neutrons. (4) Dividing M_c/Φ by the conversion coefficient $H(d)/\Phi$, the response of dose equivalent $M_c/H(d)$ is obtained. The conversion factor $H(d)/\Phi$ was documented in ICRP Publication 74 (1996) and will be replaced with a new one. The reciprocal of the response of dose equivalent is $H(d)/M_c$, the dose equivalent corresponding to one reading of the dosimeter. The above discussion is correct for monoenergetic neutrons of known energy. For a neutron spectrum of known energy distribution, the average conversion coefficient $H(d)/\Phi$ must be calculated from the neutron spectrum. For example, with a AmBe neutron source, the dose equivalent received can be calculated from $H(d)/\Phi$ and Φ , where Φ is calculated from the distance between the

detector (dosimeter) and the source and the intensity of the source.

An ideal neutron dosimeter should satisfy the following equations at all energies:

$$\frac{(M_c/\phi)}{(H(d)/\phi)} = c \quad (3.25)$$

or

$$\frac{M_c}{H(d)} = c \quad (3.26)$$

where c is a constant.

In other words, the two curves of M_c/Φ versus E_n and $H(d)/\Phi$ versus E_n can be overlapped if one of the curves is multiplied by a constant (c or $1/c$). In this case, one does not need to consider neutron energy E_n . One can directly obtain the dose equivalent $H(d)$ from the reading M_c . Up to now, a neutron dosimeter of this type has not been found. In other words, none of the existing neutron dosimeters is ideal.

CR-39 is a better neutron dosimeter than a nuclear emulsion plate (e.g., NTA nuclear emulsion) and thermoluminescence detector, but it is less efficient than a bubble detector (Guo et al., 2000) as a neutron dosimeter. A rem-counter was designed by Agosteo et al. (2010) to measure neutron dose with CR-39 and ^{10}B converter by recording tracks of (n, α) reactions as a passive detector and with a ^3He proportional counter as active detector in the rem-counter. It shows that both active and passive detectors in the rem-counter can give relatively good agreement with the ideal $H(d)/\Phi$ curve; and the CR-39 + ^{10}B detector does not undergo deleterious signal saturation, pileup effects, and the influence of intensive γ -rays as the active detector.

6. Applications of neutron detection

The neutron is one of the most important particles in modern science and technology. Nuclear energy and nuclear weapons are both most important issues in the current world. One can say that neutrons are the key to world development and security. Therefore, one cannot make a complete list to show how many fields are related to neutron detection; but one must give some examples to show how important neutron detection is in modern science and technology, including the following:

- Neutron Physics,
- Reactor Physics,
- Neutron Dosimetry,
- FTD and Geothermal Chronology (Yuan et al., 2013; Guo et al., 1996, 1999, 2013; Chen et al., 2001),
- Nuclear Transmutation by Neutrons and Accelerator-Driven Subcritical Reactor (ADS),
- Nuclear Forensics and Safeguards (Chen et al., 2013, 2015; Vlasova et al., 2015; Wang et al., 2018),

- Neutron Radiography,
- Neutron Cancer Therapy, such as BNCT (See Chapter 1, Volume 1), and
- Element Mapping.

F. Exotic particle detection

Exotic particles include several hypothetical particles including the following:

- (1) Magnetic monopoles (MMs), which was predicted theoretically by Dirac (1931) and is required by the Grand Unification theories in theoretical physics.
- (2) Q-balls, which was predicted by supersymmetry theories to be a coherent state of squarks, leptons and Higgs field. Q-balls could be a candidate, among others, of cold dark matter which is proposed to solve the problem of the missing mass in the universe.
- (3) Nuclearites are known as Strange Quark Matter (SQM). SQM is made up of approximately equal numbers of up, down, and strange quarks, and is surrounded by an electron cloud, forming a sort of atom. SQM could contribute to the cold dark matter in the universe.

1. Suitable detectors for exotic particle detection

CR-39, polycarbonate, phosphate glasses, and muscovite mica have been used to detect exotic particles.

2. Magnetic monopole detection

MMs are particles theoretically predicted by Dirac (1931). These particles are similar to protons or electrons or other charged particles, which can be separated into isolated particles from their opposite charge state. The magnetic charge of a monopole can be $g = ng_D = 68.5ne$, where $n = 1, 2, 3, \dots$, and g_D is the Dirac minimum charge: $g_D = hc/2e$.

From the relationship between magnetic charge g and electronic charge e , one can calculate the energy loss rate of a MM passing through the stopping materials.

$$(dE/dx)_m \approx (g\beta/e)^2 (dE/dx)_e \text{ if } \beta \ll \alpha = \frac{1}{137}$$

$$(dE/dx)_m \approx (n^2/4) (dE/dx)_e = K\beta \text{ if } \beta \leq \alpha = \frac{1}{137}$$

$$(dE/dx)_m \approx 33 \text{ GeV/cm for plastic if } n = 1 (g = g_D)$$

A very large value dE/dx (equivalent to the dE/dx of a heavy nucleus with charge $Z \approx 68.5e$ for $g = g_D$, and equivalent to that of a superheavy elemental ion with $Z \approx 137e$ for $g = 2g_D$) of monopoles classifies these as heavily ionizing particles, if they exist and consequently, these would be easy to detect with the use of nuclear track

detectors, such as CR-39, polycarbonate (Lexan, Makrofol), BP-1 glasses, and UG-5 glasses (Derkaoui et al., 1999; Ahlen, 1980; Pinfold, 2009; Giacomelli and Patrizzii, 2005; Kinoshita et al., 1992; Cecchini et al., 2005). Another important feature of energy loss of MMs is that the electronic energy loss dE/dx decreases as the energy E of the MM decreases in the entire electronic energy loss region, which is contrary to the feature of electrically charged particles. In the latter case (electrically charged particles), dE/dx gradually increases up to the Bragg peak as the energy of the particle decreases from $E \approx 3 \text{ GeV/amu}$.

The most sensitive etch track detector CR-39 has a threshold $Z/\beta \approx 5$. It allows the detection of a MM with one unit Dirac charge ($g = g_D$) for a velocity $\beta (= v/c)$ of around 10^{-4} and $\beta > 10^{-3}$. The detector can record $g \geq 2g_D$ MM in all the velocity regions from $4 \times 10^{-5} < \beta < 1$ (Derkaoui et al., 1998, 1999). Lexan and Makrofol polycarbonate detectors have thresholds at $Z/\beta > 50$. They can record only relativistic MMs.

The phosphate glass detector (UG-5) is less sensitive. It can record only multiply charged MMs.

The detection of MMs can also be carried out by recording tracks of bound systems (dyons) of MMs with a nucleus having a large nuclear magnetic moment, such as the proton, aluminum nucleus, and Mn nucleus. The energy loss of the bound system (MM + p, MM + Al, MM + Mn) is composed of the energy loss contributions of MM and the nucleus (Price et al., 1984; Derkaoui et al., 1999).

Up to now, no MMs have been found (Pinfold, 2009).

3. Dark matter particle detection

Great efforts have been made to detect various hypothetical dark matter particles by using solid-state track detectors. The solution to the problem of missing mass in the universe is of significance in theoretical physics, astrophysics, and cosmology. More detailed explanation of this subject is beyond the main scope of this handbook. The readers are referred to articles written by Price (2005) and Cecchini and Patrizzii (2008), from which more information can be obtained.

IV. Track formation mechanisms and criteria

A. Introduction

Track formation mechanisms are studied to determine how etchable tracks of charged particles are formed in solids and what is the criterion or standard to expect which solids can record what particles.

The inferences we derive from the track formation mechanism and the criterion we use for the selection of SSNTDs must fit with the following facts:

- (1) Insulating solids and poor semiconductors with electrical resistivity higher than about 2000 ohm-cm are basically track-recording materials;
- (2) Metals and good semiconductors are not track-recording solids;
- (3) Electrons (β -rays), x-rays and γ -rays cannot create etchable tracks in solids;
- (4) The sensitivities of different insulating solids are different, such as muscovite mica, which can record the nucleus of Ne ($Z = 10$) and heavier nuclei, but not a lighter nucleus of $Z < 10$. Polycarbonate can record α -particles, but not protons; CR-39 can record protons ($Z = 1$) and heavier particles. In other words, the SSNTD is a type of threshold detector.
- (5) Generally speaking, plastic or polymer detectors are more sensitive than inorganic solids;
- (6) Before etching, the recorded tracks in solids may be annealed out (*i.e.*, track fading) at higher temperature.

What mechanisms can cause the above phenomena and what criterion can be used to judge the differences are essential questions for our understanding and application of nuclear track detectors.

B. Track formation mechanisms

1. Ion explosion spike for inorganic solids

The incident charged particle ionizes the atoms along its trajectory. Subsequently, the ionized ions with positive charges repel each other and are rejected into the region around the trajectory by coulomb repulsion, forming a vacant region along the central line of the particle trajectory and interstitial atoms in the surrounding region as shown in Fig. 3.16.

FIG. 3.16 The ion explosion spike mechanism for track formation in inorganic solids. The incident heavy charged particle ionizes the atoms in the detector along its trajectory and forms a positively charged region. The positively charged ions repel each other by coulomb force and are rejected to the surrounding region, forming a long vacant line along the trajectory and interstitial atoms around the vacant line. These damaged materials easily react with appropriate chemicals and are dissolved in a chemical reagent, forming an etched track. From Fleischer (1998). Reprinted with kind permission from Springer Science + Business Media © 1998.

The formed interstitial and vacant region relaxes elastically, straining the undamaged matrix. The long range of the strained region can be observed under a TEM as a latent track and selectively etched by special etchant to form an etched track of the incident particle. The electrons in metals can diffuse very fast to reach the electrically positive ions and neutralize them. Therefore, no ion explosions occur in metal after the passage of a heavy charged particle. For this reason, metal cannot be used as a SSNTD.

The positive ions formed by a charged particle in good semiconductors act as holes which move relatively fast and dissipate their charges before explosion of the ions. Therefore, good semiconductor material cannot record tracks of heavy charged particles.

2. Chain breaking mechanism in high polymers

In a high polymer, molecular chains are broken by the passage of a heavy charged particle. This process needs only about 2 eV of energy. The process occurs more readily in high polymers. The open ends of the chains are easily attacked by appropriate chemical reagents. This mechanism is shown in Fig. 3.17 (Fleischer, 1981).

The energy of about 2 eV, required to break a chain of polymers, is much less than that required to ionize an atom (at least 5–17 eV) for inorganic solids. Therefore, it needs less energy to create continuous damage sites in polymers than that in inorganic solids. This is the reason that higher polymers have a higher sensitivity than inorganic solids.

C. Criteria of track formation

The study of track formation criteria involves the search for a parameter or a quantity by which one can predict whether

FIG. 3.17 Chain breaking mechanism in the formation of etchable tracks in higher polymers. Chain breaks by passage of a heavy charged particle allow preferential etching at a lower radiation damage density. For this reason, organic solids have a higher sensitivity to record tracks of heavy ions. From Fleischer (1998a,b). Reprinted with kind permission from Springer Science + Business Media © 1998.

a particle can be recorded by a specific solid and describe quantitatively the threshold of the solid. This quantity is the property of the solid and has no relationship with any kind to charged particles. Several parameters have been proposed for the criteria, but none of these satisfactorily fit all data. Every parameter is successful for certain properties but fail with respect to other properties of the solids.

1. Primary ionization rate criterion

This criterion was suggested by Fleischer et al. (1967b). According to this criterion, the formation of etchable tracks is related to the number of primary ionizations produced along the trajectory of the particles.

a. Formulation

The formulation for calculation of primary ionization rate is given as follows:

$$J = \frac{2\pi n_e Z_{\text{eff}}^2 e^4 f_e}{mv^2} \left[\ln \frac{2mv^2}{I_0} - \ln(1 - \beta^2) - \beta^2 - \delta - K \right] \quad (3.27)$$

where n_e is the number of electrons in a unit volume of the detector, v is the velocity of incident particle, m is the mass of the electron, f_e is the effective fraction of the electrons in the detector in the most loosely bound state, I_0 is the ionization potential of the most loosely bound electrons in the detector, β is the particle phase velocity, i.e., v/c where c is the speed of light in a vacuum, δ is a correction term for the effect of polarization of a medium at relativistic velocities, K is a constant depending on the composition of the stopping medium (detector), and Z_{eff} is the effective charge of the incident particle where $Z_{\text{eff}} = Z[1 - \exp(-130\beta/Z^{2/3})]$ and Z is the atomic number of the incident particle.

The value of the adjustable constant K in Eq. (3.27) is selected by measuring track etch rate V_T for at least 2 types of incident particles and adjusting the K value in Eq. (3.27) in order that for the same V_T , the corresponding J values are the same for all of the incident particles. This means that V_T is related only to J but not to the types of particles. By adopting $I_0 = 13$ eV for muscovite mica and $I_0 = 2$ eV for polycarbonate and CN, Fleischer et al. (1967b) adopted $K = 3.04$ to calculate J to fit the data well.

Fig. 3.18 shows the relationships between J values and β or energy E of various incident charged particles as well as the thresholds of different types of detector materials.

b. Successes in explanation of thresholds

The criterion of primary ionization rate can give a good fit to the experimental results both for inorganic solids and organic polymers. By adjusting the parameter K , a horizontal line (threshold) can be obtained to separate the data of track formation from that of nontrack formation.

FIG. 3.18 Relationship between primary ionization rate J and velocity β or energy E of various projectiles. The horizontal lines represent the thresholds of different types of track detectors. The solid circles denote etchable track formation in Lexan. The open circles denote that no etchable tracks were formed in Lexan. The minimum charge Z , which can form tracks in muscovite mica, is Ne ($Z = 10$). The registration threshold of CR-39 lies below the x-axis of the figure. Figure from Fleischer (1998). Reprinted with kind permission from Springer Science + Business Media © 1998.

c. Existing problems

A number of problems exist with respect to primary ionization rate criterion, which are the following:

- (1) The main problem is that it does not consider the ionization induced by δ -rays.
- (2) Another problem is that the calculated primary ionization rate is only a relative value, and the formulation has not been approved scientifically.
- (3) The third problem is that in organic polymers, the parameter I_0 must be taken as small as about 2 eV. This energy is not enough to ionize any atoms. Even though a good fit can be obtained for an organic polymer, $I_0 \approx 2$ eV indicates that the tracks are formed by molecular chain breaking, not by primary ionization.

2. Restricted energy loss for plastic track detectors

The restricted energy loss (REL) criterion was suggested by Benton (1967) and Benton and Nix (1969). The restricted energy loss is the portion of the total energy loss that produces δ -rays of less than some specified energy ω_0 . Not all of energy loss in solids contributes to track formation. A significant fraction of the energy transferred to electrons in a detector goes to electrons with sufficiently high energy and with range much larger than the scale of latent tracks. These higher-energy δ -rays will not contribute to the track formation. Only low-energy δ -rays with energy lower than ω_0 will contribute to the formation of etchable tracks.

a. Formulation

$$REL_{\omega_0} = \frac{2\pi n_e Z_{eff}^2 e^4}{mv^2} \left[\ln \frac{2mv^2}{I} \frac{\omega_0}{I} - \ln(1 - \beta^2) - \beta^2 - \delta \right] \quad (3.28)$$

where I is the mean ionization potential of the detector material, and ω_0 is the upper limit of the δ -ray energy below which the deposited energy contributes to the formation of tracks.

The value of ω_0 has been taken as 200, 350, and 1000 eV by different authors. It plays the role of an adjustable parameter in the calculation of REL .

Fig. 3.19 illustrates the relationships between REL and energy E of incident particles.

b. Successes in explanation of thresholds

The criterion of restricted energy loss rate has taken into account the insignificance of δ -rays with higher energy such as higher than ω_0 . Ideally, it is correct and easy to be accepted. For this reason, the horizontal line of the threshold fits to the data for the most part. Only in the low-energy region some deviation occurs.

c. Existing problems

No horizontal line quite fits the measured data as shown in Fig. 3.19. Ahlen (1980) showed that REL cannot fit the V_T values in a straight line for particles with different charge Z .

3. Energy deposition model (e_v)

The energy deposition model (E_v) criterion was suggested by Katz and Kobetich (1968). It suggests that a charged

FIG. 3.19 Restricted energy loss rate versus energy of the heavy charged particles in a Lexan polycarbonate track detector. The upper limit of the energy of δ -rays $\omega_0 = 1000$ eV was taken. Solid circles denote the formation of etchable tracks. Open circles denote no track formation. No horizontal line quite fits the measured data. From Fleischer (1981). Reprinted with permission from Elsevier © 1981.

particle will create an etchable track in a dielectric solid if the particle deposits energy E_v , which reaches a critical dose (volume density) by δ -rays at a critical distance r from the path of the particle. The distance r from the path is 19\AA ($1\text{\AA} = 10^{-8}\text{ cm} = 10^{-10}\text{ m}$) for muscovite mica, 15\AA for CN and 17\AA for Lexan polycarbonate. The critical energy density E_v deposited at the critical distance r of muscovite mica is $\sim 3.5 \times 10^9\text{ erg/g}$.

a. Formulation

The calculations for obtaining E_v at a distance r by δ -rays are quite complicated. The reader is referred to the original articles by Katz and his coauthors (Katz and Kobetich, 1968; Kobetich and Katz, 1968).

Fig. 3.20 shows the relationships between E_v and E of incident particles.

b. Successes in explanation of thresholds

This criterion has taken into account the energy density deposited by δ -rays and the critical radius from the trajectory of the particle, and the results can approximately predict the thresholds both for inorganic and organic solids.

c. Existing problems

The obvious shortfall of this criterion is that it ignores the energy deposition of the primary incident particles. The second problem is that it cannot obtain a horizontal line to denote the existing threshold. The third problem is the sharp cutoff at low energy of incident particles, and it does not hold true for failure to detect very low-energy incident particles.

FIG. 3.20 Energy deposition density E_v versus energy E of heavy charged particles (nuclei) in Lexan polycarbonate. Solid circles represent etchability in Lexan, open circles denote zero registration. The horizontal line denoting the threshold of Lexan is tilted toward the low energy region. From Fleischer (1981). Reprinted with permission from Elsevier © 1981.

D. Extended and transitional criteria

Besides the criteria explained in the previous paragraphs, namely, J , REL , and E_v , there are two criteria often used by others, which are Z_{eff}/β and dE/dx . The value of Z_{eff}/β may be used as a criterion for track formation, but dE/dx can be used only as a transition parameter.

1. Z_{eff}/β

Ahlen (1980) compared the measured results of V_T of ^{28}Si , ^{56}Fe , and ^{20}Ne in a Lexan detector with REL and Z_{eff}/β . He concluded that Z_{eff}/β is preferred as a universal parameter over REL , and the experimental data are sufficiently good to rule out the REL model. The reason for Z_{eff}/β being a good parameter is that when the constant K in equation for J approaches infinity (∞), it is equivalent to, i.e., $J \propto (Z_{eff}/\beta)$.² Therefore, $(Z_{eff}/\beta) \propto J^{1/2}$ will be another parameter as J to describe formation of etchable tracks.

Fig. 3.21 illustrates the response $(V_T/V_B - 1)$ versus Z_{eff}/β of BP-1 glass etched by 48% HBF_4 at 50°C , 49% HF at

FIG. 3.21 Response $(V_T/V_B - 1)$ versus Z_{eff}/β of BP-1 glass etched by 48% HBF_4 at 50°C , 49% HF at 20°C and 6.25N NaOH at 50°C where $s = V_T/V_B$, $Z^* = Z_{eff}$. The solid points are measured data with an 11.4 AGeV ^{197}Au beam and its fragments in the three etching conditions. The horizontal dotted line denotes the threshold ($s - 1 \leq 0.015$) of track registration at normal incidence. The threshold $(Z_{eff}/\beta)_{th}$ are given according to the lowest value of (Z_{eff}/β) in the figure, which are the lower limit of the instrument used. From He et al. (1994); printed with permission from Elsevier © 1994.

20°C, and 6.25N NaOH at 50°C (He et al., 1994). From the measured data, the authors found that the thresholds for formation of etchable tracks are related to the etching condition for the same detecting material. The threshold Z_{eff}/β for BP-1 glass are 57 ± 1 , 68 ± 1 and 78 ± 1 respectively for the above three etching conditions.

a. Successes and advantages of Z_{eff}/β as a criterion of track formation

The Z_{eff}/β criterion of track formation has exhibited the following success and advantages:

- (1) It is easy to convert to the charge Z of relativistic heavy charged particles which can be recorded by the detector. For relativistic energy, $\beta \rightarrow 1$, $Z_{\text{eff}} \rightarrow Z$, and $Z_{\text{eff}}/\beta \rightarrow Z$. Therefore, $(Z_{\text{eff}}/\beta)_{\text{th}} = 26$ can be considered whereby relativistic Fe ions ($Z = 26$) in cosmic rays may be recorded by the detector.
- (2) It is easy to convert the registration threshold $(Z_{\text{eff}}/\beta)_{\text{th}}$ to primary ionization J and restricted energy loss (REL), since in all equations of J , REL as well as dE/dx , $(Z_{\text{eff}}/\beta)^2$ are included. Other parameters in the equations can be obtained from the compositions of the detectors. Knowing the value of $(Z_{\text{eff}}/\beta)_{\text{th}}$, the thresholds of J , REL as well as the transitional parameter dE/dx (See below), can be obtained for the detectors.
- (3) It is easy to determine the threshold of Z_{eff}/β of a detector by using different energies of at least one type of heavy ion, or different heavy ions.
- (4) The determined value of the threshold of Z_{eff}/β for each detector is absolute and fixed, not adjustable.

From the above advantages, one can see that the criterion Z_{eff}/β for track formation is convenient, straightforward, and easy to assigning a quantity, compared with other criteria suggested.

b. Existing problems

How to derive the threshold of track formation Z_{eff}/β for each type of detector remains to be solved.

2. dE/dx transitional parameter

Some authors still use total energy loss rate dE/dx to denote the thresholds of etch track detectors. This parameter has been demonstrated by extensive experiments that it cannot give a satisfied description of the thresholds. No horizontal line separates the ions that register from those that do not register. The lines that separate the experimental data for recording tracks from the none-recording of tracks tilt up at the high-energy region. One cannot find a threshold value, which is independent of projectile charges (Z). However, the dE/dx value can be treated as a conditional reference

mark, such as the “threshold” for recording He ions are about 40 (50% CR-39), 88 (40%), 108 (30%), 125 (20%), and ~ 250 (0%) keV/ μm equivalent in water for CR-39-DAP plastics, where 50% CR-39 means the ratio of CR-39/DAP in the composition of CR-39-DAP is 50/50 (Tsuruta et al., 2008). Since the dE/dx value of a particle of charge (Z) and energy (E) in a specific detector material can be determined or calculated very well. From the dE/dx value one can trace back the energy E and to calculate REL and J .

The formula used to calculate total energy loss rate is.

$$\frac{dE}{dx} = \frac{4\pi n_e Z_{\text{eff}}^2 e^4}{mv^2} \left[\ln \frac{2mv^2}{I} - \ln(1 - \beta^2) - \beta^2 - \frac{C}{Z_2} - \frac{\delta}{2} \right] \quad (3.29)$$

where C/Z_2 is a shell correction term.

The other parameters in Eq. (3.29) are the same as in Eqs. (3.27) and (3.28). The calculation methods of C/Z_2 and δ can be found in the review articles by Ahlen (1980), Fano (1964) and Barkas and Berger (1964).

E. Incapability of the former adopted criteria

The criteria of track formation proposed in the 1960s have played important roles in our understanding of the formation of etchable tracks in insulating solids, which include (1) criterion of total energy loss rate $(dE/dx)_c$ (1964), (2) criterion of primary ionization rate $(dJ/dx)_c$ or J_c (1967), (3) criterion of restricted energy loss rate $(dE/dx)_{\omega < \omega_0}$ or REL_{ω_0} (1967), and (4) criterion of energy deposition model E_V (1968), as described in the paragraph above.

Ideally, the success of the above criteria is very limited. It cannot help scientists to do much work in the following subjects:

1. Incapability to estimate the threshold values of existing track detectors

Threshold is a general and basic property of SSNTDs. A successful theory on track formation should be able to derive the threshold value of a detector from its chemical compositions and molecular structure. Unfortunately, none of the above criterion can provide accurate values of the thresholds.

2. Incapability to design a new material possessing the expected threshold value

Since the 1980s, track workers hoped to synthesize new chemical materials which are more sensitive than CR-39 to record etchable tracks of heavy charged particles; but none of them meet with success (O'Sullivan et al., 1981).

F. Conflict between track formation criteria and chain breaking mechanism

Researchers in this field are familiar with the curves drawn in Fig. 3.18 (J vs. $\beta = (v/c)$), Fig. 3.19 (REL_{ω_0} vs. E (MeV)), and Fig. 3.20 (E_v (ergs/cm³) versus E (MeV/N)) and their corresponding Eqs. (3.27), (3.28) as well as (3.29) for dE/dx . All these criteria of track formation rely on the mean ionization energy I or its derived quantities. On the other hand, chain-breaking mechanism in Fig. 3.17 is also accepted by all. The chain-breaking mechanism is dependent on chemical bond dissociation energy (BDE, or called bond breaking energy) (Luo, 2002). One should have noticed that the above four track criteria and the track formation mechanism of polymer track detectors are in conflict with each other. The former is based on ionization energy; the latter is based on bond breaking energy. The quantitative values of I for polymer track detectors are in the range from about 57 to about 80 eV, that is, polyethylene (57.4 eV), polypropylene (59.2 eV), cellulose acetate butyrate (63.4 eV), polystyrene (68.7 eV), polycarbonate (Lexan, 69.5 eV), polyallyl diclycol carbonate (PADC, CR-39, 70.2 eV), polymethyl methacrylate (PMMA, Lucite, 74.0 eV), polyethylene terephthalate (PET, 73.2 eV), polyimide (Capton, 79.34 eV), and CN (81.1 eV) (Sternheimer et al., 1982; Durrani and Bull, 1987). The quantitative values of bond breaking energy for polymer track detector materials is in the range from a few tenths of eV to about 4 eV (Luo, 2002; Fleischer, 1998). The difference between the two parameters amounts to tenfold. If one accepts the chain-breaking track formation mechanism, one should develop theoretical formulae for the criteria based on bond breaking energy instead of ionization potential for polymer track detectors.

G. Latent track structures

Infrared (IR) absorption spectroscopy, among some other methods, such as UV and visible spectroscopy, has been extensively used to investigate the track formation mechanism in polymer track detectors since the early 1980s (Chambaudet and Roncin, 1981). In the very early stage, IR absorption spectroscopy was used by track workers to investigate the constituents of radiation damage. Later, many authors joined in the studies on modification of polymer materials (El-Shahawy et al., 1992; Gagnadre et al., 1993; Darraud et al., 1994; Balanzat et al., 1995; Chong et al., 1997; Saad et al., 2001; Costantini et al., 2002; Malek and Chong, 2002; Lounis-Mokrani et al., 2003; Phukan et al., 2003; Barillon et al., 1999; Barillon, 2005a,b; Barillon et al., 2002; Sun et al., 2004; Severin et al., 2005; Dehay et al., 2003; Mishra et al., 2003).

1. IR absorption spectrometry for polymer track detectors

In recent years, research advances have been carried out on track formation in polymer track detectors with IR absorption spectrometry, and rapid progress has been made.

Fig. 3.22 shows main IR absorption spectra and their related chemical bonds in polycarbonate track detector.

The major peaks of the IR absorption spectra marked with CH₃, C=O, C=C, and C–O–C are corresponding to methyl groups, carbonyl bonds, double bonds in phenyl rings, and carbonate ester bonds, respectively, in the polycarbonate structure (See Section II.C.2).

The peaks shown by dotted lines are for unirradiated (pristine) film of polycarbonate. The solid lines are for the irradiated film. The height of the peak of absorbance in Fig. 3.22 should be proportional to the number of bonds of the responsible types in the film if the film is thin enough. During irradiation by heavy ions, some bonds are broken by the irradiation of ions. Therefore, the heights of the peaks are reduced.

2. Cross-section of bond breaking by heavy ions

It was noticed that after irradiation of polymer film by heavy ions, the number of chemical bonds decreases with the fluence of heavy ions irradiated onto the film. Fig. 3.23 shows an example of reduction of peak intensities of the film of CN LR-115 of 12 μm in thickness as a function of proton fluence.

The straight line in Fig. 3.23 can be simply described by an equation

$$N/N_0 = 1 - \sigma_i F \quad (3.30)$$

FIG. 3.22 IR absorption spectra of pristine and irradiated PC with 24 MeV Ne ions.

FIG. 3.23 Relative bond decrease (N/N_0) versus proton fluences. Average proton energy in the film: 3.1 MeV (LET = 14 keV/ μm). Black point: nitrate functions; white points: glycosidic bonds. From Barillon and Yamauchi (2003). Reprinted with permission from Elsevier © 2003.

where N_0 represents the initial number of bonds in unit volume (cm^{-3}) of the film, N the number of bonds (cm^{-3}) left after irradiation of the film by heavy ions, σ_i a constant for each type of bond scission, F ion fluence (cm^{-2}) irradiated to the film.

If the film is thin enough and the overlapping of latent tracks of heavy ions in the film can be ignored, then $N/N_0 = A/A_0$, where A_0 is the absorbance of the pristine film for the responsible wave number of IR spectra, A is that of irradiated film. A and A_0 can be measured by Fourier transforms infrared (FT-IR) spectrometer.

Similar figures and equations as Fig. 3.23 and Eq. (3.30) were obtained for the other types of thin polymer detectors (Dehay et al., 2003; Yamauchi et al., 2008a,b,c, 2010, 2013a,b; Mori et al., 2009, 2011; Kusumoto et al., 2016).

The meaning of σ_i is the cross-section (probability) of breaking particular bonds by one heavy ion. The unit of σ_i is cm^2 , which is similar to that in nuclear reactions.

Fig. 3.24 shows that the cross-sections of breaking glycosidic groups (σ_{CO}) and nitrate groups (σ_{NO}) in CN film as a function of the energy of oxygen ions (Barillon and Yamauchi, 2003).

Fig. 3.25 illustrates the cross-sections of ester bond scission in polyethylene terephthalate (PET) as a function

FIG. 3.24 Cross-sections of glycosidic bonds (white points) and nitrate groups (black points) in CN detector as a function of the energy of oxygen ions. From Barillon and Yamauchi (2003). Reprinted with permission from Elsevier © 2003.

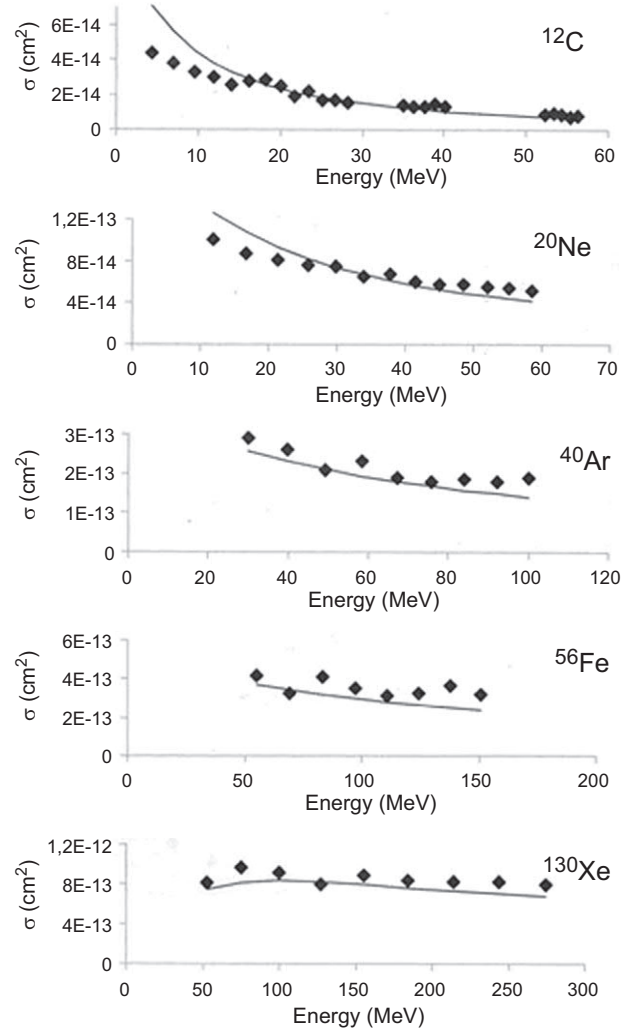

FIG. 3.25 Experimental (points) and simulated (lines) cross-sections (σ) for ester bond scission in PET according to ion energy. From top to bottom: ^{12}C , ^{20}Ne , ^{40}Ar , ^{56}Fe , ^{131}Xe . Simulation parameters: $P(r) = [1 - e^{-D(r)/D_0}]^m$, $m = 2$ and $D_0 = 1.8 \text{ MGy}$. Barillon et al. (2013). Reprinted with permission from Elsevier © 2015.

of the energy E of heavy ions: ^{12}C , ^{20}Ne , ^{40}Ar , ^{56}Fe , and ^{131}Xe .

From Figs. 3.24 and 3.25, one can see that the cross-sections of bond breaking in polymer track detectors are similar to the cross-sections of nuclear reactions induced by neutrons (Garber and Kinsey, 1976a,b) and by heavy ions (www.nndc.bnl.gov).

3. Effective track core radius

The radius r_i of a cylinder in which the responsible bonds are effectively broken in the film can be calculated by the equation:

$$r_i = \sqrt{\sigma_i/\pi} \quad (3.31)$$

FIG. 3.26 Effective track core radius for loss of carbonyl in PC. For the color version of the figure, the reader is referred to the online version of the book. From Yamauchi et al. (2010). Reprinted with permission from the author © 2018.

Fig. 3.26 shows the effective track core radius (r_i) for breaking carbonyl ($C=O$) bonds in polycarbonate (PC) by heavy ions of H, He, C, Ne, Ar, Fe, Kr, and Xe.

From Fig. 3.26, one can see that the effective track core radius for breaking bonds of carbonyl ($C=O$) by heavy ions is in the range from several tenths to several nm and the core radius is related to the stopping power of the heavy ions. In other words, the radius is related to the energies of heavy ions.

Fig. 3.27 shows a comparison of the effective track core radius from breaking bonds of carbonyl ($C=O$), phenyl rings and methyl groups (CH_3).

From Fig. 3.27, one can see that the bond ($C=O$) is easier to be broken than that of phenyl ring, and the bond in methyl group (CH_3) is the most stable among the three.

FIG. 3.27 Effective track core radius for loss of bonds $C=O$, phenyl ring and methyl group in polycarbonate (PC) track detectors. For the color version of the figure, the reader is referred to the online version of the book. From Yamauchi et al. (2010). Reprinted with permission from the author © 2018.

FIG. 3.28 Reduction of the relative absorbance A/A_0 of ether, carbonyl, and $C-O-C$ in PADC against the fluence of Ne ions. From Kusumoto (2017). Reprinted with permission from the author © 2018.

should be larger than that of $C=O$, and the diameter of the region for $C-O-C$ should be the smallest among the three.

Fig. 3.29 shows the diameters of the damaged regions for the three types of bonds in PADC.

From Fig. 3.29 one can see that the lateral distributions of breaking bonds are different for different bonds.

5. Chemical etching and OH groups in polymers

Yamauchi et al. (2005) point out that we must rewrite our overview on the nuclear track formation process in CR-39 as

4. Layered structure of latent tracks

Different chemical bond breaking needs different energy from the bombarded particles. If the energy required is in small amount, the positions of the bonds to be broken can be farther from the trajectory of the particles. On the contrary, if the bond breaking energy required is in large amount, the positions of the bonds must be close to the trajectory of the particles. Therefore, the diameters of the damaged regions for different bonds are different. Fig. 3.28 shows the reduction of the relative absorbance A/A_0 of ether, carbonyl, and $C-O-C$ in PADC against the fluence of Ne ions.

From Fig. 3.28 one can see that the ether bonds are easier to be broken than $C=O$, and further than $C-O-C$. The diameter of the region for breaking bonds for ether

FIG. 3.29 Layered structure of damaged region by C ions with an energy of 4.8 MeV/u in PADC. From Kusumoto (2017). Reprinted with permission of the author © 2018.

follows: (A) The parts between the two carbonate ester bonds should be segmented into small molecules, including CO_2 gases, along the particle trajectory; (B) after the segmentation, the CO_2 gases are diffused away and a lower density region with chemically active end points is formed simultaneously; (C) subsequent chemical modifications, including a reaction with dissolved oxygen, resulting in OH groups as new end points in the polymer network. They also conclude that inside the track core, all of the ether bonds and most of the carbonate ester bonds will break. This means that the parts of the polymer chain between two carbonate ester bonds $(-\text{O}-(\text{C}=\text{O})-\text{O}-\text{CH}_2-\text{CH}_2-\text{O}-\text{CH}_2-\text{CH}_2-\text{O}-(\text{C}=\text{O})-\text{O}-)$ should be segmented into small molecules composed by one or two carbon atoms including CO_2 . The unique sensitivity of CR-39 may be attributable to such a relatively long part segmentation.

Fig. 3.30 shows the processes of bond breaking of ether and forming OH, and bond breaking of a carbonate ester

and forming another OH group. The first formed OH group was lost due to breaking of the ester.

Fig. 3.31 shows that the number of OH groups formed in PADC is proportional to the number of ether bonds broken by the incident charged particle.

Fig. 3.32 shows the network of CR-39 (PADC) (restricted to two dimensions for our treatment of this subject matter).

The active end point OH groups are easy to react with the attacking reagent (etchant). The etching starts from the end point of OH groups, forming a hole (etched track) in the PADC detector.

6. Radial Electron Fluence around ion tracks

Kusumoto (2017) proposed a new criterion for track formation, which is named as Radial Electron Fluence around Ion Tracks (REFIT). A schematic drawing is shown in Fig. 3.33.

In Fig. 3.33A, the secondary electron trajectories are indicated as the lines in red. The purple points show the interaction points. Each secondary electron starts from each original point on the ion trajectory and reaches the terminal after its travel with a certain distance, producing the other multielectrons. As a result, the number density of secondary electrons will decrease with increasing distance from the ion trajectory. Kusumoto (2017) counted in Monte Carlo simulation the secondary electrons (fluence, nm^{-2}), which passed through the surface of the cylinder with a certain radius from the trajectory. The direction of electrons includes outward and inward through the surface. The fluence of the secondary electrons at certain distance was taken as the criterion for track formation.

This criterion is based on the study of IR absorption spectra for PADC (CR-39).

It is a new advance in the study of track formation. At this moment, it is evidenced in some aspects by using CR-39. There is a need to acquire additional evidence from

FIG. 3.30 Two steps in the damage formation process in PADC. The ether is broken in a single-hit zone (A) and a carbonate ester is lost with the OH groups in multi-hits zone (B). other types of polymer track detectors, such PC, PET, CN, and PI, and from heavy ions with higher charge Z .

The final purpose of the study of track formation mechanisms is to find theories, by which one can calculate the values of thresholds of all types of SSNTDs, and to design materials which meet the requirements for expected values of thresholds.

V. Track revelation

Track revelation refers to the techniques used to reveal charged particle tracks in solids. The most successful and

popularly used technique is track etching, which is the subject of this chapter. For other techniques of track revelation, the reader is referred to the treatise by Fleischer et al. (1975).

A. Chemical etching

1. Etching condition

Chemical etching (CE) is the basic technique used to reveal nuclear particle tracks in solids. The indispensable conditions for CE are two, namely, etchant and etching device.

a. Etchant

An etchant is a particular chemical formulation, which preferentially reacts with the damaged materials in the particle track resulting from the passage of a heavy charged particle in the SSNTD. One can find the etchants for different detector materials in the lists of etching conditions in the book by Fleischer et al. (1975) or by Wagner and Van den haute (1992). The etching conditions include three aspects: (1) compositions of the chemicals used as etchant; (2) temperature during etching; and (3) duration of the etching. The etchant is particular for each type of detector material. Selection of the wrong etchant will never reveal tracks. Usually, a higher concentration of etchant and higher temperature will etch tracks more rapidly; longer etching times will make the etched track larger in diameter.

b. Etching device

Etching devices hold etchants and ensure the etching conditions. The etchant must be held in a closed container to

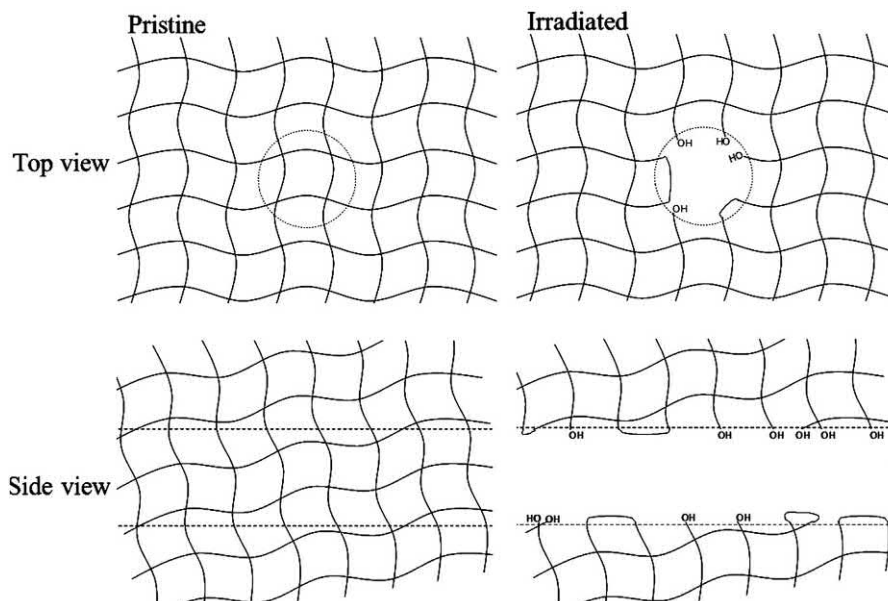

FIG. 3.32 Schematic view of the latent track formed in PADC. From Kusumoto (2017). Reprinted with permission from the author © 2018.

FIG. 3.33 Schematic description of the criterion for track formation in polymer detector—Radial Electron Fluence around Ion Tracks. For the color version of the figure, the reader is referred to the online version of the book. From Kusumoto (2017). Reprinted with permission from the author © 2018.

prevent exchange of substances from inside or outside to ensure that the concentration of etchant remains constant.

c. Etching temperature

Homogeneous and constant temperature in the whole volume of etchant are required in many studies. The etch rate increases exponentially with an increase in temperature. A small change in temperature will influence considerably the etch rate. In very precise measurements, such as in the identification of the charges of cosmic ray particles, in the identification of masses of isotopes, and in NTM production, the temperature must be controlled within $\pm 0.01^\circ\text{C}$. When using the SSNTD for the counting of tracks with the optical microscope, a precision of temperature of $\pm 1^\circ\text{C}$ is sufficient in the temperature range of $10\text{--}100^\circ\text{C}$. One or more stirrers are necessary to keep the etchant homogeneous in temperature (Guo, 1988).

2. Track etching geometry

The etching process includes two types of chemical reactions: (1) etchant with damaged material and (2) etchant with bulk material of the detector. The first proceeds with velocity V_T along the trajectory, called track etch rate. The second proceeds perpendicularly to the surface of the detector with velocity V_B called bulk etch rate. The etching process is a combined reaction of V_T and V_B .

Fig. 3.34 shows the process of CE in an amorphous solid having a track of particle perpendicularly incident to the detector.

3. Critical angle of etching

The track etch rate V_T and bulk etch rate V_B sometimes are competitive with each other. The critical angle θ_c of etching is a result of the competition of V_B with V_T , which is shown in Fig. 3.35. The first particle entered the detector with incident angle θ (the angle between the direction of incident particle and the surface of the detector).

FIG. 3.34 Track etching geometry with constant V_T and V_B in an amorphous solid. The particle perpendicularly entered the solid and stopped at depth R below the surface. The etchant preferentially reacts with the damaged materials formed along the trajectory of the particle with a constant velocity V_T for a time t . The etchant attacks the bulk material from the original surface of the detector with a constant velocity V_B . After etching for a time t , an etch cone is formed along the trajectory with pit at depth $L = V_T t$ below the original surface. During time t , the surface layer with thickness $V_B t$ of the detector is removed by the etchant. The original surface moves to the new surface that is the etched surface. The visible track length is $l = (V_T - V_B)t$. From Price and Fleischer (1971). Republished with permission of Annual Review of Nuclear Science © 1971; permission conveyed through Copyright Clearance Center.

$V_T t$ is the etched track length at time t . $V_B t$ is the removed thickness from the surface of the detector. θ is the incident angle of the particle (the angle between the particle direction and the detector surface). If $V_T t \sin \theta < V_B t$, the track will be removed away by the etchant. No etched track is left in the detector after etching for the example illustrated in part (A) of Fig. 3.35. If $V_T t \sin \theta > V_B t$, a track cone will be left after etching (parts c and d). If $V_T t \sin \theta = V_B t$, it is the critical situation for formation of an etched track (part b). In this situation, the incident angle θ is denoted as θ_c . θ_c is the critical angle of etching. Then, one has

$$\theta_c = \arcsin \frac{V_B}{V_T} \quad (3.32)$$

4. Techniques of critical angle measurements

a. Direct measurement of half cone angle

From Fig. 3.35B one can see $\theta_c = \delta$ where δ is the half angle of the etched track cone. This signifies that if one can measure the half angle δ of the etched cone, one can determine the critical angle θ_c , and V_T , provided one knows the value of V_B .

b. Direct measurement of critical angle

From Fig. 3.35B one can see that changing the beam angle θ of the incident particles, the etched tracks will start to

FIG. 3.35 Existence of critical angle of etching for observation of etched tracks.

appear at $\theta = \theta_c$. By this technique Khan and Durrani (1972) measured the critical angle θ_c of ^{252}Cf fission fragments in soda-lime glass ($35^\circ 30'$), U-2 Reference glass ($31^\circ 45'$), obsidian ($26^\circ 00'$), tektite ($25^\circ 45'$), quartz ($7^\circ 15'$), muscovite mica ($4^\circ 30'$), Makrofol polycarbonate ($3^\circ 00'$), and Lexan polycarbonate ($2^\circ 31'$).

c. Direct measurement of detection efficiency

For a point source or thin plane source of given particles, one can directly measure the detection efficiency ε of the detector for the particles, that is, the ratio of the number of recorded tracks to the number of the emitted particles, to derive the critical angle θ_c by Eq. (3.33) for an isotropic source in 2π geometry (Fleischer et al., 1975).

$$\varepsilon = 1 - \sin \theta_c \quad (3.33)$$

By this technique Guo et al. (1976b) (See also Guo et al., 1982) measured the critical angle θ_c of fission fragments of ^{235}U induced fission by thermal neutrons in muscovite mica ($3^\circ 41'$), phosphate glass ($7^\circ 6'$), silicate glass ($37^\circ 21'$), quartz ($16^\circ 2'$), polycarbonate (Chaoyang, China, $2^\circ 24'$), Makrofol K polycarbonate ($3^\circ 40'$), and polyester ($3^\circ 29'$).

5. Track etching geometry

From Fig. 3.34 one can easily obtain the diameter of a track that perpendicularly enters the surface of detector ($\theta = 90^\circ$) according to the equation

$$d = 2V_B t \sqrt{\frac{V_T - V_B}{V_T + V_B}} \quad (3.34)$$

or

$$d = 2V_B t \sqrt{\frac{V - 1}{V + 1}} \quad (3.35)$$

where $V = (V_T/V_B)$. V is called the etch rate ratio.

For an incident angle $\theta \neq 90^\circ$ and constant track etch rate V_T and bulk etch rate V_B , the major axis D of the opening of etched track is

$$D = \frac{2V_B t \sqrt{V^2 - 1}}{V \sin \theta + 1} \quad (3.36)$$

The minor axis of opening is

$$d = 2V_B t \sqrt{\frac{V \sin \theta - 1}{V \sin \theta + 1}} \quad (3.37)$$

For other parameters of etched tracks, one can find the formulas in the book written by Durrani and Bull (1987).

The equations of etched track geometry for constant V_T are only approximations to the true situation because only for a very few cases is V_T constant. Generally, V_T varies along the trajectory of a particle. Calculations based on a constant V_T often give results which are good enough for the studies of particles.

For track etching geometry with varying V_T and for track etching geometry in anisotropic solids, such as all crystalline minerals, the formulations can be found in the book by Durrani and Bull (1987).

6. Progress in track etching geometry

The study on track etching geometry has made tremendous progress. Nikezic and Kostic (1997) derived an analytical two-dimensional equation of etch pit wall in amorphous SSNTDs. Nikezic (2000) derived an analytical three-dimensional equation of track wall (for variable V_T , conical track phase) described by the equation

$$\sqrt{x^2 + y^2} = \int_Z^L \frac{d\xi}{\sqrt{v^2(\xi) - 1}} \quad (3.38)$$

where Z is the axis along the particle track; (x, y) are the coordinates of a point on the track wall; v is the etch rate ratio V_T/V_B ; L is the depth to which the chemical solution penetrates the detector material along the particle trajectory; and ξ is the parameter upon which v depends, such as REL or others.

Nikezic and Yu (2003, 2004) extended the above track wall equation to overetched tracks (or round tip tracks). The whole set of equations can be used to calculate the track wall, track opening diameter, major axis, minor axis, and other parameters for constant V_T , variable V_T , normal incidence, oblique incidence, sharp tip etched tracks, and round tip etched tracks. In summary, all parameters of tracks in amorphous solids can be calculated except the

tracks in anisotropic crystalline minerals. For more information, the reader is referred to the original papers mentioned above.

B. Electrochemical etching

Electrochemical etching was first suggested by Tommasino (1970). A plastic detector foil with tracks of particles is used to divide a cell containing a suitable etchant, such as NaOH solution. A stainless-steel electrode is placed in each half of the cell. A high-frequency oscillating voltage is connected to the two electrodes. The voltage is typically equivalent to $\sim 30\text{--}50\text{ kVcm}^{-1}$ field strength. The frequency is ranged from several KHz to several tens of KHz. A 50 Hz 220 V sinusoidal supply can also work. Under the joint reactions of etchant and electric voltage, the tracks start to be etched. The forming track tip has a strong field, which makes the foil break down near the tip as show in Fig. 3.36. The breakdown looks like a tree. The tree is a consequence of the charged particle track. Fig. 3.37 shows microphotographs of ^{252}Cf fission fragment tracks in CR-39 sheets of 485 μm in thickness.

FIG. 3.36 "Treeing" phenomenon of electrochemical etching (ECE) of charged particle tracks in plastic foil. The sharp tips of etched cones have very strong field, which makes the foil break down, forming treelike tracks. The breakdown spreads up to several hundred micrometers in width, which is easy to observe with a low magnification optical microscope or even by the naked eye. From Al-Najjar et al. (1979); printed with permission from Elsevier © 1979.

Many researchers have studied the "treeing" phenomenon (Tommasino et al., 1981; Sohrabi, 1981; Sohrabi and Mahdi, 1993; Li, 1993, 2008a, 2008b).

The advantage of electrochemical etching is that the size of the etched tracks is very large up to several hundreds of micrometers, which are easy to scan with an optical microscope or track image analyzer, or even be seen with the naked eye. The disadvantage is that the track density must be lower than $\sim 10^5\text{ cm}^{-2}$.

The applications of electrochemical etching are mainly in the detection of fission fragments, α particles and neutron-recoil tracks. The main fields of application are neutron dosimetry (Tanner et al., 2005; Dhairyan et al., 2003; Zainali and Afkar, 2005; Hankins et al., 1989) and Rn monitoring (Zainali and Afkar, 2005).

C. Track etching kinetics

1. Objectives and required parameters

The ultimate purpose of the study of track etching kinetics is to deduce the species of the particles from the tracks created by the particles.

For this purpose, two lines of calculations must be carried out.

- (1) First line of calculation—Calculation of track parameters from the parameters of the particles (Forward calculation);
- (2) Second line of calculation—Derivation of the parameters of the particles from the parameters of the etched tracks (Inverse calculation).

In the above calculation and derivation, the following parameters are required:

- (a) Particle parameters including: atomic number Z_1 , mass M_1 , and energy E_1 (or velocity v_1);
- (b) Detector parameters including: average atomic number Z_2 , average atomic mass M_2 , density ρ , and mean ionization potential I .
- (c) Radiation damage density parameter or threshold parameter, such as primary ionization rate J , or restricted energy loss rate REL , or $Z_{eff}\beta$, or others;
- (d) Track etching parameter under special etching condition, such as track etch rate V_T and bulk etch rate V_B , or track etch rate ratio $V = V_T/V_B$, or reduced etch rate $S = V_T/V_B - 1$, as a function of the radiation damage density, such as $V = f(REL)$, as well as the etching time t or the thickness h of removal on a single surface of the detector.
- (e) Track parameters, such as track diameter d on the etched surface of the detector, major axis D and minor axis d of the mouth of tracks, and etched track length L , which are represented by equations as functions of track etching parameters.

FIG. 3.37 Microphotographs of electrochemically etched tracks of ^{252}Cf fission fragments recorded in CR-39 plates. The thickness of the CR-39 plate is 485 μm . The track densities are (1) 1.5×10^3 , (2) 3.0×10^3 , (3) 1.2×10^4 , (4) 2.4×10^4 , (5) 3.6×10^4 and (6) $1.2 \times 10^5 \text{ cm}^{-2}$, respectively. The etching condition was 30 wt% KOH, 60°C, 90 min. The electrical field condition was 15 kVcm^{-1} and 40 KHz. The track densities after ECE are the same as CE. The track size changes diminish as the density increases. From Al-Najjar et al. (1979); printed with permission from Elsevier © 1979.

2. Forward calculation

For the first line of calculation (forward calculation), Z_1 , M_1 , E_1 , in (a), Z_2 , M_2 , ρ , and I in (b) are known. One should select one of the threshold parameters in (c), such as REL , and know the relationship between the track etch parameter and threshold parameter in (d), such as $V = f(REL)$, and use the equations of d , D and d , and L versus track etching parameter in (e), such as $d = \varphi_1(V)$, $D = \varphi_2(V)$, and $L = \varphi_3(V)$. After calculation through the first line, a group of curves will be obtained of d , or D (d), or L , versus Z_1 , M_1 or E_1 in the condition t or h . These curves can be used to identify the particles that created the tracks in the detector. These curves represent the relations between the tracks and particles.

The calculation through the first line is relatively easy and much progress has been made: Much work has been done along the first line on threshold parameters in (c) (Fleischer et al., 1975; Fleischer, 1981; Benton, 1967; Benton and Nix, 1969; Katz and Kobetich, 1968; Kobetich and Katz, 1968; Ahlen, 1980. See Section IV above). A large number of papers have been published on track etching parameters in (d) (Hermsdorf, 2009; Hermsdorf and Reichelt, 2010; Rana, 2008; Fromm et al., 1988; also, the articles cited by these papers). Equations for calculating track parameters in (e) have been derived in amorphous solids for constant and variable V , for conic tracks, over-etched tracks, and round-tip tracks (Nikezic and Kostic, 1997; Nikezic, 2000; Nikezic and Yu, 2003, 2004, 2006,

2008; Nikezic et al., 2008a; Ditlov, 1995; Somogyi, 1980; Somogyi and Szalay, 1973; Henke and Benton, 1971).

Track evolution in anisotropic crystals is very complicated and less work has been done on this subject. It remains to be studied in detail in the future (Fleischer et al., 1975; Durrani and Bull, 1987; Somogyi, 1980; Henke and Benton, 1971).

3. Inverse calculation

Inverse calculation by analytic formulations through the second line from the parameters of etched tracks to derive the parameters of the particles is more complicated than that of forward calculation. It should be possible, but no paper has been seen in scientific journals.

In practice, experimental calibration of detectors by using accelerator beam particles is the current way to assign the correct charge Z , mass M , and energy E of particles. These kinds of techniques have been used in the discoveries of cluster radioactivity of heavy nuclei (See Section II.A of Part 2 of this chapter) and in many other physical and cosmic ray studies (Fleischer et al., 1975; Durrani and Bull, 1987).

Experimental calibration is a more basic and straight way to retrace the particle parameters than the theoretical calculation through the track etching kinetics.

VI. Particle identification

A. Maximum track length method

The first method adopted for the identification of charges (atomic number) Z is that after an appropriate etching time, the entire portion L_{\max} of the trajectory is etched out. L_{\max} is called the maximum etchable track length, in which the density of radiation damage is higher than the critical (threshold) value. Therefore, the maximum etchable track length L_{\max} is the whole etchable length of the track. By using an appropriate model of radiation damage density (dE/dX , J , REL , or E_v), a curve (relationship) between L_{\max} and Z can be calculated (Fleischer et al., 1965a). By using the curve of L_{\max} versus Z , one can determine the unknown Z from the measured maximum track length L_{\max} . The “track-in-track” (TINT) and “track-in-cleavage” (TINCLE) techniques proposed by Lal et al. (1968) and Lal (1969) are two simple techniques to measure L_{\max} . If a track (the first track) within a detector intersects another track (the second track), and the second track intersects the outer surface of the detector, the etchant will etch the second track and then etch the first track. The first track after etching is called “track-in-track” or TINT. A second track may be formed in the past (e.g., fossil track) or by irradiation with heavy ion at accelerator. If a track within a detector intersects a crack or cleavage in the detector, the etchant will pass through the

crack or cleavage and etch the track. The track after etching is called “track-in-cleavage” or TINCLE. The maximum etchable track length L_{\max} can be achieved after a certain etching time. The L_{\max} and Z values in a specific track detector should be one to one, if the Z value is low (by restriction of the uncertainty of measurement). The techniques of TINT and TINCLE are often used in the identification of cosmic ray particles, identification of superheavy elements, FTD (determinations of detection efficiencies of the minerals and external detectors for fission events) and geothermal chronology (geothermal history).

B. Track etch rate versus radiation damage density method

This track etch rate method is based on the fact that the etching rate along a track is a function of the radiation damage density. Track etch rate can be represented by V_t along the track (Price et al., 1967), or by etch cone length $L = V_t t$, where t is etching time (Price et al., 1967; Fleischer et al., 1975), or by the etch rate ratio $V = V_t/V_B$, where V_B is the bulk etch rate of the detector material (Fleischer et al., 1969d, 1975), or by the reduced track-etch rate $V-1 = V_t/V_B - 1$ (Price, 1982). The radiation damage density is represented by the primary ionization rate J (Fleischer et al., 1967a, 1967b, 1967c, 1967d), or restricted energy loss rate (REL) (Benton, 1967), or energy density E_v (Katz and Kobetich, 1968), or by $Z_{eff}\beta$ (Ahlen, 1980).

Fig. 3.38 shows the curves of $V_t/V_B - 1$ versus $Z_{eff}\beta$ for CR-39 (DOP) and Tuffak polycarbonate. From these curves one can see that V_t for both CR-39 and Tuffak increases steeply in the range $10 \leq Z_{eff}\beta \leq 99$ and $55 \leq Z_{eff}\beta \leq 105$, respectively (Salamon et al., 1985). CR-39 is more sensitive than Tuffak polycarbonate.

C. Track etch rate versus residual range method

Fig. 3.39 shows the relationship between track reduced etch rates and residual ranges of some nuclei with different charge Z and A (isotopes) in phosphate glass (PSK-50, Schott Glass Technologies, Inc.).

The lines in Fig. 3.39 are fits to data for heavy ions of ^{28}Si , ^{24}Mg , and ^{20}Ne from the accelerator Superhilac in Berkeley, USA. The curves show that the phosphate glass has excellent charge resolution in the region of Ne and Mg. The glass was used to record and identify Mg and Ne isotopes as well as spontaneous fission from a source of ^{234}U . The points in Fig. 3.39 are the measured results (Wang et al., 1987; Price, 1987). A similar identification technique of charge Z of heavy ions emitted from cluster radioactivity has been adopted by using polycarbonate (Price et al., 1985), polyethylene terephthalate (Tretyakova et al., 1985; Barwick et al., 1985), barium phosphate

FIG. 3.38 The curves of $V_T/V_B - 1$ versus Z_{eff}/β for CR-39 (DOP) and Tuffak polycarbonate. From these curves one can see that V_T for both CR-39 and Tuffak increases steeply in the range $10 \leq Z_{\text{eff}}/\beta \leq 92$ and $55 \leq Z_{\text{eff}}/\beta \leq 105$, respectively. Here $s = V_T/V_B$. From *Salamon et al. (1985)*; printed with permission from Elsevier © 1985.

glasses (*Bonetti et al., 1993a, 1993b*), BP-1 glass (*Price et al., 1992*), PSK-50 phosphate glass (*Wang et al., 1987; Price et al., 1991; Moody et al., 1989, 1992; Bonetti et al., 1991*), LG-750 phosphate glass (*Wang et al., 1989; Moody et al., 1987*), and phosphate glass (*Tretyakova et al., 2001*).

D. Track diameter method for identification of charge Z at high and relativistic energy

Experiments show that heavy ions (projectiles) with charge Z at high and relativistic energy will interact with nuclei in

FIG. 3.39 The relations between track reduced etch rates and residual ranges of some nuclei with different charge Z and A (isotopes) in phosphate glass (PSK-50, Schott Glass Technologies, Inc.). From *Wang et al. (1987)*, <https://doi.org/10.1103/PhysRevC.36.2717>; printed with permission from *Phys. Rev. C* 36, 2717–2720 (1987). Copyright 1987 The American Physical Society.

the targets and detectors and form a series of projectile fragments with charge $Z-1, Z-2, \dots$. These fragments have nearly the same velocity as the original projectiles. These interactions and their fragments can be used to calibrate the track detector, such as CR-39, to obtain its charge resolution σ_Z (standard deviation of charge Z measured) in charge identification.

The procedure of calibration of the track detector is as follows:

- (1) A thick stack of nuclear track detectors (detector stack or stack detector), such as CR-39, is irradiated with projectiles perpendicularly to the surface of the detectors to a dose of $\sim 10^4 \text{ cm}^{-2}$. The CR-39 stack may consist of several or even several 10s of sheets (depending on the energy of the heavy ions to be detected).
- (2) After etching the detectors at appropriate etching conditions, tracks of projectiles and fragments are examined under an optical microscope.
- (3) The diameters of the tracks are scanned with an optical microscope or a track image analyzer on one surface of the detector. The track diameter distribution is drawn as a histogram. If the scanned surface belongs to the sheet in the middle of the stack, the histogram of the track

diameter distribution will show a series of peaks. The highest peak on the right hand (on larger diameter side) belongs to the projectiles (when matching the tracks with the tracks on the front surface of the first sheet, one will understand this conclusion). The charge corresponding to the highest peak is Z (the charge of the projectiles). The charge of the second peak (on the left side of the highest peak) is $Z-1$, then the third $Z-2$, and so on.

- (4) The average diameter \bar{D} and standard deviation σ_D are calculated from all the diameters of each peak.
- (5) The slope δ_D/δ_z is calculated in the figure of \bar{D} versus Z at each charge.
- (6) The charge resolution $\sigma_Z(1)$ is calculated from equation $\sigma_Z(1) = \sigma_D/(\delta_D/\delta_z)$, where $\sigma_Z(1)$ is the charge resolution on a single surface for a given charge Z .
- (7) One can follow the same projectile to the next and the third and more surfaces to measure the track diameters of the same projectile. Then, one can obtain a mean of the diameters in successive surfaces for the same projectile. When all the means for all the projectiles have been obtained, one can draw a new histogram of the distribution of the mean for all the projectiles averaged over all the surfaces. For example, in n surfaces, the peaks in the new histogram are narrower than that obtained on a single surface. One can calculate a new average diameter and its standard deviation $\sigma_D(n)$ for each peak. This $\sigma_D(n)$ is for n surfaces for each charge Z (each peak). A new δ_D/δ_z at each charge (or peak) can be obtained. The final charge resolution $\sigma_Z(n) = \sigma_D(n)/(\delta_D/\delta_z)$ can be calculated, which is for all projectiles in each peak (each charge Z) averaged over all the surfaces. It has been shown that $\sigma_Z(n) = \sigma_Z(1)/\sqrt{n}$ is correct. The correctness shows that the energy loss in each sheet of the detector and in all the detectors for measuring the n track diameters is negligible compared with the total energy of the projectile. This means that the velocity ($\beta = v/c$) of the projectile approximates no change when the projectile is traveling through the stack which is measured.
- (8) One should point out that the correctness of the $1/\sqrt{n}$ relationship is conditional, which is the following: When a heavy ion (projectile) is passing through the detectors (or stopping materials), it might pick up one or more electrons from the detector atoms to fill in its own inner shell orbits. The effective charge of the projectile changes to $Z-1$ or $Z-2$. This phenomenon disrupts the original charge state and makes the charge resolution become poorer than the $1/\sqrt{n}$ relation. This problem can be overcome by using stripping foils interleaved in the detector stack. (Ahlen et al., 1984; Salamon et al., 1984; Guo et al., 1984a).

Fig. 3.40 shows a histogram of charge distribution of nuclear interaction fragments from a 1.85 GeV/u⁴⁰Ar beam

FIG. 3.40 A histogram of charge distribution of nuclear interaction fragments from a 1.85 GeV/u⁴⁰Ar beam in CR-39 (DOP) stack by track diameter measurement, after averaging over 16 cones on surfaces of 8 sheets of the detector, the charge resolution $\sigma_Z(16) = 0.06e$. From Price et al. (1983); Salamon et al. (1984); Reprinted with permission © 1983 the American Physical Society, <https://doi.org/10.1103/PhysRevLett.50.566>. CR-39 (DOP) is a special type of CR-39 (See Section II.C.1 above).

in CR-39 (DOP) stack by the track diameter measurement, after averaging over 16 cones on surfaces of 8 sheets of the detector, the charge resolution $\sigma_Z(16) = 0.06e$ (Price et al., 1983; Salamon et al., 1984).

It should be pointed out that the charge resolution of CR-39 is much higher than that of a Si semiconductor detector with equivalent thickness. Tarle et al. (1981) was the first to demonstrate that the etch track detector CR-39 has a charge resolution superior to semiconductor detectors of equivalent thickness. Ahlen (1980) theoretically predicted the superiority of the charge resolution of plastic track detectors to those of scintillator, nuclear emulsion, ionization chamber and semiconductor detectors for high- and relativistic-energy heavy ions. The reason for the higher charge resolution of plastic track detectors is as follows:

According to the restricted-energy-loss or the REL model (Benton, 1970), it is assumed that knock-on electrons with energy greater than ω_0 (350–1000 eV) are ineffective in causing the permanent radiation damage. The high-energy δ -rays deposit most of their energy quite far from the particle track. They do not contribute significantly to the primary track. Only the low-energy δ -rays deposit energy in the core region of the track, which is effective for etching. Ionization chambers and solid-state Si detectors correspond to total energy loss, including δ -rays of all energies. Scintillators and nuclear emulsions correspond to the δ -rays with energy higher than 1500 eV. Due to Poisson

fluctuations in the collision frequency between the charged projectile and electrons within the detector medium, a large number of low-energy δ -rays are produced. The number of δ -rays then falls off rapidly as the δ -ray energy increases. The fluctuation of the number of high-energy δ -rays is the largest, which results in poor charge resolution of the scintillation detectors and nuclear emulsions. The fluctuation of the effective δ -rays is smaller in ionization chambers and Si detectors, which results in better charge resolution. The plastic track detectors correspond to δ -rays of low energy, the fluctuation is the least, thus the charge resolution is the best for high and relativistic energy heavy ions.

From a calibration with La, Kr, Fe, and Ar, [Salamon et al. \(1985\)](#) obtained the following empirical relation between charge resolution σ_z and Z/β of heavy ions for a CR-39 (DOP) detector.

$$\sigma_z = \frac{1}{\sqrt{n}} \left[0.914 + 1.94 \times 10^{-3} \left(\frac{Z}{\beta} \right) + 4.35 \times 10^{-5} \left(\frac{Z}{\beta} \right)^2 \right] e \quad (3.39)$$

Similar calibrations have been made by several groups with similar results ([Heinrich et al., 1995](#); [Cecchini and Patrizii, 2008](#); [Patrizii, 2001](#)). From a calibration with Pb projectiles, [Huntrup et al. \(1997\)](#) achieved charge resolutions for a single etch cone $\sigma_z = 0.16e$ at $Z = 6$, $\sigma_z = 0.4e$ at $Z = 50$, and $\sigma_z = 1.0e$ at $Z = 82$ for a CR-39 detector.

[He et al. \(1994\)](#) found that BP-1 glass ([Wang et al., 1989](#)) has charge resolution $\sigma_z(1) = 0.19e$ with only a single ($n = 1$) measurement of an etch-pit of ions with $Z = 79$ and $\beta = 0.997$. This charge resolution is equivalent to that of ~ 16 successive cone measurements in a CR-39 detector stack according to the law $\sigma_z(n) = \sigma_z(1)n^{-1/2}$. Better charge resolution of BP-1 glass can be achieved by measuring many successive track cones along the same particle trajectory. The unprecedented charge resolution of BP-1 glass opens up several fields of applications in nuclear physics, high-energy heavy-ion physics and cosmic-ray astrophysics.

Track diameter identification of charges Z at relativistic energy has been used in many projects including the following:

- (1) Searching for fractionally charged particles such as charges of $Z + \frac{1}{3}$, $Z + \frac{2}{3}$ in projectile fragmentations. ([Price et al., 1983](#), [Price, 2005](#); [He and Price, 1991](#); [Cecchini et al., 1993](#); [Heinrich et al., 1995](#)).
- (2) Measurements of charge pickup cross-section, in which the projectile pickups one or two charges ([Ren et al., 1989](#); [Jin et al., 1990](#); [Price, 2008](#); [Westphal et al., 1991](#)).
- (3) Relativistic projectile fission studies ([Guo et al., 1984b, 1986a](#)).

- (4) Measurements of compositions of ultraheavy cosmic rays ([Westphal et al., 1998](#)).
- (5) Cross-sections for orbital electron capture and stripping of ions in stopping materials ([Westphal and He, 1993](#)).
- (6) Charge changing fragmentation cross-section ([Cecchini and Patrizii, 2008](#), [Cecchini et al., 2002](#); [He and Price, 1994](#)).

Compared with other types of radiation detectors, such as Au–Si surface barrier detectors (ΔE – E detectors), nuclear emulsions and others, the solid-state track detector has also the following advantages ([Price and Fleischer, 1970](#)) for the identification of charge Z of particles.

- (1) Identification of heavy particles recorded during ancient times.
- (2) Identification of very rare heavy particles such as those that occur at an extremely low rate as 1 per cm^2 per year (See Chapter 1, Volume 1).
- (3) Identification of heavy particles in a high background of less heavily ionizing particles.
- (4) Identification of particles of very high ionization rate for which resolution by solid-state track detectors exceeds that of other detectors.
- (5) Cross-sections for orbital electron capture and stripping of ions in stopping materials ([Westphal and He, 1993](#)).
- (6) Charge changing fragmentation cross-sections ([Cecchini and Patrizii, 2008, 2002](#); [He and Price, 1994](#)).

E. Track length method for identification of charge Z at high and relativistic energy

This method is similar to the track diameter (D) method, whereby the length (L) of an etched cone at high and relativistic energy can also be used to identify charges Z ([Giacomelli et al., 1998](#)). The study shows that with a CR-39 sheet for one cone height (length) measurement, the charge resolution can reach $\sigma_z \approx 0.19$ – $0.29e$ for $Z = 74$ – 82 . In other words, one can separate nuclear fragments of high Z ($Z \geq 74$) by one cone length (L) measurement in a CR-39 detector. The track cone length (L) method has a better charge resolution in the charge region $74 \leq Z \leq 82$ than the track diameter (D) method ([Giacomelli et al., 1998](#)).

The track length method has been used to measure the charge-changing cross sections of 158 AGeV ^{207}Pb with Bi, Al, Cu and Pb targets. The data can be described by strong electromagnetic dissociation ([Sher et al., 2007](#); [Manzoor et al., 2000](#)).

VII. Track fading and annealing

This section describes the phenomenon of track fading and how to use this phenomenon to increase precision in the analyses of radioactivities.

A. Track fading and annealing

Latent tracks or radiation-damaged materials at higher temperature will gradually disappear. This process is called track fading. Track fading is an intrinsic behavior of latent tracks or radiation-damaged materials. Track annealing describes the same behavior of latent tracks but stresses the existence of an external factor, such as laboratory heating or heated by magma intrusion in the earth's crust.

Track fading appears as (1) shortening of the etched track length; (2) reduction of the etched track opening; (3) reduction of the number of tracks observable on internal surface compared with the fresh tracks of the same kind of particles.

B. Mechanisms of track fading

Track fading occurs presumably by the diffusion of atoms in the damaged region of inorganic solids or movements of molecular fragments within a polymer. Interstitial atoms can then recombine with lattice vacancies, and broken molecular chains may rejoin and the existed active species recombine. The activation energies of $\sim 1\text{--}2\text{ eV}$ for track annealing support these conclusions.

From thermal dynamics, one can write

$$D = D_0 e^{-E_a/kT} \quad (3.40)$$

where D is the diffusion coefficient; E_a is the activation energy for annealing; k is the Boltzmann constant; and T is the absolute temperature.

The time to diffuse to some extent is inversely proportional to the diffusion coefficient D :

$$t \sim \frac{1}{D} \sim e^{E_a/kT} \quad (3.41)$$

From Eq. (3.41) one can see that the larger the activation energy E_a , the longer time it takes to remove the latent tracks; and the higher the temperature in the annealing device, the shorter will be the time it takes to erase the latent tracks.

C. Arrhenius diagram

Eq. (3.41) can be written as

$$\log t = c + \frac{E_a}{k} \frac{1}{T} \quad (3.42)$$

The relation between $\log t$ and $1/T$ can be drawn as a straight line as in Fig. 3.41.

From the slope of the straight line, one can derive the activation energy E_a for track annealing.

It should be noted that the activation energy E_a is related to the degree of annealing, that is, how large a percentage of the tracks are annealed away, or how many

FIG. 3.41 Arrhenius diagram between $\log(t)$ and $1/T$. The slope is E_a/k , from which one can determine the activation energy E_a for track annealing. From Wagner and Van den haute (1992). Reprinted with kind permission from Springer Science + Business Media © 1992.

of the tracks (percent) are lost in the annealing process on the internal surface of a mineral. Therefore, annealing time t , annealing temperature T , and annealing degree are three parameters; from any two, one can determine the third.

D. Application of track fading and annealing

The track fading phenomenon has two sides or characteristics. In one respect, it can cause problems; and on the other hand, it can provide new information or improve analytic accuracy.

1. Problems resulting from track fading

The problems that may arise from track fading are the following:

a. Track loss increasing with etching temperature and time

Particle tracks would be lost or partly lost, if one etches the detector at an excessively high temperature and an etching time that lasts too long. Usually, for plastic track detectors, the etching temperature should not exceed 70°C in order that the annealing of tracks remains negligible.

b. Track loss increasing with temperature in the experimental environments

The temperature in the experimental environments should not be higher than that allowed by the detector. For

example, the temperature for irradiation of plastic track detectors should not be higher than 70°C. If the temperature of the environment is higher than 70°C, one should use muscovite mica track detectors instead of plastic track detectors. Muscovite mica can retain 100% of its tracks up to 450°C for 1 hour (Fleischer et al., 1975).

2. Improving analysis with the aid of track annealing

Track annealing can be used to provide an experimental advantage, as described in the following:

- a. Muscovite mica is a fission detector, but it contains spontaneous fission tracks of ^{238}U . By annealing muscovite sheets over 600°C, for more than 1 hour, one can remove the spontaneous tracks from mica. Thus, one can produce very clean detectors without track background.
- b. In FTD, the detection efficiency of an external detector is usually different from that of the minerals to be dated. In this situation, one can use the same type of minerals as detectors for uranium determination. The detection efficiency will be equal to the minerals for dating. In this case, one can anneal out all the latent spontaneous fission tracks in one aliquot of the minerals. This aliquot will be used to determine the uranium concentration of the minerals in a nuclear reactor by neutron induced fission measurements. Another aliquot is left for the ^{238}U spontaneous fission number measurement. Both aliquots are mounted, ground, polished and etched in the same condition. The detection efficiencies of the minerals for dating and for uranium determination will be equal to each other, which can be cancelled in the age equation. In this way, the dating precision can be improved.

3. Apparent fission track age and its corrections

FTD is based on the number of ^{238}U spontaneous fission tracks accumulated in a mineral from the formation of the mineral. If the temperature of the geological body containing the mineral was too high to retain fission tracks, the tracks formed in this period would be completely lost. After the geological body cooling down to some temperature (upper limit temperature of partial annealing zone (PAZ) of the mineral), ^{238}U spontaneous fission tracks would be retained, but they would be annealed partially by any higher temperature that existed later on. Only when the temperature cooled down to the lower limit temperature of the PAZ, can the spontaneous fission track be retained completely. The tracks formed in the PAZ would be shorter

than the original tracks. This shortening of the tracks would reduce the number of tracks etched on the internal surface of the mineral, consequently reducing the measured age by FTD. The reduced fission track age is named apparent fission track age.

Apparent fission track age can be corrected to true age. There are three methods to make this correction: (1) track length correction method; (2) track diameter correction method; and (3) Plateau-age correction method. For a detailed treatment on these methods, the reader is referred to the books written by Fleischer et al. (1975), Durrani and Bull (1987) and Wagner and Van den haute (1992).

4. Geothermal chronology

^{238}U spontaneous fission-fragment tracks are prints formed in minerals since the fission events occurred. Track annealing by follow-up thermal events make secondary prints on fission tracks. Every track contains plentiful records of the thermal history which the mineral experienced since it was registered. The tracks were registered at different times (year or age). Comparisons, subtractions and differentiations of the records contained in different tracks can retrieve the whole geothermal history from the time when the first spontaneous fission track was created in the minerals. Chambaudet et al. (1993) suggested a model coined as the “Smoke Convection Model” to retrieve the thermal history experienced by a mineral, such as apatite. The authors claimed that it can retrieve the thermal history uniquely. Geothermal chronology has become a hot spot in geology and nuclear tracks in solids. For more information on this field of measurements, the reader is referred to review articles written by Reiners and Brandon (2006), Reiners and Ehlers (2005) and Bernet and Garver (2005).

VIII. Instrumentation

A. Size of latent tracks and etched tracks

The lower limit of the diameter of etchable latent tracks is about 30–40 Å (3–4 nm); and the etched track diameter can range from this size to more than 100 μm (Fleischer, 1981). The first instrument to study latent tracks was the transmission electron microscope (TEM) (Silk and Barnes, 1959; Price and Walker, 1962a). The first instrument to study etched tracks was the optical microscope (Young, 1958; Price and Walker, 1962c).

Before the 1980s, there was no way to see the structures of latent and etched tracks in the range below the nanometer (nm). The dream of imaging subnanometer-size tracks was realized since 1982 by the discovery of the scanning tunneling microscope (STM) (Binnig et al.,

1982) and since 1986 after the discovery of the atomic force microscope (AFM) (Binning et al., 1986).

B. Optical microscope

The optical microscope can be used to analyze etched tracks in the size range of $\sim 0.5 \mu\text{m}$ to several hundreds of μm . Optical microscopes are composed of (1) eyepiece (one or two), (2) objective (one or more), (3) stage, (4) condenser (transmitted light and reflected light), and (5) stand.

The accessories should include: (1) standard ruler, used to calibrate the scales, (2) reticule, which can be put in the eyepiece for measurement of track or field size, (3) reticulate, which is used as a standard area for the measurement of track density (tracks/ cm^2), (4) displacement transducer (one, two or three), at least one for the measurement of depth (z axis). Another two are for x and y axis measurements.

C. Track image analyzer

The composition of a track image analyzer includes (1) optical microscope, with x, y and z controllers; (2) CCD camera; (3) image plate; and (4) computer.

The parameters which can be reported by a track image analyzer are (1) track number; (2) track width, major axis and minor axis; (3) track length; (4) track coordinates (x, y, z); (5) track orientation (Zenith angle θ , azimuth angle ϕ); (6) area of measurement; (7) areal density of tracks; and (8) gray level of tracks.

D. Electron microscope

The electron microscope is operated in a vacuum. It can be classified into two types. One type is the TEM, which requires a very thin solid as a track detector, such as a mica flake. Its resolution usually is about 1 nm – $10 \mu\text{m}$. Very high voltage and antivibration TEMs can even resolve individual atoms. Another type is the scanning electron microscope (SEM), which can resolve about 2 nm – $50 \mu\text{m}$. When using a SEM to measure tracks, it is best to have a sputter coater or a vacuum evaporation chamber to prepare to conductive layer on the surface of the etched detector so that the detector surface changes to be conductive to electrons.

E. Scanning tunneling microscope (STM) and atomic force microscope

The STM is used to scan electronic conductive substances; and the atomic force microscope (AFM) can measure

FIG. 3.42 Photograph of an α -recoil track taken by an AFM. This track can be seen with three segments. Each segment was produced by one α -emission. Three sections are consecutively produced by three α -emissions. The ^{238}U nucleus and its progeny can have 8 α -emissions. At most, it may leave 8 segments in the α -recoil track. ^{232}Th nucleus and its progeny can emit 6 α -particles. Their progeny nuclei are ^{228}Ra , ^{224}Ra , ^{220}Rn , ^{216}Po , ^{212}Pb , ^{208}Pb , respectively. At most, it may leave 6 segments in the α -recoil track. From Price (1993); printed with permission from Elsevier © 1993.

insulating solids, which is characteristic of SSNTDs. The above microscopes are capable of resolving individual atoms. Fig. 3.42 shows a photograph of an etched α -recoil etchpit taken by an AFM. In this photograph one can see three segments of track. Each segment represents one emission of α particle. The ^{238}U nucleus and its progeny may have 8 α particle emissions to decay to ^{208}Pb and at the most can create 8 segments in an α -recoil track (Price, 1993). Each segment has several steps. Each step in the photograph is 2 nm in height.

Fig. 3.43 shows a photograph taken by an AFM of a 200 keV Ag etchpit showing 1 nm steps joining pairwise. One nm is the distance between the two neighboring layers of potassium (K) atoms in the structure of muscovite mica. The layers of K atoms are known as easily cleavage planes. These layers separate the tightly bound Si-O-Al structure, i.e., the TOT structure. Here T means tetrahedron the structure within which one Si atom is in the center and three oxygen atoms at the four pinnacles of the tetrahedron. O means octahedron which is composed of Si-O or Al-O . The TOT structure is very rigid. This structure forms the step during etching. The pairing of two steps reflects the etching behavior of mica as explained by Price (1993).

From Figs. 3.42 and 3.43, one can see that the AFM is a unique tool to study the etched track structure and track-etch kinetics.

FIG. 3.43 Photograph of an etchpit of a 200 keV Ag track in muscovite mica. The black lines are etched steps bit by the HF etchant. The central part of the etchpit is the tip of the track. In certain directions two steps join together. The height of one single step is 1 nm. The height of the joining step is 2 nm. The pairing of two steps reflects the etching property of muscovite mica by HF etchant. From Price (1993); printed with permission from Elsevier © 1993.

F. Spark counter

The spark counter was first devised by Cross and Tommasino (1968), which is a very simple device; and it is a very fast counter of tracks recorded in thin foils of track detectors. The advantages of this device are: (1) It is quite accurate in counting tracks; (2) The track spots sparked in the thin foil can be seen by the naked eye. The spot distribution reflects the particle distribution entered into the detector foil. (3) It is a fast counting device. Usually, it takes several to 10 s to count all the tracks in a piece of track detector. This device is widely used in dosimetry of Rn and neutrons and in autoradiography (Eappen and Mayya, 2004).

For more information, the reader is referred to the original article by Cross and Tommasino (1968), and a book by Durrani and Bull (1987).

Part 2: Applications

I. Introduction

Applications of nuclear track detectors are widespread in science and technology, among which the most important fields are as follows:

- (1) Physical sciences including low and high energy physics, astrophysics, cosmic-ray physics, plasma physics, nuclear reactor physics, and elemental analysis.
- (2) Earth and planetary sciences including FTD, geothermal chronology, meteorite studies, lunar and solar particles, uranium and petroleum exploration and earthquake prediction.

- (3) Life and environmental sciences, which include radiation protection dosimetry, radon and thoron monitoring, neutron dosimetry, and radioactive contamination.
- (4) Nanotechnology and material sciences.

This chapter focuses on the most common and newly emerged fields of application.

II. Physical sciences and nuclear technology

Nuclear science is the first field of applications of etch track detectors (Price and Walker, 1962e). A large number of examples of research in the physical sciences with etch track detectors were reviewed in the journal articles and monographs (Fleischer et al., 1965a, 1975; Durrani and Bull, 1987). Some new research and results will be introduced below.

A. Cluster radioactivities

Since the 1980s, the application of SSNTDs to heavy ion detection has gained great success. One of the extremely exciting achievements is a series of discoveries in heavy ion emission from nuclei called cluster radioactivity, or heavy ion decay of nuclei. The first discovery of this type of nuclear decay ($^{223}\text{Ra} \rightarrow ^{14}\text{C} + ^{209}\text{Pb}$) was made with a silicon $\Delta E-E$ detector (Rose and Jones, 1984); however, for further discoveries in this field, the silicon detector cannot work well because the branching ratio of heavy ion decay to α decay is too low ($<10^{-10}$). The SSNTD can be used to find and identify the tracks of the rare heavy ions in a very intensive α track background. The branching ratio of ^{14}C decay from ^{223}Ra is $B = 3.98 \times 10^{-10}$, which already reaches the bare limit of detection of the silicon detector. For other nuclei with branching ratios below this limit, the nuclear track detector is the only capable detector for the discovery of this type of decay.

Up to now, more than 20 parent nuclei with $Z = 87-96$ and $Z = 56$ were discovered having cluster radioactivity. They are $Z = 87$ (^{221}Fr), $Z = 88$ ($^{221}, ^{222}, ^{223}, ^{224}, ^{226}\text{Ra}$), $Z = 89$ (^{225}Ac), $Z = 90$ ($^{228}, ^{230}, ^{232}\text{Th}$), $Z = 91$ (^{231}Pa), $Z = 92$ ($^{232}, ^{233}, ^{234}, ^{235}\text{U}$), $Z = 93$ (^{237}Np), $Z = 94$ ($^{236}, ^{238}\text{Pu}$), $Z = 95$ (^{241}Am), $Z = 96$ (^{242}Cm), and $Z = 56$ (^{114}Ba).

Up to now, 11 species of emitted heavy ions with $Z = 6, 8, 9, 10, 12$ and 14 were discovered in this type of nuclear decay. The emitted heavy ions are: $Z = 6$ ($^{12}, ^{14}\text{C}$), $Z = 8$ (^{20}O), $Z = 9$ (^{23}F), $Z = 10$ ($^{24}, ^{25}, ^{26}\text{Ne}$), $Z = 12$ ($^{28}, ^{30}\text{Mg}$) and $Z = 14$ ($^{32}, ^{34}\text{Si}$).

In total, 11 species of daughter nuclei with $Z = 80, 81, 82, 83$ and 50 were formed in the decay. They are: $Z = 80$ ($^{205}, ^{206}\text{Hg}$), $Z = 81$ (^{207}Tl), $Z = 82$ ($^{207}, ^{208}, ^{209}, ^{210}, ^{211}, ^{212}\text{Pb}$), $Z = 83$ (^{211}Bi) and $Z = 50$ (^{102}Sn). The daughters

are the nuclei with a magic number in Z (82, 50) or close to a magic number in Z (80, 81 and 83 are close to the magic number 82) (Price, 1993, 1994, 2005; Guglielmetti et al., 1995; Tretyakova et al., 1992). For a more detailed treatment of cluster radioactivity and magic numbers, the reader may refer to Chapter 1, Volume 1 of this book.

The half-life $T_{1/2}$ and branching ratio B measured with nuclear track detectors for heavy ion emission modes are listed in Table 3.6.

B. Heavy ion interactions

1. Relativistic projectile fragmentation

Since the 1980s, another exciting application of SSNTDs in nuclear physics is the identification and study of heavy ions resulting from high- and relativistic-energy fragmentation of nuclei carried out in Berkeley (Bevalac), Brookhaven and CERN.

These studies have opened a new branch of application in high-energy physics, astrophysics and cosmic rays (He and Price, 1995a,b; Price, 2005, 2008; Cecchini and Patrizii, 2008; Manzoor et al., 2000; Grabez and Dragic, 2008).

It has been calibrated that the CR-39 has a very high-charge resolution $\sigma_Z \leq 0.5e/\sqrt{n}$ for relativistic nuclei of $10 \leq Z \leq 65$ by measuring etch pit diameters, where n is the number of successive etch pits measured along the trajectory of a nucleus, as illustrated in Fig. 3.44 (Salamon et al., 1985). The value of n can be larger than 10 for CR-39 with a detector thickness of 0.72 mm for each sheet. The charge resolution is high enough to assign the charges of fission fragments.

Owing to the high charge resolution of CR-39, relativistic projectile fission of 1 AGeV Au nuclei in CR-39 has been studied (Guo et al., 1984b). They observed that some Au projectiles were broken into two fragments in a CR-39 stack composed of 80 sheets each in size $15 \times 15 \times 0.072 \text{ cm}^3$ doped with 1% dioctyl phthalate. After a calibration of track diameter D to charge Z , they could determine the charge Z of each fragment in the fission events. By measuring the zenith and azimuth angles of each fission fragment with respect to the direction of the projectiles, they could determine the total energy release of each event and the interaction nature between the projectile and the target nucleus C, H or O in the CR-39. They showed that the energy release in projectile fission is consistent with that of low-energy fission and the transverse momentum transferred to fissioning species is consistent with a peripheral interaction. The mass distribution of fission fragments is very broad as that of fission of nuclei with $28 \leq Z \leq 83$ by 600 MeV and 1 GeV protons (Guo et al., 1986a).

The above example shows that CR-39 is one of the best detectors to possess the highest charge resolution for fission fragments in the relativistic-energy region.

2. Sequential fission after inelastic collisions

The crystal structure of muscovite mica is anisotropic. The bulk etch rate by hydrofluoric acid parallel to the cleavage surface $V_{//}$ is much larger than that perpendicular to the cleavage V_{\perp} , that is $V_{//} \gg V_{\perp}$, and the track etch rate V_T for fission fragments is several thousand times larger than $V_{//}$. These properties make the ranges of fission fragments stable after etching. Taking this advantage of muscovite mica, Brandt and co-workers opened up a new field of research on sequential fission of heavy nuclei, such as $U + U$, $U + Pb$, breaking into 3, 4, 5 pronged fission events in the low-energy region (Brandt, 1980; Vater et al., 1977, 1986; Gottschalk et al., 1979, 1983; Khan et al., 1980; Qureshi et al., 1994, 1998a, 1998b, 2005; Khan, 1985; Shahzad et al., 1999).

In this field of research, the energy and mass of fission fragments cannot be derived from the shapes of tips, but by the ranges (lengths), zenith and azimuth angles of the fragment tracks and by mass and energy conservations (Gottschalk et al., 1983).

C. Nuclear fission and neutron physics

1. Nuclear fission

In nuclear fission, two fission fragments are emitted in opposite directions (A small number of fission events ($< 1/300$) release a third particle, called ternary fission or even release a fourth particle, quaternary fission, which is outside the scope of this chapter). To which directions (orientations) the two fission fragments fly away from the point of fission is a primitive question. Experiments show that fission events induced by thermal neutrons are isotropic. Other fission events are all anisotropic, even in the center of mass system. The emitted fission fragments have some kind of preference in directions. In order to clarify the phenomenon of the anisotropic distribution, many experiments and theoretical studies have been carried out.

The SSNTD has been used in the measurements of angular distribution of fission fragments emitted from fission. The angular distribution of fission fragments is dominated by the properties of the transit state at fission barrier of fissioning nuclei. In the transit state, fission occurs only through one or a few channels at low energy. The characteristics of the transit state will be reflected in the angular distribution of fission fragments. SSNTDs, such as muscovite mica and polycarbonate (Lexan and Makrofol) can cover very large angles from $\sim 0^\circ$ to $\sim 180^\circ$ and can withstand the bombardments of intense light beam particles, such as γ -rays, neutrons, protons, α particles and nuclei even heavier than neon with higher energies. These detectors can clearly show the tracks of fission fragments

TABLE 3.6 Cluster radioactivity nuclei discovered or confirmed by solid-state nuclear track detectors.

and without background from the light particles of the beams. Because of the importance to fission physics, researchers have carried out this research with SSNTDs (Vandenbosch and Huizenga, 1973).

A thin fission source in a small area supported by a thin foil is placed on the beam of incident particles in a vacuum

chamber. A mica or polycarbonate strip is bent into a circular arc and supported by a frame of aluminum and placed around the source at a distance and stretched to a large angle from $\sim 0^\circ$ to 90° with respect to the beam direction. Fission fragments emitted from the source are recorded by the track detector. Measuring the track density in the

FIG. 3.44 Measured charge resolution σ_z for a single etch pit ($n = 1$) as a function of Z/β in CR-39. The curve a is a weighted least squares quadratic fit to the data. From Salamon et al. (1985); printed with permission from Elsevier © 1985.

detector for a certain range of angles can provide the angular distribution of fission fragments in this special condition (Zhou et al., 1981; Guo, 1982b).

2. Neutron physics

The neutron is an uncharged particle. It cannot be recorded by direct ionization in detecting material, but it can be detected through its recoil nuclei or nuclear reaction products, which are energetic charged particles. Nuclear fission is the first reaction used for the detection of neutrons by SSNTD (Walker et al., 1963). ^{235}U , ^{237}Np , ^{238}U and ^{232}Th are often used as the fissile materials. Fig. 3.45 shows their relationships between fission cross sections and neutron energy.

The threshold energies for fission are, respectively: ^{235}U (0), ^{237}Np (~ 0.1 MeV), ^{238}U (1.0 MeV), and ^{232}Th

(1.17 MeV). The accurate data of the cross-sections can be found in BNL 325, Third Edition, Volume II (1976). The fissile sources of ^{235}U , ^{237}Np , and ^{238}U can be electrolytically deposited on metal foils. The ^{232}Th source can be made by pressure in a mold from ThO_2 powder (Guo et al., 1976a). The effective thickness of the pressed ThO_2 tablet for recording fission fragments with muscovite mica covering on its surface has been calibrated (Guo et al., 1976a) to be: $\frac{1}{2}mR\cos^2\theta_c = 2.32 \pm 0.07 \text{ mgTh/cm}^2$, where m is the mass of ThO_2 in unit volume of tablet, R is the average range of fission fragments in the tablet, and θ_c is the critical angle of muscovite mica for recording fission fragments ($3^\circ 41'$, see Guo et al., 1982).

The above fissile material mica sandwiches can be used separately to measure the flux or fluence of monoenergetic fast neutrons from accelerator neutron sources, or measure the neutron dose. Four sandwiches of detectors can be put together to measure the neutron spectrum by dividing the whole range of energy into intervals (Durrani and Bull, 1987).

D. Plasma physics

1. Laser acceleration

Since the year 2000, table-top accelerators of proton and heavy ion beams has become a focus of interest in scientific research. It is expected that table-top accelerators based on laser-plasma interactions might replace the current heavy-ion accelerators, which are large in size and length up to more than several tens of meters or even more than several kilometers. A high-intensity laser beam could produce a > 50 MeV proton beam. This result has attracted worldwide researchers to join in this new research field. The SSNTD, CR-39, has become the most important tool to study this phenomenon. The possible mechanism of proton acceleration by laser-plasma interaction is called Target Normal

FIG. 3.45 Fission cross-sections versus neutron energy of ^{235}U , ^{237}Np , ^{238}U and ^{232}Th . From Durrani and Bull (1987), reprinted with permission from Elsevier © 1987.

Sheath Acceleration (TNSA) whereby a high intensity laser beam hits on a solid target (foil), the prepulse of the laser (the small pulse before the main pulse of laser shoot) creates a thin plasma layer at the surface of the foil. Then, the intense part of the pulse (the main pulse) of the laser shoot interacts with the thin plasma layer, which accelerates the electrons toward the foil by the ponderomotive force. Finally, the electron beam reaches the rear surface (the opposite surface to the laser irradiation) and creates a strong electrostatic field which first ionizes and then accelerates protons to high energy. When the electrons have passed the foil, they act as a sheath with negative charge. The electron sheath moves very quickly. It attracts the positive protons to go to the same direction (normal to the surface of the foil). Following the electron sheath, the protons can reach a very high energy depending on the parameters of the laser and the foil. The target foil may be varied, and most accelerated particles are protons. These protons come from H₂O or a hydrocarbon adsorbed on the surface of the foil.

The proton beam accelerated by laser-plasma interaction has the following properties: (1) The direction of the proton beam is normal to the surface of the target. The beam spread is less than 20°. It is nearly a collimated beam of protons. (2) The maximum proton energy is related to the laser intensity. Therefore, the proton energy is controllable by the laser beam. (3) The intensity of proton beams can reach 10⁹–10¹³ protons per pulse. The usual frequency is about 10 pulses per second. It is strong enough for many applications. (4) The size of the beam source is about 10 μm, which is much smaller than that of the current heavy ion accelerators.

Due to the above properties, laser acceleration is expected to feasibly replace some types of current big accelerators, to work as proton beam medical accelerators or spallation neutron sources.

In laser acceleration, the proton beam duration is less than 10^{−12} seconds. In this very short time, more than 10⁹ protons will reach the detector. Electronic detectors have a dead time. It is difficult to record a single proton and analyze its energy. In this case, the CR-39 is the best detector for recording a single proton and obtaining its energy.

Many laboratories are now carrying out laser acceleration studies with CR-39 track detectors (Snively et al., 2000; Ceccotti et al., 2007; Duan et al., 2009, 2010; Li et al., 2007; McKenna et al., 2005; Hicks et al., 2001; Fukuda et al., 2013; Kanasaki et al., 2012, 2013, 2015, 2016; Macchi et al., 2013).

2. Inertial confinement fusion

In inertial confinement fusion (ICF) induced by pulsed laser with high intensity and short time, the following primary

fusion reactions in the capsules will take place, in which α particles are produced:

where D and T are the original compositions of the fuel in the capsule, ³He is the direct product of D + D → ³He [0.82 MeV] + n [2.45 MeV] reaction.

The best detector for recording α particles in these reactions is CR-39 nuclear track detector (Seguin et al., 2003). The first actual instrument for measuring the charge-particle spectra in these fusion reactions was designed with electronic detectors; but it was eventually implemented with CR-39 detectors. The reasons for the big change of detector are due to the advantages of CR-39 detector, which are the following: (1) The detection efficiency for the formed particles is high (about 100% for normal incidence); (2) The area coverage of CR-39 detector can be large and at various angles (~2π geometry being possible if necessary); (3) The energy resolution is higher by CR-39 than electronic detectors; (4) The immunity of CR-39 is superior to electromagnetic radiations (x-ray, γ-ray and electric transients accompanied by shooting of the laser); (5) There is no overloading for less than ~10⁷ cm^{−2} particles and no dead time compared with electronic detectors; and (6) The ability to distinguish the types and energies of individual particles. CR-39 detector is used in many laser-plasma fusion laboratories throughout the world (Kacénjar et al., 1982; Szydlowski et al., 2009).

E. Astrophysics and cosmic rays

Astrophysics and cosmic ray research is the oldest field of application since the discovery of SSNTDs (Price and Walker, 1962e). Great achievements were made in the past 50 years with SSNTDs in research on the following:

- (1) Galactic cosmic rays
- (2) Solar particles
- (3) Ancient cosmic rays
- (4) Search for super-heavy elements in cosmic rays
- (5) Elementary and exotic particles

These studies with etch track detectors have been reviewed in the monographs of Fleischer et al. (1975) and Durrani and Bull (1987). More recent achievements are conveyed by the following authors: O'Sullivan (1995); Zhou et al. (2009); Doke (2008); Westphal et al. (1998);

Hasebe et al. (2009); Yasuda et al. (2008); Weaver, 2001; Weaver and Westphal, 2002; Price (2005, 2008).

F. Nuclear technology

1. Nuclear reactor physics

The basic physical processes in nuclear reactors are neutron-induced fission and the consequent fission release of neutrons. These processes continue as chain reactions. To study neutron number, flux, spatial distribution, and energy spectrum is one part of the work in reactor physics. SSNTDs are used in these studies.

a. Determination of neutron temperature

In a steady-state operation of a nuclear reactor, neutrons and other molecules in the reactor are in thermal equilibrium. This state is described by temperature as in thermodynamics. The temperature is a decisive factor for the neutron energy spectrum in the thermal energy region. The neutron energy spectrum is considered to follow Maxwell energy distribution.

The principle of the determination of neutron temperature in a nuclear reactor is based on the Westcott equation:

$$\hat{\sigma} = \sigma_0 \left(g + r \sqrt{\frac{T_n}{T_0}} S_0 \right) \quad (3.43)$$

where $\hat{\sigma}$ is the effective fission cross-section of a given fissile nucleus for neutrons with velocity of 2200 m/s; σ_0 is the fission cross section of the given nucleus for neutrons with velocity of 2200 m/s (For ^{235}U , $\sigma_0 = 582.6$ b; for ^{239}Pu , $\sigma_0 = 748.1$ b); g is a correction factor for non $1/v$ fission cross section of the given nucleus in Maxwell neutron spectrum; $r\sqrt{T_n/T_0}$ is the relative ratio of epithermal neutrons (epithermal index); S_0 is the correction factor for resonance absorption of the nucleus (resonance parameter). The variables g and S_0 are functions of neutron temperature T_n .

The track number N_T recorded on a track detector is described by equation

$$N_T = N \hat{\sigma} \phi_0 \varepsilon \quad (3.44)$$

where N is the number of the specific nuclei of fissile species; ϕ_0 is the integrated neutron flux (fluence) equivalent to 2200 m/s; and ε is the detection efficiency of the detector for fission fragments (see Eq. 3.12);

Substituting Eq. (3.43) into Eq. (3.44), gives

$$N_T = N \sigma_0 \left(g + r \sqrt{\frac{T_n}{T_0}} S_0 \right) \phi_0 \varepsilon \quad (3.45)$$

In Eq. (3.45) for a combination of fissile species and a track detector, such as ^{235}U and mica, N , σ_0 and ε are known, and N_T can be measured by track counting; only ϕ_0 and the variable T_n of g and S_0 are unknown. If one uses a second fissile species, such as ^{239}Pu plus mica, one has two

equations and two unknowns. One can solve the equations to find ϕ_0 and T_n where T_n is the neutron temperature in a nuclear reactor. From T_n one can calculate the neutron energy distribution from Maxwell equation (Liu and Su, 1971).

The advantages of the track detector for the measurement of the temperature of neutrons in nuclear reactor are the following:

- (1) The measurements are simple and convenient to perform.
- (2) One can determine small disturbances to the nuclear reactor and to the neutron energy spectrum.
- (3) The neutron fluence irradiated to the fissile materials can be obtained as a by-product of the measurements. One does not need to measure the neutron fluence with other techniques.
- (4) If one uses thin sources of both fissile materials, the detection efficiency ε for both sources will be canceled in the calculation. The uncertainty of the final result T_n will not be affected by ε .
- (5) No background effects come from α -, β - or γ -rays.

The main sources of uncertainty are track counting, numbers of the atoms of the two fissile materials and the parameters of g , r , and S_0 as functions of the two species of nuclei.

The determination shows that the neutron temperatures at different positions in the nuclear reactor are different. The temperature in the core region is higher than that in the thermal column.

b. Determination of fast fission factor in nuclear reactors

In thermal neutron reactors, the ^{235}U nucleus absorbs a thermal neutron and goes to fission. On the average, ν_5 neutrons will be produced. These neutrons in the beginning are fast neutrons with an average energy about 2 MeV. The fast neutrons have a probability to be absorbed by ^{238}U nuclei and the formed compound nuclei probably go to fission and release on the average ν_8 neutrons, and the new neutrons may induce ^{238}U nuclei to go to fission again. As a result of the above process, there will be in total $\varepsilon \nu_5$ neutrons produced ($\varepsilon > 1$) where ε is called the fast neutron fission factor or fast fission factor. In the design of thermal neutron reactors, the knowledge of the fast fission factor is of practical importance. For this purpose, Shi and Li (2001) have developed a method for the determination of the fast fission factor ε with SSNTDs. The procedure is the following:

Two fission sources are electrolytically deposited on two Ni disks, one of which is natural uranium, another is enriched uranium. The thicknesses of uranium are 200 $\mu\text{g}/\text{cm}^2$ and 20 $\mu\text{g}/\text{cm}^2$ for the natural and enriched uranium,

respectively; both are thinner than the critical thickness (See Section III.C.2). The Ni disk is 30 μm in thickness. The two uranium fission sources were covered with SSNTD sheets. The sizes of the sources and track detectors were the same as the cross section of the fuel element. The two fission sources and their detectors were packed together back to back, and inserted into the fuel element assembly. After irradiation in a heavy water zero power reactor (HWZPR), the track numbers recorded on the track detectors were counted. From the two track numbers and the atom numbers of ^{235}U and ^{238}U in the natural uranium source, enriched uranium source and fuel element, they obtained the fast fission factor ϵ ($= 1.050$) which is in agreement with the theoretical calculation (1.071). The detailed formulations to calculate ϵ from the above-mentioned data of measurements are provided by Shi and Li, 2001.

c. Measurement of reactor fission rate and reactor power by track detector

The decisive factor of nuclear reactor power is how many fission events occur in the whole reactor in 1 s, that is, the fission rate in the whole reactor. One way of measuring nuclear reactor power is to determine the fission rate in the whole nuclear reactor. Basically, it is difficult to measure fission rate in the whole reactor with conventional detectors. However, with the advent of the SSNTD, the measurement of fission rate in the whole reactor becomes quite easy. Li et al. (2001) sandwiched track detector foils on the fuel elements, which are regularly at different heights and different radius in the core of a miniature neutron source reactor. In total, 80 track foils were collocated. The distribution of fission rate at each place as well as in the whole volume of reactor is obtained. By this method, they obtained the reactor power (29.9 KW), which was in agreement with that of the thermal-hydraulic method (30.9 KW) and Gold foil activation method (27.7 KW) (Li et al., 2001). The conversion factor from the whole fission rate F to reactor power P is P_0 , $P = P_0 F$ where $P_0 = 0.321 \times 10^{-10}$ Ws/fission = 200 MeV/fission. The advantages of the track detector technique for measuring reactor fission rate are by its absolute nature, simplicity, and applicability at low reactor power.

2. Accelerator-driven subcritical reactors

The accelerator-driven subcritical reactor (ADS) is a new type of proposed nuclear reactor. It has the following characteristics:

- (1) A subcritical nuclear reactor. It is stable and without any obvious nuclear reactions in it.
- (2) Reaching critical condition only when an accelerator provides enough neutrons to it. When the accelerator

stops, the criticality vanishes. It is a controllable reactor without any potential of a Chernobyl-type accident.

- (3) Generation of electricity from nuclear fission. It will be a nuclear power plant.
- (4) A breeder reactor. ^{238}U nuclei after capture of fast neutrons may turn to ^{239}Pu nuclei.
- (5) Transmuting long-lived isotopes into stable or short-lived nuclides.

The ADS was first proposed by Bowman et al. (1992); and Rubbia et al. (1997) gave a clearer explanation of the reactor. Up to now, nobody knows what target materials and beam particles of the accelerator should be used to produce neutrons, what are the adequate fuel elements to release fission energy, how to exchange heat from the core region to the coolant, what is the appropriate structure for the whole reactor. A few prototypes have been built. Some of them are quite simple, including special target material and size, special beam and energy, special reactor core and blanket (Brandt et al., 2008; Hashemi-Nezhad et al., 2008).

The SSNTD, being thin pieces, small in size, nearly no disturbance to neutron fields, easy to insert into gaps in the testing reactors, being able to measure neutron flux, energy and distributions in three dimensions, has been applied to studies on accelerator-driven critical reactors. Zamani et al. (2008) used $^6\text{Li}_2\text{B}_4\text{O}_7 + \text{LR-115}$, CR-39 and CR-39 covered with Cd foil to measure thermal-epithermal and intermediate-fast neutrons. Adloff et al. (1999) investigated the production of thermal neutrons with thin ^{235}U targets on Lexan track detectors and ^{232}Th targets on Lexan detectors for neutron energies $E_n > 2$ MeV. Dwivedi et al. (1993) used gold foils and track detectors to measure neutrons of energy $E_n > 30$ MeV (Wan et al., 2001). Zhuk et al. (2008) and Perelygin et al. (2001) used Pb foils and mica and PET foil to measure proton beam profiles and neutrons of energy $E_n > 30$ MeV. Hashemi-Nezhad et al. (2008) used Pb foils and mica to measure neutrons and compared the results with Monte Carlo predictions using MCNPX code. Guo et al. (2001) used CR-39 sheets to measure neutrons and come to conclusions that the Hg target is disadvantageous compared to U(Pb) and Pb targets for neutron yield. In order to obtain a uniform field of neutrons in an adequate target size, the energy of protons from accelerators should not be lower than 1 GeV for ADS developments.

3. Nuclear forensic analysis and nuclear safeguards

a. Nuclear forensics

For the requirements of arms control and nonproliferation of nuclear weapons, a new research field gave birth in the last decade of the 20th century. It was named as strengthened nuclear safeguards (Donohue, 2002). In this field of science, environmental samples within and outside nuclear

facilities are collected to disclose undeclared nuclear material and expose undeclared nuclear activities.

Nuclear materials for weapons are mainly ^{235}U and ^{239}Pu . The abundance of $^{235}\text{U} \geq 90\%$ and the ratio of $^{240}\text{Pu}/^{239}\text{Pu} \leq 6\%$ are requirements for nuclear weapons. Lower abundances of $^{235}\text{U} \leq 5\%$ and the ratio of $^{240}\text{Pu}/^{239}\text{Pu} \geq 20\%$ are for commercial uses. Enriched ^{234}U comes from a uranium enriching plant. The existence of enriched ^{234}U particles indicates that there is a uranium enriching plant. Existence of ^{236}U indicates the existence of a nuclear fuel reprocessing plant. The analysis of isotopic compositions of uranium and plutonium in microscopic single particles has become a decisive method in nuclear safeguards and nuclear forensic analysis to disclose the undeclared activities. See Chapter 13, Volume 2 of this book for a more comprehensive treatment of nuclear forensics.

b. Fission track technique

The fission track (FT) technique has been regarded as a feasible method to search for, locate, and transfer uranium-bearing particles from swipe samples. These particles are transferred to a thermal ionization mass spectrometer (TIMS), secondary ion mass spectrometer (SIMS), or inductively coupled plasma mass spectrometer (ICP-MS) for analysis of isotopic abundances.

The fission track (FT) technique includes the following steps:

- (1) **Picking up uranium-bearing particles.** Swipe particles are transferred onto a Lexan polycarbonate detector of size $2 \times 2 \text{ cm}^2$. The Lexan detector with the particles is covered with a newly cleaved clean surface of mica detector. The sandwich formed of Lexan-mica is marked with a needle at three points (A, B, and C) **coincident** to each other on the outer surfaces of the Lexan and mica. The marked sandwich is tightly pressed together.
- (2) **Irradiation.** The sandwich of Lexan-mica is irradiated with thermal neutrons in a nuclear reactor to a neutron fluence about $10^{15} - 10^{16} \text{ cm}^{-2}$. The neutrons induce fission of ^{235}U in the swipe particles. The fission fragments are recorded by the Lexan and mica track detectors.
- (3) **Etching.** After irradiation in the nuclear reactor, the mica detector is etched in HF and track stars will be seen under an optical microscope.
- (4) **Searching for and locating uranium-bearing particles.** Put the Lexan sheet on the mica back to back with the particles on the upper surface and the marks A, B, and C on both detectors overlapping each other. The particle on the upper surface of the Lexan coincident with the track star on the bottom surface of mica

will be the uranium particle which produces the star. In this way, uranium-bearing particles are found. The coordinates (X_U, Y_U) of each particle as well as the coordinates (X_A, Y_A), (X_B, Y_B) and (X_C, Y_C) of the marks are recorded by the instruments connected with the stage of the microscope.

- (5) **Relocating particles and isotope analysis.** After coating with carbon or aluminum on the Lexan sheet by sputtering or vacuum evaporation, the Lexan sheet is placed under a scanning electron microscope (SEM) or SIMS. By a mathematic formulation of relocation (see below) one can easily and quickly find the uranium-bearing particle. Further analyses on the elemental and isotopic composition of the particle can be carried out.
- (6) If TIMS is used to analyze the isotopic composition of the particle, one should use a micromanipulator (see Fig. 3.46) to pick up the particle and transfer it to the TIMS rhenium filament for analysis.
- (7) If ICP-MS is used for isotopic analysis, one should prepare a proper solution dissolving the particle for the measurement. A micromanipulator is also needed to transfer the particle to the solvent.

c. Mathematical formula of relocation

For relocation of a uranium-bearing microparticle on the surface of a track detector or on other substrate such as a graphite planchet, one needs two or three reference points such as the marks made on the Lexan or mica. The reference points must be very easy to be found in the instruments. For locating and relocating the particle, one should first record the coordinates of the reference points A (X_A, Y_A), B ($X_B,$

FIG. 3.46 Microphotograph of glass needle sticking a uranium-bearing particle at its tip by static electricity. The tip diameter of the needle is about $1 \mu\text{m}$. The movement of the needle is controlled by micromanipulator (NARISHIGE, TYPE MO-202D). The precision of movement of the micromanipulator is $0.5 \mu\text{m}$. The glass needle was made by using an instrument (Puller, type PC-10, NARISHIGE).

Y_B), and C (X_C, Y_C) and the coordinates of the uranium-bearing particle U (X_U, Y_U) in the first instrument. After putting the sample or planchet in the second instrument, one should first find the reference points and record the coordinates A (X'_A, Y'_A) and B (X'_B, Y'_B). The uranium-bearing particle can be found easily at the position U (X'_U, Y'_U) calculated by the following formula (Guo et al., 2008):

$$X'_U = \overline{AU} \times R \times \cos \phi' + X'_A \quad (3.46)$$

$$Y'_U = \overline{AU} \times R \times \sin \phi' + Y'_A \quad (3.47)$$

where \overline{AU} is the distance between A and U, R is the ratio of the readings of the same distance in the second instrument to that in the first instrument:

$$R = \frac{\sqrt{(X'_B - X'_A)^2 + (Y'_B - Y'_A)^2}}{\sqrt{(X_B - X_A)^2 + (Y_B - Y_A)^2}} \quad (3.48)$$

ϕ' is the angle between AU and the X' -axis in the second instrument:

$$\phi' = \alpha' + \theta' \quad (3.49)$$

where α' and θ' are the angles between AU and AB and between AB and the X' -axis in the second instrument, respectively.

$$\alpha' = \alpha \quad (3.50)$$

where α is the angle between AU and AB in the first instrument.

$$\theta' = \begin{cases} \text{Arctg} \frac{Y'_B - Y'_A}{X'_B - X'_A}, & X'_B > X'_A \\ \text{Arctg} \frac{Y'_B - Y'_A}{X'_B - X'_A} + \pi, & X'_B < X'_A \\ \frac{\pi}{2}, & X'_B = X'_A, Y'_B > Y'_A \\ -\frac{\pi}{2}, & X'_B = X'_A, Y'_B < Y'_A. \end{cases} \quad (3.52)$$

In other words, recording the coordinate of two reference points and the particle in the first instrument and the coordinates of the two reference points in the second instrument, one can immediately calculate the coordinates of the particle in the second instrument. If one uses three or more reference points, such as A, B, and C, every two reference points give a pair of coordinates (X'_U, Y'_U) of the particle. Averaging all the three coordinates X'_U as well as the three Y'_U , one can achieve better accuracy of the coordinates in the second instrument.

Guo et al. (2008) made reference points on a graphite planchet by a using NTM having a pore diameter of 10 μm and simulated particles having the same diameter. A relocation measurement in the second instrument (SEM, JEOL 6360 LV) showed that the relocation accuracy was $(5.8 \pm 2.6) \mu\text{m}$ compared with the coordinates calculated from the formula for 87 simulated particles. It is accurate enough to find the uranium-bearing particle in the second

$$\alpha = \begin{cases} \text{Arctg} \frac{Y_U - Y_A}{X_U - X_A} - \text{Arctg} \frac{Y_B - Y_A}{X_B - X_A}, & X_U > X_A, X_B > X_A, \text{ or } X_U < X_A, X_U < X_A \\ \text{Arctg} \frac{Y_U - Y_A}{X_U - X_A} - \text{Arctg} \frac{Y_B - Y_A}{X_B - X_A} + \pi, & X_U < X_A, X_B > X_A, \\ \text{Arctg} \frac{Y_U - Y_A}{X_U - X_A} - \text{Arctg} \frac{Y_B - Y_A}{X_B - X_A} - \pi, & X_U > X_A, X_B < X_A, \\ \frac{\pi}{2} - \text{Arctg} \frac{Y_B - Y_A}{X_B - X_A}, & X_U = X_A, Y_U > Y_A, \\ -\frac{\pi}{2} - \text{Arctg} \frac{Y_B - Y_A}{X_B - X_A}, & X_U = X_A, Y_U < Y_A, \\ \text{Arctg} \frac{Y_U - Y_A}{X_U - X_A} - \frac{\pi}{2}, & X_B = X_A, Y_B > Y_A, \\ \text{Arctg} \frac{Y_U - Y_A}{X_U - X_A} + \frac{\pi}{2}, & X_B = X_A, Y_B < Y_A, \end{cases} \quad (3.51)$$

instrument for further analysis. More detailed information can be found in Guo et al. (2008).

In all the above analyses, the SSNTD plays important roles (Shen et al., 2008; Guo et al., 2008, 2017; Lipponen and Zilliacus, 2004, 2003, 2002; Esaka et al., 2004; Baude and Chiappini, 2002; Donohue, 2002; Chen et al., 2013, 2015, 2018; Lee et al., 2011; Vlasova et al., 2015; Wang et al., 2018; Wang, 2018).

d. α -track technique

Research papers on plutonium-bearing particles are not common. The reason for scarce research of plutonium particles is mainly that the identification of plutonium-bearing particles is difficult by the fission track (FT) technique, which is commonly used in the study of uranium-bearing particles because one cannot efficiently distinguish between uranium fission and plutonium fission by tracks in SSNTD. The kinetic energy of fission fragments of ^{235}U induced by thermal neutrons in the nuclear reactor is 168.3 MeV on the average, while the average kinetic energy for ^{239}Pu fission fragments is 175.0 MeV. Both values of kinetic energy are too close to distinguish plutonium fission by parameters of tracks. The masses of the fission fragments of plutonium and uranium are also close to each other, which make the identification of Pu among U particles twofold difficult.

In contrast, the energies of α particles emitted from plutonium isotopes and that of uranium have relatively large differences: $\sim 5.2\text{--}5.8$ MeV and $\sim 4.2\text{--}4.8$ MeV for Pu and U, respectively. This large difference may provide more feasibility to distinguish plutonium particles from that of uranium. After a simple test, it was found that by the α track diameter alone, one still cannot efficiently identify plutonium particles in the mixture of uranium particles and plutonium particles. It was found that with more track parameters, one can distinguish α tracks more easily than with the use of only the track diameter.

Fig. 3.47 shows the difference of α -tracks between highly enriched uranium (HEU) and plutonium. The α -particles are emitted from highly enriched U ($^{235}\text{U}/(^{235}\text{U}+^{238}\text{U}) \geq 90\%$) or weapons-grade Pu. The sizes of the U-bearing solid particles and that of Pu are in micron (μm) level. The α tracks recorded on CR-39 detector from one U or Pu particle distributed like a track star. R in Fig. 3.47 is the radius of the circular α tracks in the center part of the star. Rc is the radius of curvature of the tapered α tracks which are located about $130\ \mu\text{m}$ away from the center of the star. The ratio Rc/R for HEU and Pu are different obviously at etching time from 10 hours to 16 hours. The large difference makes it very easy to distinguish Pu-bearing particles from HEU-bearing particles. After selecting the Pu particles, the Pu age is determined by ICP-MS. This technique with a micro-sized Pu particle has

FIG. 3.47 Principle to distinguish microscopic Pu particles from U particles by α tracks on CR-39 sheet. The selected Pu single particle can be used to determine the year when the Pu was produced (the age of Pu) (Wang, 2018; Wang et al., 2018).

been successful in the determination of the age of Pu (the production year of Pu) (Wang, 2018; Wang et al., 2018).

G. Elemental analysis and mapping

Elemental mapping has been discussed in detail in the book of Fleischer et al. (1975). Here only an example will be presented on boron mapping in metallurgy.

Natural boron is composed of ^{11}B (80.1%) and ^{10}B (19.9%). ^{10}B has a large cross-section (3840 ± 11 b) for thermal neutrons in nuclear reactors. The reaction products of the reaction $^{10}\text{B}(n,\alpha)^7\text{Li}$ consist of α particles with energies of 1.47 MeV (93.7%) and 1.77 MeV (6.3%). Both of these are easy to be recorded by SSNTDs (CR-39, LR-115, and cellulose acetate).

In order to observe the boron distribution in steel, a small block of steel is ground and polished to expose a smooth surface. Then, the smooth surface is covered with a thick solution of cellulose acetate (in acetone or cyclohexanone). After drying the solution, the steel block with the cellulose acetate layer is placed outside the channel of thermal column of nuclear reactor for irradiation with thermal neutrons. The reaction products α and Li particles will create tracks in the cellulose acetate. The microphotographs of tracks after etching and the microphotograph of the steel of the same area are shown in Fig. 3.48.

Boron is concentrated on the crystal boundaries and uniformly distributed within the crystal cells. The recipes, smelting temperature and quench condition of the steel, can be selected and improved through these microphotographs (Guo, 1995). A large quantity of special steels has been smelted.

FIG. 3.48 Track microphotograph of MnTiB steel (A) and its corresponding microphotograph of the steel (B). After turning 180° of (A), the two microphotographs can be matched together.

III. Earth and planetary sciences

A. Fission track dating

1. Absolute approach

Fission track dating (FDT) was first devised by Price and Walker in 1962 (Price and Walker, 1963a,b). It has become

and N_i and ϕ_0 . The equation of age of the mineral can be written as follows (Collaboration Group of Institute of Atomic Energy and Guiyang Institute of Geochemistry, Academia Sinica, 1976):

where C_{235} is the relative abundance of ^{235}U (0.720%), C_{238} is the relative abundance of ^{238}U (99.2745%), λ_D is

$$T = \frac{1}{\lambda_D} \ln \left\{ \frac{C_{235}}{C_{238}} \cdot \frac{\lambda_D}{\lambda_F} \cdot \frac{\rho_s}{\rho_i} \cdot \phi_0 \cdot \hat{\sigma} \frac{[GR_i \cos^2 \theta_{ci} + (1 - \sin \theta_{ci})l_i]}{R_s \cos^2 \theta_{cs} + (1 - \sin \theta_{cs})l_s} + 1 \right\} \quad (3.53)$$

one of the important dating techniques in geology and archeology (Fleischer et al., 1975; Durrani and Bull, 1987; Wagner and Van den haute, 1992; Dumitru, 2000).

a. Age equation

The principle of FTD is the following:

The fragments of spontaneous fission of ^{238}U nuclei in minerals create radiation damage tracks which can be developed as etched tracks in the mineral and can be observed with an optical microscope. The number of spontaneous fission tracks (N_s) is proportional to the age (T) of the mineral and the uranium content (N_u) in the mineral. After counting the spontaneous fission tracks and measuring the uranium content in the mineral, one can determine the age of the mineral. The easiest way to determine the uranium content in the mineral is to irradiate the mineral with thermal neutrons in a nuclear reactor. Thermal neutrons induce fission of ^{235}U in the mineral. The induced fission will be recorded in the mineral. Counting the induced fission tracks (N_i) and measuring the neutron fluence (ϕ_0) irradiated to the mineral, one can derive the uranium content from the fission cross section ($\hat{\sigma}$) of ^{235}U

the total decay constant of ^{238}U ($1.5514 \times 10^{-10} \text{a}^{-1}$), λ_F is the spontaneous fission decay constant of ^{238}U , ρ_s is the spontaneous fission track density of ^{238}U (cm^{-2}), ρ_i is the induced fission track density of ^{235}U (cm^{-2}), R is the average etchable range of fission fragments in the mineral (cm), θ_c is the critical angle of fission fragments in the mineral, l is the thickness of the single surface layer removed by etchant (cm), s denotes that the quantity is for spontaneous fission fragments, i denotes that the quantity is for induced fission fragments, G is a geometry factor where $G = 1$, when an internal surface is used to record induced fission fragment tracks and $G = 1/2$, when an external surface is used to record induced fission fragment tracks.

In a special case, one can assume that $R_i = R_s$, $\theta_{ci} = \theta_{cs}$ and $l_i = l_s = 0$. Then, Eq. (3.53) is simplified to the equation

$$T = \frac{1}{\lambda_D} \ln \left\{ \frac{C_{235}}{C_{238}} \cdot \frac{\lambda_D}{\lambda_F} \cdot \frac{\rho_s}{\rho_i} \cdot \phi_0 \cdot \hat{\sigma} \cdot G + 1 \right\} \quad (3.54)$$

It should be pointed out that if the detector used for recording induced fission tracks is not the same kind of

mineral as that to be dated (by spontaneous fission tracks), then $R_i \neq R_s$, $\theta_{ci} \neq \theta_{cs}$ and $l_i \neq l_s$. In this case, Eq. (3.54) cannot be used to calculate age T .

It is always necessary to calibrate the ratio of the detection efficiency of an external detector for induced fission fragments to that of the mineral for spontaneous fission fragments (Guo, 1982a; Guo et al., 1980; Durrani and Bull, 1987; Holden and Hoffman, 2000). Otherwise, the resulting age value of T calculated from the simplified Eq. (3.54) would be erroneous.

If $\lambda_D T \ll 1$ ($T \leq 2 \times 10^8$ a), then Eq. (3.54) can be further simplified as follows:

$$T = \frac{1}{\lambda_f} \frac{C_{235}}{C_{238}} \frac{\rho_s}{\rho_i} \cdot \phi_0 \cdot \hat{\sigma} \cdot G \quad (3.55)$$

Eq. (3.55) has the same limitations as Eq. (3.54) in addition to condition $T \leq 2 \times 10^8$ a.

The technique of FTD by using Eqs. (3.53), (3.54) and (3.55) is called the absolute approach (Wagner and Van den haute, 1992; Hurford, 1990).

Two problems have been met with the absolute approach, which are described subsequently.

b. ^{238}U spontaneous fission decay constant λ_f

Up to now, more than 30 data of λ_f have been published in the literature (Wagner and Van den haute, 1992; Bigazzi, 1981; Durrani and Bull, 1987). The values of λ_f spread over a very broad range. No one can recommend an integrated value from them. In the year 2000, the International Union of Pure and Applied Chemistry (IUPAC) published a Technical Report on "Spontaneous fission half-lives for ground-state nuclides" (Holden and Hoffman, 2000) and gave a special treatment on the ^{238}U spontaneous fission decay constant λ_f .

The IUPAC did not include the results of all λ_f values of ^{238}U spontaneous fission measured by SSNTDs. They averaged the results measured by the other detectors (ionization chamber, double ionization chamber, rotating bubble chamber, fission products from ^{238}U , third-order coincidence, and multiple neutron coincidence) and give a recommended half-life value $t_{1/2} = (8.2 \pm 0.1) \times 10^{15}$ a of ^{238}U spontaneous fission, which is equivalent to a $\lambda_f = 8.45 \times 10^{-17} \text{ a}^{-1}$. They considered that the recommended value of $t_{1/2}$ is the correct spontaneous fission half-life of ^{238}U .

The reasons for not including the results measured by SSNTDs are the following:

- (1) The values of half-life derived from track detectors do not agree with that derived from other techniques. The specific activity (λ_f), in general, is lower than that determined from other detectors.
- (2) The lower λ_f values are related to special properties of track detectors. The lower λ_f values are suitable to

FTD, in which the factors that cause the lower values can be compensated in age determination. For a detailed explanation, the readers are referred to the abovementioned Technical Report.

It has been demonstrated that no trend can be found with respect to whether the zeta calibration (see below) or the decay constant of $7 \times 10^{-17} \text{ a}^{-1}$ was used in FTD. The results based on a decay constant of $8.46 \times 10^{-17} \text{ a}^{-1}$ tend to be low compared with the mean age obtained in an international comparison of fission track ages for the 1988 fission track workshop (Miller et al., 1990). It means that by using $\lambda_f = 6.85 \times 10^{-17} \text{ a}^{-1}$ (Fleischer and Price, 1964) or $7.03 \times 10^{-17} \text{ a}^{-1}$ (Roberts et al., 1968), the age values obtained are in agreement with that of age standard, or in agreement with the mean value obtained by different techniques in FTD (population method, external detector method and zeta calibration approach). By using $\lambda_f = 8.46 \times 10^{-17} \text{ a}^{-1}$ the results of ages are generally lower than those obtained by other techniques.

In the absolute approach of FTD, an important point is to state which decay constant λ_f of ^{238}U spontaneous fission was used in calculation of age, so that other workers can make comparison with other age determination by substituting a new λ_f value (Durrani and Bull, 1987).

In dating with the absolute approach, the effect of track fading on age must be corrected. The correction techniques include: track diameter method (relation of track diameter d/d_0 to track density ρ/ρ_0 , where the subscript "0" signifies that for no fading of tracks), track length method (relation of track length l/l_0 to track density ρ/ρ_0) and plateau-age correction method (annealing spontaneous and induced tracks simultaneously before etching until ρ/ρ_i reaches a constant value. The age calculated by the constant ρ_s/ρ_i is the true age of the sample.)

c. Neutron fluence ϕ_0

Neutron fluence determination in nuclear reactors is a mature technique for reactor physicists. For thermal neutron determination, the often-used technique is activation foil measurements. Co, Au, and Cu foils are most suitable for thermal neutron fluences of 1.5×10^{15} – 6×10^{15} , 1×10^{11} – 1×10^{14} , and 1×10^{12} – $1 \times 10^{15} \text{ cm}^{-2}$, respectively. Co foil is most suitable for FTD.

In the irradiation of dating samples in nuclear reactors, one must pay attention to the total thickness of the samples. If the sample package is too thick, the outlayer of the sample will absorb neutrons and reduce the expected fluence of neutrons for the central part of sample. In this case, one should insert more than one (at least two) activation foils to get an average value of neutron fluence. Similar attention must be paid to the thickness of the activation foils. If the thickness of the activation foil is too large, the surface layer of the foil will absorb a significant amount of

neutrons and a reduced fluence of neutrons reaches the central part of the foil (self-shielding). In this case, the fluence of thermal neutrons can be written as following equations:

$$\phi_0 = nv_0t = \frac{A_0t}{N\hat{\sigma}(1 - e^{-\lambda t})} \quad (3.56)$$

$$\hat{\sigma} = \sigma_0 \left(K_{th}g + r\sqrt{\frac{T_n}{T_0}}S_0K_r \right) \quad (3.57)$$

where n is the volume density of thermal neutrons in the nuclear reactor (cm^{-3}), v_0 is the neutron velocity (2200 m/s), K_{th} is the self-shielding factor of activation foil for thermal neutrons, K_r is the self-shielding factor of activation foil for epithermal neutrons, A_0 is the activity of the activation foil, t is the exposure time of the activation foil to the reactor thermal neutrons in seconds (s), and λ is the decay constant of the nuclei formed in the exposure (s^{-1}).

The nuclear parameters of the activation foils of ^{59}Co , ^{63}Cu , and ^{197}Au , as well as the ^{235}U (n,f) reaction for thermal and epithermal neutrons in nuclear reactors are listed in Table 3.7. For example, 50 mg/cm² of Co foil will have $\sim 3\%$ ($K_{th} = 0.97$) and $\sim 11\%$ ($K_r = 0.885$) effects on thermal and epithermal neutrons, respectively. These effects will be brought to the fluence value. If one does not give a correction for these effects, the final value of fluence of thermal neutrons (ϕ_0) calculated from the Co foil activity A_0 will be $\sim 3.6\%$ smaller than the real fluence. This reduction of calculated ϕ_0 would result in a younger age of the sample as calculated from Eqs. (3.53), (3.54) or (3.55).

2. Zeta approach

In order to avoid direct measurements of fluence of thermal neutrons ϕ_0 in nuclear reactors and avert adoption of the decay constant λ_f of ^{238}U spontaneous fission in the calculation of age, the Zeta approach was proposed (Fleischer et al., 1975) and advocated (Hurford and Green, 1982, 1983) and extensively accepted and adopted (Miller and Duddy, 1985; Miller et al., 1990; Van den haute and Chambaudet, 1990; Wagner and Van den haute, 1992; Durrani and Bull, 1987; Wang and Kang, 1993; Wang et al., 1993; Yang et al., 2003).

a. Age equation

The Zeta approach of FTD is based on the adoption of standard uranium glass to measure fluence of thermal neutrons in nuclear reactors and the utilization of age standards to replace the decay constant of ^{238}U spontaneous fission.

When adopting standard uranium glass, one has the following equation:

$$\phi_0 = B\rho_D \quad (3.58)$$

where ρ_D is the areal track density on the external detector attached to the standard uranium glass, and B is a proportionality constant.

If the age standard mineral is employed in dating, whose age is known to be T_{st} , the ratio of track density for spontaneous to induced fission is $(\rho_s/\rho_i)_{st}$, and assuming that $l_i \approx l_s \approx 0$, $\theta_{ci} \approx \theta_{cs}$, $R_i \approx R_s$, $C_{235}/C_{238} = I$, Eq. (3.53) becomes:

$$T_{st} = \frac{1}{\lambda_D} \ln \left\{ 1 + \frac{\lambda_D B \rho_D \hat{\sigma} I G \left(\frac{\rho_s}{\rho_i} \right)_{st}}{\lambda_f} \right\} \quad (3.59)$$

If we let

$$\zeta = \frac{B \hat{\sigma} I}{\lambda_f} \quad (3.60)$$

we have

$$T_{st} = \frac{1}{\lambda_D} \ln \left\{ 1 + \lambda_D \rho_D \zeta G \left(\frac{\rho_s}{\rho_i} \right)_{st} \right\} \quad (3.61)$$

$$\zeta = \frac{(e^{\lambda_D T_{st}} - 1)}{\lambda_D (\rho_s/\rho_i)_{st} G \rho_d} \quad (3.62)$$

b. ζ value

For a given age standard, ζ is approximately a constant. The minor difference would come from: (1) different external detectors used, whose $\theta_{ci} \neq \theta_{cs}$, (2) different etching conditions adopted where $l_s \neq 0$, and (3) differences in subjective judgments by different workers for the numbers of spontaneous and induced tracks.

Once the ζ value is obtained, the age of unknown sample can be determined after co-irradiation with the standard uranium glass from Eq. (3.61), but all the quantities in Eq. (3.61) change to unknown quantities: $Tu = 1/\lambda_D \ln\{1 + \lambda_D \rho_D u \zeta G(\rho_s/\rho_i)u\}$, where the letter “ u ” indicates that the quantities are for unknown sample and the track density for uranium glass is for the irradiation with unknown sample.

The Zeta approach has been demonstrated to be a good way to train newcomers into the FTD field. It forces them to count tracks correctly so that the determined age is close to the real age. Zeta approach is a relative method of determination of age and it relies on the age value of the age standard mineral, which was dated by other isotopic techniques. Therefore, it is not an independent dating method.

The age standards proposed and adopted by the FTD community are listed in Table 3.8.

It should be noted that the age obtained by ζ approach is an apparent age of the mineral. In the case where track

annealing occurred in the history, age correction for track annealing must be made.

3. LA-ICP-MS-based fission track dating

FTD has provided a great amount of age data in geology, archeology, and thermochronology. However, it has two problems. The first problem is the need of irradiation with nuclear reactor. After irradiation, the samples and the devices used for irradiation are heavily activated. The second problem is that the dating cycle is quite long. Several weeks even several months are needed to cool down the radioactivity. Even if one waited for the cooling down, the samples and the devices will still have residual radioactivity, which is also harmful to workers. The main purpose of reactor irradiation is to determine the number of atoms of ^{238}U in the sample (mineral). Another advantage of reactor irradiation is to cancel the two detection efficiencies of the mineral and the external detector for fission fragments. However, the irradiation is troublesome for dating practice.

In order to solve the problems above, some scientists intended to use laser ablation inductively coupled plasma spectrometry (LA-ICP-MS) to determine the number of atoms of ^{238}U in the mineral to avoid nuclear reactor irradiation of samples.

a. Age equation

The basic equation for age determination is simple.

$$N_S = N_{238} \lambda_F T \varepsilon \quad (3.63)$$

where N_S is the number of spontaneous fission tracks of ^{238}U , N_{238} the number of atoms of ^{238}U , λ_F the decay constant of spontaneous fission of ^{238}U , T the age of the mineral, ε the detection efficiency of internal surface of the mineral for spontaneous fission fragments of ^{238}U .

If one adopts the absolute approach for dating as explained in the previous section, one can write the following equation (Soares et al., 2014):

$$T = \frac{1}{\lambda_D} \ln \left[1 + \frac{\lambda_D}{\lambda_F} \frac{1}{g_{4\pi}[\eta q]_{IS} r_S} \frac{\rho_S}{N_{238}} \right] \quad (3.64)$$

where $g_{4\pi}$ is the geometry factor for an internal surface of the mineral ($g_{4\pi} = 1$), $[\eta q]_{is}$ is the detection efficiency of the internal surface of the mineral for the spontaneous fission tracks of ^{238}U in the mineral, $[\eta q]_{is} = \epsilon$ for the special geometry, r_s is the mean length of horizontal confined spontaneous fission tracks, and ρ_s is the spontaneous fission track density in the polished surface. The other parameters are the same as previously defined.

If one adopts the *Zeta* approach, one can write the following equation:

$$T = \frac{1}{\lambda_D} \ln \left[1 + \zeta_{ICPMS} \frac{1}{[\eta q]_{is} r_s} \frac{\rho_s}{238_U} \right] \quad (3.65)$$

where

$$\zeta_{ICOMS} = \frac{\lambda_D}{\lambda_F} \frac{M}{g_{4\pi} \cdot N_A \cdot 10^{-6} \cdot d} \quad (3.66)$$

where ζ_{ICOMS} is a constant for the mineral, ρ_s is the spontaneous fission track density in the internal surface of the mineral, M is the isotopic weight of ^{238}U , N_A is the Avogadro constant, and d is the average density of the mineral ($d = 3.19 \text{ g/cm}^3$ for apatite).

b. Determination of ^{238}U content in mineral by LA-ICP-MS

It is not easy to determine the content of ^{238}U in minerals by LA-ICP-MS. There are two difficulties for this determination:

- (1) U occurs in minerals in a minute amount of the element. For apatite, $\text{Ca}_5(\text{F,Cl})(\text{PO}_4)_3$, the often adopted mineral in FTD, the content of U is about 10^{-5} g/g . Within one instrument, such as a LA-ICP-MS, the measurement of two compositions simultaneously with the number of the other elements which differ greatly in amount, is difficult. In other words, to count accurately the number of atoms of uranium (^{238}U) with the counting of the huge number of the other atoms (Ca, F, Cl, P, and O) in the MS, is very difficult.
- (2) The mass of the atoms of ^{238}U is much heavier than that of the atoms of the main compositions of the minerals (Ca, F, Cl, P, and O). It is difficult to collect different ions of the atoms of the elements with so big differences in masses (238–16 for O). In order to reduce the differences, one must find some way to overcome the obstacles.

c. Determination of ^{43}Ca to derive the effective mass of minerals

Soares et al. (2014) tried to use ^{43}Ca as a representative of the atoms of minerals and a bridge between U and the mineral atoms to determine ^{238}U content. Fortunately, they dated the mineral (apatite) by using LA-ICP-MS.

d. Determination of detection efficiency of internal surface for spontaneous fission fragments

Soares et al. (2014) adopted the technique horizontal projected confined track method to determine the detection efficiency of the internal surface of apatite for spontaneous fission fragments of ^{238}U (Jonckheere and Ven den haute, 1999, 2002). Their results of dating are in agreement with that by other methods. This work shows that LA-ICP-MS may be used in FTD to avoid using nuclear reactors in the future. Certainly, one should make more improvements in dating processes to ensure that every step is reliable.

4. Continental drift and ocean-bottom spreading

One of the most prominent achievements of FTD is the direct demonstration of the conjectures of continental drift and ocean bottom spreading by dating the ages of the basalts taken at different distances from the Median Valley in the Atlantic Ocean where lava rose out from the interior of the earth and cooled down forming the basalts. The fission track ages of basalts increase as the distance increases from the Median Valley, which is consistent with the K–Ar age, but ruled out some of the spurious ages of K–Ar dating. Both fission track and K–Ar dating showed that the American and African continents are moving apart from each other and the ocean bottom is spreading about 3 cm/a in more recent time since about 2 Ma ago. The old spreading rate is much slower, which was about 0.6 cm/a before 2 Ma ago (Fleischer et al., 1968, 1971 and 1975).

5. Archeology and anthropology

One of the advantages of FTD is the wide range of age from about 10^5 to 10^9 years which can be dated, especially in the range from 10^5 to several million years. In this very young range of age, other dating techniques have some deficiencies. FTD is almost unique in some cases.

a. Fission track dating of ancient man in Bed I, Olduvai Gorge, East Africa

One of the best examples of dating ancient man is in East Africa. FTD of volcanic pumice from Bed I, Olduvai Gorge showed that ancient man *Zinjanthropus* lived 2.0 (± 0.3) Ma ago (Fleischer et al., 1965c, 1965e), which is in agreement with the age 1.75 (± 0.05) Ma by K–Ar dating (Fleischer et al., 1975). The dating by K–Ar was originally treated as unbelievable, but the agreement by FTD made this site to be regarded as one of the best-dated of the anthropological sites. Consequently, it was established that the earliest man up to now is believed to be *Zinjanthropus*.

b. Dating of Peking Man

The first skull of Peking Man Site at Zhoukoudian near Beijing, China, was discovered in 1929. The model of Peking Man is shown in Fig. 3.49. About 50 years transpired since the skull was discovered before the first dating of the site by fission tracks in 1979. The difficulty of dating the site was caused by the lack of suitable materials in the deposited cave. Guo et al. (1980) separated sphenes, a kind of fine minerals of 50–300 μm size from the ashes left by Peking Man for FTD. The sphenes minerals were burnt to high temperature in the fire made by Peking Man. The original ^{238}U spontaneous fission tracks recorded in the sphenes before firing were completely annealed out. New spontaneous fission tracks formed after firing were used to date Peking Man. The age of the Peking Man Site at layer 10 of Locality 1 is $0.462 (\pm 0.045)$ Ma (Guo et al., 1980, 1982a) and layer 4 of Locality 1 is $0.299 (\pm 0.055)$ Ma. It should be noted that the annealing degree of fission tracks in each grain of the sphenes was judged individually (Guo et al., 1980, 1982a). This is one of the advantages of FTD over other dating techniques.

c. Dating of ancient man in Baise, China

More than 50 years ago Harvard University anthropologist Hallam Movius divided the peoples of the Early Stone Age into two cultures: those who could make sophisticated, two-sided stone hand axes, known as Acheulean or mode 2 technology and those who could not. This invisible technological barrier, which came to be known as Movius's line, separated handy *Homo erectus* in Africa, the Middle East, and Europe from their less-adept cousins in Asia, who left only mode I technology such as, simple stone flakes and cobbles used for chopping. Movius therefore wrote off

FIG. 3.49 Restored figure of Peking Man. For the color version of the figure, the reader is referred to the online version of the book.

the entire Asian continent as “a marginal region of cultural retardation”. Because the climate and terrain in the forests of Asia remained stable for the past 2 million years, Movius wrote, humans there did not advance in culture but stayed backward for eons (Gibbons, 1998). In the 1980–90s, archeologists discovered a large number of bifacial hand axes in the Baise basin in South China. Tektites were also found in the undisturbed primitive layer of deposits (red soil or laterite) within which bifacial hand axes were found nearby tektites.

Fig. 3.50A shows two photographs of the two sides of a bifacial hand axe and Fig. 3.50B shows a photograph of tektite found in the same layer of the red soil.

Guo et al. (1996, 1997) used the fission track method to date the tektite. Their result after correction for track fading was 0.732 ± 0.039 Ma, about the same age as the Australia–Indochina tektite fall. This age is also similar to the reversal time of the geomagnetic field from the Matuyama epoch to the Brunhes epoch (0.789 ± 0.008 Ma), which led Guo and coworkers to conjecture that impacts of space objects on the Earth might cause at least some reversals of the geomagnetic field (Price, 2008).

The dating result also shows that at least a few early Asians were also making two-sided, or bifacial, stone tools as much as 730,000 years ago. Gibbons (1998) wrote a paper in “Science” announcing that “the Movius line is breached” by the discovery and dating of the bifacial hand axes and tektites in the Baise basin.

For more information about FTD, the reader is referred to the series of proceedings of Fission Track Dating Symposiums and the articles by Yuan et al. (2009), Hadler et al. (2009), Shen et al. (2009) and the book by (Wagner and Van den haute, 1992).

6. Tectonic up-Lift rate determination

a. Retention temperature of minerals

Fission tracks are very sensitive to temperature. If the temperature is higher than the effective retention temperature T_r of the mineral, the tracks will be annealed away. Only when the temperature drops to lower than T_r , the tracks can be retained. Different minerals have different T_r values. For apatite, $T_r = 100 \pm 20^\circ\text{C}$; Zircon, $210 \pm 40^\circ\text{C}$; epidote, $240 \pm 40^\circ\text{C}$; sphenes, $250 \pm 40^\circ\text{C}$; garnet, $270 \pm 30^\circ\text{C}$ (Wagner and Van den haute, 1992).

b. Height difference method

For geological reasons, some mountains are rising up. For example, Himalayan mountains are rising up as a result of the thrusting of the Indian continental block toward the Tibet–Qinghai crust. The Qinling mountains in central China are rising by the clash between the Southern China and Northern China blocks.

FIG. 3.50 Photograph of (A) bifacial hand axe (two sided, the two photographs in (A) were taken from two sides of the same hand axe) excavated from Baise basin, South China, and (B) a tektite found within the same layer as the axe. For the color version of the figure, the reader is referred to the online version of the book.

The rising of the Himalayan mountains stops the humid air from the Indian plain from reaching the Tibet–Qinghai plateau, resulting in a dry and cold climate in the Tibet–Qinghai plateau.

Similarly, the Qinling mountains stop humid air from the south from reaching the north, resulting in a dry climate and the loess (yellow soil) in North China. At the same time, the Qinling mountains prevent the south from attack by the dry wind from the north.

Chen et al. (2001) measured the uplift rate of the Taibai mountains (the western part of the Qinling mountains) by fission tracks in apatites and determined that the Taibai mountains were formed around 40 Ma ago (according to apatite apparent age). The uplift rate by height difference over age difference was about 130 m/Ma in the first stage from 40 Ma to about 35.5 Ma. Then, the overburden on the mountains started a denudation accompanying the uplift. The sum of the uplift rate plus denudation rate was 430 m/Ma.

c. Mineral pair method

Yin et al. (2001) determined the uplift rate of the highest peak of Hua mountains (the east part of the Qinling mountains) by the height difference method (apatites) and mineral pair method (apatite and zircon), that is:

$$V = \frac{T_r(\text{Zircon}) - T_r(\text{Apatite})}{t_{\text{Zircon}} - t_{\text{Apatite}}} / \text{geothermal gradient}$$

where V is the uplift rate, T_r is the effective retention temperature, t is the age of the mineral by FTD, and the geothermal gradient was taken as 35°C/km. The effective retention temperatures were taken as 110°C and 220°C for apatite and zircon, respectively. It shows that the Hua mountains started rising 68.2 Ma ago according to the

zircon apparent age, which is equivalent to about 41 Ma of the apatite apparent age.

The average uplift rates were determined to be 120 m/Ma and 140 m/Ma, respectively by the height difference method and the mineral pair method.

The whole Qinling mountains including Taibai and Hua mountains are growing year by year. It is bad for North China but good for South China.

B. Geothermal chronology

The temperature in a room can be measured by a thermometer. What thermometer can measure the temperature in the deep underground, especially in ancient time and the temperature as a function of time (year)? The answer is ^{238}U spontaneous fission tracks.

Latent fission tracks are sensitive to temperature. At normal temperature, fission tracks are stable for a long time. But at higher temperature track fading occurs, latent fission tracks shrink in etchable lengths and gradually disappear.

The degree of fading depends on two factors: temperature and time. The higher is the temperature, the faster is the fading. The longer the time at higher temperature, the greater is the shrinkage of the track length.

In minerals, ^{238}U spontaneous fission tracks are continually generated with time. At the same time, track fading accompanies every track. The first track suffered the longest history of heating. Its length is the shortest. The last track was created just a moment ago. It suffered the shortest history of heating. Its length remains intact. Every track records the thermal history of its own. An analysis of the track length distribution in the mineral will provide information on the whole thermal history experienced by the mineral (Lutz and Omar, 1991; Chambaudet et al., 1993; Wang et al., 1993).

In a retrieving test of geothermal history (Guo et al., 1999), a mono constant activation energy E_0 was used for the isothermal annealing process:

$$l = l_s \exp\{-\alpha_0 \Delta\tau \exp[-E_0 / (k\theta)]\} \quad (3.67)$$

or

$$\theta = \frac{E_0}{k \ln \left[\frac{\alpha_0 \Delta\tau}{\ln(l_s/l)} \right]} \quad (3.68)$$

where l is the length of track at the end of the isothermal annealing interval, l_s is the length of track at the beginning of isothermal annealing interval, $\Delta\tau$ is the length of time of the isothermal annealing interval, θ is the temperature of isothermal annealing, α_0 is the coefficient of annealing, and k is the Boltzmann constant.

Before making the calculation (inverse modeling), the track length distribution is obtained by careful measurements. The whole range of distribution is divided into many small intervals. In each interval, the temperature is regarded as a constant (isothermal annealing process). The corresponding time length of the small interval can be calculated as

$$d\tau = \omega(l)dl/b(\tau) \quad (3.69)$$

where $d\tau$ is the differential form of $\Delta\tau$, dl is the differential form of Δl , $\Delta l = l_s - l$, the length of the small interval, $b(\tau)$ is the effective generation rate of ^{238}U spontaneous fission at time τ , $\omega(l)$ is the track density in the small interval having track length l , and $b(\tau)$ is calculated by the equation:

$$\int_0^T b(\tau)d\tau = \int_0^\infty \omega(l)dl \quad (3.70)$$

where T is the age of the mineral for retaining tracks.

From Eqs. (3.68), (3.69), and (3.70) one can calculate the temperature θ and the time τ of each small interval. Thus, one determines the ancient temperature θ as a function of time (age) τ .

The results of retrieved (inverse modeling) temperature is consistent with that by the smoke convection model developed by Chambaudet et al. (1993) and in agreement with that by a direct modeling from thermal history to track length distribution (Guo et al., 1999).

C. Uranium and oil exploration and earthquake prediction

Radon is harmful to human health, but sometimes, it provides valuable information about the underground resources of uranium, petroleum, and natural gas.

The technique of radon measurement used for geological purpose is similar to that for radon dosimetry. Additional schemes are required for geological investigations.

For uranium exploration, first one must select a promising uranium-bearing area designated by geologists. Then, a grid pattern is set with distance about 50 meters (or closer if necessary) between neighboring grid-points. At each grid-point, plastic track detectors (CR-39 or LR-115) inside cups are buried at a small distance below the surface of the soil. After several weeks the CR-39 sheets are collected, etched and the tracks counted. The track densities on the detectors over uranium ores should be higher than those in surrounding areas deficient in ore deposits. In uranium ores, more radon (^{222}Rn) is produced from ^{226}Ra , which is the progeny of ^{238}U . The radon gaseous atoms will diffuse upwards to the surface of the soil. According to measurements, the diffusion length of ^{222}Rn in soil is about 1.2 m. If a uranium ore contains 10^4 times more uranium than that of common earth's crust rocks, the radioactivity of the ^{222}Rn from the ore will reach the background level of the crust rocks after diffusion to a distance ~ 12 m. It means that uranium ore at more than 12 m depth will not be detected. However, Fleischer et al. (1980) located uranium ore at 100 m depth. How can ^{222}Rn move such a long distance (100 meters in depth)?

There is evidence that the radon transport is faster than that expected by simple diffusion of radon gas in the earth. Some upward bulk flow of radon-bearing air must be occurring underground. The possible source of upward flow motion is fluid convection caused by nonuniformity in geothermal distribution. The ore body has a higher temperature and produces more radon gas. The air above the ore increases in buoyance than the surrounding area (Fleischer, 1998; Durrani and Bull, 1987; Durrani and Ilic, 1997).

For petroleum or gas exploration, the method of the deployment of a nuclear track detector (CR-39 or LR-115) is similar to that for uranium exploration and the selection of the area must be guided by geologists. The upward air flow around the oil-bearing structure is caused by the leakage of oil vapor from the edge of the structure shaped like a big bowl placed upside down similar to a dome (Fleischer, 1988, 1998; Durrani and Bull, 1987).

The detection of α particles from radon can also serve as a tool for the prediction of an earthquake. The basic technique is similar to that used in uranium exploration, but the deployment of CR-39 detectors is on the seismic belt. Unusual subterranean activity and possibly attendant fissures and strains result in release of larger quantities of radon gas from the U and Th content of the earth's crust than at normal conditions. The radon intensities, once measured in the underground soil at three prediction stations, exhibited a significant increase starting 6 weeks prior to a $M_s = 6.3$ magnitude of earthquake even at a 178 km distance from the epicenter (Fleischer and Mogro-Campero, 1985; Fleischer, 1988).

Fission track uranium exploration was developed based on hydrogeochemical prospecting of uranium. The original prospecting adopted a fluoro-colorimeter and a laser-fluorometer for the determination of uranium. After testing the application of the fission track technique, it was found that the fission track measurement of uranium is more sensitive than the other two instruments.

Uranium readily forms compounds dissolvable in water. Due to groundwater movement, uranium in ores disperses outward to form uranium-rich halos around the ores. Nearly all uranium ores have uranium-rich halos around them. The uranium-rich halos can be found in the field by uranium determination in ground and surface water.

A small droplet (5 μm) of ground or surface water is picked at each point in the field and dropped onto a small piece of polycarbonate (PC) sheet. After drying the water, the uranium contained in the water is deposited in the residue on the surface of the PC sheet. It is covered with another PC sheet to form a specimen. Many specimens are made at many points which are distributed in the field as a grid net. These specimens are packed together and put into a nuclear reactor core for neutron irradiation. Thermal neutrons induce fissions of ^{235}U in the specimens. The fission fragments are recorded in the PC sheets. After etching and counting the tracks, the distribution of uranium concentration is mapped and uranium-rich halos can be found on the map.

The fission track technique has been found to be the most sensitive method in the determination of uranium in natural water. Its sensitivity reaches 10^{-12} g/g, while the sensitivity is $\sim 10^{-11}$ g/g for laser-fluorometry and $\sim 5 \times 10^{-11}$ g/g for fluoro-colorimetry (Guo et al., 1986c). Fission track detectors are considered among the best sensors for uranium ore.

A test exploration of uranium ore with fission track technique showed that several regions have been found to be rich in uranium. The distinction of different regions is clearer by fission tracks than by laser-fluorometry, while fluoro-colorimetry was senseless to the difference. A region outlined by fission tracks was excavated and identified to have a uranium ore in underground deposits (Guo, 1993; Guo et al., 1992).

IV. Life and environmental sciences

A. Radiation protection dosimetry

1. Radon and thoron monitoring and dosimetry

Radon (^{222}Rn) and thoron (^{220}Rn) are produced in the decay series of ^{238}U and ^{232}Th , respectively. The latter nuclear species ^{238}U and ^{232}Th exist ubiquitously on the earth in rocks, soils, building materials, and waters. ^{222}Rn and ^{220}Rn are inert gases, which diffuse through all kinds of materials: solids, liquids, and gases, and may undergo rapid convection

under the influence of external flows or pressure. It has been estimated that α decays of radon and thoron and their progeny contribute more than 55% of the annual effective dose equivalent (μSv) to the general population in the world from all sources of ionizing radiation exposure (ATSDR, 1999; Lowder, 1990, 1993). It is a big hazard to mankind. For this reason, a worldwide investigation is underway to monitor radon and thoron concentrations in houses, mines, caves, and all places where mankind can reach. There are two types of radon monitoring devices: active and passive detectors. The active detector, such as the silicon solid detector, can get results of radon concentrations very quickly, but for long-term monitoring, it is not so easy as the SSNTD, such as LR-115 and CR-39. The quantities, which can be measured for radon α detection with the track detector, include radon concentration in indoor air, open air, mines, working places, caves, and in natural water; radon emanation rate, or exhalation rate from various substances, such as rocks, soils, all kinds of building materials; radon diffusion rates through various materials; and radon dosimetry evaluation (Baixeras et al., 2005; Font, 2009; Font et al., 2008; Narula et al., 2009a, 2009b; Chauhan et al., 2006, 2008; Eappen and Mayya, 2004; Shweikani and Raja, 2009; Kumar et al., 2008; Chauhan and Chakarrarti, 2002; Nain et al., 2006, 2008; Mahur et al., 2005; Mayya, 2004; Kant et al., 2006; Mujahid et al., 2005; Abumurad and Al-Omari, 2008; Urosevic and Nikezic, 2003; Tian and Xiao, 1994; Xiao et al., 2001; Yang et al., 2002; Yang, 2007; Chen et al., 2006; Shang et al., 2006; Nikolaev, 2015; Nikezic et al., 2009).

2. Neutron dosimetry

a. Bonner neutron rem counter

Alpha-particle recording from the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ reaction with CR-39 detector has been used in the neutron Bonner rem counter for neutron dosimetry (Agosteo et al., 2010, 2009, 2007). Its sensitivity ranges from thermal energies up to 1 GeV of neutrons. The Bonner rem counter is composed of outer polyethylene sphere with lead shell, seven cadmium buttons and inner shell of polyethylene. Passive CR-39 and enriched ^{10}B converter are plugged inside the inner polyethylene shell. Adjusting the thicknesses of the outer and inner shells and the size of the cadmium buttons, Agosteo et al. (2010) has optimized the response function close to the $H^*(10)/\Phi$ fluence to ambient dose equivalent conversion coefficients in the whole range from thermal to 1 GeV neutrons. The calibration factor of the rem counter is 6.91 ± 0.45 tracks/($\text{cm}^2 \mu\text{Sv}$). The rem counter has been demonstrated to be able to measure the cosmic neutron background and to give nonzero background when used in environmental monitoring applications. This rem counter is suitable for routine radiation safety monitoring in public areas around particle accelerators. This counter does not

suffer from α pulse pile-up and γ -ray background in neutron- γ -ray mixed fields.

Kralik et al. (2008, 2010) used CR-39 sheets sandwiched with ^{10}B radiators in 10 Bonner sphere spectrometers (BSSs) with different diameters to measure the response of each BSS and unfold the responses from all the BSS. They obtained the energy spectra of photoneutrons at the therapeutic accelerator. See Chapter 9, Volume 1 of this book for additional information on BSSs.

b. Recoiling carbon and oxygen nuclei method

Wang et al. (1998) have suggested a method by measuring the major and minor axes of the track opening and the depth of the track tips of recoiled carbon and oxygen nuclei in CR-39 by fast neutrons to determine $V (= V_t/V_B)$ and to obtain a REL spectrum. They combine the REL spectrum with the differential recoiling cross sections of neutrons with carbon and oxygen nuclei to separate the REL spectrum to carbon and oxygen and use computer simulation to find the true neutron energy spectrum.

c. Radiator-Degrader-CR-39 method

Aslam et al. (1988), Dajko (1990), Durrani et al. (1988), Wan et al. (2003) and Oda et al. (2009) have studied the Radiator-Degrader-CR-39 assembly as a neutron energy spectrometer. Fast neutrons induce proton recoils in the radiator (polyethylene). If the energy of the recoil protons is high enough, the protons will pass through the degrader (a foil of Pb, Au or Al) and reach the CR-39 detector. If the energy of the protons after the degrader is in the range of the energy window of CR-39 detector, the protons will be recorded as tracks in the CR-39. Therefore, each thickness of the degrader corresponds to an energy interval of protons. By using a group of thickness of degrader, one can compose a neutron energy spectrum. Wan et al. (2003) have made a Monte Carlo program to simulate this process and reached an agreement with the experiments by Durrani et al. (1988).

d. Bonner spheres spectrometer filled with boron radiators plus CR-39

An upsurge in research on Bonner spheres filled with boron radiators plus CR-39 detectors is evident in laboratories. Kralik et al. (2010) used a series of diameters of Bonner Spheres: 3, 3.5, 4, 4.5, 5, 6, 7, 8, 10, and 12 inches (1 inch = 2.54 cm) to compose the spectrometer. They used the GRAVEL Code from the UMC3.3 Package (Reginatto, 2004) to unfold the spectrum.

Similar Bonner spheres have been built in Barcelona (Fernandez et al., 2007) in Frascati (Bedogni et al., 2010), in which CR-39, TLD, Au foil and other types of passive detectors are used. (Domingo et al., 2010).

B. Environmental sciences

1. Radioactive fallout from nuclear accidents

In the processes of production and transportation of nuclear fuel (U and Pu), or in serious nuclear accidents, or in the detonation of nuclear weapons, small amounts or a large number of radioactive solid particles containing U or Pu will be produced, which mostly have sizes from several tens of nanometers (nm) to several hundreds of micrometers (μm). The particles less than several micrometers can be suspended in air for very long time, which are referred to as aerosols. These particles fall out onto the surface of the earth due to their gravity or rainfall. The larger particles are deposited more easily onto the earth's surface. Because all of these particles carry radioactivity, they are often called radioactive fallout as a whole, or hot particles as individuals. These particles, such as those exploded from the Chernobyl nuclear reactor, from uranium mining combinations, or from testing of nuclear weapons, results in serious environmental contamination and are harmful to human health. One of the main species of radioactivities of these hot particles is alpha radioactivity. SSNTDs, such as CR-39 and LR-115, are used to record tracks of α particles emitted from the hot particles. If one covers a sheet of track detector on a sample containing the hot particles, a specific feature of the tracks formed by a hot particle shapes like a sunburst or star of tracks on the surface of the track detector. The α particles are emitted isotropically from the hot particle. If one extrapolates all the tracks, they will approximately intersect at one point where the hot particle is located. This feature makes it easy to find and to locate a hot particle among a huge number of common dust or common aerosol particles. Counting the α tracks allows one to derive the α radioactivity of the hot particle. If the isotopic composition is known, one can derive the amount of radioactive nuclei in the hot particle. In a brief summary, with the use of a SSNTD, one can find, locate and estimate the intensity of radioactivity and roughly derive the amount of radionuclides in the aerosol particle. The problem is that one must wait for a relative long time to make the exposure of α particles, usually several days depending on the intensity of the α particle emissions.

Another scheme involves combining α track counting with fission track counting. In other words, after α exposure of one sheet of track detector to the hot particles, another sheet of track detector is put on the same sample having the hot particles. The whole sandwich is inserted into the core of a nuclear reactor for irradiation with thermal neutrons. The thermal neutrons induce fission of ^{235}U or ^{239}Pu in the hot particles. The fission fragments are recorded by the track detector. After etching the detector, the tracks of fission fragments emitted from the same hot particle are counted, whose distribution is similar

to the α tracks like a star, but the tracks are much longer than the α tracks.

Measuring the fluence of thermal neutrons irradiated to the hot particle and counting the tracks of fission fragments, one can derive the number of atoms of uranium (U) or plutonium (Pu) in the hot particle.

For a given hot particle with special composition of isotopes, the number of fission tracks irradiated at constant neutron fluence and the number of α particle tracks at constant exposure time are both constants. All of the hot particles with the same composition of isotopes will fall on a straight line in the figure of the number of fission tracks versus the number of α tracks, if their irradiation in the nuclear reactor and exposure to α particles are both the same, respectively.

Fig. 3.51 shows the straight lines of natural uranium (U) and ^{239}Pu under the conditions of thermal neutrons ($1 \times 10^{15} \text{ n/cm}^2$) and α exposure time (1 h).

Comparing the results of measurements for an unknown hot particle with the straight lines, one can roughly infer the composition, origin and migration information of the hot particle (Vlasova et al., 2008). For more exact information about the composition, origin and migration of the hot particle, one can use a SEM with energy disperse x-ray spectrometry (EDX) to measure the elemental composition, and secondary ion mass-spectrometer (SIMS) to analyze the isotopic composition, and silicon semiconductor detector to measure the α particle energy (Vlasova et al., 2008). All of the above measurements must use the same hot particle, which can be located and relocated in each instrument by its α tracks or fission tracks in the track detectors. The movements of the hot particle from one instrument to another can be performed with a micro-manipulator.

FIG. 3.51 The straight lines of natural ^{238}U and ^{239}Pu under the conditions of thermal neutrons ($1 \times 10^{15} \text{ n/cm}^2$) and α exposure time (1 h). From Vlasova et al. (2008); printed with permission from Elsevier © 2008.

An α particle track investigation in soil samples from the region of the Chernobyl nuclear power plant accident was carried out (Kashkarov et al., 1995, 2003; Bondarenko et al., 1995). The investigation showed that at least four groups of α -hot particles can be identified. The first group consists of the smallest ($\leq 5 \mu\text{m}$) hot particles with a very high α activity ($\leq 10 \text{ Bq/particle}$); the second group is characterized by size $8\text{--}12 \mu\text{m}$ and activity $1\text{--}5 \text{ Bq/particle}$; the third and fourth groups are aggregates of hot particles with soil dust. The results showed that the major process of the formation of the hot particles was high-temperature melting and explosion of reactor core substance in the Chernobyl nuclear power plant and subsequent fast cooling of the hot particles, which formed the first and second groups of high α -intensity hot particles with small sizes. Afterward, aggregates of the hot particles with soil dust were formed. The hot particles (aerosols) fell out gradually from the air and deposited onto the soils. The number of the fallout hot particles in the soil decreases with increase of the distance from the nuclear power plant (Dushin et al., 1995).

Nuclear weapons testing at the Nevada test site (Mercury, Nevada, USA) formed a tremendous amount of hot particles with α -radioactivity. CR-39 detectors pressed tightly onto the surface of the soil sample for several days had provided the information of α radioactivities in the soils in the area. It showed that α radioactivity reached a maximum value in the depth between 0 and 5 cm beneath the surface of the soils (Espinosa et al., 1995).

2. Drainage contamination of nuclear plants

Hot particles with α radioactivity are always more or less produced in nuclear plants. A solid-state track detector sensitive to α particles can be used to measure the density of the hot particles in the working places and surrounding environments. The techniques used in this type of measurement are similar to those used in the investigation for the fallout of hot particles from nuclear disasters like Chernobyl. Detailed investigations have been carried out with track techniques among other techniques for the measurement of contamination of the Yenisey River bottom sediments near the Krasnoyarsk Mining and Chemical Combine in Siberia, Russia (Vlasova et al., 2008, 2015; Pavlotskaya et al., 2003; Baskaran et al., 1995; Bolsunovsky and Tcherkezian, 2001; Linnik et al., 2006).

V. Nanotechnology and radiation induced material modifications

This field of science includes: (1) nuclear track membranes, (2) microstructures, (3) nanostructures, and (4) material modifications. All these fields are derivatives from

SSNTDs. These fields developed rapidly since the 1980s. In light of these developments, the nuclear track community changed the name of the series of international conferences from Solid State Nuclear Track Detectors to Nuclear Tracks in Solids in 1992, because the micro- or nanodevice is no longer a detector for recording radiation. Micro- or nanostructures might be used as detectors in the future, but not in the present. The interested reader is referred to the treatise “Ion Tracks and Microtechnology, Principles and Applications” by Reimar Spohr (1990) and the review papers by Chakravarti (2009), Fink et al. (2008), Spohr (2008), Apel et al. (2008), and articles: Liu et al. (2006); He and Guo (2015); Yang et al. (2018); Lounis-Mokrani et al. (2003); Mishra et al. (2003); Severin et al. (2005); Sun et al. (2004); Vater, 1988; Vonderau et al. (1995); Zhu et al. (1988); Guo (1998); Wang et al. (2018); Shakeri Jooybari et al. (2015); Shakeri Jooybari et al. (2015a); Zagorskiy et al. Acknowledgments

The authors wish to thank Michael F. L’Annunziata for his careful correction of the manuscript sentence by sentence and giving valuable help and suggestions at every stage in finishing the manuscript. The authors also thank Academician Prof. Wang Yannai and Prof. Guo Bing in China Institute of Atomic Energy (CIAE) for their help and support in drafting the manuscript. The authors are also grateful to Liu Senlin, Wang Chen, Shen Yan, Chen Yan, Liu Fulong, Tian Baoxian, Huang Haiyan, and Guo Li in CIAE and Zhang Yanxia in National Library of China for their generous help in preparation of the manuscript.
