Shi-Lun Guo

Shi-Lun Guo is a professor in the China Institute of Atomic Energy (CIAE), former President of the International Nuclear Track Society (INTS) and honorary member of the INTS. He was born in Hebei, China in 1937 and graduated in Zhengzhou University in China in 1961 and then joined the CIAE. He initiated studies on solid state nuclear track detectors (SSNTD) in the CIAE in 1965 and continued in the University of California at Berkeley in USA in 1982–4 and Kernchemie, Universitat Marburg, Germany in 1984, 1985, 1988 and 1990. He established the first laboratory on fission track dating (FTD) in China in 1975 and determined the age of Peking Man by ancient ashes from which grains of mineral sphene annealed completely by Peking Man were identified and used. He worked on nuclear track membranes (NTMs) and applied it to the determination of solute concentrations in various solutions and removal of bacteria from water and removal of solid particles from liquid medical injections. He created a new field of bubble detectors (BD) for recording tracks of high energy heavy ions. He is working on nuclear forensics and nuclear nonproliferation with fission- and α -tracks and on laser acceleration with CR-39 detectors. He has published more than 200 scientific articles in journals and won 2 awards by the National Congress of Science and Technology of China in 1978 and 5 awards by the China

National Nuclear Corporation and the People's Liberation Army of China.

Bao-Liu Chen

Bao-Liu Chen is an associate professor in the China Institute of Atomic Energy (CIAE). He was born in Fujian, China in October 1968 and graduated from East China University of Geology in 1989. In the early 1990s he participated in dating of the Baise (Bose) archaeological site in South China by fission tracks in tektites imbedded in undisturbed stratum containing bifacial stone artifacts (bifacial hand axe) made by ancient man with the measured age 0.732 Ma. This result breached “the Movius Line” theory in paleoanthropology. He was in charge of dating by fission tracks and determining the uplift rate of the Qinling mountains in Central China and demonstrated that the Qinling mountains are still uplifting till now, which will exert an increasing influence upon climates in South and North China. He undertook the preparation of bubble detectors for detecting and identifying high-energy heavy ion tracks in collaboration between China and Japan. He is also specialized in oil field logging, radioisotope tracing and γ -ray tower scanning. He has quite a number of scientific publications, patents and is a winner of awards in science and technology from the China National Nuclear Corporation.

I. Introduction

A. The gas-filled ionization chamber

A semiconductor detector can be best compared with a classical ionization chamber described elsewhere in this book (Chapter 3). A schematic diagram of such an ionization chamber is given in Fig. 4.1. It consists essentially of a gas-filled (Kr, Xe, ...) capacitor to which a bias (H.T.) is applied. An ionizing particle (alpha, p, d, beta, ...) will create a certain number N of pairs of positive ions and electrons, where N is given by

$$N = \frac{E}{\epsilon} \quad (4.1)$$

where E represents the kinetic energy of the particle and ϵ the energy necessary to create one ion–electron pair.

To act as a spectrometer (i.e., an instrument able to count the number of entering particles and to measure their energy), an ionization chamber must fulfill three basic conditions:

1. The ionizing particle must lose all its kinetic energy inside the sensitive volume of the detector.
2. All created charges must be collected by the applied bias and contribute to the pulse formation.
3. In the absence of any ionizing particles, no charges may be collected by the electric field.

B. The semiconductor detector

A reverse-biased p-n or p-i-n Ge or Si diode fulfills all three of these basic conditions to function as a solid-state ionization chamber (Fig. 4.2). Indeed, the intrinsic or depleted region of the junction acts as the sensitive volume, and the whole may be regarded as a capacitor having a (small) leakage current between the p+ and n+ contacts in the absence of any ionizing radiation. From an electronic point

FIGURE 4.1 Schematic view of a gas-ionization chamber. The positive and negative charges formed by the ionizing particle are integrated, and the resulting pulse, whose height is proportional to the deposited energy, is sent to the amplifier for further treatment.

FIGURE 4.2 Band structure of a p-n junction. The probability $P(E)$ of occupation of an electronic level E in a solid is given by $P(E) = 1 / \{ \exp[(E - E_F)/kT] + 1 \}$, where E_F represents the Fermi level, k the Boltzmann constant, and T the temperature. Note that $P(E_F) = 0.5$. In a p-type semiconductor, E_F lies close to the valence band, in an n-type semiconductor close to the conduction band, and in an intrinsic semiconductor approximately halfway between both bands. In an unbiased p-n junction, the height of the Fermi level E_F depends only on the temperature. Five regions are distinguished in a p-n junction: the p-region, the negative space charge region, the intrinsic region, the positive space charge region, and the n-region. In a reversed biased p-n junction, the potential barrier is enhanced, and the p-n junction acts as a diode. In a p-i-n junction, E_F is no longer constant, and the intrinsic region is increased.

of view, it may be regarded as a capacitor in parallel with a direct current (DC) source.

The detector capacitance depends on the detector dimensions. Its magnitude is determined by the area of the p+ and n+ contacts, their separation, and the dielectric constant of the semiconductor. The p+ contact carries a negative space charge, and the n+ contact carries a positive space charge. In the intrinsic region, an electrical field exists due to both the space charges and the applied reverse bias. In Ge detectors, this intrinsic region may be very large (up to 60 mm), typical values for silicon detectors are 150–1000 μm , and Si(Li) detectors have a thickness of 3–4 mm.

An ionizing particle entering (or created in) the intrinsic region will excite a certain number of electrons from the valence band, into the conduction band, generating a certain number of pairs consisting of positive holes and negative electrons swept away to the p+ and n+ contacts, respectively, by the existing electric field.

Variations in shape and rise time make the amplitude of the current pulse unsuitable for spectroscopic aims, as its

FIGURE 4.3 Charge-sensitive preamplifier.

intensity is not proportional to the deposited energy (Kröll et al., 1996). What is important for spectroscopic applications is the integral of the current pulse. Therefore, a charge-sensitive (integrating) preamplifier (Fig. 4.3) has to be used, which transforms the current pulse, i_{in} , into a step voltage V_0 . The latter is proportional to the incident energy, if the amplification factor, A , is very large:

$$V_0 = \int i_{in} dt / C_F = Q / C_F = Nq / C_F = Eq / (\epsilon C_F) \quad (4.2)$$

where Q represents the total charge Nq and ϵ the energy necessary to excite an electron–hole pair. This energy may not be confused with the forbidden energy gap, which is much smaller (Table 4.1). It means that about 33% of the available energy is actually converted into electron–hole pairs. The rest serves to excite lattice vibrations and is lost in the pulse formation (Leo, 1987; Goulding and Landis, 1982). Protracted accumulation of charges on the

FIGURE 4.4 Schematic drawing of a resistive feedback preamplifier.

feedback capacitor C_F must be avoided. Therefore, C_F has to be discharged in time, most commonly by a resistor R_F or by pulsed reset techniques (see Fig. 4.4).

Apart from the integrator stage, a (resistive feedback) preamplifier may have a second stage. A differentiation and a pole-zero cancellation circuit couple the two stages (Fig. 4.4). The rise time of the signal is determined by the output signal of the detector along with the preamplifier response time. A typical fall time is of the order of 50 μ s. For digitization, the signal has to be further transformed by a shaping amplifier. The task of the shaping amplifier is complex. It transforms the shape and amplitude from the preamplifier signal to do the following:

1. Improve the signal to noise ratio via adjustable shape form and width.
2. Make it suitable for digitization in an analog-to-digital converter (ADC).
3. Make the output independent of the signal rise time.
4. Facilitate calibration of the spectrum.

A well-chosen peaking time, that is, the time needed for the signal to reach its maximum amplitude, is important to reduce the electronic noise and thus to improve the detector resolution. The output pulse should not be too long to prevent spurious summation of independent pulses separated by very small time intervals. On the contrary, for very short peaking times ($\sim 1 \mu$ s), the peak shaping may be ended before completion of the integration, which would mean important loss of information. This so-called ballistic deficit is particularly important in large γ detectors. Analog (“gated integrator”) or digital techniques may be incorporated in the pulse processing to minimize spectrum broadening due to ballistic deficit. A comparative study of different ballistic deficit correction methods versus input count rate has been carried out (Duchêne and Moszynski, 1995). Finally, the signal is transferred to an ADC and a multichannel analyzer (MCA), which measures the pulse height and constructs a spectrum, which is a histogram of pulses classified as a function of their pulse height. The

TABLE 4.1 Some important Ge and Si properties.

	Ge (at 77 K)	Si (at 300 K)
Electron mobility: μ_e in $\text{cm}^2/\text{V}\cdot\text{s}$	3.6E4	1350
Hole mobility: μ_h in $\text{cm}^2/\text{V}\cdot\text{s}$	4.2E4	480
Energy ϵ needed to create 1 $e^- - h^+$ pair	2.96 eV	3.62 eV
Atomic number Z	32	14
Forbidden energy gap	0.746 eV	1.115

analog amplifier and ADC can be replaced by a digital signal processing (DSP) module. DSP is a technique whereby the detector signal is digitized directly as it comes from the preamplifier, with only some minor pre-conditioning. The digitized data are then filtered and optimized using digital processing algorithms and finally transferred to the MCA for storage, view, and analysis. DSP allows implementation of signal filtering functions that are not possible through traditional analog signal processing. Benefits include higher throughput, reduced sensitivity to ballistic deficit, adaptive processing, improved resolution, and improved temperature stability for repeatable performance.

C. Fundamental differences between Ge and Si detectors

In Table 4.1, three important differences between Ge and Si are given. These are the energy gap, the atomic number Z , and the mobilities μ_e and μ_h of the majority carriers. Together with the purity and charge-carrier lifetime, they influence the thickness of the depletion region of a biased p-n junction.

1. The energy gap

There is a 50% difference between the energies needed to create an electron–hole pair in germanium and silicon. A Si detector may be used at room temperature for the spectroscopy of charged particles. A Ge detector has to be cooled below 100 K to reduce the leakage current due to thermal generation of charge carriers to an acceptable level.

This has important consequences: a Ge detector has to be operated inside a vacuum chamber. The sensitive detector surfaces are thus protected from moisture and other condensable contaminants. Consequently, independent of the junction itself, traditional Ge detector cryostats have an entrance window that makes Ge detectors less suited for the detection of charged particles and also affects the efficiency for low-energy photons.

2. The atomic number

In Chapter 1, Volume 1, the three typical interactions of electromagnetic radiation with matter have been detailed. The electrons scattered (photoelectric effect or Compton scattering) or generated (pair production) by one of the three basic interactions excite a certain number of electron–hole pairs and are responsible for the peak formation. For γ spectroscopy, the photoelectric effect contributes directly to the full-energy peak (FEP). Indeed, as the total energy of a γ ray is transferred to an electron, the kinetic energy of the electron will be proportional to the energy of the incoming γ ray. For the efficiency of a γ spectrometer, preference should thus be given to a semiconductor material having a high photoelectric cross section. Fig. 4.5 shows the photoelectric cross section of Si and Ge as a function of energy. One sees immediately that Ge cross section is greater than that of Si by one to two orders of magnitude. This is expected, as the photoelectric cross section depends roughly on the fifth power of the atomic number Z . Fig. 4.6 shows the Compton, photoelectric, and pair production cross section of Ge for γ ray energies up to 10 MeV.

FIGURE 4.5 Photoelectric cross section (barns) of Si (lower curve) and Ge (higher curve) as a function of energy (keV).

FIGURE 4.6 Compton scattering, photoelectric, and pair production cross section of Ge for high-energy γ rays.

The Compton scattering (or inelastic scattering) cross section is the dominant one for all energies except the very lowest ($E_\gamma \leq 150$ keV) and the very highest ($E_\gamma 8.5$ MeV). In this energy range, most full-energy depositions occur via several Compton scattering interactions—or multisite events inside the germanium crystal under the condition that the last interaction is a photoelectric one and that all the preceding Compton interactions take place in the Ge crystal. In large-volume detectors, the probability of multiple Compton scattering increases. If the last interaction does not occur by the photoelectric effect or if one of the multiple Compton scattering interactions takes place outside the sensitive volume of the detector, the pulse will contribute to the Compton continuum. Depending on the size and shape of the crystal and the energy of the interacting gamma quantum, in about half of the interactions, there is only one interaction point inside the crystal. The continuum background in this energy range has therefore a high probability for single site interactions (single site events, SSE). This observation has led to techniques to lower the continuum background by rejecting SSE using pulse-shape discrimination (Budjas et al., 2009).

The threshold of 1022 keV for the pair production process (see Chapter 1) is clearly seen. It is remarkable that the pair production cross section of a 10 MeV γ ray equals that of the photoelectric cross section at about 300 keV. It plays an important role in the spectroscopy of high-energy γ rays. Full absorption of two, one, or none of the 511 keV annihilation lines will contribute to the “full energy,” the “single escape,” or the “double escape” peak. All three peaks carry full spectroscopic information and are discussed in some detail in Section II.B.2.

3. The purity or resistivity of the semiconductor material

It is known (Knoll, 1999) that the thickness of the depletion region of a planar semiconductor is given by

$$d = \sqrt{\frac{2\varepsilon V}{qN}} \quad (4.3)$$

where V represents the applied bias, N the net concentration level of electrically active impurities in the bulk, q the electronic charge, and ε the energy needed to excite one e^-h^+ pair. For Ge, net active impurity concentration levels as low as 10^{10} atoms/cm³ of either p or n type can be achieved. This corresponds roughly to 1 impurity atom per 10^{12} atoms! The application of a reversed bias of up to 5000 V thus leads to a depletion thickness of several centimeters. This is not the case in Si. Indeed, the resistivity ρ of the semiconductor material can be expressed as

$$\rho = \frac{1}{q\mu N} \quad (4.4)$$

where μ represents the mobility of the majority carrier. Eq. (4.4) may thus be written as

$$d = \sqrt{2\varepsilon V \rho \mu} \quad (4.5)$$

From Table 4.1 one sees that μ is much smaller for Si than for Ge. If d is expressed in μm , V in volts and ρ in ohm-cm, Eq. (4.5) reduces for Si to

$$d = 0.562\sqrt{\rho V} \quad (4.6)$$

A thickness of up to 315 μm can be obtained for typical resistivities of $\approx 3000 \Omega\text{-cm}$ and a bias of $\sim 100 \text{ V}$. It is thus not possible to realize high-volume detectors with Si. Except for X-rays or low-energy γ rays, Si detectors are used mainly for charged particles. Since Si detectors may be used at room temperature, they may be placed in a vacuum chamber together with the source. The absence of any supplementary entrance window allows the particles to reach the sensitive volume of the detector.

In Si(Li) detectors, the excess acceptor ions in p-type Si may be compensated by Li donor ions. This way, a thickness of up to 5 mm of the active p-i-n region can be obtained. These detectors are predominantly used in X-ray spectroscopy.

4. Charge carrier lifetime τ

The charge carrier lifetime τ is the time that the carriers (electrons in the conduction and holes in the valence band) remain free. Trapping centers reduce this lifetime. The maximum signal height V_0 (Eq. 4.2) from the preamplifier after interaction of the detector with the ionizing radiation is given by

$$V_0 = \frac{Eq}{\epsilon C_F} \left(1 - \frac{d}{\mu E \tau} \right) \quad (4.7)$$

where d is the distance traveled by the charge, E the energy deposited in the detector, E the electric field, μ the mobility of the charges, q the elementary charge, ϵ the energy needed to excite one e^-h^+ pair, τ the charge carrier lifetime, and C_F the feedback capacitor value.

To have good charge collection and thus to avoid tailing, $\mu E \tau \gg d$ where the minimum value for τ for detector grade semiconductor material is 5 ms for Si at 300 K and 20 μs for Ge at 77 K.

II. Ge detectors

A. High-purity Ge detectors: merits and limitations

The depletion layer of a gamma detector must have a thickness of several centimeters to enhance the probability of an interaction of a γ ray with the sensitive detector material and thus be useful as a γ ray spectrometer.

Today, Ge crystals of either p or n type are grown with the low-impurity levels needed with dimensions up to 10–12 cm. The detectors fabricated from these crystals are called intrinsic or high-purity detectors. They can be stored at room temperature; however, the detector response will decrease if stored at room temperature for a prolonged time, especially with respect to p-type coaxial detectors. The effect of storing a germanium detector for a prolonged time in warm condition is discussed in Section II.C.3.f entitled “Stability of the Germanium Detector Efficiency.”

The facts that germanium can be made in large sizes, that it can be purified to the levels needed for full depletion, and that it needs only a very small energy to create one electron–hole pair make it a unique gamma ray detection material. A Ge detector produces more electron–hole pairs for a given gamma ray that is totally absorbed in its active volume than any other detector material. By consequence, energy resolutions are obtained that are more than 10 times better than by competing gamma detector technologies. The advantage that Ge has with regard to the small bandgap also represents the operational challenge for these detectors because they must be cooled to very low temperatures. Historically, this cooling has been achieved using liquid nitrogen baths, but, today, electromechanical coolers are becoming the standard (see commercial information Canberra, Ortec, PHDs Inc., and others). This also requires that, for most applications, the Ge detector crystal be stored in a cryostat having a window that stops (partly) low-energy gamma rays (see Fig. 4.15 further on in this chapter).

Because of these unique advantages, the applications in which Ge detectors are used span a very wide range from fundamental scientific research to nuclear material safeguards and security, environmental protection, and human health and safety.

Yet, for some applications, gamma spectroscopy alone does not suffice to quantify and qualify gamma emitters to a level that is acceptable for safety and security. Particular examples of these are the transuranic isotopes. Some of these isotopes are only weak gamma emitters that could be hidden in dense waste matrices or behind thick, absorbing walls and/or masked by very strong gamma emitters such as fission and activation products. For some applications, it may be necessary to use more detectable signals emitted by these special nuclear materials, besides their gamma signature. These detectable signals that are emitted per gram of this isotope are summarized in Table 4.2. The associated nondestructive assay techniques that can be used to make best use of these signals are well described in Reilly et al. (1991).

B. Analysis of typical γ spectra

Ge detectors of different size or geometry, such as planar detectors, coaxial detectors, and well-type detectors, are available. Others differ in the choice of contacts, of the choice of the entrance window, the selection of the cryostat construction materials, and so on. In Section II.E, these will be briefly described together with their main applications. However, before doing so, it is important to analyze the main features of a γ spectrum, to understand the influence of the parameters that are used to characterize a germanium detector, and to know the different sources of background. Only a clear understanding of these features will allow the user to choose the right detector for a specific application.

TABLE 4.2 List of transuranic isotopes with characteristic signals that could be used to detect these.

1. Spectrum of a source emitting a single γ ray with $E_\gamma < 1022$ keV

Fig. 4.7 shows the decay scheme of ^{137}Cs , one of the important long-lived ($T_{1/2} = 30.17$ y) fission products and a common contaminant. It emits two β -rays of 1176 (6%) and 514 keV (94%) exciting a 2.55-min isomeric level of ^{137}Ba . This isomeric level deexcites itself by the emission of a single γ ray of 661.66 keV. The M4 isomeric transition is highly converted ($\alpha_{\text{total}} = 0.11$); that is, the deexcitation can take place through the emission of a γ ray but also by the ejection of an atomic electron (a conversion electron) with subsequent delayed emission of the characteristic ^{137}Ba X-rays. Even though ^{137}Cs generates one of the simplest

spectra possible (Fig. 4.8), it is worthwhile to take a closer look at it. The spectrum was taken with a 25% n-type Ge (“REGe”) detector placed in an RDC low-background cryostat and a ULB Pb castle. The most striking is the FEP at 661.66 keV carrying the full spectroscopic information. The X-rays of the daughter element $^{137\text{m}}\text{Ba}$ are clearly seen: two doublets at 31.82–32.19 keV and 36.4–37.3 keV. For most other γ transitions, the intensity of the X-rays of the daughter element will be less pronounced, as most γ transitions have a much smaller total conversion coefficient. The small peak at 693.9 keV corresponds to the random sum peak between the Ba X-rays and the 661.66-keV photopeak. The weak peaks at 651.8, 22.31, and 26.52 keV correspond to the Ge escape peaks (see Section II.B.3) of the 661.66-keV line and of the Ba X-rays.

In addition to these well-defined peaks, two broad peaks are seen, namely, the Compton edge and the backscatter edge. The first has an energy of about 478 keV. It is due to a 180 degrees Compton scattering inside the active volume of the detector with subsequent escape of the Compton γ ray from the detector’s active volume. The second is due to a 180 degrees Compton scattering in the detector surroundings with subsequent detection in the detector of the escaped Compton-scattered γ ray having an energy of about 184 keV. The broadness of these peaks is due to the fact that the scattering angle of 180 degrees is only approximately fulfilled. Finally, the broad elevation in the continuum around 845 keV is due to the summation of the backscatter edge with the photopeak. In Fig. 4.9, the energies of the Compton edge and the backscatter edge are given as a function of energy of the primary gamma ray. Notice that the backscatter edge tends toward a saturation value of about 200 keV. The energy of the Compton edge is given by

$$E_{CE} = E_\gamma - E_{BS}. \quad (4.8)$$

FIGURE 4.7 Decay scheme of ^{137}Cs ; I.T. stands for isomeric or internal transition.

FIGURE 4.8 Gamma spectrum of ^{137}Cs emitting a single γ -ray at 661.66 keV taken with a 25% n-type Ge detector placed in an RDC low-background cryostat and a ULB Pb castle. Besides the photopeak at 661.66 keV, the X-rays of the daughter element $^{137\text{m}}\text{Ba}$ are seen: two doublets at 31.82–32.19 keV and 36.4–37.3 keV. The weaker lines at 22.11, 26.3, and 651.8 keV correspond to the Ge escape peaks, and the 693.9 keV peak is a random sum peak between the Ba X-rays and the 661.66 keV main peak.

Note that both curves cross at about 250 keV. For γ rays with $E_\gamma < 250$ keV, the positions of the Compton edge and the backscatter edge are thus reversed. The continuum at the lower energy side from the Compton edge is due to Compton scattering inside the active volume of the detector with subsequent escape of the Compton-scattered γ ray and to the bremsstrahlung emitted during the interaction of the betas and electrons

with the detector surroundings. The maximum of this bremsstrahlung continuum is equal to that of the emitted beta, 1176 keV in the case of ^{137}Cs .

The continuum between the Compton edge and the FEP is due to multiple Compton scattering, where the last interaction is a Compton event rather than a photoelectric effect. This leads to the fact that the continuum to the left of the FEP is generally higher than to its right.

FIGURE 4.9 Backscatter edge and Compton edge as a function of primary γ ray energy.

The background above the FEP is due to the bremsstrahlung of the 1176-keV β transition and to origins not related to the source, as discussed in greater detail later in Section D.

2. Spectrum of a multiple- γ -ray source emitting at least one γ ray with an energy ≥ 1022 keV

The spectrum can be complicated even when only a small number of γ rays are emitted during the radioactive decay. The case in which one or several γ rays surpass the energy of 1022 keV is especially interesting. This will be illustrated with the help of the γ spectrum of ^{24}Na formed, for example, by the $^{23}\text{Na}(n,\gamma)^{24}\text{Na}$ reaction and decaying with a half-life of 15.03 hours to ^{24}Mg . This decay takes place in >99% of all cases by a β transition of 1.389 MeV and in 0.06% by a β transition of 276 keV. From the decay scheme shown in Fig. 4.10, one sees that two strong (>99%) coincident γ rays of 1368.9 and 2755.2 keV exist, as well as a weak γ transition of 3867.2 keV (0.06%), also in coincidence with the 1368.9-keV line. The total of only three γ rays, all surpassing the threshold for a possible pair production, leads to the quite complex spectrum of Fig. 4.11. It shows, besides the backscatter peak at about 200 keV, a total of 13 well-defined peaks.

The three FEPs at 1368.9, 2755.2, and 3867.2 keV are clearly seen. The intense first two are accompanied by a well-pronounced Compton edge at approximately 1100 and

FIGURE 4.10 Decay scheme of ^{24}Na .

2400 keV, whereas the Compton edge of the weak 3867.2-keV line is almost lost in the general background.

If pair production takes place, two annihilation quanta of 511 keV are emitted at 180 degrees. When the two are fully absorbed, they contribute to the FEP. When one escapes from the detector without interaction, a discrete single escape (SE) peak is generated having an energy of

$$E_{SE} = E_{\gamma} - 511\text{keV}. \quad (4.9)$$

FIGURE 4.11 γ spectrum of ^{24}Na -emitting two strong (>99%) coincident γ rays at 1368.9 and 2754.2 keV and a weak γ ray at 3867.2 keV (0.06%). Thirteen well-defined peaks are observed. Their origin is explained in the text.

When both annihilation quanta escape, the double escape peak (DE) is generated with an energy of

$$E_{DE} = E_{\gamma} - 1022 \text{ keV}. \quad (4.10)$$

Besides the Doppler-broadened 511-keV line (see Section C.1.c), all six escape peaks can be recognized in the spectrum. Those of the 1368.9-keV line are weak, as the energy is too close to the threshold energy of 1022 keV (Fig. 4.6). It is worthwhile to take a closer look at the strong DE peak at $2755.2 - 1022 = 1733.2$ keV and the corresponding SE peak at 2243.2 keV. The peak shape of the first one is a mirror image of the FEP. The background to the right of the peak is higher than that to the left! This is due to multiple Compton scattering of one or both annihilation quanta (the last interaction not being a photoelectric effect), whereby the energy of the Compton electron adds to the energy of the DE peak, increasing the continuum to its right. On the contrary, the SE peak is perfectly symmetric, as the continuum to the left and the right of the peak is increased by multiple Compton scattering. These shapes are characteristic for the escape peaks. For weaker peaks, however, they are often masked by the general continuum. Note also that the SE peak is accompanied by a Compton edge but that the gap between the SE peak and its Compton edge does not correspond to that of a 2243.2-keV γ line but to that of a Compton scattered 511-keV γ line (Fig. 4.9). Indeed, one of the two annihilation quanta escaped from the detector, whereas the other was Compton scattered. Note also that the SE peak is Doppler-broadened. Indeed, this is due to the summation of a sharp DE peak with a Doppler-broadened 511-keV quantum. To a lesser amount, the same is also true for the FEP of high-energy γ rays due, partially, to the full absorption of the two annihilation quanta.

Finally, one recognizes the sum peak at 4123.1 keV of the two strong coincident γ rays at 1368.9 and 2755.2 keV as well as the two escape peaks corresponding to this energy.

It is not always easy to distinguish these different peaks in an unknown spectrum. The best criterion for recognizing the different escape peaks is the exact energy difference of 511 or 1022 keV. For complicated spectra, a comparison of their relative intensities with the expected ones from the relative efficiency curves for the three peak types can give further confirmation.

3. Peak summation

In Fig. 4.11, different sum peaks are discernible. They merit further attention. Real sum peaks have to be distinguished from random sum peaks. Real sum peaks are due to coincident γ rays simultaneously detected. Their energies equal the sum of two individual energies. The interpretation can be confirmed by their intensities if measured with the

same detector at a different source-to-detector distances. Indeed, the probability P of a real sum peak is given by:

$$P = I \cdot p \cdot \varepsilon_1 \cdot \varepsilon_2 \quad (4.11)$$

where I is the intensity (Bq) of the source, ε_1 , ε_2 are the counting efficiencies for γ_1 and γ_2 , respectively, and p is the intensity of the less abundant of the two coincident γ rays summing up.

If $\varepsilon_1 \approx \varepsilon_2$, one sees that the intensity of the sum peak varies roughly as the square of the efficiency. The phenomenon of true coincidence summing, also referred to as cascade summing, and its impact on gamma ray FEPs is discussed in Section II.B.4 of this chapter.

In addition to real sum peaks, spurious sum peaks due to the finite time resolution can occur. Their probability is given by

$$P = 2 \cdot \tau \cdot I^2 \cdot \varepsilon_1 \cdot p_1 \cdot \varepsilon_2 \cdot p_2 \quad (4.12)$$

where τ is the time resolution of the detection system and p_1 and p_2 are the branching ratios of the two γ rays summed up accidentally.

The intensity of random sum peaks depends, therefore, on the square of the source intensity and on the time resolution. An illustration of a random sum peak is given in Fig. 4.8. Avoid, if possible, the use of intense sources to minimize random summation. If the radioactive source decays with a certain transition probability λ , the intensity I is given by

$$I = I_0 \cdot e^{-\lambda \cdot t} = I_0 \cdot e^{-\frac{0.693}{T_{1/2}} \cdot t} \quad (4.13)$$

where I_0 represents the initial intensity and $T_{1/2}$ the half-life. Inserting Eq. (4.13) into Eq. (4.12), one sees that the probability P of occurrence of a spurious sum peak depends on $I^2 = I_0^2 \cdot e^{-2 \cdot \lambda \cdot t}$. The probability of occurrence of a spurious sum peak decays thus with a transition probability of $2 \cdot \lambda$ rather than λ , or a half-life $T_{1/2}/2$ rather than $T_{1/2}$, i.e., twice as fast as the isotope itself. This is a firm criterion for their recognition. Pulse pileup rejection in modern processing electronics can reduce random summing to a great degree.

4. True coincidence summing effects

In most cases of radioactive decay, a parent nuclide decays to an excited energy level of a daughter nuclide by emitting an alpha or a beta particle, or via electron capture. The transition from the excited state to the ground state of the daughter nuclide may then occur by the emission of two or more gamma rays in a cascade. Since the excited states have life times on the order of picoseconds, it is highly probable that the γ rays emitted in a cascade are detected within the resolving time of a gamma ray spectrometer. The γ rays are then said to be detected in true coincidence. In the case of a nuclear decay occurring via electron capture,

X-rays will be emitted, which may also be detected in true coincidence with a gamma ray. As a result of true coincidence summing or cascade summing, the detector accumulates the sum total of the energy deposited by the cascading gammas from a given nuclear decay. Therefore, events are lost (summing-out) or gained (summing-in) from the FEP of the gamma ray of interest, and any activity determination based on the FEP will be in error. It is, therefore, necessary to correct for true coincidence effects.

Fig. 4.12 gives an example of a radioactive decay where cascade summing occurs. In the above example, the parent nuclide undergoes a beta decay to the excited energy state E_1 of the daughter nucleus. The deexcitation to the ground state of the daughter nuclide occurs via the emission of gamma rays γ_1 and γ_2 in a cascade or via the emission of gamma ray γ_3 directly to the ground state. Assuming that the gamma rays γ_1 and γ_2 are detected in true coincidence, an FEP measurement of γ_1 or γ_2 suffers from cascade summing losses and the FEP measurement of γ_3 suffers from cascade summing gains. It must be noted that cascade summing losses are not just limited to the counts appearing in the sum peak. Rather, the detector may accumulate the full-energy deposition from one of the gamma rays (say γ_1) and a partial energy deposition from the second gamma ray (say γ_2), resulting in a count being lost from the FEP of γ_1 . In the pulse height spectrum, these events will appear in the continuum between the energy of γ_1 and the energy of the sum peak. The same argument can be made for γ_2 as well. Therefore, the cascade summing losses depend on the *total efficiency* of the detector for the gamma rays in the cascade. In the case of cascade summing gains, the two gamma rays γ_1 and γ_2 in the above example deposit their full energy in the detector. The resulting event appears at the same energy as that of γ_3 . Cascade summing gains are dependent on the peak efficiencies of the detector at the gamma ray energies of interest. Besides the detection efficiencies, cascade summing losses or gains also depend on the gamma ray emission probabilities and any angular correlations involved in the gamma ray emission. It is important to note that the magnitude of cascade or *true* coincidence summing losses or gains is dependent on the counting geometry, and not on the source activity.

FIGURE 4.12 An example decay scheme showing cascading gamma rays.

Angular correlation between two gamma rays emitted in a cascade is defined as the relative yield of γ_2 about the 0° direction defined by the detector position, given that γ_1 is emitted in the same direction. Angular correlations arise because the direction of emission of the first gamma ray is related to the orientation of the angular momentum of the intermediate state. If the lifetime of the intermediate state is short, the orientation of the angular momentum will persist. The direction of the second gamma ray will be related to the angular momentum of the intermediate state, and hence to the direction of the first gamma ray (Evans, 1955). Angular correlation effects, in general, are not very significant when correcting for cascade summing effects. But for measurements requiring a high degree of accuracy (few tenths of a percent), it is indeed necessary to take angular correlation effects into account.

Detailed discussions on the subject of true coincidence summing can be found in several standard text books (Debertin and Helmer, 1988; Knoll, 1999).

a. True coincidence correction for a simple case

For a simple decay scheme such as the one shown in Fig. 4.12, it is straightforward to derive a correction factor for cascade summing losses or gains. For γ_1 , the FEP rate in the absence of cascade summing can be written as follows:

$$\dot{N}_{10} = A \cdot p_1 \cdot \varepsilon_1 \quad (4.14)$$

The quantity A is the source activity, p_1 is the emission probability of γ_1 , and ε_1 is the FEP efficiency at the energy of γ_1 . Since γ_1 and γ_2 are emitted and detected in true coincidence, the energy deposited in the detector may be the sum of the full energy from γ_1 and a part of the energy (up to the full energy) from γ_2 . This results in events being lost from the FEP of γ_1 . Since any type of interaction involving γ_2 will result in a loss of count from the FEP of γ_1 , the *total detection efficiency* of γ_2 is used in determining the cascade summing loss.

The peak rate of γ_1 in the presence of cascade summing is written as follows:

$$\dot{N}_1 = A \cdot p_1 \cdot \varepsilon_1 - A \cdot p_1 \cdot \varepsilon_1 \cdot \varepsilon_{t2} \quad (4.15)$$

The correction factor is derived from Eqs. (4.14) and (4.15):

$$COI = \frac{\dot{N}_1}{\dot{N}_{10}} = 1 - \varepsilon_{t2} \quad (4.16)$$

In deriving a correction factor for γ_2 , one has to keep in mind that not all emissions of γ_2 are preceded by γ_1 . A fraction of γ_2 is preceded by beta decay. The peak rate of γ_2 in the presence of cascade summing is given in Eq. (4.17).

$$\dot{N}_2 = A \cdot p_2 \cdot \varepsilon_2 - A \cdot p_2 \cdot \varepsilon_2 \cdot \left(\frac{p_1}{p_2} \right) \varepsilon_{t1} \quad (4.17)$$

The cascade summing correction factor for γ_2 is therefore,

$$COI = \frac{\dot{N}_2}{\dot{N}_{20}} = 1 - \left(p_1/p_2 \right) \varepsilon_{t1} \quad (4.18)$$

From Eqs. (4.16) and (4.18), it is evident that total efficiency ε_t should be known to determine the correction factor for cascade summing losses.

In the case of γ_3 , one has to correct the FEP for cascade summing gains. The peak count rate in the absence of cascade summing is written as

$$\dot{N}_{30} = A \cdot p_3 \cdot \varepsilon_3 \quad (4.19)$$

The FEP of γ_3 will gain events only when γ_1 and γ_2 deposit their full energies in the detector.

$$\dot{N}_3 = A \cdot p_3 \cdot \varepsilon_3 + A \cdot p_1 \cdot \varepsilon_1 \cdot \varepsilon_2 \quad (4.20)$$

The correction factor is therefore

$$COI = \frac{\dot{N}_3}{\dot{N}_{30}} = 1 + \left(p_1 \varepsilon_1 \varepsilon_2 / p_3 \varepsilon_3 \right) \quad (4.21)$$

For decay schemes involving three or more gamma rays in a cascade, the analytical formulae for summing out probabilities especially become quite cumbersome to calculate. Over the past two decades, several authors have generalized these formulae for complex decay schemes and have reported them in the literature (Andreev et al., 1972; Moens et al., 1982; De Corte, 1987).

b. True coincidence correction using Canberra's Genie2000 software

Cascade summing losses could be as high as 30%–40% at close-in geometries, depending on the type of detector used and the specific nuclide that is being measured. If the detector is calibrated with a standard source identical in shape and size to that of the sample, and the nuclide(s) under study are the same in the standard and sample, then no correction needs to be applied for true coincidence summing. In all other cases, correction factors must be applied if measurements are required to be performed at close-in geometries. Canberra Industries has developed and patented a technique for calculating correction factors for true coincidence or cascade summing losses and gains (U.S. Patent 6,225,634). The algorithms that perform the calculations have been incorporated into Canberra's Genie2000 Gamma Analysis software package (version 2.0 and later). In version 3.2 of Genie2000 and later, the capability to compute true coincidence summing losses due to X-ray and gamma ray summing or annihilation photon (511 keV) and gamma ray summing has been incorporated (Zhu et al., 2009a,b). The coincidence library is created using nuclear data directly extracted from the internationally recognized database ENSDF. This provides direct

traceability to the ENSDF database. Using Genie2000, one can thus calculate the true coincidence correction factors for a wide variety of counting geometries and for an exhaustive list of nuclides and gamma ray lines. To compute the correction factors, Canberra's method requires a single intrinsic peak-to-total efficiency curve or alternatively, the total efficiencies directly calculated from Canberra's ISOCS (In Situ Object Calibration Software) method. In addition, the true coincidence correction algorithm also uses the so-called spatial response characterization or ISOCS characterization for the specific detector. Canberra's ISOCS is a powerful mathematical tool to calculate HPGe FEP efficiencies for practically any source geometry (Bronson and Young, 1997; Venkataraman et al., 1999). For thin window HPGe detectors, the capability to compute correction factors to include X-ray and gamma ray coincidences was made possible by extending the lower energy limit of the ISOCS methodology down to 10 keV (Mueller et al., 2009).

The Genie2000 algorithms for calculating the true coincidence correction factors for voluminous sources are based on the work done by Kolotov et al. (1996). In this method, the voluminous source is first divided into a large number of equal volume subsources. A point location is selected within each subsurface using a pseudorandom sequence. The true coincidence correction factor at each of these point locations is calculated and then integrated to determine the overall correction factor for the entire source.

It was previously noted that the total efficiency of the detector, ε_t , is required to compute the correction factor for true coincidence losses. For a point source at a location "I," the total efficiency at a given gamma ray energy may be determined, provided the FEP efficiency ε_p and the peak-to-total ratio (P/T) are known at the given energy.

$$\varepsilon_{t,i} = \varepsilon_{p,i} / (P/T) \quad (4.22)$$

The FEP efficiency is calculated using the ISOCS characterization for the given detector. The P/T ratio is obtained from the intrinsic peak-to-total efficiency curve determined for the detector. It is possible to determine the total efficiency directly by using Canberra's ISOCS methodology. However, this capability currently exists for HPGe detector measurements only.

In general, the TCS correction factor (COI_A) for the analytic γ ray (denoted by subscript "A") due to γ - γ and γ -X (γ -511 keV) TCS can be written as

$$COI_A = (1 - L_A^{\gamma-\gamma}) \cdot (1 + S_A^{\gamma-\gamma}) \cdot (1 - L_A^{\gamma-X,511}) \cdot (1 + S_A^{\gamma-X,511}) \quad (4.23)$$

where $L_A^{\gamma-\gamma}$ ($S_A^{\gamma-\gamma}$) is the loss (gain) probability due to γ - γ and γ -X (IC) TCS, and $L_A^{\gamma-X,511}$ ($S_A^{\gamma-X,511}$) is the loss (gain) probability due to γ -X (EC) and γ -511 keV TCS; where L_A is the probability of summing out and S_A is the probability

of summing in. These probabilities are the sum of the partial probabilities calculated for individual decay chains involving the gamma line of interest.

$$L_A = \sum_{i=1}^N L_{A,i} \quad (4.24)$$

$$S_A = \sum_{j=1}^M S_{A,j} \quad (4.25)$$

The calculation of summing out probability L_A requires the knowledge of nuclear data such as the gamma ray yields, branching ratios, and internal conversion coefficients, as well as total detection efficiencies. Summing in probability S_A requires the knowledge of nuclear data and FEP efficiencies. F. De Corte has worked out the general formulae for the γ - γ true coincidence loss (gain) probability in a 5- γ cascade chain, where the loss probability depends on the location of the analytic γ ray in the decay chain. The generalized formulae reported in the literature to compute the summing out and summing in probabilities for complex decay schemes have been incorporated into the methodology developed by [Kolotov et al. \(1996\)](#). The extensions to the γ - γ true coincidence loss or gain due to γ -X-ray true coincidence are given by [Zhu et al. \(2009a,b\)](#). By calculating the coincidence correction factors ($\text{COI}_{A,i}$) for a large number of infinitesimally small sub-sources and then integrating, the correction factor for the whole voluminous source is obtained.

It is desirable to use the spatial characterization for the specific HPGe detector, if available. However, it is not a necessary condition. [Koskelo et al. \(2001\)](#) have shown that it is sufficient to use an approximate detector characterization to obtain good cascade summing results with Genie2000. Venkataraman and Moeslinger have demonstrated the feasibility of employing a discrete number of generic detector response characterizations for carrying out cascade summing corrections on gamma ray spectra obtained with noncharacterized HPGe detectors ([Venkataraman and Moeslinger, 2001](#)). A set of generic detector characterizations has therefore been made available within Genie2000.

c. Monte Carlo methods to compute true coincidence summing correction factors

[Berlizov \(2006\)](#) has developed an upgraded patch for the general-purpose Monte Carlo code MCNP (Monte Carlo N-Particle) code to allow computations with a source of correlated nuclear particles. The upgraded version of the code, MCNP-CP, performs statistical simulation of processes accompanying radioactive decay of a specified radionuclide, yielding characteristics of emitted correlated nuclear particles, which are then tracked through the problem geometry within the same history. When

radioactive decay is modeled, MCNP-CP considers the emission of cascade gamma rays; continuum energy electrons at β^- decay; annihilation photons accompanying β^+ decay; monoenergetic electrons at the internal conversion on the atomic K-shell and L1,2,3-subshells; K- and L X-rays due to single and double fluorescence occurred at both electron capture and internal conversion processes; the K-L X and K-M X Auger electrons. Quantity, types, energies, and times of emitted particles are sampled according to the properties of a decay scheme of a particular radionuclide, which are taken from the evaluated nuclear structure data file ENSDF. γ - γ angular correlations are taken into account at sampling emission directions of cascade γ rays. As a basic source of information about the decay properties of a radionuclide of interest, MCNP-CP uses ENSDF. When necessary, the ENSDF data are supplemented by the calculations with application of known theoretical models and approaches.

To estimate true coincidence summing losses or gains using MCNP-CP, an accurate model of the detector and the source geometry must be developed. To ensure that the computed correction factors are accurate, it will be necessary to validate the Monte Carlo model of the detector using sources of known activities, located in geometries where true coincidence effects are negligible. In general, it is a good practice to validate and benchmark computational methods with real measurements before applying the computational method to solve other problems. Besides modeling the detector, the source geometry for which true coincidence summing losses or gains are needed must be accurately modeled. Two runs are performed using MCNP-CP; first with the correlated particle (CP) emission turned on, and a second computation with the correlated particle emission turned off. The ratio of pulse height tally with CP turned on to the pulse height tally with CP turned off gives the fraction of counts lost or gained due to true coincidence summing.

Besides MCNP-CP, other Monte Carlo codes such as GEANT can also be used to compute true coincidence summing losses and gains. These codes provide an independent method to verify cascade summing corrections obtained using analytical methods, e.g., in Genie2000. True coincidence correction factors computed using the analytical and ray tracing methods used in Genie2000 have been compared with those computed using MCNP-CP ([Zhu et al., 2008, 2009a,b](#)).

d. True coincidence correction using Ortec's GammaVision software

The technical details given in this section are from a paper published by [Keyser et al. \(2001\)](#). The method for true coincidence correction implemented in Ortec's GammaVision software is based on the work by [Blaauw \(1993\)](#). In this method, the probability of recording a count in the FEP is given by,

$$P_{Ei} = g_i \epsilon_{fullenergy, Ei} \prod_{j \neq i} (1 - g_j \epsilon_{total, Ej}) \quad (4.26)$$

where P_{Ei} is the probability of a count in the FEP, $\epsilon_{fullenergy, Ei}$ is the full energy efficiency at an energy E_i , $\epsilon_{total, Ej}$ is the total efficiency at an energy E_j , and g_i and g_j are the transition probabilities for gamma rays with energies E_i and E_j , respectively. Thus, the determination of the correction factor is reduced to knowing the full energy efficiency, the total efficiency, and the decay scheme of the nuclides in question. In addition to the full energy efficiency, the total efficiency includes the peak-to-total ratio, an absorption correction, and terms that correct the efficiency for an extended source.

5. Ge-escape peaks

For low-energy γ rays or for extremely thin detectors, when the interaction takes place close to the detector border, a certain probability exists that a Ge X-ray escapes from the detector. This probability is thus particularly important in detectors having thin windows (see Fig. 4.20). The parasitic peaks are observed at energies of

$$E_\gamma - 9.88 \text{ keV (escape of the } K_\alpha \text{ line)}$$

and

$$E_\gamma - 10.98 \text{ keV (escape of the } K_\beta \text{ line)}$$

The latter is five times less probable than the former. An illustration of several Ge escape peaks can be found in Fig. 4.8.

With these general aspects of a γ spectrum in mind, it is time now to take a closer look at the characteristics of a Ge detector such as resolution and efficiency, which play an important role in the choice of an appropriate detector.

C. Standard characteristics of Ge detectors

1. Energy resolution

From the spectra discussed in Section B, it is clear that the observed peaks have a finite width. Peak broadening is due to the statistical fluctuations in the number of electron-hole pairs created in the active detector volume $(FWHM)_{det}$ and to the electronic noise of the different elements of the amplification chain. The resolution is expressed by full width at half-maximum $(FWHM)$, and it can be readily obtained from the spectra. The different noise contributions add quadratically according to the equation

$$FWHM = \sqrt{(FWHM)_{det}^2 + (FWHM)_{elect}^2} \quad (4.27)$$

$(FWHM)_{det}$ and $(FWHM)_{elect}$ represent the detector and the electronic contribution in the total $FWHM$.

The energy E released in the detector is shared by two processes, namely, direct ionization and lattice vibrations. Both processes may lead to the generation of

$$N = \frac{E}{\epsilon} \quad (4.28)$$

electron-hole pairs according to Eq. (4.1) described in Section I.A. The second process obeys a Gaussian distribution and, if direct ionization would be negligible, the variance σ_N of the number of charge carriers N would be given by the equation

$$\sigma_N = \sqrt{N} = \sqrt{\frac{E}{\epsilon}} \quad (4.29)$$

When the variance σ is expressed in energy units (eV), Eq. (4.29) becomes

$$\sigma = \epsilon \sqrt{N} = \sqrt{E\epsilon} \quad (4.30)$$

and the intrinsic $FWHM_{det}$ is calculated as

$$(FWHM)_{det} = 2.35 \sqrt{E\epsilon} \quad (4.31)$$

where the factor 2.35 is a statistical property of the Gaussian distribution and gives the ratio between FWHM and the variance of a Gaussian distribution. In practice, however, direct ionization is not negligible at all, justifying the introduction of a correction factor F , the so-called Fano factor:

$$FWHM_{det} = 2.35 \sqrt{FE\epsilon} \quad (4.32)$$

Fitting this formula at various energies and with various Ge and Si detectors shows that the effective Fano factor may vary between 0.08 and 0.15. The average value is 0.1 for Ge and Si. In Fig. 4.13, the approximate intrinsic FWHM is given as a function of γ ray energy (Fig. 4.13).

a. The electronic noise contribution $(FWHM)_{elect}$ and its time behavior

Depending on the detector type, resolutions (FWHM) lower than 1.8 keV at 1332 keV, 0.50 keV at 122 keV, and 0.15 keV at 5.9 keV are common. This implies an electronic noise contribution of <0.8, 0.22, and 0.10 keV, respectively. The electronic noise depends mainly on two factors: the capacitance of the detector and any current flowing over the detector. The capacitance of the detector depends on the detector dimensions and geometry.

Electronic noise is any undesired fluctuation that is superimposed on the signal. It contributes to the finite resolution of the detector. In electrical circuits, it stems from random processes such as the random collection of electrons or the arbitrary thermal movement of electrons in a resistor (Goulding and Landis, 1982). It can be represented as a voltage or current generator with zero average value and random positive and negative peaks. Noise is a

FIGURE 4.13 Approximate intrinsic full width at half-maximum as a function of γ -ray energy.

statistical phenomenon and can be described as a time average of the squares of all positive and negative values. One has to realize that a counting rate of one 1-MeV γ ray per second losing its complete energy in the active volume of the detector generates a current of only 5.41×10^{-14} C/s, and this has to be registered with a precision of better than 0.2% if a resolution (FWHM) of 1.8 keV is desired. This is a very difficult task for any electronic measuring chain.

In a detector amplifier system, three different noise contributions may be distinguished as function of their time behavior.

The Step Noise or Parallel Noise (FWHM)_S arises from the discrete character of any current i_n flowing in the input circuit of the preamplifier. This current is integrated on the capacitor C_f (see Figs. 4.3 and 4.4). The two main sources of step noise are the detector leakage current and the thermal noise of the feedback resistor. It can be represented by a current generator, generating current pulses at the input of the preamplifier. It is proportional to

$$(FWHM)_s \propto \sqrt{\left(I_l + 2 \frac{kT}{R_f}\right) \tau} \quad (4.33)$$

where I_l represents the total current of the detector (leakage current plus current generated by the detected radiation), k the Boltzmann constant, T the temperature of the feedback resistor, and τ the shaping time (measuring time) of the amplifier.

Step noise can be reduced by

1. measuring at shorter shaping times;
2. reducing the current through the detector (e.g., by measuring at a lower counting rate); and
3. choosing a feedback resistor with a high resistance, or avoiding it by using a different reset mechanism.

The delta noise or series noise (FWHM)_D is mainly associated with the shot noise in the first stage of the preamplifier (FET). Delta noise is proportional to

$$(FWHM)_D \propto C \sqrt{\frac{T}{g_m \tau}} \quad (4.34)$$

where g_m represents the transconductance of the FET and C is the total capacitance at the input of the preamplifier.

Delta noise can thus be reduced by

1. measuring at longer shaping time;
2. minimizing the detector and stray capacitance; and
3. selecting a low-noise FET with large transconductance.

The Flicker noise or 1/f noise (FWHM)_F is independent of the detector capacitance and exists only in association with a direct current. It is independent of the shaping time τ and is thus less relevant for the present discussion.

All these different noise contributions sum up quadratically with the intrinsic noise discussed in Section C.1. The total noise is thus given by

$$(FWHM)_{tot} = \sqrt{(FWHM)_{det}^2 + (FWHM)_D^2 + (FWHM)_S^2 + (FWHM)_F^2} \quad (4.35)$$

FIGURE 4.14 Noise as a function of the shaping time τ .

It is particularly instructive to look at the dependence of the noise on the shaping time τ . Fig. 4.14 gives a schematic view of the square of the total FWHM. For most detectors, the optimum resolution is obtained with a shaping time between 3 and 12 μs (if a Gaussian, analog shaper is used) or a signal rise time between 10 and 28 μs (if a digital amplifier is used). It is important to realize that, at high counting rates, the average DC current through the detector will increase and consequently also the step noise. The optimum shaping time will thus tend to lower values at high counting rate! In either case, the optimum shaping/peaking time for a given measurement condition should be determined experimentally.

The importance of step noise and delta noise also depends on the actual shape of the amplifier signal. A semi-Gaussian shaper gives a good compromise between both step noise and delta noise. For high-count-rate measurements with large coaxial detectors (see Section E), a gated integrator (e.g., the Canberra model 2024 Spectroscopy Amplifier) or longer “Rise-” and “Flat Top-” times with DSP processors may be used to minimize the ballistic deficit.

b. Interference with mechanical vibrations and with external radio frequency noise

Vibrations of the detector cryostat, or even audible noise, may also lead to spectrum broadening. This has to do with the fact that the germanium detector crystal and some leads are at high voltage, whereas they are closely surrounded by conductors on ground potential. This way, effective capacitors are formed. Their value can change when the crystal, the leads, or cryostat parts vibrate. Since a capacity, C , can be written as the ratio of a charge, Q , over a voltage, V , a changing capacity can be interpreted by the detector’s

electronics circuit as being due to a changing charge, in the same way as a detected photon gives rise to a change of charges. Provided that the frequency of the mechanical vibration or noise is not filtered out by the RC filter network of the amplifier, this noise can sum up with real photon events and show up as peak broadening.

To minimize this sensitivity for “microphonics,” the user should avoid excessive audible noise and vibrations in the vicinity of the detector, e.g., by placing the detector on some damping material. Detectors are also less sensitive for microphonics at lower shaping times. For extreme applications, e.g., for use on board of helicopters or air planes, detector manufacturers can change the mechanical construction of the detector so that its eigen frequencies do not correspond with the characteristic noise or vibration frequencies of the plane or helicopter.

The spectroscopy system can also behave as an effective antenna for strong RF signals from the environment. Pick up of these may also lead to peak broadenings. Sensitivity for pickup depends strongly on details such as orientation, grounding and bundling of cables, and contact resistance between the various components of the spectroscopy system components. For extreme RF noise, detector manufacturers can change the cryostat and preamplifier hardware to render them virtually immune for pickup of RF signals.

Finally, peak degradation resulting from more fundamental physical processes can also occur, including detector temperature change, Doppler broadening, recoil shift, and recoil broadening. These will be discussed briefly.

c. Other sources of peak degradation

Temperature change of the detector. A small temperature dependence of the energy gap and the energy ϵ necessary

for creating an electron–hole pair (Table 4.1) of Si and Ge exists and is given by

$$\frac{\Delta\epsilon}{\epsilon} \approx \frac{0.00015}{K} \quad (4.36)$$

The peak position of a 1.3-MeV transition thus changes by about 0.2 keV per kelvin. This effect can cause some peak broadening, especially at higher γ ray energies, when the cryostat temperature is not stable.

Doppler broadening. This is observed when the γ ray is emitted by an “object” that is not at rest. The most commonly observed Doppler-broadened gamma line is the 511-keV annihilation line. When a positron (e^+) comes to rest, it combines (“annihilates”) with an electron (e^-) to form a positronium that decays almost immediately into two quanta of 511 keV. Due to momentum conservation, these are emitted at 180 degrees (see Chapter 1). As the annihilating electrons may have a rest kinetic energy, the annihilation lines are Doppler-broadened.

Doppler broadening can also occur when a γ ray is emitted by an isotope “in flight” after a nuclear reaction. An example is provided by the well-known 479.9-keV γ line emitted in the reaction

As the cross section for this reaction is very high (3837 b), boron constitutes a very effective thermal neutron shield but adds an intense Doppler-broadened background line if no special shielding is used.

Note that because of the almost isotropic emission of γ rays, a Doppler broadened line is always symmetric.

Recoil broadening. This must not be confused with Doppler broadening. A fast neutron can transfer a large amount of its energy to a recoiling nucleus (see Chapter 1). This recoil energy is generally not seen by the detector as it takes place in the target. However, Stelson et al. (1972) showed that, in the case in which the target is the detector itself, the supplementary energy from the recoil contributes to the formation of electron–hole pairs in the detector. These supplementary charge carriers add to those due to the γ transition, resulting in an odd-shaped peak, having a normal low-energy and a long high-energy slope. Bunting and Kraushaar (1974) detected this phenomenon. It was further described by Verplancke (1992) and Heusser (1993). In particular, it is seen for certain background lines induced by (n, n') reactions in the Ge crystal itself, such as the 691.0-keV line due to the $^{72}\text{Ge}(n, n')^{72}\text{Ge}$ (see Table 4.4 further on in this chapter). Recoil broadening always results in a right-side asymmetric peak.

Recoil Energy Shift. A γ ray is emitted by a nucleus when it passes from an excited state to a lower energy state. The latter can be an excited state or the ground state. However, depending on the nature (multipolarity) of the transition, the excited state can deexcite alternatively

through the emission of a conversion electron. Furthermore, it shares its energy with the energy of the recoiling nucleus. This recoil energy E_R is given by

$$E_R = \frac{E_\gamma^2}{2Mc^2} \quad (4.37)$$

where E_γ represents the energy of the emitted γ ray, M the mass of the nucleus, and c the speed of light (see Chapter 1 for the derivation of Eq. 4.37). If the energy is given in keV and the mass in atomic units (M of $^{12}\text{C} = 12$), the corresponding energy difference E_g of the nuclear states involved is given by

$$E_g = E_\gamma + E_R = E_\gamma \left(1 + \frac{E_\gamma}{1,862,300M} \right). \quad (4.38)$$

This effect is completely negligible, in general, and therefore, $E_g \approx E_\gamma$. However, if M is small and E_γ is high, the difference between E_g and E_γ can be significant, as pointed out by Greenwood and Chrien (1980), among others. For instance, the γ ray of 10,829.1 keV produced in the $^{14}\text{N}(n, \gamma)^{15}\text{N}$ reaction populates the ground state and is issued from an excited level at 10,833.3 keV. This energy corresponds to the binding energy of the neutron. Note that medium- and high-efficiency Ge detectors perform excellently even at this very high energy, the most useful peak being the double escape peak, which suffers no Doppler broadening as outlined in Section II.B.2.

Radiation damage. Low-energy tailing can be due to electronics but also to the presence of trapping centers or “deep levels” in the detector. These trap electrons or holes for periods longer than the time needed for pulse formation (Eq. 4.7). Trapping centers may be created by radiation damage in the detector induced by fast charged particles and/or fast neutrons. A 16-MeV neutron creates four times more trapping centers than a 1.6-MeV neutron. Charged particles are easy to shield. This is not true for fast neutrons. They have to be thermalized by a large, hydrogen-rich layer and must be subsequently absorbed by a high-cross section material. The effects of deep-level defects in a high radiation environment have been studied by Lutz (1996).

d. The Gaussian peak shape

The peak shape is closely related to the resolution. In principle, the peak shape follows Poisson statistics. If the number of counts is ≥ 20 , the shape of the FEP is given by a Gaussian distribution of the values x around the energy channel E according to the equation

$$f(x) = e^{-(x-E)^2/2\sigma^2} \quad (4.39)$$

The maximum of the distribution lies at $x = E$. Table 4.3 gives the width of the distribution for a few points. Few detectors, if any, exhibit the theoretical peak shape. Most modern detectors have a ratio FWTM (full

TABLE 4.3 Theoretical Gaussian peak widths.

A = fraction from the maximum	B = width at fraction	B/ FWHM
1/2 (FWHM)	2.35σ	1
1/10 (FW1/10M)	4.29σ	1.82
1/20	4.9σ	2.08
1/50	5.59σ	2.37

FWHM, full width at half-maximum.

width at tenth-maximum) to FWHM (full width at half-maximum) of better than 1.9, but a ratio of 2 is common for larger detectors. Mainly, detectors made of n-type germanium may show higher FWTM/FWHM ratios.

An FWTM/FWHM ratio smaller than 1.82 may indicate that the peak has shifted during the accumulation of the spectrum or that the peak is actually a doublet.

2. The peak-to-compton ratio

Following the IEEE standards (ANSI N42.14, 1991), the peak-to-Compton ratio is defined as the ratio between the maximum number of counts in the channel at the top of the 1332.5-eV peak of ^{60}Co and the average channel count between 1040 and 1096 keV. It depends not only on the resolution and efficiency but also on the presence of material in the vicinity of the active detector region, as these materials may backscatter γ rays into the detector. It plays a role in the “background due to the presence of the source,” as will be discussed in Section II.D.

3. The detector efficiency

The efficiency ε_γ is a measure of the probability (expressed in absolute values or in %) that a γ ray of energy E_γ is fully absorbed in the active volume of the detector or, in other words, the probability that it contributes to the FEP. It depends basically on the solid angle Ω under which the source is seen by the detector and on intrinsic factors characteristic of the detector.

a. Geometrical efficiency factor

In the case of a point source situated on the axis of a circular detector with a flat surface facing the source, the geometric efficiency η is given by a simple analytical formula

$$\eta = \frac{\Omega}{4\pi} = \frac{1 - \cos[\arctan(r/d)]}{2} \quad (4.40)$$

where r represents the radius of the detector, d the distance between detector and source including the distance between detector and endcap, and Ω the solid angle under which the source sees the detector. Moens et al. (1981) and Moens and Hoste (1983) proposed an extension of this formula for the case of an extended source or a nonaxial source. More realistic computations are based on numerical approaches (e.g., Monte Carlo, Canberra’s ISOCS/LabSOCS software) (see Section C.3.e below and references Mueller et al., 2009, Bronson and Atrashkevitch, 2001 and Venkataraman et al., 1999).

b. The intrinsic efficiency ε_i and the transmission T_γ

T_γ

The overall efficiency may be given by

$$\varepsilon_\gamma = \eta \varepsilon_i T_\gamma \quad (4.41)$$

FIGURE 4.15 Some typical transmission curves. Plain curves: Ge dead layer of 0.3 μm (implanted window for *REGe* detector or “thin window” for Canberra’s *XtRa* or *BEGe* detectors) and 0.5 mm (Li diffused layer). Dashed curves: cryostat Be window of 0.05, 0.1, and 0.5 mm. Dotted curve: cryostat Carbon window of 0.5 mm. Dashed-dotted curve: cryostat Al window of 0.5 mm.

Fundamental effects such as the photoelectric effect and multiple Compton scattering discussed in Section II.B.1 are included in an intrinsic factor ε_i . Other factors such as the thickness of the different entrance windows, the p^+ or n^+ layers and the encapsulation of the source itself are included in the transmission factor T_γ , and η represents the geometric efficiency (Eq. 4.40). Fig. 4.15 gives the transmission through different endcaps and dead Ge layers. The importance of T_γ is illustrated in Fig. 4.16, which shows two experimental efficiency curves for the same low-energy germanium detector (LEGE) of 200 mm² surface and 10 mm thickness obtained with a mixed ²⁴¹Am ¹³⁷Cs ⁶⁰Co source placed at 5 cm. The only difference is the entrance window, 0.15-mm Be in the first case and 0.5-mm Al in the second. A big difference in efficiency is observed below 20 keV. The increase in efficiency at the very low-energy side is due to the beginning of the influence of the K-absorption edge of Ge. It is clearly seen in the upper curve (Be window) but is strongly reduced by the higher absorption of Al as shown by the lower curve.

The transmission T_γ is given by

$$T_\gamma = e^{-\mu d}. \quad (4.42)$$

Here, μ represents the total absorption coefficient for the γ ray and d the thickness of the specific absorber. The absorption coefficient μ can be expressed in g/cm² (the mass absorption coefficient μ_m) or in cm⁻¹ (the linear absorption coefficient μ_l) whether d is expressed in g/cm² or in cm. The following relation exists between both:

$$\mu_m = \frac{\mu_l}{\rho} \quad (4.43)$$

where ρ represents the density of the absorber in g/cm³. It is sometimes convenient to express the thickness d as half-thickness $d_{1/2}$. The relation between both is given by

$$d_{1/2} = \frac{\ln 2}{\mu} \quad (4.44)$$

where μ stands for either μ_l or μ_m .

c. Relative efficiency

The efficiency cited by the manufacturer of a Ge detector following the IEEE standards (ANSI/IEEE Standard 325-1986) does not represent the absolute efficiency of the detector. It represents the ratio of the absolute detector efficiency at 1332.5 keV (⁶⁰Co) to that of the same γ ray obtained with a 3 × 3 inch NaI(Tl) scintillation detector, the point source being placed at 25 cm on the axis of the endcap (measured from the center of the source to the front of the endcap). The absolute efficiency at 1.3 MeV of such a 3 × 3 inch NaI(Tl) scintillation detector measured at the same distance of 25 cm is 1.2×10^{-3} . The relative efficiencies offer some means to compare detectors. In Section E, however, it will be shown that the notion of “relative efficiency” could lead to completely false expectations.

The relative efficiency can be helpful to construct a very crude absolute efficiency curve when, besides the detector’s relative efficiency, the diameter of its active volume is also given. Indeed, two points of this curve for a point source at 25 cm from the endcap may be roughly estimated. The first point, at 1.3 MeV, can be calculated from the relative efficiency (absolute efficiency at 1.3 MeV and at 25 cm = relative efficiency × 1.2×10^{-3}). The second

FIGURE 4.16 Superposition of two efficiency curves for the same low-energy detector mounted with two different endcaps: 0.15 mm Be (upper curve) and 0.5 mm Al (lower curve). The source-to-detector distance was 5 cm. The curves are polynomial fits through the experimental points.

point, at 100–150 keV, can be approximated as $\varepsilon = \eta$ with η calculated from Eq. (4.25) using the information about the active diameter. This approximation is based on the assumption that, around 100–150 keV, ε_i is near 100% and the transmission correction negligible (at this precision). These two points may be joined by a straight line on a log-log scale. It is evident that such a rough estimate may not be used for actual measurements, as large errors are introduced by the application of the oversimplified assumptions.

d. The experimental efficiency curve

To analyze a gamma ray spectrum to obtain a source activity or gamma emission rate, it is necessary to know the detection efficiency for each peak observed in the spectrum. This can be accomplished by mapping the detection efficiency curve versus gamma ray energy over a range of energies. Such a curve can be established by the use of one or more calibration sources. If N_0 represents the number of radioactive atoms present in the calibration source at the starting moment of the measurement and $\lambda = 0.693/T_{1/2}$, its transition probability, where $T_{1/2}$ represents the half-life,

$$N_d = N_0(1 - e^{-\lambda \Delta t}) \quad (4.45)$$

atoms decay during the measuring time Δt . If Δt is small with respect to $T_{1/2}$ as is generally the case, Eq. (4.45) reduces to

$$N_d = N_0 \lambda \Delta t = I_0 \Delta t \quad (4.46)$$

I_0 being the activity in Bq. The number N_r of registered counts in the FEP is thus given by

$$N_r = I_0 \Delta t \varepsilon p \quad (4.47)$$

where ε contains all efficiency factors discussed and p represents the branching ratio of the γ ray measured. The efficiency can thus be readily calculated. Evidently, I_0 has to be corrected for the decay during the time elapsed when the calibration source was certified, according to the equation

$$I_0 = I_{cert} e^{-\lambda t} \quad (4.48)$$

where I_{cert} represents the certified intensity of the source for a given day and hour and t the time elapsed until the actual measurement.

To establish the complete efficiency curve, a great number of efficiencies ε_γ for various energies should be obtained experimentally, either by the use of several calibrated standard monoenergetic γ sources such as ^{137}Cs or, depending on the energy range desired, by the use of one or several multigamma sources such as ^{241}Am (11.9–59 keV), ^{60}Co (1173–1333 keV), ^{56}Co (1–3 MeV), ^{152}Eu (121–1408 keV), or ^{133}Ba (53–383 keV). For still lower energies, X-ray sources such as the Mn X-rays [5.88, 765 keV (50.5%), 5.89, 875 keV (100%), and 6.49 keV (20.3%)]

emitted during the EC decay of ^{55}Fe can be useful. This calibration work is straightforward using modern software such as GENIE (Canberra Industries). Nevertheless, attention should be paid to the following points:

1. Ensure that all standard sources have the same form and are placed at the same distance from the detector. These must be identical to those of the samples to be measured.
2. Ensure that the encapsulations used for all calibration sources and the samples to be measured are the same, especially when (very)-low-energy measurements have to be performed.
3. Do not use intense sources if multigamma ray sources are used emitting two or more coincident gammas. This will lead to losses due to random summing (see Section II.B.3).
4. If the standard source used in the calibration emits multiple gamma rays in true coincidence (^{152}Eu , ^{60}Co , ^{88}Y , etc.), then one has to be cognizant of true coincidence summing (or cascade summing) losses or gains affecting the FEPs. True coincidence summing losses or gains lead to an underestimation of the measured efficiencies, whereas the summing gains lead to an overestimation. These effects become worse with high efficiencies (small source-to-detector distances and/or large detectors). A correction factor may have to be used to correct for the effects of true coincidence summing (see Section II.B.4) before the efficiency calibration curve can be used in the analysis.

Fig. 4.17 shows a typical efficiency curve of a 25% p-type coaxial detector. A mixed ^{133}Ba ^{137}Cs ^{60}Co source was placed at a distance of 5 cm. The full line represents a fourth-order polynomial fit in $1/E$, E being the energy in keV of the experimental points.

e. Mathematical efficiency calculations

As described in the previous section, the detection efficiency curve may be obtained by measuring one or more calibration standards. These standards should emit gamma rays that span the range of energies expected to be present in the actual samples to be measured. In addition, it is essential that the calibration measurements have the same geometry as the actual samples. Specifically, this means that the source dimensions, source material and density, container wall thickness, container wall thickness and density, and source-to-detector positioning must all be same for the calibration standards versus the samples. In many cases it is not practical to obtain calibration standards that match the samples to be counted. Examples of this situation are as follows:

- The samples to be counted span a large variety of shapes and sizes and densities (e.g., decommissioning

FIGURE 4.17 Experimental efficiency curve of a 25% p-type coaxial detector. A mixed ^{133}Ba – ^{137}Cs – ^{60}Co source was placed at a distance of 5 cm. The full line represents a fourth-order polynomial fit in $1/E$, E being the energy in keV of the experimental points.

activities), thereby requiring an unacceptably large number of calibration standards to buy, count, and dispose of.

- The samples to be counted are too large to fabricate equivalent calibration standards (e.g., railroad cars full of soil and debris).

In such cases, it becomes necessary to utilize mathematical methods to obtain detection efficiency curves. One common approach is to use Monte Carlo computer modeling techniques. These techniques derive their name from the use of computer-generated random numbers to mimic the random processes that take place in real-life gamma ray emission, scattering, absorption, and detection events. Three computer packages that are in common use are as follows:

- MCNP (Monte Carlo N-Particle). See [Briesmeister, 2002](#).
- EGS (Electron Gamma Shower). See [Nelson et al. \(1985\)](#).
- GEANT. See [CERN Applications Software Group, 1994](#).

These codes allow for description of the counting geometry as well as features of the source gamma ray emission spectrum and features of the detector. These packages are extremely flexible and, consequently, extremely complex. To obtain accurate results, it is particularly important to provide detailed information about the structure of the detector. The best results are obtained by benchmarking the calculations from a detector model against measurements with calibration standards; in effect, calibrating the mathematical model. An example of this sort of approach, including rather sophisticated details of the detector structure, is given in [Friedman et al. \(2001\)](#). After developing an accurate model of the detector (i.e., a model proven to be

able to reproduce measured efficiencies), it can be used to calculate efficiencies for other source geometries. Clearly, this is a very complex process. Development of the geometry model and execution of the calculation take a lot of time and require a high level of sophistication and experience on the part of the user. It is well rewarded; however, a good Monte Carlo model can reproduce detection efficiencies with accuracies that rival those obtainable with calibration standards.

To reduce the amount of time and expertise necessary to obtain reliable efficiencies from Monte Carlo techniques, other approaches have been developed. Typically, these are simplified discrete-ordinated calculations that divide the source region into small volume pixels (“voxels”) that can be approximated as point sources. The detection efficiency for a given voxel is obtained by approximating the efficiency for the equivalent naked point source and then accounting for the attenuation losses through any absorbing materials between the point source and the detector. The detection efficiency for the entire source is simply obtained by summing the efficiencies for all the voxels.

Examples of such computer codes are Canberra’s ISOCS and LabSOCS software packages ([Venkataraman et al., 1999](#)). At the Canberra factory, a given detector is “characterized” by developing an MCNP model that reproduces several standard source measurements made with the detector. From there, the MCNP code is used to map out the efficiency of the detector for a naked (i.e., unattenuated) point source at any location within 500 m of the detector. This map of efficiency versus position and energy (referred to as the “characterization” for that detector) is then provided in the form of a lookup table to be used with the ISOCS and LabSOCS software. The software itself provides a simple interface for users to select a basic geometry template (e.g., box, cylinder, planar source, etc.)

and to specify the details of the source and possible passive absorbers (e.g., dimensions, densities, etc.) as well as the details of the source-to-detector vector. Utilizing the characterization to obtain the naked point source efficiencies, the software divides the source into point like voxels to calculate the detection efficiency as described in the previous paragraph. Typical calculation times for common geometries are on the order of seconds and rarely more than 1 minute; the calculated results are typically accurate to better than 10% depending on the complexity of the geometry. For detectors that have been characterized by Canberra, this is an extremely flexible and powerful technique.

f. Stability of the germanium detector efficiency

Users of HPGe detectors must know that the efficiency of their detector may change over time. The probability that this happens and the degree of change depends on the type of detector used as well as on the temperature at which this detector is stored.

As explained in [Section E](#) below, all germanium detectors have surface “dead layers” that are necessary for operation. These dead layers do not have charge collection and therefore are not part of the active detector. P⁺-contacts as well as the thin N⁺-contacts that Canberra applies on their BEGe and XtRa detectors are both very thin and stable with time and temperature. All germanium detectors available today still have Li-diffused contacts. This N⁺-contact is both thick (several hundred microns) and unstable at elevated temperatures. The diffused lithium layer is unstable because it continues to diffuse over time. The rate of diffusion is a function of temperature and lithium concentration gradient, with warmer temperatures, resulting in higher diffusion rates. Dead layer thickness growth is affected by the amount of time spent at higher (room) temperatures. When kept at liquid nitrogen temperatures, the dead layer growth rate is insignificant!

The effect of this basic property of Li-diffused contacts on the stability of the germanium detector efficiency depends on the precise geometry of each type of germanium detector. [Fig. 4.20](#) shows the various detector models offered by Canberra and the locations of the problematic thicker, unstable n-type dead layer. From this table, it is clear that the detection efficiency at low energies with a p-type coaxial detector (SEGe) is most affected. With the growth of the Li-diffused contact, the transmission of low energies may decrease strongly. Also the detection efficiency at low energies of an XtRa or BEGe detector model is affected when the source is located in a Marinelli beaker wrapped around the germanium detector. The effect on other detector models is limited to the loss of some active detector volume when the thickness of the inactive Li layer increases, which, in practice, is negligible.

Comparing the Li layer thickness of new germanium detectors with germanium detectors that have been used in the field for a number of years shows that the typical growth rate of the Li layer is 0.2 mm/y. Diffusion theory predicts that the growth rate will decrease over time, so this linear approximation is conservative. In practice, the typical dead layer thickness of “fresh” germanium detectors is between 0.3 and 0.6 mm. Detectors that have been in the field for some years have typical Li layer thicknesses between 0.7 and 1 mm, occasionally up to 2 mm. Consequently, the detector efficiency may degrade with 5%–10% in less than a year for 60 keV and in 2–4 years at higher energies measured with a standard p-type coaxial detector (SEGe). Similar efficiency losses are observed with BEGe or XtRa detectors in 4–5 years’ time of “typical” use. N-type coaxial detectors (REGes) hardly show any efficiency degradation with time.

The gamma spectroscopist must be aware of these phenomena. He or she can minimize the effects on measured data by taking some basic precautions, such as the following:

- Use the proper detector for a given application. If an important measurement includes ²⁴¹Am, then a standard coaxial p-type detector, or a BEGe or XtRa detector in combination of a Marinelli geometry, should not be used.
- Check the detector calibration periodically with a QC check source. These data can then also be used to correct the mathematically generated efficiency curves in a simple way if needed.
- Keep the detector at liquid nitrogen temperatures as much as possible and practical. If not, store it in a cool place. Storage in an air-conditioned room rather than in a hot area may reduce the dead layer growth rate by 20%–40%. Storing it in a deep freezer is not a good alternative since this may freeze the O-ring seal used and ruin the detector vacuum.

D. Background and background reduction

It seems natural to define the background as all pulses registered by the detection system when no source is present. However, it was seen earlier (see [Section II.B](#)) that the Compton effect and bremsstrahlung give rise to an important continuum that also has to be regarded as a real background. It is thus useful to distinguish between the background with and without a source.

1. Background in the presence of a source

The background due to the source itself is essentially the continuum generated by Compton scattering and by bremsstrahlung. These effects have been analyzed in [Section II.B](#), and no further discussion is needed. However, it is this background that very often governs the detection limits.

2. Background in the absence of the source

Background in the absence of a source has three different origins: man-made isotopes, natural isotopes, and cosmic radiation. In contrast to the background from a source, it contains, besides a continuum due to cosmic interactions in the crystal (Verplancke, 1992), many discrete γ lines. The most common discrete lines are summarized in Table 4.4. The first column of Table 4.4 gives the energy, the second column gives the isotope in which the nuclear transition responsible for the emission of a γ ray takes place, and the third column gives the decaying isotope and/or the reaction responsible for the formation of the isotope. The fourth column gives the intensity of the γ ray. A fifth column is reserved for various remarks, such as the origin of the γ ray, the principal decay mode, the half-life, and, when possible, the intensity of the prompt reaction of γ rays.

a. Man-made isotopes

Here, we find essentially fission isotopes such as ^{137}Cs due to fallout from the former bomb testing in the atmosphere, nuclear accidents, or isotopes formed by man-made nuclear reactions such as those of ^{60}Co .

b. Natural isotopes

Here, we find ^{40}K and the isotopes belonging to the natural decay chains: ^{238}U (Table 4.5), ^{235}U (Table 4.6), and ^{232}Th (Table 4.7). These tables give the decay mode, the half-life, and the main γ rays of the various isotopes. The parent nuclei, ^{238}U , ^{235}U , and ^{232}Th , are very long lived. Their half-lives are several orders of magnitude longer than those of the longest-lived daughter elements. They reach a secular equilibrium meaning that the intensities of the various γ rays may be compared directly with each other after correction for α or β branching (see Chapter 1). However, the equilibrium may be disturbed if physical or chemical separation took place. Just two examples:

1. The “emanation” of noble gases (^{222}Rn , ^{220}Rn , ^{219}Rn), daughters from natural U and Th. In particular, U is often found underground or in the construction materials of buildings. Consequently, ^{222}Rn (radon) may concentrate in closed rooms. The characteristic γ rays of its daughters ^{214}Pb and ^{214}Bi are very common background lines. The intensity of Rn lines in the background spectrum may fluctuate a lot with the weather conditions.
2. Separation in geological time due to different solubilities of the various elements. This can be used for dating of geological formations based on the $^{234}\text{U}/^{230}\text{Th}$ ratio.

When there is a chance that the equilibrium of the daughter isotope with its parent is disturbed, only the intensities of the γ rays belonging to the partial decay chain of this daughter can be compared directly. These long-lived

isotopes, whose equilibrium with the parent can be disturbed, are marked by a frame in Tables 4.5, 4.6, and 4.7.

3. Background of cosmic origin

Cosmic rays comprise primarily very high-energy (up to 10^8 – 10^9 GeV) protons and α particles originating from stellar processes in supernovas with a mean energy between 5 and 10 GeV per nucleon. These particles undergo collisions in the stratosphere, where they give rise to various π and K mesons as well as to muons, neutrinos, electrons, neutrons, and photons. Typical fluxes at sea level are 10^{-2} particles/cm² • s • steradian distributed according to a $\cos^2\theta$ law, θ being the polar angle. About 75% of all particles at sea level are π -mesons, and the absolute proton flux is of the order of 0.1% of all particles. These cosmic rays constitute a very important part of the background in the absence of a source and contribute to the continuum as well as to the activation of various nuclei. These effects continue to attract the attention of various researchers, such as Wordel et al. (1996) Heusser (1996), Laubenstein and Heusser (2009), and Jovancevic et al. (2010). A comprehensive overview of the origin of cosmic rays has been given by Celnikier (1996).

a. “Prompt,” continuously distributed background

Charged particles can penetrate the sensitive volume of the detector, giving rise to a continuous background in coincidence with the primary particle. The energy loss per collision of 10-MeV electrons, 100-MeV mesons, or 1000-MeV protons is approximately 1.8 MeV/g • cm², generating in a Ge detector a signal of about 10 MeV per centimeter traversed. Cosmic particles also produce showers of secondary particles (p, e[−], e⁺), mainly in the detector shielding. In turn, these secondary charged particles produce bremsstrahlung and annihilation lines. This secondary radiation contributes more specifically to the background in the lower energy region of a shielded detector.

b. Neutron-induced “prompt” discrete γ rays

Fast neutrons can induce prompt γ rays by the (n,n') reaction. This is particularly important when the reaction takes place in the Ge itself or in other materials in the vicinity of the detector such as Cu, Fe, Pb, and Cd. These lines are summarized in Table 4.4. The Compton scattering of these γ rays also adds to the continuum.

c. “Delayed” γ rays

Delayed γ rays are due to the deexcitation of isotopes formed either in the Ge itself or in the material surrounding the detector. They are due to capture of thermalized neutrons or to more exotic nuclear reactions also mentioned in Table 4.4. These isotopes also contribute to the continuum by bremsstrahlung and Compton scattering.

TABLE 4.4 Background lines observed in Ge spectra (This list is neither complete nor should all lines be present in each spectrum).

γ line (keV)	Isotope ^{a)}	Reaction ^{b)}	$I_{\gamma}^{c)}$ (%)	Remarks
13.26	^{73m} Ge	⁷² Ge(n, γ) ^{73m} Ge	0.09	$T_{1/2} = 0.5$ s: isomeric transition produced continuously by thermalized neutrons from cosmic origin, (see also 66.7 keV line).

463.38	¹²⁵ Te	¹²⁴ Sn(p, γ) ¹²⁵ Sb	0.15	β^{-} -decay ($T_{1/2} = 2.77$ a): protons from cosmic origin.
510.8	²⁰⁸ Pb	²⁰⁸ Tl	22.6	β^{-} -decay ($T_{1/2} = 3.05$ m): ²³² Th series.
511.0	Anni.			This very common Doppler broadened line finds its origin in the annihilation of β^{+} -particles occurring in the β^{+} -decay or the pair production process induced by high-energy γ rays ($E_{\gamma} > 1022$ keV) of cosmic origin and/or due to nuclear decay or various nuclear reactions. Many possible origins allow no prediction of its intensity. It may not be used to estimate the intensity of a β^{+} -decay branching. Is also produced by muon-induced pair production.

TABLE 4.4 Background lines observed in Ge spectra (This list is neither complete nor should all lines be present in each spectrum).—cont'd

γ line (keV)	Isotope ^{a)}	Reaction ^{b)}	$I_{\gamma}^{c)}$ (%)	Remarks
549.7	²¹⁶ Po	²²⁰ Rn	0.1	α -decay ($T_{1/2} = 55.6$ s): ²³² Th series.
558.2	¹¹⁴ Cd	¹¹³ Cd(n, γ) ¹¹⁴ Cd		Prompt neutron capture γ -ray, $I = 79.71\%$ in nat. isotope mixture; is produced continuously by thermalized neutrons of cosmic origin.
562.9	⁷⁶ Ge	⁷⁶ Ge(n,n') ⁷⁶ Ge		Prompt γ -line produced by inelastic scattering of fast neutrons from cosmic origin. Right asymmetric line-shape due to recoil of the Ge-atoms induced by (n,n')-reaction.
563.3	¹³⁴ Ba	¹³³ Cs(n, γ) ¹³⁴ Cs	8.38	β^- -decay ($T_{1/2} = 2.06$ a). This isotope is found in reactor waste (Chernobyl fallout) but not in the fall-out of bomb testing. This is due to the fact that it is no fission product, as it is screened by the stable ¹³⁴ Xe. It is however found among the reactor fission products, as ¹³³ Cs is the stable end product of the $A = 133$ fission chain having a yield of 7.87%.
568.7	²³⁴ U	²³⁴ Pa	3.3	β^- -decay ($T_{1/2} = 6.7$ h): ²³⁸ U series.
569.5	²³⁴ U	²³⁴ Pa	10.0	β^- -decay ($T_{1/2} = 6.7$ h): ²³⁸ U series.
569.79	²⁰⁷ Pb	²⁰⁷ Pb(n,n') ²⁰⁷ Pb ²⁰⁶ Pb(n, γ) ²⁰⁷ Pb		Prompt γ -line produced by inelastic scattering of fast neutrons from cosmic origin or by thermal neutron capture.
583.2	²⁰⁸ Pb	²⁰⁸ Tl	84.5	β^- -decay ($T_{1/2} = 3.05$ m): ²³² Th series.
595.9	⁷⁴ Ge	⁷³ Ge(n, γ) ⁷⁴ Ge ⁷⁴ Ge(n,n') ⁷⁴ Ge		Prompt neutron capture γ -ray, $I = 34.65\%$ in nat. isotope mixture; is produced continuously by thermalized neutrons from cosmic origin. Prompt γ -line produced by inelastic scattering of fast neutrons from cosmic origin. Right asymmetric line shape due to recoil of the Ge atoms induced by (n,n') reaction.
604.7	¹³⁴ Ba	¹³³ Cs(n, γ) ¹³⁴ Cs	97.6	See comments 563.3 keV line.
651.0	¹¹⁴ Cd	¹¹³ Cd(n, γ) ¹¹⁴ Cd		Prompt neutron capture γ -ray, $I = 15.23\%$ in nat. isotope mixture; is produced continuously by thermalized neutrons from cosmic origin.
600.55		¹²⁴ Sn(p, γ) ¹²⁵ Sb	17.78	β^- -decay ($T_{1/2} = 2.77$ y): protons from cosmic origin.
606.64	¹²⁵ Te	¹²⁴ Sn(p, γ)	5.02	β^- -decay ($T_{1/2} = 2.77$ y): protons from cosmic origin
609.3	²¹⁴ Po	²¹⁴ Bi	44.8	β^- -decay ($T_{1/2} = 19.9$ m): ²³⁸ U series.
635.9	¹²⁵ Te	¹²⁴ Sn(p, γ) ¹²⁵ Sb	11.32	β^- -decay ($T_{1/2} = 2.77$ y): protons from cosmic origin.
661.66	^{137m} Ba	¹³⁷ Cs	85.0	Fission isotope β^- -decay ($T_{1/2} = 30.17$ y): bomb testing + - Chernobyl fallout.
669.6	⁶³ Cu	⁶³ Cu(n,n') ⁶³ Cu		Prompt γ -line produced by inelastic scattering of fast neutrons from cosmic origin
671.40	¹²⁵ Te	¹²⁴ Sn(p, γ) ¹²⁵ Sb	1.8	β^- -decay ($T_{1/2} = 2.77$ y): protons from cosmic origin.
691.0	⁷² Ge	⁷² Ge(n,n') ⁷² Ge		Prompt γ -line produced by inelastic scattering of fast neutrons from cosmic origin. This line is a 0+ to 0+ and can thus only take place by internal conversion as electrical monopole transitions are strictly forbidden. The asymmetric right-side shape is due to imperfect transformation of the recoil energy due to the neutron scattering and is observed—in contrary to other (n,n') reactions, due to the fact that the recoil takes place in the Ge and thus inside to the detector.

4. Background reduction

Background reduction is a difficult and delicate operation. The optimum shielding should take the isotopes to be measured into account as well as the energy range and the lower limit of detection desired. But as local conditions can vary strongly, no off-the-shelf solution can be given for all cases. Some general rules remain valid under all conditions and will be discussed subsequently.

a. Passive background reduction

Passive background reduction is based on the absorption of undesired γ rays by an absorber placed between the detector and the source of the background. The transmitted intensity is given by Eq. (4.49). If the absorption coefficient is expressed in half-thickness (cm), the transmitted intensity I is given by

$$I = I_0 e^{-0.693d/d_{1/2}} \quad (4.49)$$

where I_0 is the initial flux, $d_{1/2}$ the half-thickness, and d the actual thickness of the shielding. In Fig. 4.18, the half-thickness for Cu, Sn, Pb, and Si is given as a function of energy. Good shielding should be sufficiently thick; for example, 10 times the half-thickness, to reduce the background by a factor of 1000. This would translate into a Pb thickness of 8.8 cm for a 1000-keV γ ray. In practice, a thickness of 10 or 15 cm is often chosen. It must be remembered here that lead contains ^{210}Pb ($T_{1/2} = 21$ y), as the Pb ores and the coke used in the melting process contain U traces that continuously form ^{210}Pb . The ^{210}Pb content in lead varies according to its origin and age.

Specific lead is available for ultralow background shielding (Fig. 4.18).

On the other hand, the Pb shield should not be too thick, to reduce the production of fast neutrons by cosmic particles with the subsequent production of n-induced background lines summarized in Table 4.4. Fast neutrons are difficult to stop. Several tens of centimeters of hydrogen-rich material is needed to thermalize them. Once thermalized, they can be stopped by high-cross section materials such as B or Cd. However, the absorption process generates new γ rays, including a Doppler-broadened 480 keV for B and a whole spectrum of neutron capture γ rays for Cd. Shields have been built to minimize the effect of cosmic neutrons on the background spectrum. These consist of a “sandwich,” combining materials that slow down fast neutrons and absorb these neutrons and materials that stop environmental gamma rays and gamma rays produced in the process of eliminating the (n, γ) signals (Heusser, 1996).

Fluorescent Pb X-rays can be reduced by a supplementary lining of the Pb shield by lower Z material such as Cd or Sn. A 1-mm thickness of Sn stops 95% of all Pb X-rays, and a supplementary lining of 1.5 mm of Cu stops most of the Sn X-rays and raises the total absorption of lead X-rays to 98.5%. Once again, thick linings should not be used; otherwise, the continuous background due to the backscattering of the source γ rays will increase. This is due to the fact that the Compton effect, responsible for the backscattering, varies with the atomic number Z , whereas the photoelectric effect is proportional to Z^5 . Also, the plastic inner layer often used to prevent contamination of the shield should be as thin as possible. Lining a 10-cm Pb shield with

FIGURE 4.18 Half-thickness in centimeter for Pb (lower plain curve), Sn (dashed curve), Cu (dotted curve), and Si (upper plain curve) as a function of energy.

1-mm Cd, 2-mm Cu, and 10-mm Plexiglas increases the background by as much as 30% at 25 keV and 15% at 1000 keV.

Cosmic background and the associated activation and reaction lines can be adequately reduced by placing the detector deep underground. At a depth of 1000-m water equivalent, the neutron flux induced by cosmic particles is less than 1% of the flux observed at sea level.

b. Active background reduction

In active background reduction, we cover all measures that are not based on the absorption of the undesired γ rays. Active background reduction techniques eliminate their causes or limit their effect.

Venting. It has been seen that ^{222}Rn and its daughters may accumulate in a closed area and, in particular, inside the shielding of the detector. Venting with an Rn-free gas such as N_2 or Ar may help to reduce their presence strongly. This can easily be achieved by using the nitrogen gas boiling off from the liquid nitrogen tank used to cool the germanium detector.

Choice of construction materials and cryostat design. Materials used in the detector surroundings and especially for the construction of the cryostat as well as the electronic components of the preamplifier can contain elements such as Al, Be, and Sn, which may contain traces of U or Th, constituting an undesired source of background. The industry offers different types of cryostats whose design and selection of construction materials minimize these effects. Figure 4.19 shows the experimental background per keV per hour (cph/keV) for the same detector

element mounted in different Canberra cryostats: the classical vertical dipstick cryostat and the same cryostat with the materials close to the detector element selected for low background. The third spectrum is taken with the same cryostat but with an additional low-background lead disk between the crystal and preamplifier. It is seen that this additional lead disk reduces the background from the preamplifier and from the floor at higher energies only. The lowest background at all energies is obtained with the 7500SI-RDC-ULB cryostat. In this cryostat, the low-background detector chamber is separated from the preamplifier chamber and from the rest of the cryostat with a thin tube holding the cold finger. This part of the cold finger is off-set from the lower part in the dipstick cryostat, preventing a direct line of view between the detector element and the floor (Ceuppens et al., 1996) (Fig. 4.19).

The Compton suppression Spectrometer. The Compton continuum is observed when the Compton-scattered γ ray escapes from the detector. When a large scintillation detector [NaI(Tl), plastic or BGO) surrounds the Ge detector and the source, a coincidence signal between this shield and the Ge detector can be used to suppress the Compton pulse. However, the following two important aspects must be noted.:

1. Above 200 keV Compton scattering occurs predominantly in the forward direction. The optimum active shield should be designed with this property and the actual source-detector geometry in mind. By Compton suppression, the remaining continuum after adequate passive shielding, can be reduced by a factor of 5 or more.

FIGURE 4.19 Background in counts per keV and per hour for the same detector placed in different cryostats: Upper plain curve: standard Canberra vertical dipstick cryostat; dashed curve: same cryostat with the building materials close to the crystal replaced by low background alternatives; dotted curve: same cryostat but with an additional low-background lead disk between the crystal and preamplifier; lower plain curve: ultralow-background Canberra cryostat model 7500SL RDC-ULB.

2. A Compton suppression active shield also rejects coincident lines such as the 1173.2- and 1332.5-keV lines of ^{60}Co . For isotopes having two or more coincident lines, strong spectrum deformation will occur, and the previously established efficiency curve will no longer be valid. The application of this technique is limited, therefore, to specific applications. This effect is similar to that observed in a well-type detector with one important difference. In both cases, the intensity of coincident γ lines is reduced, but in the case of a well-type detector, the intensity of the coincident lines is recovered back in the sum peaks, as will be discussed in Section E.

The cosmic veto shield. High-energy charged cosmic particles contribute to the continuum in the spectrum. This background can be drastically reduced by an active veto detector, generally a plastic scintillator, placed above, or surrounding, the Ge detector's passive shield (see, for instance, Semkow et al., 2002). Any cosmic particle entering the Ge detector will also interact with the veto detector generating two coincident signals that can be used to suppress the Ge pulse. Long dead times of a few tens of microseconds will also reduce the “delayed” cosmic background. With the help of a veto shield, background reductions of 99% have been obtained in the 10-MeV region, where the background is solely due to cosmic events (Müller et al., 1990).

E. The choice of a detector

1. General criteria

The industry offers a large variety of germanium detector models each of which is tailored for a particular application or energy range. Fig. 4.20, for instance, summarizes the various models offered by Canberra. This figure is self-

explanatory. More details of each of the models can be found in the catalogs from the various manufacturers.

2. Increasing the size of high-purity germanium detectors

High-purity germanium (HPGe) became industrially available in the late 1970s and the beginning of 1980s. To satisfy the demand for devices that provide continually better measurement statistics in less counting time, optimum detector geometries as well as the enabling contacting technologies have continually developed since the beginning of the 1980s. This also led to the race to grow the biggest germanium ingot between the few industrial Ge crystal manufacturers. This resulted in the first 100% detector (i.e., a germanium detector with roughly 80 mm diameter and 80 mm length that has the same efficiency at 1.3 MeV as a $3'' \times 3''$ NaI detector) in 1988, the first 150% detector in 1992 (diameter 90 mm, length 86 mm), and the first 200% detector (diameter 100 mm and length 126 mm) built in 1998. This latter achievement (produced in Canberra Oak Ridge) ended the race for ever bigger germanium detectors. Development of larger detectors ceased because the costs to grow such huge crystals turn out to be unacceptably high and, secondly, the extra detector dimensions do not lead to a sizable improvement in “counting efficiency” for an industrial lab, over the energy domain between 100 and 2 MeV, which is their primary range of interest. Indeed, these gamma rays do not penetrate germanium more than about 7–8 cm. Anything beyond this length only sees background radiation from the environment. This long size also increases the detector capacitance and, thus, the noise and energy resolution. This explains why these very large crystals are almost exclusively used to make well-type Ge detectors. In this type of detector, the source is located in a well drilled in the detector crystal.

FIGURE 4.20 Summary of the various Ge detector models offered by Canberra, with the energy range they cover and their salient performance characteristics. Image courtesy of Mirion Technologies.

3. The germanium well-type detector

A well-type detector is designed to surround the sample so that close to 4π geometry is obtained. The source sees the negligible thin ion-implanted p^+ contact. It is thus the ideal detector when small samples (test tube sized) have to be measured routinely. It must be emphasized, however, that with this detector type, coincident γ rays are subject to intense summation, leading to strong spectrum deformation, namely a reduction of the individual peaks and an enlargement of the sum peaks. Consequently, for each sample (or at least for each isotope mixture), a specific and carefully established efficiency calibration is needed.

Also, it should be noted that, when large quantities of source materials are available that can be put on the detector window, or around the detector chamber, lower minimum detectable activities (MDAs) per gram of source material can be obtained than when only a very small portion is measured in the favorable well-type geometry.

4. Limitations to the “relative efficiency” quoted for coaxial detectors

Traditionally, the shapes and geometries of most HPGe coaxial detectors that are offered on the market today are designed to optimize resolution and relative efficiency as defined in [Section II.C.3](#). The notion of “relative efficiency,” however, does not tell the spectroscopist anything about the real behavior of this detector at energies other than 1.3 MeV or in real measurement situations with sources different from a point source at 25 cm distance. [Fig. 4.21](#), for instance, compares the absolute efficiencies of the two detectors from [Fig. 4.22](#). Both detectors have the same “relative efficiency” of 35%, but the absolute efficiencies, even for a point source at 25 cm, are very different

for all energies different from 1.3 MeV. It is seen that the detector with the best absolute efficiency in the energy range considered has a large diameter, a shorter length, and sharper edges at the side of the entrance window (this window is facing down in this picture) than the other detector.

A goal that is pursued by most environmental and low-level gamma spectroscopists is to lower the MDA of their detection system, i.e., to obtain more statistical evidence in less time. It has been shown that the MDA depends in the first place on the detection efficiency and in the second place on number of background counts and peak width. It thus appears that it pays the most to increase the detection efficiency. This, however, does not always mean that one needs to choose a bigger detector or a detector with a higher relative efficiency. More important is to select a detector that is better matched with the source to be measured.

This principle is dramatically demonstrated with the following example, summarized in [Table 4.8](#). It shows the net count rates, the number of background counts, energy resolutions, and relative MDAs obtained with a cylindrical multigamma source positioned on the endcaps of two different detectors. The “50% XtRa” detector is a Canberra thin window p-type coaxial detector with relatively sharp edges at the window side, a diameter of 65.5 mm and a length of 65 mm, similar to the shape of the crystal on the left side in [Fig. 4.22](#). The “70% n-type” or “REGe-type” detector has strongly rounded edges—beyond the diameter of the source, a diameter of 69.7 mm and a length of 80.3 mm. It is seen in [Table 4.8](#) that the “smaller” detector for this particular detector-source geometry yields a higher counting rate at all energies below 1.2 MeV, a lower background, better energy resolutions, and thus lower MDAs than the “bigger” detector!

FIGURE 4.21 Absolute efficiency curves for the two “35%” detectors shown in [Fig. 4.22](#). Point sources at 25 cm from the endcap were used to obtain these curves.

FIGURE 4.22 Two germanium crystals yielding a relative efficiency of 35%. The entrance windows are facing down. The right crystal has rounded edges at the window side.

5. The Broad-Energy Germanium, or “BEGe” detector

Observations like those described in Section 3 above led some detector manufacturers to build detectors that are optimized for certain specific applications (Verplancke, 1999; Keyser et al., 1998). The broad-energy germanium or “BEGe” detector from Canberra is developed to give a detector that is best adopted for low-level applications with extended sources and energies ranging from 5 keV to >2 MeV. It makes use of the best available and selected

germanium material (generally of p-type) and has relatively sharp edges, a very thin window that is 100% transparent for energies of 3 keV and up, a low capacitance (and thus very low electronic noise), very high resolutions (low FWHM) at lower energies, large active surfaces (up to 5000 mm²), and fixed dimensions. The cryostat is equipped with a carbon window that has a transmission of more than 85% at 10 keV and close to 100% for energies higher than 20 keV.

It is interesting to note that detectors with either small p⁺-contact (like this BEGe detector) or small n⁺-contacts (like the LEGe geometry—see Fig. 4.20) have long been rated as less suitable for physics experiments involving precise timing information (such as time-of-flight experiments) because the time of interaction between the impinging gamma ray on the detector cannot be determined as precisely as with a coaxial-type detector. Indeed, the time to collect the signal generated in such a small-contact detector depends very strongly on the place where the signal is generated. The collection time is very short when the gamma interaction takes place in the vicinity of the central small contact, and can be much longer if it takes place near the rim of the detector. More recently, it has been recognized that this same phenomenon can be used to discriminate “single-site events (SSEs)” from “multisite events (MSEs)” (where the observed signal is due to multiple Compton interactions in the crystal), using pulse shape analysis. Distinction between SSE and MSE can be used to suppress Compton backgrounds and increase the signal-to-noise ratio when searching for full-energy gamma lines.

TABLE 4.8 Performance of a long, 70% n-type detector with rounded edges versus a 50% thin window (XtRa) p-type Ge detector.

Energy (keV)	Net count rate (cps)		Background (cps)		FWHM (keV)		Relative MDA	
	70%	50%	70%	50%	70%	50%	70%	50%
	n-type	XtRa	n-type	XtRa	n-type	XtRa	n-type	XtRa
59	16.3	18.9	2.06	1.81	1.04	0.82	1	0.72
88	16.3	18.6	0.82	0.65				
122	16.2	17.5	1.11	0.77				
165	11.7	13.1	1.08	0.79				
392	6.84	7.42	0.74	0.56				
514	5.45	5.87	0.78	0.34				
662	4.63	4.89	0.61	0.46	1.63	1.34	1	0.75
898	3.24	3.33	0.56	0.45				
1173	2.63	2.66	0.33	0.26				
1333	2.38	2.36	0.16	0.14	2.23	1.81	1	0.85
1836	1.87	1.83	0.11	0.06				

The source is a disk source on the detector window.

This technique is also proposed to look for a very rare SSE, namely, the neutrinoless double beta decay. For that purpose, more “point-contact” (or “small-contact”) detector types have been built (Budjas et al., 2009; Agostini et al., 2011; Barbeau et al., 2007). See also Chapters 1, 6, and 9 of Volume 1 for the theory and detection methods applied in the search for neutrinoless double beta decay.

III. Si detectors

A. Si(Li) X-ray detectors

Si(Li) detectors are made by compensating the excess acceptor ions of a p-type crystal with Li donor ions by a process called lithium drifting. The nominal thickness varies between 2 and 5 mm, and the active area between 12 and 80 mm² and resolutions between 140 and 190 eV are achieved. Like Ge detectors, they are operated in a liquid nitrogen cryostat. They find their application mainly in X-ray analysis. From this point of view, they should be compared with low-energy or ultralow-energy Ge detectors. The latter have better resolutions for reasons explained in Section I.C. All generalities mentioned in Section II related to Ge detectors can be transposed readily to Si(Li) detectors. As with low-energy Ge detectors, the efficiency for low-energy γ rays is governed by the various entrance windows. The efficiency for high-energy γ rays drops drastically above 20 keV and reaches nearly zero at 100 keV, whereas a low-energy Ge detector still has appreciable efficiency at 1000 keV as illustrated in Fig. 4.16. What seems to be a disadvantage may turn out to be an advantage in many applications. Indeed, the low efficiency for higher energy γ rays reduces not only the FEPs but also the continuous background due to the presence of the source and more particularly to Compton scattering decreasing the lower limit of detection in the X-ray region. Finally, γ spectra or X-ray spectra taken with Si(Li) detectors are less disturbed by the escape of Si X-rays than Ge detectors by the escape of Ge X-rays (see Section II.B.3). Indeed Si K α X-rays have an energy of only 1.74 keV. The choice between a low-energy Ge detector and a Si(Li) detector is thus governed solely by the projected application. At room temperature, Si(Li) detectors are sometimes used as high-energy particle detectors.

B. Si-charged particle detectors

Silicon-charged particle detectors, such as diffused junction detectors (DJDs) or silicon surface barrier detectors (SSBs), have served the scientific and industrial community for several decades (Knoll, 1999). In the gold-silicon detector, the n-type silicon has a gold surface barrier as the front contact and deposited aluminum at the back of the detector as the ohmic contact. Current applications, however, require detectors having lower noise, better resolution,

higher efficiency, greater reliability, more ruggedness, and higher stability than older technologies could produce. Modern ion-implanted detectors such as the passivated implanted planar silicon (PIPS) detectors are now recommended as charged particle detectors. They surpass the older detector types in almost every respect.

Salient advantages of PIPS technology include the following:

- Buried ion-implanted junctions. No epoxy edge sealant is needed or used. This increases the detector stability. Ion implantation ensures thin, abrupt junctions for good α resolution.
- SiO₂ passivation. It allows long-term stability and low leakage currents.
- Low leakage current, typically 1/10 to 1/100 of an SSB (surface barrier detector).
- Low noise.
- Thin windows (≤ 500 Å equivalent of Si). This results in less straggling in the entrance windows and thus yields better α resolution.
- Ruggedness (cleanable surface).
- Bakeable at high temperatures.
- Long lifetime.

In the detection process, the particle is stopped in the depletion region, forming electron–hole pairs. The energy necessary to form a single electron–hole pair depends on the energy gap ϵ (Table 4.1) of the detector material, but it is essentially independent of the energy of the incoming particle. Consequently, the number N of electron–hole pairs ultimately formed is directly proportional to the energy of the stopped particle as expressed in Eq. (4.1). This eventually results in a pulse proportional to the energy of the charged particle. The thickness d (Eq. 4.6) of the depletion region depends on the applied bias voltage. Partial or full depletion with or without overvoltage is possible as illustrated in Fig. 4.23. The capacitance in pF for a PIN diode structure is given by

$$C = \frac{1.05A}{d} \quad (4.50)$$

FIGURE 4.23 Thickness d of the depletion layer as a function of applied bias: (A) partially depleted detector, (B) fully depleted detector, and (C) fully depleted detector with overvoltage.

where A represents the surface area of the junction in cm^2 and d its thickness in cm. The surface seen by the charged particles is called the active area of the detector. It is required for the calculation of the efficiency. The junction area is typically 20% larger than the active area.

The noise level of charge-sensitive preamplifiers is usually given by the manufacturer for zero input capacitance. It increases with capacitance (Eq. 4.34), and the rate of increase is also specified by the manufacturer. The detector capacitance is reduced at higher bias voltages as long as the detector is not fully depleted. The lowest noise and best resolution are thus obtained at higher voltages within the recommended range. At voltages above that recommended by the manufacturer, the reverse leakage current is likely to increase, causing excessive noise and loss of resolution.

1. Alpha detectors

Alpha spectroscopy finds applications in widely different disciplines such as follows:

- Radiochemical analysis
- Environmental studies and surveys
- Health physics
- Survey of nuclear sites through the off-line detection of emitted actinides
- Geological and geomorphologic studies (such as U–Th dating)

It requires high resolution, high sensitivity, and low background.

1. High resolution is ensured by the thin entrance window over the detector surface. It reduces energy straggling in the entrance window. Energy straggling is due to the random nature of the interaction of a charged particle with the detector material. This leads to a spread in

energy if a beam of charged particles passes through a certain thickness of absorber and, consequently results in an increase of the peak width (Knoll, 1999). Since the alpha radiations generally penetrate the entrance window with variable angles of incidence, alphas will undergo different travel lengths in this layer, leading to variable energy losses and, thus, to a broadening of the peak. A thin window means less straggling and better resolution. Furthermore, the low leakage current ensures a low electronic noise contribution. Both properties together allow high α resolution. Values ≤ 16 keV (FWHM) are routinely achieved for a detector with an active area of 450 mm^2 . Note, however, that the obtainable resolution depends not only on the detector but also on external factors such as vacuum and source preparation described later in this chapter. Table 4.9 shows some typical specifications and operating characteristics for modern, ion-implanted α detectors.

2. High sensitivity is enhanced by good resolution, which reduces the background below the peak. A depletion depth of $140 \mu\text{m}$ is enough to absorb α particles of up to 15 MeV covering the complete range of all α -emitting radionuclides. For larger detector diameters (1200 mm^2), absolute efficiencies $\geq 40\%$ can be achieved. This is illustrated in Fig. 4.24 and discussed in more detail later in this section. Packaging and mounting materials have to be carefully selected to avoid possible contaminants. Low background is further ensured by clean manufacturing and testing procedures. Backgrounds of $\leq 0.05 \text{ cts/(h cm}^2\text{)}$ in the energy range $3\text{--}8 \text{ MeV}$ are achieved routinely.

a. Factors influencing resolution and efficiency

Detector–Source Distance. All α particles reaching the active area of the detector will be counted. The counting

TABLE 4.9 Some examples of operating characteristics for α detectors.

Active area (mm^2)	300	450	600	900	1200

At 2 mm spacing	36.8	40.2	41.0	43.6	44.5
At 5 mm spacing	23.5	28.3	31.2	34.8	36.9
At 15 mm spacing	7.3	10.1	12.4	16.1	18.9

FIGURE 4.24 Calculated efficiencies for a 1200 mm² (upper curve), a 900 mm² (middle curve), and a 300 mm² (lower curve) detector as a function of the source–detector distance h ; the source diameters were respectively 35, 32, and 15 mm.

efficiency is thus given by the geometric efficiency, $\eta = \Omega/4\pi$, where Ω is the solid angle under which the detector subtends the source. For the case of a circular detector on axis with a circular isotropic source disk, this solid angle can be computed by Monte Carlo calculations (Williams, 1966; Carchon et al., 1975) and is available in tabulated form (Gardner et al., 1980). Fig. 4.24 gives the calculated efficiencies for 1200-, 900-, and 300-mm² detectors as a function of source-to-detector distance. The source diameters are 35, 32, and 15 mm. Actual efficiencies may be slightly different, especially at small source–detector distances, because of factors such as self-absorption in the source. Efficiencies of $\geq 40\%$ are obtainable.

In Table 4.9, alpha resolutions (FWHM) for the 5.486-MeV alpha line of ²⁴¹Am are given in the case of a detector–source distance of $d = 15$ mm, using standard Canberra electronics. When the source approaches the detector, line broadening is expected, as the mean slope of the α particles entering the detector is increased, resulting in an effectively increased maximal path in the entrance window and subsequent increase of the spread of incident angles and therefore higher energy straggling (Aggarwal et al., 1988). For ion-implanted detectors, this energy straggling is minimized because of the very thin entrance window of 500 Å. For comparison, the entrance window in equivalent Si is $\cong 800$ Å for an SSB with a gold window and >2000 Å with an aluminum window. Empirically, it has been proven that for a 300- to 600-mm² detector the increase in FWHM stays below 50% for distances as small as 2 mm. Consequently, for a 300-mm² detector, the increase

of the α resolution at a source–detector distance of 2 mm with respect to that at 15 mm is thus expected to be $\leq 17 \times 0.50$ or ≤ 8.5 keV. This results in an FWHM ≤ 26 keV. The increase in FWHM decreases to 10% at $d = 8$ mm and is practically negligible for distances >10 mm.

Source radius. It is interesting to take a closer look at the influence of the source diameter on the efficiency. Fig. 4.25 shows the geometric efficiency of a 450-mm² and a 1700-mm² detector as a function of the source radius for a source to detector distance of 5 mm. One sees immediately that the efficiency of the bigger detector is much greater, whatever source radius is chosen. Note, however, the existence of an inflection point for $R_s = R_d$ as well as the sharp decrease in efficiency beyond this point. R_s and R_d represent the source and detector radii. The diameter of the source should thus never exceed the diameter of the detector. If a uniform specific source activity A_s (Bq/cm²) is assumed, the total number of counts registered in a time t is proportional not only to the efficiency but also to the total activity of the source deposited on the surface area or, in other words, the efficiency multiplied by A_s . Fig. 4.26 gives this number as a function of the source radius in arbitrary units. Note that when the source radius exceeds that of the detector, the gain in source surface is exactly compensated by the loss in efficiency. The optimum source radius thus equals the radius of the detector. This general rule is independent of the source-to-detector distance.

Source thickness. Sources must be homogeneous and thin to avoid energy straggling due to self-absorption

FIGURE 4.25 Geometrical efficiency of a 1700 mm² (upper curve) and a 450 mm² (lower curve) α detector as a function of the source diameter given in mm for a source detector distance of 5 mm.

(Burger et al., 1985). Self-absorption is proportional to the thickness of the source and inversely proportional to the specific activity. For typical values of specific activities on the order of 100 Bq/cm², the self-absorption is generally negligible for carrier-free sources. However, the effect of thickness of the carrier-free source depends on the transition probability of the isotope in question, which increases with increasing half-life. Expressed in energy loss, it is on the order of 0.03 keV for “short”-lived isotopes such as ²³⁹Pu ($T_{1/2} = 2.4 \times 10^4$ y) and ²³⁰Th ($T_{1/2} = 7.5 \times 10^4$ y),

whereas for “long”-lived isotopes such as ²³⁸U ($T_{1/2} = 5.7 \times 10^9$ y), it is on the order of 5 keV. Indeed, a 10^5 times smaller transition probability requires the presence of 10^5 times more source material to reach the same activity (see Chapter 1). When estimating the source thickness of a non-carrier-free source, all isotopes deposited together with the isotope of interest must be considered. This can be due either to a different isotope of the same element or to the simultaneous deposition of other elements during source preparation.

FIGURE 4.26 Number of counts registered during a certain time Δt (arbitrary units) for a 1700 mm² and a 450 mm² detector, as function of the source radius in mm.

Problems can also arise with very intense sources, as the source thickness and, therefore, the self-absorption is proportional to the total source activity. For a given total activity, the specific activity can be reduced by choosing a larger source diameter. In this case, preference should be given to a detector with a diameter about equal to that of the source to increase the efficiency (Fig. 4.26) and to reduce the energy straggling, as relatively fewer α particles will strike the detector at an acute angle.

b. Factors influencing contamination and stability

Oil contamination. Alpha sources have to be placed together with the detector in a vacuum chamber to avoid any energy loss in the air gap. Typical α spectroscopy systems use a rotary vacuum pump to evacuate the α spectrometer(s). When static conditions are established in the vacuum system (the ultimate pressure has been reached) and there is no substantial gas flow toward the pump, oil particles can back-stream toward the spectrometer and deposit on the detector and the source surfaces. The same can happen in a more dramatic fashion if the pump is disabled and the spectrometer draws air backward toward the manifold connecting the two. For this reason, a dry pump or a back-streaming filter is recommended between the pump and the detector source vacuum chamber to prevent oil contamination.

Particulate and recoil contamination. Contamination of detectors can take place when particles from sources gravitate to the detector surface and stick there or are splattered, sputtered, or splashed onto the detector surface by the recoil energy imparted to the nucleus of an α -emitting atom. In the latter case, the energy of the particles may be sufficient to implant themselves in the detector so that they cannot be removed nondestructively. Much of the casual contamination can be removed from PIPS detectors by cleaning with a cotton ball saturated with isopropanol. Vigorous scrubbing will not harm the PIPS detector. Recoil contamination is almost never 100% removable. It is best avoided by careful sample preparation, avoiding hot samples, or using the techniques reported by Sill and Olson (1970), which involve operating the spectrometer with an air barrier and/or a bias voltage between the detector and source. They show that recoil contamination can be reduced by a factor of up to 1000 if an air layer of about 12 mg/cm² exists between the detector and source and if the source is negatively biased by a few volts. By straggling, the air gap will increase the FWHM of α peaks by a few keV, which is probably acceptable in all but the most demanding of applications.

c. Stability of the detection system

Both long-term stability and temperature stability are important in detectors used for α spectroscopy because count times are often many hours or days and gain shifts during data accumulation lead to erroneous or unusable spectra.

Long-term stability. Long-term stability is affected by the impact of the environment on the detector junctions. SSB detectors sometimes fail with prolonged exposure to room atmosphere and at other times fail when operated for prolonged periods under high vacuum. This instability is caused by the epoxy edge encapsulation that is required for this type of detector. The PIPS detector has junctions that are buried in the silicon bulk, and no epoxy encapsulation is needed or used, which ensures intrinsic long-term stability.

Temperature stability. The leakage current of silicon diodes doubles for every 5.5–7.5°C change in ambient temperature. Since the preamplifier HV bias resistor is a noise contributor, it is necessarily of high value, typically 100 M Ω . With an SSB detector having a leakage current of 0.5 μ A, the change in bias voltage at the detector for a 2°C change in ambient temperature can be as much as 13 V. This is enough bias change to affect the overall gain of the preamplifier by a substantial amount. Modern PIPS detectors have a typical leakage current of less than one-tenth that of SSB detectors or DJD. Consequently, system gain change as a function of temperature is proportionally less, so that for operational temperatures of up to 35°C, no significant peak shifts are observed.

d. The minimum detectable activity

The MDA at the 95% confidence level is given by

$$MDA = \frac{2.71 + 4.65\sqrt{b}}{t\eta P} \quad (4.51)$$

where t is the counting time, η the counting efficiency, P the yield of the α measured, and b the background counts. The numerator on the right-hand side of Eq. (4.51) corresponds to the detection limit at the 95% confidence limit based on the Currie formalism (Currie 1968)

The two detector-bound parameters, background (B) and efficiency (η), are particularly favorable in the case of an α -PIPS detector. For a 450-mm² detector ($\eta = 0.40$, $b = 6$ counts/d) and for an overnight run ($t = 15$ hours = 54,000 seconds), one has thus $MDA = 0.54$ mBq if a 100% yield for the α ray is assumed, as well as the worst-case condition that all background counts are in the peak or region of interest. The limiting factor is often not the absolute MDA expressed in Bq, but rather the specific minimum detectable activity (SMDA) expressed in Bq/cm²:

$$SMDA = \frac{MDA}{S_s} \quad (4.52)$$

where S_s represents the area of the source in cm².

The background in practical applications is often compromised by the presence of higher-energy α lines that produce counts in the spectrum at lower energies. PIPS detectors are notably free of these tailing effects in

comparison with SSB detectors of equivalent efficiency, in part because of their thin entrance window. Comparisons between the two types of detectors have shown a difference of as much as a factor of 3 in this background tailing or continuum. This translates into an improvement in MDA by a factor $\sqrt{3}$.

2. The Si drift detector technology

For applications where low energies must be measured, such as electron spectroscopy and low-energy X-ray spectroscopy, and for the read-out of scintillators, the electronic noise of the Si detector becomes more important. The drift detector geometry is very useful here because the capacitance of this detector is much lower than with conventional Si detector structures.

Silicon drift detectors are multielectrode photodiodes realized with double-sided technology. These photodiodes were introduced by Gatti and Rehak (Castoldi et al., 2000). The main differentiator in comparison with the well-known PIN technology is that the collection of the charge in the SDD is realized onto a very small readout anode (\varnothing 100 μm) using a lateral drift field within the detector. Radiations (such as X-rays or visible photons) absorbed in the detector generate electron–hole pairs. The path of electrons migrating toward the anode is shown in Fig. 4.27.

The complexity of the structure depicted (a double-sided multielectrode diode) is justified by the drastic reduction of capacitance of this device. In a PIN diode of similar size, this capacitance will typically be 90 pF, whereas with SDDs, the capacitance ranges from 0.1 pF for a traditional SDD to 3 pF for a linear anode segmented silicon drift detector (LA-SSDD—see further). This fact leads to detector benefits that explain the popularity of this detector type for X-ray spectroscopy. Indeed, low capacitance diodes create less noise and thus better energy resolution. They can be operated at lower processing times, which allows higher counting rates, without resolution loss. An FWHM of 130 eV at the 5.9 keV K_α X-ray line of ^{55}Mn has been measured.

FIGURE 4.27 The Si drift detector.

3. Electron spectroscopy and β counting

Traditional PIPS detectors and SDDs can be used for electron spectroscopy and β counting. The thin entrance window of these detectors provides little attenuation even for weak beta particles. In the β ray and (conversion) electron energy region (<2000 keV), the resolution (FWHM) is approximated by the pulser line width. Due to the limited thickness of these detectors (0.3–0.5 mm), the absorption of X-rays is only efficient in the 0–30 keV range. In such applications, the SDD or PIN diode is directly absorbing X-rays.

Canberra provides special β PIPS detectors fabricated from higher ohmic material, having a minimum thickness of 475 μm and allowing full absorption of electrons of up to 400 keV. Note, however, that higher-energy electrons can be fully absorbed too. This is due to the fact that high-energy electrons do not follow a straight path inside the detector but rather change direction, so the real path of the electrons inside the detector is much greater than the detector thickness d . For example, the conversion electrons of the 661-keV γ line of ^{137}Cs at 625.8 and 629.7 keV are clearly seen. If only β counting is needed, the efficiency is uncompromised as long as the detector absorbs enough energy from the β ray to exceed the noise level.

As in the case of α -spectroscopy, the main factor influencing detector efficiency for electron spectroscopy (e.g., spectroscopy of low-energy conversion electrons) is governed by the geometric efficiency η . Note, however, that in the calculations the junction area and not the active area has to be taken into account, as the detector mount is partially transparent for electrons. Furthermore, backscattering of low-energy electrons from the detector surface may cause significant loss of efficiency. By analogy with the experimental values of the fraction of normally incident electrons backscattered from thick slabs of aluminum (see, e.g., Knoll, 1999), it can be inferred that between 10% and 13% of the electrons of energies between 50 and 700 keV are backscattered by thick slabs of Si, and the backscattered fraction drops sharply for higher energies. On the other hand, if backscattering occurs in the source, it may increase the apparent number of β particles, as electrons emitted outside the solid angle, sustained by the detector, can be scattered inside this solid angle. Efficiency calibration for electron spectroscopy must be done, therefore, with multienergy standards, prepared in the same way as the unknowns. Source backings should be of low-Z materials to minimize source backscattering effects. Conversion electrons show up most clearly if they are not in coincidence with β particles. This is the case if the decay takes place through an isomeric level of the daughter such as in the decay of ^{137}Cs (Fig. 4.7) or if it takes place by almost pure electron capture (such as with ^{207}Bi , often used as standard). If the conversion electrons are in coincidence with the β particles, they can sum up with the

nuclear electrons (Eq. 4.11). The resulting sum peak will be continuously distributed as the β particles. If β activities have to be measured, these conversion electrons can furnish supplementary counts. This is the case, for example, if the sum peak surpasses the energy of the β threshold. This effect is isotope specific. The β threshold is not given by the thickness of the entrance window, which is negligible for all practical cases, but by the noise of the detector and electronics. In practice, a value of three times the electronic noise (FWHM) is taken. As β rays have a continuous energy distribution, this effect has to be taken into account when source intensities have to be measured. Indeed, part of the emitted electrons can lie under the threshold. This depends essentially on the form of the β spectrum and has to be considered individually.

Beta particles can “channel” between crystal planes of the detector and lose energy at a lesser rate than if they cross planes. To minimize this effect, β -PIPS detectors [(as well as continuous air monitoring (CAM))] are made from silicon wafers that are cutoff axis. Small errors in calculated efficiency, however, remain possible.

Finally, it has to be noted that β detectors with an active thickness of 475 μm have small sensitivity for γ rays. Indeed, from Fig. 5.18, it follows that the half-thickness of Si for the total absorption of γ rays of 50 and 100 keV is 0.631 and 1.63 cm, respectively, so that for these energies 5.72% or 2.00% of all γ rays falling on the detector undergo an interaction. This can lead to a supplementary pulse or a sum pulse (Eq. 4.11).

4. Readout of scintillators

SDD diodes can also be used as readout electrode for scintillators (Fiorini et al., 2006) and contribute to the detection of gamma rays of much higher energies (60 keV–3 MeV range). As shown in Fig. 4.28, the gamma ray is converted into tens of thousands of visual photons reaching the SDD in a continuous distribution from the center to the border of the SDD. The upper limit of the number of scintillated photons generated by a gamma photon is the ratio of the gamma ray energy and the product of the beta factor times the bandgap of the scintillator:

$$N_{\text{photons}} = \frac{E_{\gamma}}{\beta \cdot E_g} \quad (4.53)$$

where E_{γ} is the gamma photon energy, E_g is the bandgap of the scintillating material, β is the beta factor having a value of 2.5 eV.

Table 4.10 lists the bandgap and the number of photons generated by a 1 MeV photon for three of the most luminous scintillators.

The very broad distribution of visual photons leads to the generation of electron–hole pairs across the whole radius of the SDD as illustrated in Fig. 4.28. This situation is therefore different than in the case of direct X-ray absorption. Directly absorbed X-rays lead to the generation of electron–hole pairs in a single point, which all arrive with a quasisimultaneity to the anode. In the case of scintillated

FIGURE 4.28 The conversion of a gamma ray into visual photons and the generation of electron–hole pairs in the SDD detector. For the color version of the figure, the reader is referred to the electronic version of the book.

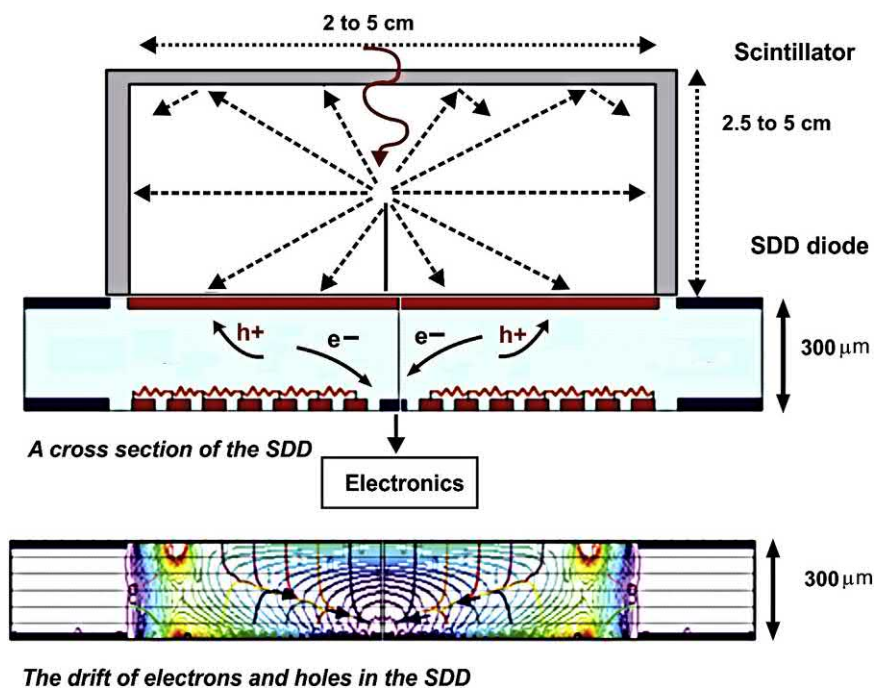

TABLE 4.10 Three of the most luminous scintillators.

	Bandgap E_g	Number of photons scintillated by a 1 MeV photon
LuI_3	4.2 eV	100,000
SrI_2	4.8 eV	90,000
LaBr_3	5.3 eV	60,000

events, a continuous signal will be generated, its width being the longest drift time.

The key detector parameters to reach optimum resolutions are a good quantum efficiency, a low leakage current density, small drift lengths, and a small detector capacitance.

While the low capacitance of the diodes allows SDD X-ray detectors to be used at low shaping times, the peaking times used for scintillation applications must be higher than the largest drift time seen by electrons generated at the border of the SDD.

To collect the complete charge, the shaping time of the shaper amplifier following the charge-sensitive amplifier needs to be higher than the pulse signal width and thus the longest electron drift time. The use of lower shaping times will lead to incomplete charge collection.

SDDs are attractive at low shaping times because of their small series noise, but are not as good as PIN diodes at high shaping times, because of their higher leakage current density. So, SDDs having a large radius are not attractive for scintillation applications because of the need of using long shaping times.

LA-SSDDs have been developed and optimized for scintillation applications to overcome this problem (Moriuchi et al., 2011). These detectors are circular shaped and have areas of 250 and 300 mm² and a thickness of 300 μm . The drift length of electrons is minimized by the implementation of a series of concentric ring-shaped anodes. This permits minimization of the number of anodes while keeping very small drift distances, thus allowing the use of short shaping times.

5. Continuous air monitoring

The increasing demand for safety of nuclear installations calls for continuous survey of airborne radioactive particles inside and around nuclear sites, and the potential for nuclear accidents calls for a worldwide survey of the atmosphere. In particular, it is important to know whether, instantaneously or over a certain time, β and/or α activities remain below imposed limits. For a judicious choice of a continuous air monitoring system, the influence of the detector on the system performance should be understood.

Airborne radioactive particle concentration limits are expressed in derived air concentration (DAC) units and are isotope specific. One DAC corresponds to an isotope concentration of 1 Bq/m³. For certain α emitters, these limits are extremely low. For example, for ²³⁹Pu in soluble form, the DAC limit corresponds to a value of 0.08 Bq/m³. The exposure is expressed in DAC hours, that is, the concentration in Bq/m³ multiplied by the exposure time in hours. To detect these activities, air is pumped through a filter at a speed of about 1 m³/h. A detector continuously measures the accumulated activity. An instrument should be able to detect an activity concentration of 8 DAC-hours, that is, 1 DAC in 8 hours, 2 DAC in 4 hours, and so on.

This requirement is further complicated by the fact that the α background varies due to simultaneous collection and counting of the α activity from ²²²Rn progeny, which can be significantly higher than the desired MDA. The β background also varies but, unlike the cause of the α background, this is mainly due to cosmic events.

For off-line measurements of filter samples, standard α or β detectors can be used under certain conditions. Online measurements, however, require special characteristics, in particular, light-tightness, moisture resistance, and corrosion protection. Fig. 4.29 shows an exploded view of a Canberra CAM PIPS detector. Depletion layers between 120 and 325 μm are possible. Their main characteristics are as follows:

1. Operable in light to 5000 lumens
2. Corrosion-resistant varnish coated
3. Moisture-resistant varnish coated
4. Low bias voltage (10–90 V)
5. β and α discriminated by energy
6. Wide temperature range and low leakage current
7. High β sensitivity, 300 μm active thickness

a. Light-tightness and resistance to harmful environments

Silicon detectors are fundamentally light sensitive. In continuous air monitoring, the detector is not protected by a vacuum chamber, and light may reach the detector in some cases. CAM PIPS detectors are made with a front surface coating of 0.5- μm -thick aluminum, which blocks the light. Furthermore, because of the nature of continuous air

FIGURE 4.29 Exploded view of a Canberra CAM detector. Image courtesy of Mirion Technologies.

monitoring, detectors are often used in a harmful environment, such as a humid and/or dusty atmosphere charged with corrosive gases. To extend the useable lifetime of the detectors, CAM detectors are covered with a 1 μ m varnish coating, providing mechanical and chemical resistance against abrasion, solvents, and corrosion. This varnish

corresponds to a supplementary absorption layer of about 0.6 μ m silicon equivalent. In vacuum, these supplementary windows cause roughly a doubling of the α resolution. However, one has to take into account the energy straggling in the air gap between filter and detector and in the filter itself, which makes straggling in the entrance window relatively unimportant. This is illustrated by Fig. 4.30, showing the empirical resolution (FWHM) of a CAM450 and a CAM1700 detector for the 5499.2-keV α line of ^{238}Pu as a function of the source–detector distance. The FWHM decreases with the distance, contrary to the situation for a detector in a vacuum. Note the quasilinear increase of the FWHM for distances of up to 10 mm. This degraded resolution is, however, still good enough to separate completely the α and β activity as illustrated in Fig. 4.31, showing the β spectrum of ^{137}Cs (decay scheme illustrated in Fig. 4.7) in the presence of a ^{239}Pu alpha source taken with a CAM1700 detector with a source–detector distance of 5.3 mm.

b. Efficiency

In normal continuous air measurements, no efficiency loss is expected due to the air gap between the source and the detector. Indeed, the range in air of typical α particles of about 5 MeV is several centimeters, and the air gap is normally <1 cm. All earlier remarks on the efficiency remain valid, in particular that the optimum source diameter equals the detector diameter. The advantage of a big detector and a large source radius is evident, as the resolution is dominated by the air gap and not by the detector radius as in normal α spectroscopy. However, the source diameter should never exceed the detector diameter as seen in

FIGURE 4.30 Empirical resolution (FWHM) of a CAM450 and CAM1700 detector for the 5499.2 keV α line of ^{238}Pu as a function of the source–detector distance.

FIGURE 4.31 Beta spectrum of ^{137}Cs in the presence of an alpha source of ^{239}Pu , taken in air with a CAM1700 detector.

Fig. 4.25. Furthermore, the total activity deposited on the filter depends on the pumping speed, which in turn is limited by the pressure drop through the filter. The pressure drop increases linearly with the pumping speed. For a given throughput, the required pumping speed decreases with the square of the filter diameter. A large detector, therefore, permits the use of a large filter and, as a consequence, higher air flow for the same pressure drop, permitting larger total activities to be deposited on the filter in less time.

c. Background and minimum detectable activity problems in continuous air monitoring

In the case of continuous air monitoring, Eq. (4.51) can be written in the form:

$$MDA = \frac{2.71 + 65\sigma_b}{t * \eta * 3600} \quad (4.54)$$

where t is the pumping and measuring time expressed in hours, σ_b the standard deviation of the background, and η the fractional counting efficiency. Besides the measuring time t , the most important parameter is the standard deviation of the background, which is quite different in the α and β regions. The MDA, therefore, must be examined separately for α and β emitters.

For α emitters, the background b is no longer given by the proper background of the detector but rather by the activity of the ^{222}Rn progeny accumulated simultaneously on the filter, which can be higher than the α activity of concern. Whether or not the air in the laboratory is filtered,

values of 4–40 Bq/m³ can be regarded as quite normal, and DAC values of 0.08 Bq/m³ have to be detected for soluble ^{239}Pu . Furthermore, the concentration of the Rn progeny in air varies with time. Therefore, the standard deviation σ_b is determined not only by the square root of the registered number of background counts but also by the concentration fluctuations. Indeed, all α lines due to ^{222}Rn and its progeny lie above the α energies of ^{239}Pu . Consequently, due to tailing effects, these peaks contribute to the background beneath the ^{239}Pu peaks. The energy discrimination shown in Fig. 4.30 is good enough to ensure complete α and β separation despite the tailing effects inherent in continuous air measurements.

If a counting efficiency of $\eta = 40\%$, a pumping speed of 1 m³/h, a pumping time of 8 hours, and a constant background of 40 Bq/m³ are assumed, a total number of $0.5 \times 8 \times 3600 \times 40$ disintegrations occur due to the background accumulated on the filter. This leads to an MDA (Eq. 4.51) of 0.3 Bq in 4 m³ of air or 0.08 Bq/m³. Up to four times better results can be obtained by using background subtraction based on stripping methods, that is, by subtracting the independently determined contribution of higher-energy background peaks under the peak of interest.

The background in the β region (2.1 ct/min cm²) is largely of cosmic and γ ray origin. Let us assume that a 450-mm² detector is used close to a filter of almost equal size. The background in an 8-hour run is thus $8 \times 60 \times 2.1 \times 5.5 = 4536$ counts. Assuming an 8-hour

accumulation on the filter, this leads to an MDA of 0.03 Bq for the mean 4 m^3 counted during 8 hours or to 0.01 Bq/m. We must emphasize that the actual MDA will depend on the experimental setup.

IV. Cadmium zinc telluride detectors

A. Characteristics of cadmium zinc telluride detectors

In recent years, cadmium zinc telluride (CZT) semiconductor detectors are being increasingly used in applications involving X-ray and gamma ray detection. CZT has a “tunable” bandgap from 1.5 to 2.2 eV, depending on the concentration, x , of zinc present in the $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$ a relatively high bandgap energy that makes room temperature operation possible. The effective Z of CZT is relatively high, which results in a high stopping power for photons of energies of several hundred keV. CZT has many of the desirable properties for detector applications, such as a high resistivity ($\sim 10^{11} \Omega\text{-cm}$) for low leakage current operation and absence of significant polarization effects. However, until the last 10 years or so, limitations due to charge transport properties (poor hole mobility) and availability of large volume crystals have restricted the use of CZT detectors to photon energies in the 10–200 keV energy range. The typical thickness of CZT for detecting energies less than 200 keV is around 6 mm. While this is adequate for applications such as X-ray astronomy or gamma imaging in nuclear medicine, gamma spectrometry applications involving the detection of higher energy gamma rays (200–20,000 keV) such as those in homeland security require the use of thicker CZT crystals. Advances in crystal growth techniques and the development of methods to

alleviate limitations due to poor hole mobility have resulted in CZT crystal sizes of several cubic centimeters. CZT detectors with energy resolutions on the order of 1% at 662 keV are commercially available. The widespread use of CZT detectors (along with LaBr_3 scintillation detectors) has resulted in the emergence of a class of instruments known as medium-resolution gamma spectrometers (MRGS). The MRGS instruments fill the gap in the application space between low-energy resolution detectors such as NaI(Tl) and high-energy resolution detectors such as HPGe . The material properties of CZT are presented in Table 4.11.

B. Crystal growth techniques

Detector-grade CZT is typically grown by melt growth techniques or solution growth techniques. Melt growth techniques involve melting the material and then crystallizing the material using changing pressure, temperature, or a combination of the two. CdTe and CZT single crystals have historically been grown using the Bridgman method and the traveling heater method (Del Sordo et al., 2009).

1. The Bridgman process

The Bridgman technique uses a “hot” and “cold” zone to create a temperature difference within a furnace as shown in Fig. 4.32 (Dutta, 2010, Dhanraj et al., 2010). The hot zone is kept at a temperature above the melting point of the material. The precursor material used to create the product material is sealed within a crucible or an ampoule and placed in the furnace along with a seed material. The seed crystal is of a known orientation and is placed at the base of the crucible or the ampoule used for crystal growth and is used to facilitate crystal growth in the same orientation as

TABLE 4.11 Physical properties of CdZnTe at 25°C .^{a,b}

CdZnTe material property	Specification
Growth method	HPB, THM ^a
Bandgap energy	Tunable from 1.5 to 2.2 eV at 300 K ^b
Atomic number	Cd = 48, Zn = 30, and Te = 52 ^{a,b}
Density	5.78 g/cm ^{3a}
Electrical resistivity	$10^{10} \Omega\text{-cm}^a$, $10^{11} \Omega\text{-cm}^b$
Electron mobility \times lifetime	$\mu_e\tau = 10^{-2}$ to $10^{-3} \text{ cm}^2/\text{V}\cdot\text{s}^{a,b}$
Electron mobility	$\geq 1000 \text{ cm}^2/\text{V}\cdot\text{s}^b$
Pair creation energy (ionization potential)	4.6 eV ^a
Poor hole transport	$\mu_h\tau_h = 10^{-5} \text{ cm}^2/\text{V}^{a,b}$, $\mu_h = 50 \text{ V s}^b$

the seed crystal. The precursor material is then melted in the hot zone and translated into the cold zone by motion. The material solidifies as it moves through the temperature gradient in the furnace. Bridgman method can be performed in the vertical or horizontal configurations.

Two types of methods have been employed for growing CZT crystals: high-pressure Bridgman (HPB) and low-pressure Bridgman (LPB) methods. In both HPB and LPB processes, CZT is grown using a stoichiometry of $\text{Cd}_{0.9}\text{Zn}_{0.1}\text{Te}$ with a hot zone temperature of 1100°C (Schlesinger et al., 2001). Quartz and graphite are commonly used materials for crucibles due to their high temperature and pressure-resistant properties. Typical growth rates are in the 1 mm/h with a temperature gradient of about 1.5°C/cm (Schlesinger et al., 2001). HPB methods typically employ 5 MPa of argon pressure (Kolesnikov et al., 1997), whereas LPB methods evacuate the crucible/ampoule to an ultrahigh vacuum (approximately 10^{-6} torr). CZT crystals grown using either HPB or LPB methods suffer from a large amount of defects due to impurities introduced because of the high growth temperature. CZT crystals grown using the HPB method are inhomogeneous on the scale of a few centimeters, due to macro defects such as small grain sizes. Also, there are significant variations in the concentration of zinc present from one end of the ingot to another (Del Sordo et al., 2009). These issues limit the size of the CZT crystals that can be grown; HPB results in 25% of an ingot that yields sizable single crystals and only 10% of the ingot yielding detector-grade CZT (Schlesinger et al., 2001). The LPB method requires a simpler furnace setup than the HPB, but the yields are similar to the HPB method.

2. Traveling heater method

The traveling heater method (THM) requires that the material to be grown be dissolved in a compatible solution. In this method, a molten zone of material slowly migrates through a solid, homogeneous source material. Matter transport occurs through convection and diffusion across the solvent zone due to the temperature gradient (Grille, 1991). This method also purifies the source materials due to the zone melting nature of this technique. CZT growth using the THM involves placing the presynthesized $\text{Cd}_{0.9}\text{Zn}_{0.1}\text{Te}$, the dopant In, and additional tellurium as the solvent material within a quartz ampoule (Roy et al., 2009). The ampoules are sealed under ultrahigh vacuum and placed in a furnace with a hot zone. Before the THM is initiated, another furnace heats and evenly distributes the material to ensure all of the material is dissolved in Te. The material is then placed in the THM furnace, and multiple passes of the heater moving through the material collect all of the excess Te to one end of the ingot. The THM has several advantages over the Bridgman method. THM combines the low growth temperatures of a solution growth method with the steady-state conditions present between the dissolution of the source material before the heater and the crystal growth section after the heater. This ensures that Zn does not segregate and is uniform throughout the ingot (Roy et al., 2010). However, THM requires a homogeneous ingot be used.

C. Correction schemes to mitigate poor hole mobility in cadmium zinc telluride detectors

Poor hole mobility results in significant tailing on the low-energy side of the gamma ray peaks recorded using CZT detectors. Correction schemes have been developed to

mitigate the impact of poor hole mobility and improve the energy resolution of CZT detectors. Two such schemes, the Frisch grid and coplanar grid (CPG) electrode configurations are discussed in the following two subsections.

1. Frisch grid device configuration

A good way to address the hole trapping issue in room temperature semiconductor detectors is to utilize single-polarity charge sensing. This term is derived from the manner that only one polarity of charge (electrons) is sensed to infer the energy deposited by the incident gamma ray. This is advantageous because the effect of poor hole mobility can be mitigated, since the resulting signal will only be sensitive to the fast-moving electrons. This method was first carried out by Frisch in 1944 for gas ionization chambers (Frisch 1944). Frisch employed a gridded electrode, now known as a Frisch grid, placed inside the ionization chamber surrounding the anode. The Frisch grid acts as an electrostatic shield to the region between the cathode and the grid, while making the region between the grid and the anode highly sensitive to the movement of charge. Therefore, events that occur between the cathode and the grid, which constitutes most of the detector volume, will result in the fast-moving electrons passing through the grid and inducing all of their charge on the anode, whereas the slow-moving positive charges will travel in the opposite direction and induce no charge on the anode.

In the recent years, many improved Frisch grid designs have been developed, including the so-called virtual Frisch grid. A schematic drawing of the virtual Frisch grid is given in Fig. 4.33. This is from the report by Cui et al. (2009) from Brookhaven National Laboratory (BNL).

The design includes the capture device (CZT) and the Frisch ring (or capacitive Frisch grid) detector. The shielding electrode (Frisch ring), separated from the cathode by a layer of insulator and grounded in the final assembly, overlaps the cathode and extends up to the far end near the anode. This shielding, together with the cathode cap, ensures that the side surfaces of the crystals are shielded properly. When the cathode is biased negatively, this configuration (cathode, anode, and shielding) forms a focusing electrical field in the crystal's bulk.

The focusing electrical field defines an active region in which the device's response changes only a little (i.e., <5%) from its maximum. The boundary of this region is defined as the virtual Frisch grid; since the cathode is isolated from the shielding on the side surfaces, the signal readout from cathode also can serve as a depth-sensing technique to correct the charge loss caused by electron trapping and further improve the spectral response.

Frisch grid detectors offer many advantages such as ease of device fabrication (and hence high yields) and a low power consumption compared with pixelated three-

dimensional CZT detectors. The low power requirements enable the implementation of Frisch grid CZT detectors in portable device configurations. Energy resolution of less than 1.4% at 662 keV can be achieved by Frisch grid detectors.

2. Coplanar grid device configuration

The coplanar grid (CPG) is another single-polarity charge-sensing device configuration used in CZT. The CPG consists of a series of narrow strips, which are connected together in an alternate fashion producing two sets of interdigitated grid electrodes (Luke 1994). By biasing these grid electrodes properly and taking the difference between the two grid signals, one can achieve a resulting signal that is only sensitive to the movement of electrons. Hence, the CPG structure achieves single polarity charge sensing much like the Frisch grid. The primary advantage of this electrode design is that it can be constructed on the surface of the crystal.

CPG detectors use a subtractive method to compensate for tailing due to hole trapping. The anode electrodes take the form of interdigitated grids that are connected to separate charge-sensitive preamplifiers (Figure XX). An electric field is established in the detector bulk by applying bias to the cathode, which is a full-area contact located on the side opposite the grid electrodes. The two grid preamplifiers are connected to a subtraction circuit to produce a difference signal. Bias is applied between the grid electrodes so that one of the grids preferentially collects charge. Charge motion within the detector is sensed equally by the grid electrodes. Consequently, the difference signal is insensitive to charge motion within the bulk of the detector. When charge approaches the anode, the grid signals begin to differ and a signal is registered at the output of the difference circuit. In a well-designed detector and in the absence of electron trapping, the magnitude of the difference signal is the same no matter where the charge is generated in the device. This results in a large improvement in performance for gamma ray spectroscopy when compared with conventional planar device technology (Prettyman et al., 1999) (Fig. 4.34).

V. Spectroscopic analyses with semiconductor detectors

Semiconductor detectors (e.g., SSB, PIPS, Ge(Li), HPGe, and Si(Li) detectors) are typically operated in a pulse mode, and the pulse amplitude is taken as a measure of the energy deposited in the detector. Typically, the pulse amplitude data are presented as a differential pulse height spectrum. Because of real-world effects (such as electronic noise and the various interactions that can occur within the sample, between the sample and the detector, and within the detector itself), the peaks that result in alpha spectra have a

very different shape from those that result in gamma spectra. The peak shapes that occur in gamma ray spectra have been studied and described extensively in the literature (e.g., [Gunnink R., and Niday, J.B., 1972](#); [Helmer and Lee, 1980](#)). Fig. 4.35 shows a detailed analysis of a gamma ray peak and the shape components proposed by [Gunnink and Niday \(1972\)](#) to model the peak. The shape of a peak in an alpha particle spectrum has been described and modeled by [Wätzig and Westmeier \(1978\)](#). Other models of alpha particle peaks have been proposed by [Garcia-Torano and Aceña \(1981\)](#), [Amoudry and Burger \(1984\)](#), and [Kirby and Sheehan \(1984\)](#). Representative examples of a gamma ray peak and alpha particle peaks are presented in Figs. 4.36 and 4.37, respectively.

FIGURE 4.35 The detailed shape of an observed peak from a Ge(Li) detector with the principal shape components indicated. Adapted from [Gunnink \(1990\)](#).

A. Sample preparation

Warning: The chemical procedures discussed in this section involve the use of strong acids, caustic solutions, and very high temperatures. Appropriate precautions should be observed when handling such materials or working with such conditions. Particular caution should be exercised when working with perchloric acid, as the addition of perchloric acid to a solution containing any organic (carbon) material can result in a very vigorous reaction or explosion!

The very different interaction mechanisms and thus attenuation characteristics of gamma rays and alpha particles demand very different considerations in their sample preparations. As alpha particles lose energy virtually continuously along their track, they have a distinct range. In the energy range of interest (typically 4–7 MeV), alpha particles can be stopped by a sheet of paper or approximately 2–8 cm of air (at STP). Thus, encapsulating the sample is out of the question. In fact, even minimal amounts of material between the emitting nuclide and the detector can degrade the energy of the alpha particles to the point that spectroscopic identification becomes difficult, if not impossible. On the other hand, gamma rays can penetrate relatively long distances in a material without interaction or loss of energy, so containment of volumetric (thick) samples of γ emitters is not only possible but routinely employed.

1. Sample preparation for alpha spectrometry

Sample preparation must convert the raw sample into a form that is suitable for alpha spectrometry. This implies two requirements for the preparation:

1. Produce a thin sample.
2. Chemically separate elements that would produce chemical or radiochemical interferences.

In addition, the final form of the source should be rugged enough to be handled safely, chemically stable, and free of all traces of acid and solvent to prevent damage to the counting chambers and detectors. Proper sample preparation is essential to ensure an accurate quantitative assay as well as high resolution. In general, sample preparation requires three steps:

1. Preliminary treatment
2. Chemical separation
3. Sample mounting

These three steps will now be reviewed, starting with sample mounting and ending with preliminary treatment. This order has been chosen because it is easier to understand why certain conditions are required in the early steps after which one understands the requirements of the later steps.

FIGURE 4.36 A 661.6 keV peak from ^{137}Cs as observed at approximately 0.5 keV/channel.

FIGURE 4.37 The 5.276 and 5.485 MeV alpha peaks of ^{243}Am and ^{241}Am , respectively. Note the asymmetry (tailing) of the peaks.

a. Sample mounting

In addition to energy straggling, there are geometric effects that alter the energy resolution of alpha spectra. The need for a thin sample is demonstrated in Figs. 4.38 and 4.36. Fig. 4.35 demonstrates that the variation in the energy of (originally) monoenergetic particles escaping the sample is proportional to the sample thickness, and Fig. 4.36 illustrates the fact that particles leaving the sample or entering the detector at angles other than perpendicular have a longer path length in the energy-degrading materials of the sample matrix and detector dead layer. This variation of the track length in energy-degrading material causes a variation in the observed energy, which contributes to increased line breadth and tailing. Referring to the notation of Fig. 4.39,

the difference in the track length of a particle traveling along path a versus path b is given by

$$\Delta = \text{difference in track length} = (d+t) \left(\frac{1}{\cos \theta} - 1 \right) \quad (4.55)$$

Thus, one can reduce the line breadth by

1. minimizing d , the dead layer (window) on the detector;
2. minimizing t , the thickness of the sample; and
3. minimizing θ , the acceptance angle of the detector

These items were introduced in a general sense in Sections III.B.1.a and III.B.1.b.

FIGURE 4.38 Three atoms of an alpha-emitting nuclide (labeled 1, 2, and 3) are deposited at different depths within the thickness of the sample. The energy of the alpha particle from the atom labeled #1 will be degraded more than that of #2, which in turn is degraded more than that of #3. Thus, the observed energy of the alpha particles from a thick (monoenergetic) sample will have a distribution of energies reflecting the thickness of the sample (as well as due to straggling).

FIGURE 4.39 Since the sample (may) and the detector (definitely does) have a finite radius, alpha particles can leave the sample and enter the detector at angles other than perpendicular. Track *a* leaves the sample and enters the detector at right angles, whereas track *b* leaves the sample and enters the detector at an angle θ from perpendicular. Track *b* has a path length (through the sample and through the detector dead layer) that is greater than track *a* by a factor of $1/\cos \theta$. Thus, an alpha particle emitted along track *b* will have a greater energy degradation than a particle emitted along track *a*.

From the preceding discussion, it is clear that (all else being equal) the thinner the sample, the better the resolution. Thus, the optimum sample mount in terms of resolution would be a monatomic layer of sample atoms; however, in practice, thicker mounts are typical. Methods that have been used to mount sources for alpha spectrometric measurements using semiconductor detectors include the following:

1. Vacuum sublimation
2. Electrospaying
3. Electrodeposition (A) from an aqueous solution and (B) from an organic solution—also referred to as molecular plating
4. Hydroxide or fluoride coprecipitation and filtration as a thin source
5. Evaporation from an organic solvent
6. Evaporation from an aqueous solution

An excellent review of the various sample mounting methods is given by [Lally and Glover \(1984\)](#).

Vacuum sublimation. If the overriding concern is to achieve the highest possible resolution, one should consider mounting the sample by vacuum sublimation. Although the method is capable of producing very good resolution, it is not quantitative, and it is more appropriate to metrology applications (such as the precise measurement of alpha particle energies) than to general radiochemical assay. Vacuum sublimation requires an apparatus in which the sample is heated to a sufficiently high temperature in a vacuum that the sample is vaporized and then sublimed onto a substrate. Samples mounted by this method have produced resolutions of 4–5 keV with magnetic spectrographs and approximately 11 keV (FWHM) with a surface barrier detector.

Electrospaying. Sample mounting by electrospaying can produce extremely thin sources as well as deposits of up to 1 mg/cm^2 with high efficiency. The method requires an apparatus in which the sample is dissolved in an organic solvent and sprayed from a fine capillary tube or hypodermic needle (with the tip squared off) against a substrate that forms the cathode of the apparatus. An electrode may be placed in the solution, or the needle itself can be made the anode of this device. With a potential of up to 8 kV applied between the needle and substrate, the organic solution is ejected as a fine spray so that the organic solvent evaporates before reaching the cathode. In this manner, only solid particles reach the cathode. To ensure a uniform deposit, the cathode is typically rotated during the spraying. Electrospayed sources have produced resolutions of approximately 17 keV (FWHM).

Electrodeposition. Samples may be mounted by electrodeposition from an aqueous solution or an organic solution, in which case the method is generally referred to as molecular plating. The method produces rugged sources that may be kept in the laboratory indefinitely and is frequently used for preparing rugged alpha sources. Electrodeposition is applicable to a wide range of work from metrology measurements to radiochemical assays. Resolutions of $<20 \text{ keV}$ are possible with semiconductor detectors. In addition to the production of thick sample deposits, impurities can affect the yield of the technique. Thus, steps to chemically separate the element of interest

and place this element in an appropriate solution for electrodeposition must precede the electrodeposition.

Electrodeposition from organic solutions. This technique involves passing a low current at high voltage through an organic solution. It is reasonably rapid and virtually quantitative; near-quantitative recoveries of many of the actinides have been reported in about 1 hour. The method requires the use of reasonably pure solutions. As little as 100 μg of iron or aluminum (which deposits on the cathode along with the actinides) in solution can cause the deposit to be thick and produce degraded resolution. One precaution concerning molecular plating, which should be noted, is the use of high voltages and volatile organic solvents. This combination can present a hazard, particularly in confined areas such as a glove box.

Electrodeposition from aqueous solutions. In contrast to molecular plating, electrodeposition from aqueous solutions is usually performed at voltages of approximately 12–20 V with sufficient current capacity to provide a few hundred mA/cm^2 . The method can produce quantitative yields from pure actinide solutions; however, impure solutions may produce less than quantitative yields. The use of a complexing agent, such as hydrofluoric acid, sodium bisulfate, tri-/diethylenetriaminepentaacetic acid (DTPA), or ethylenediaminetetraacetic acid (EDTA), can make the electrolyte more tolerant of impurities. One drawback of electrodeposition from an aqueous solution is that it is somewhat time-consuming, taking up to several hours to complete a deposition. Fig. 4.40 shows the amount of Pu remaining in the plating solution as a function of time for electrodeposition of Pu from a 1 M H_2SO_4 solution. It is apparent from this figure that, to achieve high recovery, one must commit a substantial amount of time to the electrodeposition step.

Electrodeposition is applicable to many elements, including the actinides (Talvitie, 1972). Procedures for electrodepositing radium (Roman, 1984), thorium (Roman, 1980), and uranium, thorium, and protactinium (McCabe et al., 1979; Ditchburn and McCabe, 1984) have been presented. For alpha spectrometry, Cable et al. (1994) have investigated the optimization of the chemical and physical parameters affecting the electrodeposition of uranium, thorium, protactinium, americium, and plutonium using a custom-designed electrodeposition unit.

Electrodeposition cells vary from very simple to rather elaborate. Schematic drawings of two designs are presented in Figs. 4.41 and 4.42. The sample is electrodeposited on a metallic substrate, typically a disk of stainless steel, nickel, or copper (although other materials have been used successfully), which functions as the cathode of the electrodeposition cell. Only one side of the disk should be exposed to the plating solution. The anode is normally made of platinum.

FIGURE 4.40 The results of an experiment designed to evaluate the rate of electrodeposition of Pu from 1 M H_2SO_4 (pH = 3.2). Such experiments are used to optimize conditions and evaluate plating times. From Burnett (1992), image courtesy of Mirion Technologies.

In general, the actinide elements thorium through curium can be electrodeposited as hydrous oxides from a buffered, slightly acidic aqueous solution without prior oxidation. Following electrodeposition, the cathode disk is often heated to convert the deposited actinide compound to the anhydrous state or flamed to convert it to an oxide. The high temperature will also volatilize the spontaneously volatile component of any polonium that may have inadvertently deposited on the disk. Sill and Olson (1970)

FIGURE 4.41 Schematic drawing of a simple electrodeposition cell.

FIGURE 4.42 Schematic drawing of a rotating disc electrodeposition unit. The disc upon which the sample is to be deposited (cathode) is mounted on the end of the spindle, which rotates at 3600 rpm. From Burnett (1990), image courtesy of Mirion Technologies.

report that heating the disk on an uncovered hot plate for 5 minute reduces the spontaneously volatile component of polonium to a generally acceptable level without loss of lead or polonium. As the volatility of polonium produces a pseudorecoil effect, by which the detector can become contaminated, it is desirable to eliminate the spontaneously volatile component of polonium to prevent contamination of the detector (see Section IV.B.1) and counting interferences. Care should be taken in heating the disk, as ignition at red heat can volatilize lead (if present), which can carry other nonvolatile components with it, resulting in a loss of material. The volatility of polonium is highly dependent on the disk material and the conditions of the deposition. Contamination of samples by polonium has been shown to occur via a variety of pathways, including spontaneous deposition from the air and from acid baths used to clean recycled deposition disks. For a more complete discussion of the role of polonium as a contaminant and interference, see Sill and Olson (1970) and Sill (1995).

Coprecipitation and filtration as a thin source.

Coprecipitation and filtration is a fast, inexpensive method used to mount samples for alpha spectrometry. Basically, the method provides for the coprecipitation of the nuclides of interest as either a hydroxide or a fluoride using either cerium or neodymium² as a carrier to produce an extremely finely divided precipitate, which is deposited by filtration

over a substrate of ceric hydroxide, cerous fluoride, or neodymium fluoride. The substrate is prepared by filtering the substrate solution (typically ceric hydroxide or neodymium fluoride) through a 0.1 μm membrane filter. These very finely divided precipitates plug the filter and provide a very smooth and nearly impenetrable surface upon which the coprecipitated (with cerous hydroxide or neodymium fluoride) nuclides of interest lie.

The method as presented by Sill and Williams (1981) uses cerium carrier and substrate (in both the oxide and fluoride forms), and it was proposed that lanthanum and neodymium could be used equally well. Subsequent extensions of this procedure tended to focus on the chemical separations that allow the elements of interest to be separated from each other and placed in a chemical form that permits them to be coprecipitated (typically as a fluoride or hydroxide). Hindman (1986) presented a method by which the actinides (thorium, uranium, plutonium, and americium) are separated from each other by coprecipitation and mounted as fluorides on a neodymium fluoride substrate, and Sill (1987a) presented methods for the precipitation of actinides as fluorides or hydroxides for high-resolution alpha spectrometry.

The method continues to evolve, being combined with many separation procedures to handle a wide variety of sample types (Sill, 1987b; Sill and Sill, 1989). More recently, it has been demonstrated that satisfactory resolutions can be obtained even with the sample mounted directly upon the filter, that is, without first depositing a substrate on the filter (Sill and Sill, 1994).

The method can produce excellent resolution³ provided the total mass of the sample layer (nuclides of interest, carrier, and any impurities) is kept below approximately 100 μg .⁴ Using an SSB detector, Sill and Williams (1981) found an FWHM for ^{239}Pu of about 65 keV when mounted by this method compared with an FWHM of about 50 keV for a ^{239}Pu source electrodeposited on polished stainless steel. Noting the limitation on the size of the mounted sample, some care should be exercised in selecting the initial size of the sample. If the sample contains more than 100 μg of the nuclide of interest, the resolution will suffer. Obviously, a smaller initial sample size should be chosen.

In addition, it should be noted that certain sample types (e.g., soils) frequently contain trace quantities of elements

2. Lanthanum has also been proposed as a carrier (Sill and Williams, 1981); however, later work (Hindman, 1986) indicated that there are certain disadvantages associated with the use of lanthanum: the purity of available lanthanum reagents is a problem, lanthanum is not as soluble as neodymium in the small pyrosulfate fusions of this procedure, and the precipitation characteristics of lanthanum are not as advantageous as those of neodymium.

3. Today, possibly because of improved filters and detectors, one can expect to achieve routinely a resolution of 40–50 keV with samples mounted by coprecipitation and filtration, while electrodeposited samples typically produce a resolution of 20–40 keV.

4. The 100- μg limit applies when deposited in a 7/8-inch-diameter circle (on a 25-mm filter) producing a thickness of ~ 25 $\mu\text{g}/\text{cm}^2$. Sill and Williams (1981) warn against attempting to distribute the sample over an area greater than that of the detector in an attempt to decrease the sample thickness, as the large entry angle of alpha particles into the detector produces unacceptable amounts of tailing in the spectrum.

that produce chemical interferences with the elements of interest. This can lead to degraded resolution if the total mounted mass exceeds approximately 100 μg . In this case, one has two choices:

1. If the mass of the interfering elements exceeds 100 μg , then a more specific separation is required.
2. If the mass of the interfering elements is less than approximately 75 μg , one might be able to use them in place of the carrier in the coprecipitation of the sample fraction in which these interfering elements occur. For example, 1 g of an average soil contains approximately 75 μg of the light lanthanides (lanthanum, praseodymium, neodymium, etc.), which can be used in place of the cerium carrier to coprecipitate the (actinide) element of interest that occurs in the same fraction as the light lanthanides. (As the light lanthanides are typically trivalent, they typically end up in the americium fraction.)

This method of sample mounting is not limited to chemical separations by coprecipitation. Any separation scheme that produces purified fractions of the elements of interest (e.g., ion exchange, extraction) can precede this method of sample mounting.

Direct evaporation of an organic solution. Direct evaporation of an organic solution produces sources with reasonable resolution by generating nearly solid-free deposits of some alpha-emitting elements. Basically, the method requires extraction of the elements of interest into an organic solution followed by the evaporation of this solution on a stainless steel disk. Examples of organic solutions that may be used include the nyltrifluoroacetone (TTA) in benzene or xylene to complex uranium and thorium and TTA in toluene to chelate plutonium.

The method typically starts with reasonably pure fractions of the elements of interest obtained by ion exchange or solvent extraction. This solution is then evaporated to dryness and treated with a small volume⁵ of perchloric and nitric acids to oxidize any residual organic matter. Following the dissolution of the sample, the pH is adjusted to about 3.0 by the addition of 1.0 M NaOH, and the elements of interest are extracted into approximately 1 mL of an approximately 0.4 M TTA solution. Small stoppered centrifuge tubes may be used to avoid the introduction of excessive amounts of air during the mixing of the organic and aqueous phases. A small Pasteur pipette may then be used to transfer the separated organic phase dropwise onto the stainless steel disk for evaporation. To promote uniform

drying, the disk can be placed on a heated brass cylinder or common iron washer. As a final step, the disk may be flamed to a dull red to ensure the removal of all residual organic material.

Direct evaporation of an aqueous solution. This method is typically not used for the preparation of high-resolution sources as the material does not deposit uniformly. Any salts in the aqueous solution, including the active material itself, tend to deposit as crystals and aggregates. The resulting self-absorption causes a decrease in resolution. Although spreading agents (such as tetraethylene glycol) can be added to the solution to reduce the crystallization problem during the evaporative deposition, they tend to leave substantial quantities of organic material in the deposit that must later be burned off, causing poor adherence of the nuclide to the disk.

b. Chemical separation

As the initial sample may be rather large (on the order of 1 g or more) and the mounted sample needs to be very small (in the microgram range), it is necessary to separate the elements of interest from the bulk of the sample. Once the alpha-emitting elements are separated from the bulk sample, it may not be necessary to separate the various alpha-emitting elements from each other before counting; see, for instance, [Sill and Sill \(1994\)](#). However, as the alpha particle energies of many nuclides differ by as little as 15–30 keV (which is comparable with the energy resolution of the detectors used in alpha spectrometry), chemical separation of such nuclides is required to eliminate these radiochemical interferences and make quantitative analysis possible.

Unlike cold chemistry, in which standard methods abound, there are no standard (prescribed) methods for radiochemical procedures other than for drinking water as given in the EPA 900 series. The trend in the United States in recent years has been for the acceptability of a radiochemical procedure to be performance based. That is, there is no one mandatory procedure with which to perform a given analysis. Rather, a procedure is considered acceptable if one can demonstrate acceptable performance in cross-checks, analysis of knowns, and so forth.

To perform the necessary chemical separations, one must get the elements of interest into solution. This will be discussed in [Section IV.A.1.c](#). Assuming the elements of interest have been dissolved, numerous separation procedures are available. A brief overview of the various methods is presented in the following with references to the scientific and commercial literature from which the detailed procedures may be obtained.

Separation by precipitation/coprecipitation. This technique has been documented extensively in the literature ([Sill, 1969, 1977; 1980; Sill and Williams, 1969; Sill et al.,](#)

5. As the organic solution will eventually have to be evaporated, it is expedient to keep the volume to a minimum. Since the chemical yield of the extraction increases as the ratio of the volume of the aqueous phase to that of the organic phase decreases, it follows that the extraction should be carried out from small volumes (~ 5 mL) to maximize the recovery.

1974). The method is frequently used in conjunction with sample mounting by the method of coprecipitation and filtration as a thin source (Sill and Williams, 1981; Hindman, 1986; Sill and Sill, 1994), but it can also be used preparatory to electrodeposition.

Separation by ion exchange. This is probably still the most common method of chemical separation for the preparation of samples for alpha spectrometry. The method depends on the selective adsorption and desorption of ionic species on ion exchange resins and thus requires that the element of interest be in a form that may be adsorbed by the resin.

Numerous procedures for chemical separations by ion exchange have been presented. Quantitative separation of uranium, thorium, and protactinium by ion exchange has been demonstrated by McCabe et al. (1979). An improved method for the purification of protactinium was later presented by Ditchburn and McCabe (1984). Numerous other procedures for chemical separations by ion exchange have also been presented in the literature. In addition to the numerous texts on the subject (e.g., Small, 1989), manufacturers of ion exchange resins⁶ are often excellent sources of resource material.

Chemical extraction. Chemical extraction is a separation technique that relies on the difference in the solubility of the element of interest in an organic solvent versus an aqueous solution. Traditionally, the two components of the system were maintained in the liquid phase, and the method was referred to as liquid–liquid extraction. However, an innovative application of solvent extraction has been developed at the Argonne National Laboratory in which the solvent extraction system is adsorbed on a macroporous polymeric support that immobilizes the extractant and diluent to form the stationary phase of an extraction chromatographic system.

Separation by liquid–liquid extraction. This method of extraction requires that the element of interest be in true ionic solution in an aqueous medium and not complexed (chelated or bound) in any manner. That is, liquid–liquid extraction will not extract the element of interest from suspended solid or colloidal material. In addition, the presence of organic (and in some cases inorganic) complexing materials in the aqueous phase will, in many cases, cause the extraction to be unsuccessful.

The difference in the solubility of the element of interest in the organic solvent versus the aqueous solution is expressed in terms of the distribution coefficient, K_d , which is defined as

$$K_d = \frac{C_{\text{org}}}{C_{\text{aq}}} \quad (4.56)$$

From this definition, it follows that the percent recovery of an extraction is given by

$$\% \text{ recovery} = \frac{K_d V_{\text{org}}}{K_d V_{\text{org}} + V_{\text{aq}}} \times 100 \quad (4.57)$$

In general, organic acids, ketones, ethers, esters, alcohols, and organic derivatives of phosphoric acid have all been used for extraction. The Purex process, which is generally used for the reprocessing of nuclear fuel, makes use of tributyl phosphate (TBP) in an inert hydrocarbon diluent to extract both uranium and plutonium. Methyl isobutyl ketone (MIBK) has also been used for the extraction of U and Pu from spent fuel. The nonyltri-fluoroacetone (TTA) can be used to extract some actinides. Sill et al. (1974) have presented a procedure by which the actinides are extracted into Aliquat 336, followed by stripping of these elements from the organic extracts. Although liquid–liquid extraction can be used as a precursor to further separations, samples are frequently mounted directly from the organic phase by evaporation of the organic solvent.

Extraction chromatographic systems. This extraction system is used much like ion exchange resins. One advantage of these materials is their high specificity. They are marketed by Eichrom Industries, Inc.⁷ Procedures are available for the separation of americium, plutonium, and uranium in water (Eichrom Industries, 1995a); uranium and thorium in water (Eichrom Industries, 1995b); uranium and thorium in soil (Eichrom Industries, 1994); and thorium and neptunium in water (Eichrom Industries, 1995c). A method for screening urine samples for the presence of actinides using these extraction chromatographic materials has been presented by Horwitz et al. (1990).

c. Preliminary treatments

Preliminary treatments typically vary with the objectives of the experiment and the sample matrix. Basically, they are performed to attain one or more of the following objectives:

1. To separate the component(s) of interest from the remainder of the sample
2. To ensure that the sample is representative of the bulk sample
3. To ensure that the sample remains representative of the bulk sample
4. To preconcentrate the component(s) of interest
5. To introduce chemical tracers and ensure equilibration with analyte isotopes

6. For example, Bio-Rad Laboratories, Inc., 2000 Alfred Nobel Drive, Hercules, CA 94547 and The Dow Chemical Company, P.O. Box 1206, Midland, MI 48641-1206.

7. Eichrom Industries, Inc., 8205 S. Cass Avenue, Suite 107, Darien, IL 60559.

6. To prepare the sample for the chemical procedures that are to follow, that is, dissolve the sample

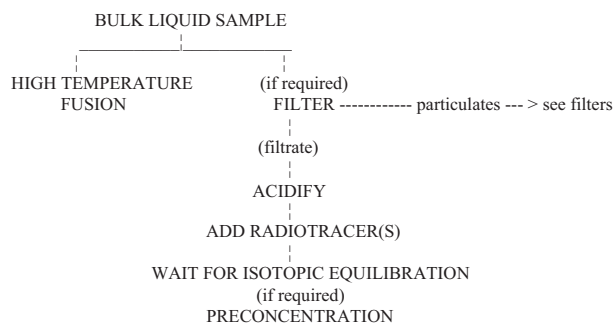

Variable and/or incomplete sample dissolution is a major cause of inaccurate radiochemical analyses. To ensure accurate and reproducible results, it is essential that all of the element of interest be brought into solution. A variety of methods have been suggested and used to prepare samples for alpha spectrometry, including high-temperature fusions, acid leaching, and a variety of “digestions” typically involving acid bombs at elevated temperature and pressure. [Sill and Sill \(1995\)](#) provide convincing arguments for the use of high-temperature fusions, citing examples of the failure of other methods to place selected elements into solution. For a more complete discussion of decomposition methods, see [Bock \(1979\)](#) or [Sulcek and Povondra \(1989\)](#).

For liquid samples, one must first decide what is of concern. Is it the dissolved material, the particulate material, or the total (both together)? If the sample is to be separated into soluble and particulate components, the first step should be to filter the sample. Following filtration, the liquid portion should be acidified to prevent biological growth as well as to keep trace elements in solution (at $6 < \text{pH} < 8$, many metallic elements form insoluble hydroxides, which can then “plate” onto the walls of the sample container). Acidification of a liquid sample before filtration can introduce a bias in the individual components, as the acidification of the sample will leach the particulate matter. Radiochemical tracers, if they are to be used, should be added immediately following acidification. Sufficient time for isotopic equilibration should be allowed before any further chemical procedures are performed. [Burnett \(1990\)](#) suggests that “24 h appears to be sufficient for equilibration of most radiotracers with uranium-series isotopes in natural waters.”

Following isotopic equilibration, one can perform a preconcentration step if desired. Preconcentration is frequently used to obtain sufficient material when the concentration of the material of interest is very low. Common methods of preconcentration include ion exchange, coprecipitation, and the use of adsorptive filters such as manganese-coated acrylic fibers, which have high adsorptive capacities and can be used to preconcentrate elements such as radium, thorium, protactinium, and actinium.

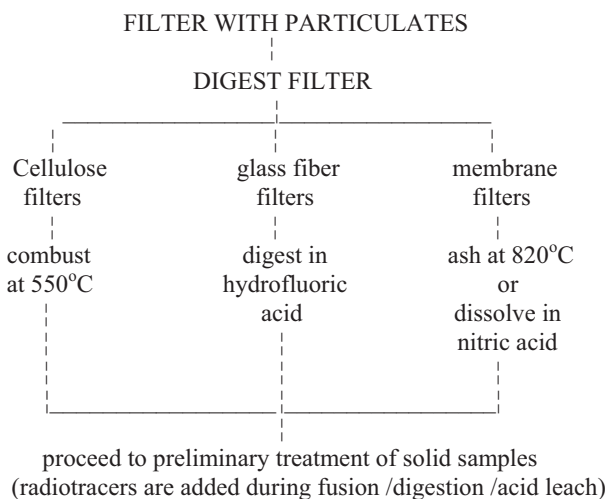

To ensure total dissolution of the element(s) of interest in a total water sample or even the liquid phase when there is a possibility that the element(s) of interest is chelated with organic material or otherwise bound in a form that would interfere with its separation, a high-temperature fusion may be employed. Such a procedure is described by [Sill and Sill \(1994\)](#).

A simple flowchart for the preliminary treatment of liquid samples might appear as follows:

The particulate fraction can be treated in the same way as solid samples (soils, etc.) once the presence of the filter is addressed. Typically, the filter is “digested” either by ashing or by dissolving in strong acid and treating the residue as one would a solid sample; however, polycarbonate (membrane) filters are resistant to acids and do not submit to acid dissolution.

A simple flowchart for the preliminary treatment of filtrates might appear as follows:

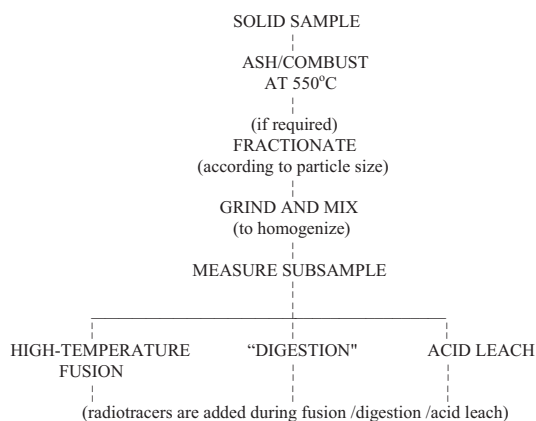

For solid samples, one must first decide what is of concern. Is it the total sample or some fraction thereof? Typically, for soil samples, one is concerned with the sample in total; however, if the sample is to be separated according to particle size, then the first step should be to fractionate the sample according to particle size. Following fractionation, the sample should be ground and mixed well to ensure homogeneity. Finally, the subsample, on which the chemical separations will be performed, should be measured.

As with any sample being prepared for alpha spectrometry, the elements of interest need to be brought into solution before their separation. Although in some cases, it may be possible to remove the element(s) of interest from the bulk of the sample by leaching in strong acid and

separating the liquid and solid phases by centrifuging or filtration, it is generally recommended that a total dissolution of the sample be performed to ensure that the element(s) of interest is indeed brought into solution.

Typically, a high-temperature fusion (e.g., pyrosulfate or potassium fluoride fusion) is used to ensure the total dissolution of a solid sample (Sill and Williams, 1981; Hindman, 1986; Sill and Sill, 1994). Detailed procedures for this technique have been presented by Hindman (1984) and Sill and Sill (1994). One drawback of this method is the expense of the required platinum dish and its limitations in terms of compatibility with certain chemicals and processes. Acknowledging this drawback, Sill and Sill (1995) have presented a procedure for performing a pyrosulfate fusion in borosilicate glassware.

A simple flowchart for the preliminary treatment of solid samples might appear as follows:

2. Sample preparation for gamma spectrometry

Before the advent of high-resolution spectrometers, radiochemical separations were often required prior to counting. Although such procedures are still useful in some cases, they are not covered in this section. Rather, this section focuses on the preparation of samples that do not require extensive chemical preparation.

The first step in sample preparation is to collect the sample. Care should be taken during sample collection to ensure that the sample is representative of the bulk material. For example, air sampling for particles should employ isokinetic sampling. For soil sampling, care should be taken to prevent cross-contamination of samples by the collection tools.

Assuming one is analyzing bulk samples (e.g., there is no chemical separation or preconcentration), the basic function of the sample preparation is to make the sample look like the standard that was assumed for the efficiency

calibration. Whether the calibration standard is an actual source or a mathematical model such as that used for Monte Carlo calibrations, the standard is prepared with or assumed to have certain properties (e.g., dimensions, density, distribution). The sample must be prepared in a manner that reproduces these properties. For example, if it is assumed that the active material is uniformly distributed in a liquid sample, then plating of the active material on the walls of the container must be avoided. To this end, liquid samples may be acidified.

A significant difference between alpha and gamma spectrometry is that in gamma spectrometry, the nuclides of interest are not removed from the bulk sample, so the properties of the bulk sample (density, homogeneity, etc.) become important.

In other ways, the sample preparation considerations for gamma spectrometry are similar to those for alpha spectrometry. For example, for liquid samples, one must still decide which component is of concern. Is it the dissolved material, the particulate material, or the total (both together)? If the sample is to be separated into soluble and particulate components, the first step should be to filter the sample. Following filtration, the filtrate should be acidified both to prevent biological growth and to keep trace elements in solution (at $6 < \text{pH} < 8$, many metallic elements form insoluble hydroxides, which can plate onto the walls of the sample container). In alpha spectrometry, one wants to keep the active material in solution so that it might be chemically separated; however, in gamma spectrometry, one tries to keep the active material in solution to ensure that the geometric distribution of the active material is consistent with the assumed distribution of the calibration standard. Acidification of a liquid sample before filtration can introduce a bias in the individual components, as the acidification of the sample will leach the particulate matter. If the sample is to be analyzed in total (without regard to which fraction contains what activity), acidification as the first step in sample preparation is appropriate as it keeps trace elements in solution. The fact that acidification also leaches the particulate matter is not critical in this case, as the dissolved material will then be uniformly distributed in the liquid, which is most likely the distribution assumed for the efficiency calibration. In fact, if a sample is to be analyzed in total and it contains particulate matter, one should pay particular attention to ensuring that the material is distributed as assumed. That is, if one prepares the calibration standard assuming the active material is uniformly distributed, then one should attempt to ensure that the active material in the sample is also uniformly distributed. In other words, shake it up. Particulate matter in liquid samples can present a difficulty, particularly with long sample counts, as the particulate matter can settle during the counting period, causing a bias to develop.

B. Analysis—analytical considerations

1. Analytical considerations in alpha spectrometry

One can use a peak search program to identify peaks in an alpha spectrum, but it is more typical to use a library-driven and/or user-defined search, as the separations that are typically performed in the preparation of the sample severely limit the nuclides that could be found in any given fraction. Thus, one simply analyzes the regions of the spectrum where the nuclides of interest could be. In addition, library-driven routines are more suited to the analysis of small, poorly defined peaks that are frequently encountered in low-level (environmental) alpha spectrometry.

If the peaks are fully resolved from one another, a simple summation of the counts in each peak provides an accurate value for the peak area. If there is any overlap of peaks, one should use an algorithm (typically implemented in a computer program) that is capable of calculating the areas of peaks that overlap. The algorithm should use a peak model that includes a low-energy tail, which is typical of alpha peaks. A variety of mathematical models and methods have been used in various computer codes designed to analyze complex alpha spectra. Examples of these include ALFUN (Wätzig and Westmeier, 1978), NOLIN (Garcia-Toraño and Aceña, 1981), DEMO (Amoudry and Burger, 1984), and GENIE-PC (Koskelo et al., 1996).

These programs assume no continuum distribution under the peaks, as alpha particle interactions do not provide a mechanism by which a continuum distribution could be generated. Rather, any alpha particle interaction in the detector would necessarily contribute to the peak (or tail of the peak). This should not be interpreted as meaning that there is no “background” contribution, but rather that the background contributions also form or contribute to a peak (or tail). Background contributions may result from

1. contamination of the counting chamber and/or detector, which can be determined by counting the empty chamber
2. contaminants in the process reagents and/or mounting materials, which can be determined by counting a method blank

For radiochemical analyses (assays), these background contributions must be subtracted from the observed spectrum to determine the sample (only) count rate to determine accurately the sample activity. Some commercially available alpha spectrometry software packages differentiate between these two contributions as an area correction (item I above) and a reagent correction (item II above). The reagent correction is often implemented by scaling the contribution of one (reagent) nuclide to another (reagent nuclide), in which case the area correction should be implemented before the reagent correction. For example, if a ^{242}Pu tracer is used that contains trace

levels of ^{239}Pu , one would need to subtract the tracer's contribution to the ^{239}Pu peak from the observed spectrum to determine the sample's contribution to the ^{239}Pu peak. The tracer's contribution to the ^{239}Pu peak may be determined as a fraction of the ^{242}Pu that is present due to the tracer. However, if ^{242}Pu contamination is present in the counting chamber, the chamber's contribution to the observed ^{242}Pu peak must be subtracted from the observed ^{242}Pu peak before the ^{242}Pu peak can be used to determine the quantity of reagent present and thereby the reagent's contribution to the ^{239}Pu peak.

As discussed in Section III.B.1.a, the efficiency for the detection of alpha particles is independent of energy or emitter and is strictly a function of the geometric efficiency of the source–detector configuration. Thus, the question becomes, what is the ideal source–detector configuration?

As discussed in Section III.B.1.a, for a given specific source activity, A_s (Bq/cm^2), the optimum source diameter (from efficiency considerations only) is equal to the detector diameter. However, for a fixed amount of activity (as one would obtain from a given sample), the count rate depends only on the geometric efficiency, which, as Fig. 4.25 shows, increases with decreasing source diameter. The practical ramification of this is that one can increase the counting efficiency by depositing the sample in a smaller diameter. However, as the sample diameter decreases, the sample thickness increases and can cause a decrease in resolution. Thus, the minimum sample diameter is constrained by the effect of sample thickness on resolution. For example, a 100- μg sample deposited in a diameter of 1 inch ($\sim 5\text{ cm}^2$) results in a sample thickness of 20 $\mu\text{g}/\text{cm}^2$, as does a 25- μg sample deposited in a diameter of 1/2 inch ($\sim 1.25\text{ cm}^2$). With approximately equal sample thicknesses, the resolution of the two samples will be roughly equivalent,⁸ but the smaller diameter sample will have a higher counting efficiency. Thus, the counting efficiency for low-activity (actually low-mass) samples can be increased by depositing them in a smaller diameter within the constraints imposed by the effects of sample thickness on resolution. The resolution of samples mounted by the fluoride precipitation method is generally acceptable if the sample thickness is kept at 25 $\mu\text{g}/\text{cm}^2$.

However, in practice, the diameter of the sample deposition is not adjusted from sample to sample but rather specified by the sample mounting procedure. The size of the sample deposition, as well as the initial mass of the sample, called for in a procedure should be based on the anticipated sample quantities (concentrations), maximum desired sample thickness, diameter of the detector, and available sizes of commercially available filters, filter holders, electrodeposition disks, and so on. Thus, instead of altering the diameter of the deposition to increase the count

8. Actually, the smaller diameter sample should produce a slight advantage in terms of spectral tailing, as the maximum entry angle (of alpha particles into the detector) is less for the smaller diameter sample.

rate of low-activity (low-mass) samples, one typically increases the size of the initial sample. Applying these considerations to the practical problem of achieving the lowest possible MDA (in terms of Bq/g) for a given sample analysis produces a protocol that requires

1. The diameter of the sample mount should be approximately equal to the diameter of the detector.
2. The amount of initial raw sample to be used in the analysis should be maximized within the constraint that the final mounted sample thickness does not exceed $25 \mu\text{g}/\text{cm}^2$ (or whatever thickness is demanded by resolution considerations).

Although it has been recommended by Sill and Olson (1970) that “sources should be placed at least 1.5 diameters from the detector to obtain optimum resolution,” one needs to appreciate that there is a trade-off between efficiency and resolution. While placing the source closer to the detector causes a decrease in resolution (larger FWHM), it also increases the counting efficiency. As discussed in Section III.B.1.a, the increase in the FWHM at distances as close as 2 mm can be expected to be no greater than 50% (for 300- to 600-mm² detectors). Such a decrease in resolution may be deemed tolerable in light of the increase in efficiency so obtained. For low-level counting, it is not unusual to sacrifice resolution to increase the counting efficiency.

Another important consideration in alpha counting is the problem of recoil contamination, which can occur when the progeny of the alpha-emitting nuclides being observed is ejected from the sample (due to the kinetic energy of recoil from the initial alpha emission) and becomes attached to the detector. The short-lived alpha-emitting progeny then contributes to the alpha spectrum.

Sill and Olson (1970) have demonstrated a reduction in recoil contamination “by a factor of at least 10^3 with a loss in resolution of only 1 or 2 keV by leaving enough air in the counting chamber to produce $12 \mu\text{g}/\text{cm}^2$ of absorber between the source and detector, and applying a negative potential of 6 V to the source plate.” Fig. 4.43 summarizes the relationship between distance and pressure required to stop recoiling ²²¹Fr atoms as described by Sill and Olson (1970), who observed that “the range of the recoiling atoms was between 12 and $16 \mu\text{g}/\text{cm}^2$ for all distances checked.”

Neither the air layer nor the negative bias on the sample plate individually is sufficient to prevent recoil contamination of the detector. Both the air layer and the negative bias together are required to prevent recoiling daughter atoms from reaching the detector. Today, most commercially available alpha spectrometers provide a readout of the chamber pressure and a negative bias on the sample plate relative to the detector.⁹

FIGURE 4.43 Relationship between distance and pressure required to stop recoiling ²²¹Fr atoms. From Sill and Olson (1970), reprinted with permission from the American Chemical Society, © 1970.

In summary, the resolution is improved with the following:

1. A thinner entrance window on the detector.
Trade-off: None.
2. Thinner sample deposition.
Trade-off: Larger diameter samples (of the same total activity) have a lower counting efficiency and greater low-energy tailing due to large angle entry of the alpha particles into the detector.
3. A thinner air column (absorber) as measured in g/cm^2 between the sample and detector.
Trade-off: Increased recoil contamination if the air column is too thin ($<12 \mu\text{g}/\text{cm}^2$).
4. A longer (straighter) path between the sample and detector.
Trade-off: Lower counting efficiency.

2. Analytical considerations in gamma spectrometry

The American National Standards Institute has published a standard that provides guidance in the calibration and use of germanium spectrometers:

Methods for the calibration and use of germanium spectrometers for the measurement of gamma ray energies and emission rates over the energy range from 59 keV to approximately 3000 keV and for the calculation of source

9. Equivalently, the detector can be biased positive relative to the sample plate.

activities from these measurements are established. Minimum requirements for automated peak finding are stated. Methods for measuring the FEP efficiency with calibrated sources are given. Performance tests that ascertain the proper functioning of the Ge spectrometer and evaluate the limitations of the algorithms used for locating and fitting single and multiple peaks are described. Methods for the measurement of and the correction for pulse pileup are suggested. Techniques are recommended for the inspection of spectral analysis results for large errors resulting from summing of cascade gamma rays in the detector. Suggestions are provided for the establishment of data libraries for radionuclide identification, decay corrections, and the conversion of gamma ray rates to decay rates.¹⁰

Typically, an automated gamma spectral analysis requires the following steps:

1. Peak location
2. Calculation of peak areas
3. Correction of peak areas (if required; e.g., subtraction of system background or reference peak correction for random summing losses)
4. Calculation of the efficiency at the peak energies
5. Calculation of activity

Generally, the activity of a sample is calculated in gamma spectrometry from the following equation:

$$\begin{aligned} \text{Activity (in Bq at } t = 0) \\ = \frac{\text{Net Peak Area}(E)}{T_L \text{Efficiency}(E) \text{Intensity}_\gamma(E)} \frac{\lambda T_R}{1 - e^{-\lambda T_R}} \end{aligned} \quad (4.58)$$

where $t = 0$ is the starting time of data acquisition, T_L the live time of the count, T_R the real time of the count, and λ the decay constant:

$$\lambda = \frac{\ln(2)}{T_{1/2}} \quad (4.59)$$

where $T_{1/2}$ is the radionuclide half-life and¹¹

$$\frac{\lambda T_R}{1 - e^{-\lambda T_R}} = \text{decay correction for decay} \quad (4.60)$$

during the counting period

$$\text{Intensity}_\gamma(E) = \frac{\text{gamma emission rate (at energy } E)}{\text{disintegration rate}} \quad (4.61)$$

and

$$\text{Efficiency}(E) = \frac{\text{full-energy deposition rate (at energy } E)}{\text{gamma emission rate (at energy } E)} \quad (4.62)$$

The efficiency is supposed to express the relationship between the full-energy deposition rate and the emission rate of a sample. Typically, the full-energy deposition rate is approximated by the net count rate, so that the emission rate of a sample is determined by a simple proportional scaling of the observed count rate from a standard of known emission rate as follows:

$$\begin{aligned} \frac{\text{Emission rate of sample}}{\text{Count rate of sample}} \\ = \frac{(\text{known}) \text{ emission rate of standard}}{\text{observed count rate of known standard}} \end{aligned} \quad (4.63)$$

so that

$$\begin{aligned} \text{Emission rate of sample} \\ = \frac{\text{count rate of sample}}{\left(\frac{\text{observed count rate of known standard}}{(\text{known}) \text{ emission rate of standard}} \right)} \quad (4.64) \\ = \frac{\text{count rate of sample}}{\text{efficiency}} \end{aligned}$$

In other words, the efficiency is supposed to specify the number of full-energy depositions (of energy E) in the detector per gamma ray (of energy E) emitted by a source of a given geometry.¹² The efficiency may be determined by mathematical methods such as Monte Carlo calculations.¹³ More traditionally, it is determined by dividing an observed count rate for a calibration standard of a given geometry by the known emission rate of the standard as indicated above. The assumption inherent in this methodology is that the observed count rate (or total net counts in a given time period) is equal to the full-energy deposition rate of the standard (or total number of full-energy depositions of energy E in a given time period).

Most problems in the quantification of gamma spectra can be traced to a discrepancy between the observed count rate and the full-energy deposition rate. There are many

10. ANSI N42.14-1991, copyright © 1991, IEEE. All rights reserved.

11. This correction factor [which essentially converts the nominal count rate (peak area/ T_L) to the count rate at time $t = 0$] is derived assuming the dead time is constant during the counting period. As such, it is an approximation that is valid only for materials whose half-life is long relative to the count time.

12. The term geometry is used to indicate the geometric distribution of a source (or sample) relative to the detector, the materials between the source and detector, the size and configuration of the detector, and so forth.

13. With the increase in computer power that has become available in recent years, mathematical calibrations have become more practical and more widely available. Mathematical calibrations are particularly well suited to in situ counting and other geometries for which the production of a calibration standard would be impractical if not impossible.

potential causes for such a discrepancy, among which are the following:

- Failure to correct for dead time causes full-energy depositions to be unrecognized.
- Pulse pileup causes full-energy depositions to be unrecognized.
- Random summing causes full-energy depositions to be unrecognized.
- Coincidence summing causes full-energy depositions to be unrecognized.
- Incorrect assessment of peak area produces an incorrect count rate that does not properly represent the full-energy deposition rate.

The basic steps involved in a gamma spectral analysis will now be reviewed.

a. Peak location

The first step in the analysis is to locate the peaks in the spectrum. This can be accomplished by either a library-driven routine or a search-driven routine.

The library-driven routine uses a list of energies (a library¹⁴) of peaks for which one wishes to search. It then calculates the net area of the region over which each listed peak, if present, would exist. The area so calculated may then be reported (even if it is negative), whereas other programs first determine whether the net area is statistically significant. The region over which the peak is assumed to exist is usually determined from a “shape calibration,” that is, a relationship of the FWHM versus energy and possibly a tailing parameter versus energy.

The ability of a library-driven routine to identify peaks (and nuclides) is limited to the entries in the library. One should also be aware that spectral artifacts (such as the backscatter peak) can produce false-positive peak identifications.

On the positive side, library-driven routines provide the following advantages:

1. The ability to identify small peaks
2. The ability to identify poorly shaped peaks
3. The ability to unfold complex multiplets

This last strength is used to great advantage in a program known as MGA (Gunnink, 1990), which quite arguably epitomizes the capabilities of library-driven routines. It was designed to determine the isotopic abundances of a plutonium sample. A mixture of plutonium isotopes (238–242) produces a spectrum that is too complex to analyze by traditional means. However, knowing that the

sample was pure plutonium at one time, all of the potential component nuclides are known and a library of all their energy lines and relative abundances can be specified. By knowing the detailed line shape of gamma and X-ray peaks, one can generate the envelope function for a given mixture of the component nuclides. Essentially, a least-squares fit of the envelope function to the observed spectrum using (among other parameters) the relative abundances of the plutonium isotopes as independent variables then yields the relative abundances of the plutonium isotopes.

A search-driven routine applies some mathematical methodology to the spectral data to distinguish peaks from the continuum distribution. A method that is often employed is to apply a symmetric zero-area transform (often referred to as a sliding transform, sliding filter, digital filter, or filter) to the spectral data. The method was proposed by Mariscotti (1967) and employed in the programs SAMPO (Routti and Prussin, 1969) and HYPERMET (Phillips and Marlow, 1976) and several commercially available programs that followed (e.g., Canberra Industries’ GENIE family of spectrometry systems). The transformed spectrum (which can be thought of as a response function) will be zero where the spectrum is constant, nearly zero where the spectrum is slowly varying, and large (either positive or negative, depending on the definition of the transform) in the region of a peak. Thus, one merely needs to scan the response for regions that exceed some threshold value to find peak locations in the spectrum. The response will be strongest when the width of the feature in the spectrum (ideally a peak) most closely matches the width of the filter. This has two implications:

1. The width of the filter should be chosen to match the expected width of the peaks. This is typically accomplished by use of a shape calibration.
2. This algorithm tends to discriminate against features that are both wider and narrower than the filter width. Hence, spectral artifacts in Ge and Si(Li) detector spectra whose width differs significantly from the expected peak width (such as the backscatter peak) tend to be filtered out.

A common error in the use of search-driven routines is failure to match the sensitivity of the peak search routine to the detection limit assumed in the calculation of the MDA or the lower limit of detection (LLD). These calculations assume that peaks of a given size (relative to the background) can be detected at a given confidence level. This is not necessarily true if the sensitivity (response threshold) is not selected appropriately. This has been recognized and addressed in ANSI standard N42.14 (1991), which states in Section 5.

If an automated peak-finding routine is used in the spectral analysis, it should be able to find small well-formed single peaks whose areas are statistically significant (above background)

14. As the library is typically used again during the analysis process for nuclide identification and activity calculation, it generally includes the nuclide name, the nuclide half-life, and the gamma ray intensities, in addition to the gamma ray energies.

and provides a test for automatic peak-finding algorithms in Section 8.1, which

... has been designed to determine how well singlet peaks on a flat baseline that are at or above an “observable” level can be found (i.e., detected) with the peak-finding algorithm.

The standard goes on to state that

the peak-finding algorithm is expected to find a peak in a spectrum whose area, A , $= L_P \sqrt{[(2.55)(FWHM)y_i]}$, where 2.55 is based on $\pm 3\sigma$ for a Gaussian peak, FWHM is the full width in channels at half maximum of the peak, y_i are the average counts in each baseline channel, and $L_P = 2.33$ corresponds to the value L_P initially suggested for this test.¹⁵

The value of 2.33 for L_P was chosen to correspond to the critical level, L_C as defined by Currie (1968) to be the decision limit at which a count is assumed to be detectable with 95% confidence (i.e., α = probability of a false positive = 5%).¹⁶

Advantages of search-driven routines include the following:

1. The ability to locate peaks even if one did not anticipate their presence
2. The ability to differentiate between peaks and other spectral features

A search-driven algorithm should also be able to locate the individual components of a multiplet (two or more peaks that overlap). Depending on the methodology employed, this functionality can be incorporated in the peak-locating routine; however, some other methods can be implemented only during the peak (area) analysis routine. Therefore, the discussion of multiplet deconvolution will be taken up in the next section on peak area analysis.

b. Peak area analysis

The next step in the analysis is to calculate the net area of the observed peaks. This is typically accomplished either by a summation method or by fitting a function that represents the assumed peak shape to the observed data and reporting the area under the peak function as the net area:

$$\text{Summation : Area} = \sum_{i=\text{left}}^{\text{right}} y_i - b_i \quad (4.65)$$

$$\text{Fit : Area} = \int P(\alpha_1, \alpha_2, \alpha_3, \dots, x) dx \quad (4.66)$$

where i = channel number, left = the leftmost channel of peak region (to be fitted), right = the rightmost channel of peak region (to be fitted), y_j = number of (gross) counts in channel i , b_i = continuum contribution to channel i , and $P(\alpha_1, \alpha_2, \alpha_3, \dots, x)$ = the “best fit” mathematical function that models the assumed peak shape. The best fit is typically determined by the method of least squares, which requires that χ^2 be minimized, where χ^2 is defined as

$$\chi^2 = \sum_i w_i [y_i - b_i - P(\alpha_1, \alpha_2, \alpha_3, \dots, x_i)]^2 \quad (4.67)$$

where w_i is the weighting applied to the i th point and the α_k are the free parameters of the model.

The fit method is applicable to both singlets and multiplets; the summation method (by itself) cannot assess the contributions from the individual components of a multiplet. Thus, multiplet analysis requires some sort of fit to be performed. Notice that both the summation and fit methods require that the continuum contribution (background) under the peak, b_i , be specified. One way to estimate this contribution is to assume a particular mathematical model for the background and determine its parameters from the channels immediately to either side of the peak.

Two commonly used background models are the linear background and step background (Gunnink, 1979),¹⁷ which may be determined from the spectral data as follows:

$$\text{Linear model : } b_i = \frac{B_L}{n} + \frac{B_R - B_L}{n(N+1)} i \quad (4.68)$$

$$\text{Step model : } b_i = \frac{B_L}{n} + \frac{B_R - B_L}{nG} \sum_{i=\text{left}}^i y_i \quad (4.69)$$

where

$$B_L = \sum_{i=\text{left}-n}^{\text{left}-1} y_i \quad (4.70)$$

15. ANSI N42.14-1991, copyright © 1991, IEEE. All rights reserved.

16. Currie’s derivation of the limit of detection was based on single-channel (gross counting) considerations and, as such, is not strictly applicable to multichannel analysis; however, it has become common practice to apply the equations and concepts from his derivation to multichannel analysis even though there are additional considerations and uncertainties in multichannel analysis that are not incorporated in these equations. For instance, the probability of a false-positive identification is not strictly a function of the size of the background, as the peak-locating algorithm will not (falsely) identify a peak if the region of the null spectrum under consideration is reasonably flat (regardless of size). Furthermore, the uncertainty associated with the ability to detect a peak as a function of peak shape is not included. As an example, consider two peaks with equal net area at (or slightly above) the critical level. A peak-locating algorithm may detect one and not the other, because its ability to recognize a peak is dependent on the shape of the spectral distribution.

17. Mathematically, a step function can be expressed by a variety of functions. The function presented here is the one proposed by Gunnink (1979) and used in Canberra Industries’ GENIE software.

$$B_R = \sum_{i=\text{right}+1}^{\text{right}+n} y_i \quad (4.71)$$

where n is the number of channels to be averaged on each side of the peak to determine the background, N is the number of channels in the peak region, and

$$G = \text{integral of the peak region} = \sum_{i=\text{left}}^{\text{right}} y_i \quad (4.72)$$

For single well-resolved peaks, the linear and step backgrounds produce approximately equivalent results for the area calculation. However, for multiplets, the linear and step backgrounds can produce different results. As shown in Figs. 4.44 and 4.45, the step background is greater than the linear background on the left side of the multiplet and less than the linear background on the right side. For multiplets containing a large component and a small component, the step background places the major portion of the background change under the major component, and the linear background changes linearly across the peak region. This results in the linear approximation understating (relative to the step approximation) the background under the minor component (thus overstating the net area) when the minor component is on the left side of the multiplet and overstating the background (relative to the step

Comparison of Step versus Linear Background for a Multiplet with the Small Component on the Right Side

FIGURE 4.44 A comparison of a step background versus a linear background for a multiplet with the small component on right side.

Comparison of Step versus Linear Background for a Multiplet with the Small Component on the Left Side

FIGURE 4.45 A comparison of a step background versus a linear background for a multiplet with the small component on left side.

approximation) under the minor component (thus understating the net area) when the minor component is on the right side of the multiplet.

The accuracy of the analysis of multiplet components and the ability to detect the presence of these components are also addressed in ANSI standard N42.14 (1991), as Section 5 states:

... The peak fitting routine should be able to find multiplet peaks that meet the peak area criteria for a singlet, are approximately the same intensity, and are separated by 1 FWHM. (see Section 8 for the test procedures). Optimization of the peak search parameters of the peak-finding algorithm is left to the user or software vendor. These should be adjusted so that statistically significant peaks are found with a minimum number of false peaks being reported (see performance tests in Section 8).¹⁸

Section 8.3 of the standard (ANSI N42.14, 1991) provides performance tests for “the Doublet-Peak Finding and Fitting Algorithms.” These tests can be used to determine which background function provides the most accurate multiplet analysis as well as to evaluate an algorithm’s overall accuracy in determining the areas of the

18. ANSI N42.14-1991, copyright © 1991, IEEE. All rights reserved.

components of a multiplet. Investigations using such tests have been presented by Koskelo and Mercier (1990) and Mercier and Koskelo (1992), in which several commercially available analysis programs were evaluated.

As stated previously, the ability to detect a multiplet can be incorporated in the peak locate routine or the peak (area) analysis routine. Peak search algorithms that employ a symmetric zero-area transform (and determine the presence of the peak from a large response in the transformed spectrum) to detect the individual components of a multiplet at the peak search stage can generally resolve components of equal size separated by one FWHM or more. As the difference in size of the individual components increases, the separation required to be able to detect the smaller component becomes greater. The individual components of a multiplet can also be detected during the peak fit stage by inspecting the residuals of the fit. After the initial fit, the residuals are examined. The presence of an unresolved component causes the residuals to deviate significantly from zero. Thus, one can add another component (peak) to the fitting function and fit the data again. This algorithm (particularly when used in conjunction with shape information) tends to be more sensitive to the detection of multiplet components than the symmetric zero-area transform; however, some care should be taken in the application of this method, as one needs to distinguish between normal statistical fluctuations and significant deviations.

c. Peak area corrections

The next step in the analysis is to correct the observed net area of the peaks for any systematic errors. Such errors can be caused by (but are not limited to)

- Environmental background
- Pulse pileup
- Random summing
- Coincidence summing

Correcting for the presence of environmental background can be done by subtracting the count rate of the environmental background peak from the observed count rate of the sample peak. The count rate of the environmental background peak should be established by counting a sample blank (as opposed to an empty shield), as the sample itself can shield the detector from the source of the environmental background. Counting the empty shield rather than a sample blank biases the environmental background count rate high, resulting in a low bias for the corrected sample count rate.

Pulse pileup, random summing, and coincidence summing all cause an event of energy E to increment a channel that corresponds to an energy $E' > E$. Thus, the net area of the peak at energy E does not accurately represent the number of full-energy events of energy E .

For purposes of this discussion, random summing is defined as two independent depositions occurring within ΔT of one another, where ΔT is less than the discrimination time of the fast discriminator used by the pileup rejector (PUR) (typically, approximately 500 ns), so that the amplifier pulse appears to be a single event.

Pulse pileup is defined as two depositions occurring within ΔT of one another where ΔT is greater than the discrimination time of the fast discriminator used by the pileup rejector but less than the amplifier pulse width, so that one amplifier pulse starts before the preceding pulse has ended. The resulting pulse is thus distorted in that it has an amplitude and/or width that differs from the first event alone. The distinction between pulse pileup and random summing is that the pileup rejector can tell that the pileup pulse is the result of two events (and thus discriminate against these pulses, whereas it cannot discriminate against pulses resulting from random summing).¹⁹

Coincidence summing is defined as two depositions originating from a single event within ΔT of one another, where ΔT is less than the discrimination time of the fast discriminator used by the pileup rejector, so that the amplifier pulse appears to be a single event. The distinction between coincidence summing and random summing is that coincidence summing originates from a single event. Examples are cascade gammas (such as the 1332-keV gamma that follows the 1173-keV gamma following the decay of ^{60}Co), coincident x and γ rays following electron capture (such as the 14-keV X-ray and 1836-keV γ ray following the electron capture decay of ^{88}Y), and coincident emission of γ rays along with the 511-keV annihilation photons following positron emission (such as in the decay of ^{58}Co in which the daughter emits the 810-keV gamma in coincidence with the annihilation photons). A further distinction between random summing and coincident summing is that coincident summing is independent of count rate, but random summing is a function of count rate.

The discrepancy (bias) caused by pulse pileup between the number of full-energy counts (net peak area) and the number of full-energy events can be reduced by the use of a pileup rejector or corrected for in software by use of a reference peak correction. PURs can keep the observed full-energy count rate (net area divided by live time) within approximately 1% of the true full-energy deposition rate for input count rates²⁰ below approximately 20,000 counts/s. A PUR is ineffective against random summing, as the summed pulse appears to be a single event, against which the

19. With a further distinction that $\Delta T < \text{the linear gate time (LGT)}$ of the ADC in the case of "leading-edge pileup," and $\text{LGT} < \Delta T < \text{pulse width}$ in the case of "trailing-edge pileup."

20. Where the input count rate must be defined as the full-spectrum input rate, because an event of any size summing with an event of interest will remove the count from the peak of interest.

PUR cannot discriminate. With a discrimination time of 500 ns, the probability of random summing approaches 1%²¹ at rates of approximately 20,000 counts/s.

An alternative to PUR is reference peak correction, which can be used to correct for both pileup and random summing (even dead time if the count times are measured in real time rather than live time). The corrected peak area is given by

$$A_C = A_O \frac{P_{\text{NOM}}}{P_O} \quad (4.73)$$

where A_O is the observed net peak area, P_{NOM} the nominal (net) count rate of the reference peak, and P_O , the observed (net) count rate of the reference peak.

The reference peak can be produced by either a pulser or a radioactive source in a fixed position. It should be noted that when a pulser is used to inject a signal into the preamplifier, the preamplifier output may have a shape slightly different from that of the output that results from charge injection by the detector (i.e., the detection of a gamma ray). The difference in preamplifier pulse shapes makes it impossible to pole zero the amplifier properly for both pulse types. This will cause a slight degradation in the system resolution.

Both pileup rejection and reference peak corrections are ineffective for correcting for coincidence summing. However, correction factors of the form

$$C = \frac{\text{full-energy events (of energy } E\text{)}}{\text{full-energy counts (at energy } E\text{) (i.e., net peak area)}} \quad (4.74)$$

can be calculated as presented by Andreev et al. (1972, 1973) and McCallum and Coote (1975). Debertin and Schötzig (1979) have extended these equations and incorporated them in the computer program KORSUM, which allows calculation of true coincidence summing corrections for arbitrary decay schemes. This program does not include effects due to angular correlations or coincidence with β rays or bremsstrahlung, as the authors considered contributions from these effects to the total summing correction to be low and smaller than the uncertainty of the correction. The authors used the program to calculate correction factors for a point source geometry and a beaker geometry and obtained good agreement with experimental values.

Note that to correct for true coincidence summing, the correction factors must be calculated and applied on a line-by-line basis, and their calculation requires knowledge of the peak and total efficiencies for the particular detector—

geometry combination. The specificity of the correction factors to be determined made it difficult to incorporate the techniques into a commercial analysis package, until now. Within the past few years, however, manufacturers such as Canberra Industries, and Ortec, have developed their own analysis packages that include algorithms to correct for true coincidence summing (or cascade summing) effects. The effects of true coincidence summing and the techniques employed to correct for it are discussed in Section II.B.4. of this chapter.

Virtually, all commercially available spectrometers include live-time correction and pileup rejection, and some systems also include reference peak correction capability in their software.

d. Efficiency calculation

The next step in the analysis is to calculate the efficiency at the energy of each observed peak. Because it would not be practical to try to measure the efficiency at every possible energy that might be encountered in a sample, most software uses an efficiency calibration to calculate the efficiency for any given energy. Typically, these calibrations consist of a functional expression of efficiency as a function of energy:

$$\text{Efficiency}(E) = f(E) \quad (4.75)$$

The functional dependence is typically determined by the method of least-squares fitting or sometimes spline fitting. The energy efficiency coordinates from which these functions are calculated can be determined by measuring a source of known emission rate or by mathematical calculation, such as with the Monte Carlo method. A typical efficiency calibration from a commercial spectroscopy package is shown in Fig. 4.46.

Care should be taken to ensure that the calibration standard represents the samples to be counted. That is, the calibration standard and samples should be identical in size, shape, density, spatial distribution of active material, and so on. Source position is relatively more critical for close geometries. These precautions apply to mathematical calibrations as well as to those performed with radioactive standards.

e. Nuclide identification and activity calculation

The next step in the analysis is to identify the nuclides that are present in the sample and to calculate their activity. Some simple schemes allow the nuclide identification to be independent of the activity calculation, whereas other schemes depend on the activity calculation to identify a nuclide positively. This will be clarified subsequently by example.

A variety of nuclide identification algorithms have been used in commercial software packages. Following is a list

21. Note that this application of a PUR does not imply an overall accuracy or precision of 1%, but rather a limitation on the *bias* caused by just pulse pileup. All of the normal considerations associated with the measurement of a nuclear count rate still apply.

FIGURE 4.46 A typical efficiency calibration as displayed by a Canberra GENIE-PC system.

of some of the nuclide identification algorithms that have been used in commercial packages.

1. The simplest algorithm requires that for a particular nuclide to be identified, a peak must exist in the spectrum (within some user-defined energy tolerance) at every gamma ray energy listed in the library for that nuclide.
2. Another algorithm requires that only a given (user-defined) fraction of the listed gamma rays of a particular nuclide be observed (as peaks within some user-defined energy tolerance) to identify that nuclide positively.
3. Yet another algorithm requires that only a given (user-defined) fraction of the listed gamma rays of a particular nuclide be observed (as peaks within some user-defined energy tolerance) to identify the nuclide potentially, its positive identification being dependent on a nonzero activity being calculated for it.

The equation for activity is obtained from the following expression:

Observed net peak area (E)

$$= \int_{t=0}^{t=T_R} A_0 e^{-\lambda t} \text{Intensity}_\gamma(E) \text{Efficiency}(E) (1 - DT) dt \quad (4.76)$$

where DT is the fractional dead time. If the dead time is assumed to be constant for the duration of the acquisition, one can solve this equation for A_0 to obtain Eq. (4.77) (as stated previously and restated here):

$$\begin{aligned} \text{Activity (in Bq at } t = 0) \\ = \frac{\text{Net Peak Area } (E)}{T_L \text{Efficiency } (E) \text{Intensity}_\gamma(E)} \frac{\lambda T_R}{1 - e^{-\lambda T_R}} \end{aligned} \quad (4.77)$$

where $T_L = T_R (1 - DT)$.

This equation has been applied in a variety of ways in commercial packages. One of the simplest nuclide

identification—activity calculation methodologies calculates the activity of a nuclide from a single “key line.” Following an independent nuclide identification routine (typically, algorithm 1 or 2 from the preceding list of nuclide identification algorithms), the activities of the identified nuclides are calculated from Eq. (4.77).

The most serious deficiency of these simple independent nuclide identification algorithms occurs in spectra that have an interference (i.e., two or more nuclides contributing to a single peak). In particular, these algorithms tend to produce both false-positive identifications and grossly inaccurate quantifications due to the presence of interfering nuclides. This is easily demonstrated by considering the case of ^{75}Se . If one were to analyze a sample containing only ^{75}Se , there would be (at least) five peaks in the spectrum at 121, 136, 264, 279, and 400 keV. With a 1-keV energy tolerance, these peaks would also be identified as ^{57}Co and ^{203}Hg in addition to ^{75}Se .

If one were to calculate the activities of the “identified nuclides” by assigning the entire area of a peak to each nuclide without regard to the interferences, then for every 100 Bq of ^{75}Se , the following activities (within statistical fluctuations) would be reported:

^{57}Co : 20.0 Bq based on the 121-keV peak
 545.6 Bq based on the 136-keV peak
 X Bq where $10.0 < X < 545.6$

If a weighted mean activity is employed

^{203}Hg : 30.4 Bq based on the 279-keV peak
 ^{75}Se : 100.0 Bq based on any of the lines

Of course, for mixtures, the situation is even worse, as none of the nuclides are calculated correctly. To remedy this situation, one of two algorithms is generally employed. The first makes use of an interference library in which one explicitly identifies which lines of which nuclides interfere with what other nuclides. The activity of the nuclide that

⁷⁵ Se		⁵⁷ Co		²⁰³ Hg	
Energy	Intensity	Energy	Intensity	Energy	Intensity
121.117	17.14%	122.061	85.60%		
136.001	58.27%	136.474	10.68%		
264.658	58.5%				
279.544	25.79%			279.197	81.46%
400.660	11.37%				

has lines without interference is then calculated from the peaks for which there is no interference (e.g., the 264- and 400-keV lines of ⁷⁵Se in the preceding case). This nuclide's contribution to the peaks with which it interferes is then calculated and subtracted from the observed area of these peaks. In the preceding example, the contribution of ⁷⁵Se to the 121- and 136-keV peaks is calculated from the calculated activity of ⁷⁵Se and subtracted from the observed areas of the 121- and 136-keV peaks. The balance of the peak areas is then attributed to ⁵⁷Co, and its activity is calculated from these "corrected" peak areas. Similarly, the contribution of ⁷⁵Se to the 279-keV peak is calculated from the calculated activity of ⁷⁵Se and subtracted from the observed area of the 279-keV peak. The remaining area is then attributed to ²⁰³Hg and used to calculate the activity of ²⁰³Hg. One limitation of this algorithm is that the user must explicitly identify all of the potential interferences before the analysis for this method to identify the interferences that are present.

Another algorithm, originally proposed by [Gunnink and Niday \(1972\)](#) and implemented in SAMP080 ([Koskelo et al., 1981](#)) and GENIE-PC ([Koskelo and Mercier, 1995](#)), that can resolve this situation involves setting up a simultaneous set of equations that expresses each potentially identified nuclide's contribution to each observed peak. Using the previous example, in which the observed peaks (at 121-, 136-, 264-, 279-, and 400-keV) cause ⁷⁵Se, ⁵⁷Co, and ²⁰³Hg to be identified, one would obtain the following set of equations:

$$\text{Int}_{121-\text{Se}} * A_{\text{Se}} + \text{Int}_{122-\text{Co}} * A_{\text{Co}} = \frac{\text{Peak Area}(121)}{\epsilon(121) * T_L} \quad (4.78a)$$

$$\text{Int}_{136-\text{Se}} * A_{\text{Se}} + \text{Int}_{136-\text{Co}} * A_{\text{Co}} = \frac{\text{Peak Area}(136)}{\epsilon(136) * T_L} \quad (4.78b)$$

$$\text{Int}_{264-\text{Se}} * A_{\text{Se}} = \frac{\text{Peak Area}(264)}{\epsilon(264) * T_L} \quad (4.78c)$$

$$\text{Int}_{279-\text{Se}} * A_{\text{Se}} + \text{Int}_{279-\text{Hg}} * A_{\text{Hg}} = \frac{\text{Peak Area}(279)}{\epsilon(279) * T_L} \quad (4.78d)$$

$$\text{Int}_{400-\text{Se}} * A_{\text{Se}} = \frac{\text{Peak Area}(400)}{\epsilon(400) * T_L} \quad (4.78e)$$

in which A_{Se} is the (unknown) activity of ⁷⁵Se; A_{Co} the (unknown) activity of ⁵⁷Co; A_{Hg} the (unknown) activity of ²⁰³Hg; $\text{Int}_{121-\text{Se}}$ the gamma intensity of the 121-keV emission from ⁷⁵Se, and so on; peak area(121) is the observed peak area of the 121-keV peak; $\epsilon(121)$ is the peak efficiency at 121-keV, and T_L is the live time of the data acquisition.

This set of five equations in only three unknowns is obviously overdefined; however, a best fit solution can be obtained by minimizing chi squared (the sum of the squares of the residuals²²). Because each observed emission rate has some uncertainty associated with its measurement, we might prefer to place more weight on the lines that have the smallest uncertainty and less weight on the lines that have the greatest uncertainty. This weighting can be accomplished by multiplying the residual (for each line) by a weighting factor, which is the inverse of the variance of the measured emission rate (for that line) so that a weighted chi squared is given by

$$\chi^2 = \sum_{i=\text{lines}} \sum_{j=\text{nuclides}} w_i \left[\frac{\text{Peak Area}(i)}{\epsilon(i)T_L} - \text{Int}_{ij}A_j \right]^2 \quad (4.79)$$

This quantity is minimized when the activities, A_j , satisfy the condition

$$\frac{\partial \chi^2}{\partial A_j} = 0 \text{ for all } A_j \quad (4.80)$$

The solutions obtained with this formalism are the weighted average activities for each nuclide. One advantage of this algorithm is that the user is not required to

22. The residuals being defined as the differences between the observed emission rate and the emission rate implied by the solution.

identify explicitly all of the potential interferences before the analysis for this method to identify the interferences that are present. As long as the nuclides that need to be included in the interference set satisfy the identification criteria of the nuclide identification algorithm, their interferences will be recognized by this method.

To take fullest advantage of this algorithm, one should have a very complete nuclide library—in terms of both nuclides and lines of each nuclide—to ensure that all potential nuclides and interferences can be identified. To illustrate the need for a complete library, consider the analysis of a natural soil containing ^{228}Ac , which has a gamma emission of 835.7 keV with an intensity of approximately 1.7%. Because of this low intensity, people often omit it from their library. As a result, ^{54}Mn (which has a gamma emission of 835.8 keV) is reported because there is nothing else to which the 835-keV peak can be attributed. If the 835.7-keV line is included in the library for ^{228}Ac , the 835 keV peak can be (correctly) attributed to the ^{228}Ac , and the simultaneous solution can eliminate the (false) identification of the ^{54}Mn .

Another precaution that should be taken when setting up libraries is related to the half-life that is entered for each nuclide. Most commercial software implement corrections for decay during data acquisition decay back to some sample time and, if the sampling occurred over an extended period, decay during sample collection. These corrections produce erroneous (high) values for short-lived material in equilibrium with a long-lived parent if the true half-life of the short-lived material is used for the decay correction. If the short-lived material is in equilibrium with the long-lived parent, one can substitute the half-life of the long-lived parent in the decay corrections by using the parent's half-life in the short-lived daughter's library entry.

VI. Advances in HPGe detector technology: gamma-ray imaging with HPGe detectors

With modern low-noise electronics and the quality of Ge material available, the energy resolution that can be achieved using HPGe detectors is very close to the fundamental limits imposed by charge carrier generation statistics. So, further improvement in energy resolution is not expected. The attention has shifted to manufacturing larger volume crystals that can yield higher detection efficiencies. Another area of focus for HPGe applications is gamma ray imaging (Luke et al., 2005).

There are different methods to image gamma rays, including the use of parallel-hole collimators, pinholes, coded apertures (Fennimore and Cannon, 1978), and Compton cameras (Phillip 1995). In almost all cases, position-sensitive detectors are needed to implement an

imaging system. A common method to provide position sensitivity is to segment the contacts of a detector. Conventional contacts used in Ge detectors are lithium (Li)-diffused contacts (n-type) and boron-(B) implanted contacts (p-type). The Li contacts are typically several hundred microns thick, making it difficult to segment using standard etching processes. Often times, mechanical means such as cutting using diamond saws or ultrasonic machining were employed, although segmentation using a photolithography technique has also been developed. Whatever the segmentation methods employed, the relatively large thickness of the Li contact limits the minimum feature size of contact elements to >1 mm. In addition, the diffusion of Li, which occurs even at room temperature, could lead to electrical shorts between contact elements when detectors are stored at room temperature for long periods of time, or when radiation damage annealing becomes necessary. Another difficulty in making multisegment detectors is the instability of the Ge surface. When contacts of a detector are segmented, the intrinsic Ge surface between the contact elements can often become unstable with time or with changes in ambient conditions, which may lead to increased leakage current, increased noise, or inadequate isolation between contact elements. Some type of surface passivation is desirable, but it must be able to be applied to the surface between contacts without affecting the ability to make electrical connections to each contact element. In recent years, improved contact segmentation techniques have been developed, contributing to the increasing use of segmented Ge coaxial and planar detectors (Vetter et al., 2000; Yang et al., 2001; Philips et al., 2002).

In recent years, improved contact segmentation techniques have been developed, contributing to the increasing use of segmented Ge coaxial and planar detectors. As an example, the design developed at Lawrence Berkley National Laboratory (LBNL) is highlighted (Luke et al., 2005). The LBNL design employs contacts made of an amorphous-Ge (a-Ge) thin film to create an electrically blocking junction between it and the bulk Ge crystal. The blocking junction permits the application of bias voltage to fully deplete the detector while maintaining a low leakage current. The structure of a multisegment detector using such contacts is shown schematically in Fig. 4.47. The fabrication process involves the sputter deposition of an a-Ge layer onto the surface of the Ge crystal. Selected areas of the a-Ge film are then metalized to form the contact elements. The resistivity of the a-Ge film is sufficiently high to provide good electrical isolation between contact elements, whereas the small thickness of the film ensures that it does not affect the detector signals or the passage of signal currents to the metal contacts. An interesting property of the a-Ge contact is its ability to block carrier injection under either polarity of bias voltage. Therefore, the same process can be used on both sides of a detector to

FIGURE 4.47 Structure of a-Ge contact. From Luke et al. (2005); reprinted with permission from Springer Nature © 2005.

realize double-sided segmented detectors. One advantage of this contact technology is its simplicity, which involves very few processing steps and can be carried out entirely with the detectors at room temperature. Another advantage is that the a-Ge film covers the full surface of the Ge crystal, forming a passivation layer. There is no need for additional processes to passivate the surface between contact elements afterward. The amorphous contacts are thin and stable with annealing up to 150 °C. Very small-scale contact structures, on the order of $\sim 100\ \mu\text{m}$ or less, can be realized.

A number of orthogonal strip detectors have been successfully produced using the a-Ge contact technology (Amman and Luke, 2000a; Hull et al., 2001). These detectors are amenable to the development of practical gamma ray imaging systems.

In addition to the two-dimensional position information obtained from the orthogonal strips, the depth of gamma ray interaction in the detector can also be determined by measuring the time difference between signals from strips on opposite sides of the detector (Amman and Luke, 2000b). The ability to localize events within the detector in three dimensions improves the accuracy of reconstructed images.

Dreyer et al. (2014) describe the application of a portable, mechanically cooled gamma ray imaging spectrometer referred to as the GeGI, which has become commercially available (PHDs Co). The imaging capability is largely due to the advances made in the segmentation techniques (Hull and Pehl, 2005; Hull et al., 2011). The GeGI is a 16×16 strip detector with 5-mm pitch strips on an 8 cm diameter, 1-cm-thick germanium crystal. As a spectrometer, the instrument has a useable energy range from 30 keV to several MeV. Two imaging modalities are available, the choice of which depends on the energy of interest. For gamma-ray energies ranging from 40 to 500 keV, a collimator can be placed in front of the detector

FIGURE 4.48 Compton image of highly enriched uranium sample, taken using a GeGI Spectrometer (Dreyer, 2014).

for pinhole imaging. This modality offers high contrast and spatial resolution; however, it is limited to a 60 degrees forward field of view. Compton imaging can be used for higher energy radiation from $\sim 150\ \text{keV}$ to $<1\ \text{MeV}$ and provides a 4π field of view with a spatial resolution of ~ 6 degrees.

Fig. 4.48 shows the Compton image of highly enrichment uranium ($\sim 100\ \text{g}$ of material) located in a building approximately 28 m away, taken using a GeGI spectrometer. The 186 keV gamma ray from ^{235}U was detected spectrally in 15 minutes and localized within 40 minutes (Dreyer, 2014).

VII. Segmented Ge detectors and their applications in nuclear physics research

The structure of the atomic nucleus has been studied to a large extent by gamma ray spectroscopy using germanium detectors. Ge detectors were developed in the 1960s and still offer the best compromise between energy resolution and efficiency for high-resolution gamma-ray spectroscopy. In the 1970s and 1980s, the main advances were in the purity and volume of the Ge crystals. More recently, the development of highly segmented Ge detectors has significantly increased the performance and power of detection systems. In a segmented Ge detector, the crystal is divided into sections by isolating the contacts. This enables the position of interaction to be determined. The accuracy of the position determination can be improved by the analysis of the shape of the charge signals and of the transient signals in adjacent segments. This technique has led to the concept of gamma ray tracking in a segmented Ge detector whereby the energy, time, and position of all interactions are recorded and the full interaction is reconstructed. This enables a spectrometer system with unprecedented efficiency and energy resolution to be realized.

A. Segmented HPGe detectors

Gamma ray imaging using HPGe detectors has become possible as a result of the segmentation technology that was developed in the 1990s. In his paper titled “Photomask Technique for Fabricating High Purity Germanium Strip Detectors,” D. Gutknecht (Gutknecht 1990) describes a new technology for realizing germanium strip detectors. The technique uses a photomask process that needs no growing and etching and allows various kinds of segmented electrodes. Using his technique on planar detectors, Gutknecht successfully produced a double-sided X–Y HPGe strip detector with a thickness of 30 mm, and a pitch of 200 μm . The segmentation techniques that Gutknecht pioneered have been implemented on coaxial HPGe detectors. Large-volume segmented HPGe detectors have been available for a couple of decades now (Shepherd et al., 1999; Boston 2000; Boston et al., 2007, 2009; Akkoyun et al., 2012).

The use of internal and external contacts of a segmented detector provides information on interaction position: (1) vertically and transversally by analyzing signals induced by mirror charges, and (2) radially by performing a pulse shape analysis. The external contact of a detector can be longitudinally or transversally segmented without a dead zone generation. Segmentations on the front side of the detector (like a checker-board pattern) and laterally (in one or two directions) can be realized. Segmentation separation is such that cross-talk between adjacent segments is avoided. Fig. 4.49 shows the picture of a segmented germanium detector.

B. Neutrinoless double beta decay

Double beta decay is a type of radioactive decay in which two protons are simultaneously transformed into two neutrons, or vice versa, inside an atomic nucleus. Unstable nuclei may undergo $2\nu\beta\beta$ if single β -decay is

energetically forbidden or highly suppressed by conservation of angular momentum. This process has been observed in many nuclei and has a half-life on the order of 10^{19} – 10^{21} years. As in single beta decay, this process allows the atom to move closer to the optimal ratio of protons and neutrons. As a result of this transformation, the nucleus emits two detectable beta particles, which are electrons or positrons.

The literature distinguishes between two types of double beta decay: ordinary double beta decay and neutrinoless double beta decay. In ordinary double beta decay, which has been observed in several isotopes, two electrons and two electron antineutrinos are emitted from the decaying nucleus. In neutrinoless double beta decay, a hypothesized process that has never been observed, only electrons would be emitted. This is possible only if neutrinos are their own antiparticles (called Majorana particles). In this case, neutrinoless double- β ($0\nu\beta\beta$) decay could be observed, a process in which lepton number is not conserved. Several experiments are underway or are under preparation searching for this decay using a variety of suitable isotopes. The sum of the kinetic energies of the two electrons emitted in the $0\nu\beta\beta$ decay is equal to the mass difference or (Q value) $Q_{\beta\beta}$ (equal to 2.039 MeV) of the two nuclei. A sharp peak in the energy spectrum is the prime signature for all $0\nu\beta\beta$ experiments. Key parameters of these rare event searches are large mass M and long measuring time t on the one hand, and high energy resolution and low background on the other. ^{76}Ge is one of the isotopes that undergoes double beta decay. Therefore, using an HPGe detector, enriched in ^{76}Ge , would be very convenient; the sample and the detector will be one and the same! There are two major collaborations, Majorana and the GERmanium Detector Array (GERDA) that are currently in progress, based on the approach of using HPGe detectors, enriched in ^{76}Ge .

C. Majorana collaboration

The Majorana project is an international effort to search for neutrinoless double-beta ($0\nu\beta\beta$) decay in ^{76}Ge . The project builds upon the work of previous experiments, notably those performed by the Heidelberg–Moscow (Klapdor-Kleingrothaus et al., 2001) and IGEX (Aalserth et al., 2000) collaborations, which used high-purity germanium (HPGe) detectors, to study neutrinoless double-beta decay (Klapdor-Kleingrothaus et al., 2004).

The first stage of the project is the Majorana Demonstrator (Fig. 4.50), designed to demonstrate the backgrounds low enough to justify building a ton-scale experiment, and to establish feasibility to construct and field modular arrays of Ge detectors. Cryostats housing up to 40 kg of natural and enriched germanium detectors are being deployed in low-background vacuum cryostats, underground at the Sanford Underground Laboratory in Lead, South Dakota. Following the Demonstrator, the collaboration intends to merge with the GERDA collaboration to build a much larger experiment.

The principal goal of the Majorana Demonstrator is to demonstrate the feasibility of achieving the background required in a ton-scale experiment. This corresponds to four counts/ton/yr in a 4 keV window around the $0\nu\beta\beta$ Q value of 2.039 MeV, which scales to one count/ton/yr in a ton-scale experiment. The experiment will use a mixture of detectors made with natural germanium and enriched germanium, allowing it to confirm or refute the controversial claim for $0\nu\beta\beta$ observation in ^{76}Ge . Electroformed copper and lead bricks protect the cryostats. Polyethylene shields the setup and includes PMTs to act as a veto. Nitrogen flushing removes trace radon. If low enough electronic noise is achieved, the Demonstrator may also be used to search for weakly interacting massive particles (WIMPs)

FIGURE 4.50 Majorana Demonstrator detector array. Abgrall et al. (2016a); reprinted with permission from Elsevier © 2016.

in dark matter research. The Majorana Demonstrator measurement setup is illustrated in Fig. 4.51.

The detector array consists of “strings” of P-type point-contact (PPC) detectors (Luke et al., 1989), with four to five detectors stacked in a string. The modular cryostat has the cooling capacity for seven strings of detectors (up to 22.5 kg of Ge). The Majorana Demonstrator detector array is illustrated in Fig. 4.52. The insets in Fig. 4.52 show an individual PPC detector and a “string” of detectors.

PPC detectors allow efficient discrimination of multiple scattering gamma backgrounds. This results from the weighting potential being strongly peaked close to the small electrode, meaning that as charge drifts toward the electrode, there is a high probability of seeing distinct signals from each energy deposition, thus being able to reject events corresponding to these signals. Other advantages include the low capacitance due to the small contacts, reducing electronic noise and thresholds; and shielding surface alpha decays by the thick outer n-type contact.

The projected background rates from Majorana Demonstrator experiment is shown in Fig. 4.53.

D. GERDA collaboration

The GERDA experiment is located at the Gran Sasso underground laboratory (LNGS) of Istituto Nazionale di Fisica Nucleare (INFN) or “National Institute of Nuclear Physics” in Italy. HPGe detectors made from material with enriched ^{76}Ge fraction of $\sim 87\%$ are operated in a 64 m^3 liquid argon (LAr) bath. The argon cryostat is located inside a tank filled with 590 m^3 of high-purity water. LAr and water shield against the external radioactivity. The water tank is instrumented with photomultipliers and operates as a Cherenkov detector to veto residual muon-induced events. Material for structural support of the detectors and for cabling is minimized to limit the background from nearby radioactive sources.

FIGURE 4.53 Projected background rates from Majorana Demonstrator. From Green et al. (2015); reprinted with permission © 2015.

A schematic drawing of the GERDA experiment is illustrated in Fig. 4.54.

A first phase of data taking ended in 2013 with no indication of a signal (Agostini et al., 2013). The background index achieved at the ^{76}Ge $Q\beta\beta$ value of 2.039 MeV was 10^{-2} counts/(keV Kg Year). For the second phase, a new component has been installed to detect argon scintillation light (Agostini, to be published). The enriched germanium mass was doubled in the form of small readout electrode detectors (the Canberra Broad Energy Germanium or BEGe detector

model) supplementing the previously used coaxial detectors. A schematic drawing of BEGe detectors is shown in Fig. 4.55.

The detector is made of p-type HPGe with Li^- drifted by n^+ contact (0.7 mm specified thickness) covering almost the entire outer surface of the detector. The small p^+ contact is located in the middle of the bottom surface.

Both enhancements allow for a more efficient rejection of background events, which can be characterized by their energy deposition in the LAr, in several detectors or in several locations (including the surface) of a single detector. In contrast,

FIGURE 4.54 Section of the GERDA experiment. Human figures are illustrated in the upper left and lower center of the figure to illustrate the relative dimensions of the experimental setup. From *D'Andrea et al. (2016)*.

$0\nu\beta\beta$ energy deposits are made by two electrons, which typically release all their energy in a small volume of a single detector. Localized and delocalized energy deposits are distinguished by pulse shape discrimination (PSD) based on the time profile of the detector signal.

Phase II data taking started in December 2015 with a target background index of 10^{-3} counts/(keV Kg Year), a tenfold reduction of background with respect to Phase I. Thirty BEGe detectors (20.0 kg total mass) and seven coaxial detectors (15.6 kg) are deployed, whose energy resolution at $Q_{\beta\beta}$ is typically better than 3 and 4 keV FWHM, respectively.

As in Phase I, a 25-keV window around $Q_{\beta\beta}$ was blinded: events with an energy in one detector within this window were hidden until the entire data selection was finalized. The first unblinding of Phase II took place in June 2016, and no $0\nu\beta\beta$ signal was found. A lower limit of half-life for neutrinoless decay $T_{1/2}^{0\nu} > 5.3 \times 10^{25}$ yr (90% confidence level) was extracted with a sensitivity, defined as

FIGURE 4.55 Schematic drawing of BEGe detector configuration. From *D'Andrea et al. (2016)*.

the median expected lower limit assuming no signal, of 4.0×10^{25} yr (*Agostini et al., 2017*).

The low background index (BI) of BEGe detectors, previously based on one single event, has been confirmed with a more than threefold exposure to be 1×10^{-3} counts/(keV Kg Year). If normalized according to the energy resolution and total signal efficiency ϵ , i.e., $BI \times FWHM/\epsilon$, this value corresponds to 4.9 counts/(ton year). Hence the average background in the energy interval $1 \times FWHM$ at $Q_{\beta\beta}$ is expected to be less than 1 for the entire design exposure of 100 kg yr.

With the same normalization for BI, the Majorana collaboration has reported a background is 5.7 counts/(ton year) (*Aalserth et al., 2018*).

Ramkumar (“Ram”) Venkataraman

Dr. Ramkumar (“Ram”) Venkataraman has been in the field of radiation detection and measurements for more than 25 years. His areas of interest include gamma

spectroscopy, gamma- and neutron-based nondestructive assay methods for nuclear safeguards applications, new detector materials, neutron activation analysis, and mathematical modeling of radiation detectors and systems. Ram is a staff member in the Safeguards and Security Technology group at Oak Ridge National Laboratory (ORNL). At ORNL, Ram is developing new methods for accurate identification and quantification of special nuclear materials of interest in nuclear safeguards and nonproliferation. Ram has authored more than 75 papers in the field of nuclear science and technology and has made numerous presentations at international scientific conferences. Ram actively participates in standard committees. He has been serving as the Chairman of the of ASTM Subcommittee C26.10 (Nuclear Fuel Cycle: Non-Destructive Assay Techniques) since 2008.

Ram holds a master’s degree in Physics from the University of Madras, India, and a doctoral degree in Nuclear Engineering from the University of Michigan, Ann Arbor, MI.

I. Introduction

Alpha particle spectrometry (in short alpha spectrometry) is a widely applied radioanalytical technique, primarily due to its high counting efficiency and low intrinsic background (resulting in a high sensitivity), its versatility both in terms of the range of radionuclides that can be determined and sample types that can be analyzed, and the reliability of the technique due to the possibility to use an alpha particle—emitting isotope of the element of interest as an internal tracer.

For some special applications, it is possible to carry out alpha spectrometry using only minimal sample preparation or no sample processing at all (Surbeck, 2000; Röttger et al., 2001; Ranebo et al., 2010; Samuelsson, 2011). However, the short range of alpha particles through matter means that, in general, separation of the radionuclides of interest from the bulk sample matrix is required. This involves dissolution of the sample and chemical separation of the radionuclides prior to source preparation.

In practice, a separate source is normally prepared for each element for which radioisotopes are to be determined. For each of these sources, the chemical separation should fulfill three aims. Firstly, it should remove elements that would interfere in the final source preparation step in such a way as to reduce the recovery of the element of interest. Secondly, it should remove elements that would deposit on the final source, resulting in a thick source and hence degraded spectral resolution. Thirdly, it should remove other alpha particle—emitting radionuclides that might interfere with the peaks of interest in the spectrum. A major part of the effort expended in development of alpha spectrometry relates to improvements in these chemical separation procedures, and in particular minimizing the time required.

The number of radionuclides that can be reliably determined using alpha spectrometry is quite large. It includes almost all of the alpha particle—emitting radionuclides with half-lives long enough relative to the time required for source preparation. Beta particle—emitting radionuclides can also be determined if they have alpha particle—emitting progeny, which may be measured on the source following a suitable ingrowth period. For example, ^{228}Ra may be determined using its progeny ^{228}Th and ^{224}Ra (Hancock and Martin, 1991), and ^{227}Ac may be determined using ^{227}Th and ^{223}Ra (Bojanowski et al., 1987).

Another major advantage of alpha spectrometry is its high sensitivity, with detection limits as low as 1 mBq per sample being easily achievable. This arises due to several factors. The first of these is the high yield of the alpha decay process. For most alpha-particle emitting radionuclides there are only a few peaks within a relatively small energy range, representing a total intensity of or close to

100% of decays. Secondly, semiconductor alpha detectors have a low intrinsic background, being typically 10^{-5} to 10^{-6} counts per second for an uncontaminated detector. Thirdly, the intrinsic efficiency of the detector system is close to 100% for incident alpha particles. Consequently, the counting efficiency is dominated by the geometric efficiency, which is typically about 20%–40% for sources placed close to semiconductor detectors. A fourth factor is the elimination of competing radiation by chemical separation, and the last factor is the low sensitivity of the semiconductor alpha detector to beta and gamma radiation.

An outcome of the sensitivity of the technique is the ability to analyze relatively small sample sizes. For example, for the determination of uranium and thorium series radionuclides in environmental samples, common sample sizes are of the order of 1–10 g for soils, sediments, and biological samples and 0.1–1 L for water samples.

The use of an alpha particle—emitting isotope as an internal tracer makes alpha spectrometry a highly reliable analytical technique, provided no losses occur before the sample and tracer isotopes have been equilibrated. The internal tracer compensates not only for losses during the chemical separations but also for the counting efficiency of the detection system. This is because the result is obtained directly from the ratio of sample to tracer peak areas. Consequently, a highly accurate knowledge of the counting efficiency is not required to achieve accurate determinations of the target radionuclides.

A further advantage is that the capital cost for alpha spectrometry equipment, including the detector, counting chamber and associated electronics, is significantly lower than that for a number of other systems capable of isotope discrimination. Counterbalancing this is the requirement for chemical laboratory facilities and reagents.

The major disadvantage of alpha spectrometry is that time-consuming chemical separation procedures are normally required to remove the bulk matrix, elements that interfere with recovery of the element of interest, and other alpha emitters. Alpha spectrometry without chemical separation is possible only in some special applications (such as the determination of airborne concentrations of radon progeny). Typically, the full chemical digestion, separation, and source preparation procedure require several steps over several hours. Some automated systems have been developed to reduce the need for operator time (Kim et al., 2008). In recent years, various efforts have been made to develop rapid procedures for sample preparation by combining the chemical separation with the source preparation. Preparation of good-quality alpha sources has been reported by treating (coating, drafting) polymer films with element-specific reagents. For example, Ra was selectively retained on MnO_2 disks; Pu, Am, and U nuclides were

retained by various ligands anchored on polymer films. The disks and the polymer ligand films (PLFs) were directly counted by alpha spectrometry (Aggarwal, 2016).

Unlike many other radioanalytical techniques, alpha spectrometry is element based in the sense that each spectrum consists of the alpha-emitting radionuclides of typically one element (plus those alpha particle—emitting progeny, which grows in on the source during data acquisition and in the interval between preparation and counting). This means that a separate source must be prepared and counted for each element of interest in the sample. However, it also gives rise to the advantage that the spectrum is in a sense “predictable.” Given the element for which the source has been prepared, the analyst knows which peaks are expected in the spectrum, with only the relative areas under each peak varying for different sources. This simplifies spectrum analysis. It also enables an important quality control check, which is the examination of the spectrum for peaks, which would not be expected for a source of the given element. The presence of such unexpected peaks may indicate that the chemical separation was not sufficiently effective in removing other alpha-emitting radionuclides from the sample extract.

In some cases, alpha spectrometry has disadvantages in comparison with other techniques for case-specific reasons. One important example is the impossibility of distinguishing ^{239}Pu and ^{240}Pu with conventional alpha spectrometry due to their overlapping peaks.

Alpha spectrometry has applications in diverse fields, from the analysis of alpha particle—emitting radionuclides in nuclear materials of high activity to environmental samples of low and ultralow activity (Aggarwal, 2016). An example of its widespread use in environmental studies is the measurement of ^{210}Po in soil and sediment samples, as an indirect measure of ^{210}Pb for erosion and sedimentation investigations (Robbins, 1978). Other examples include measurement of U and Ra radionuclides to investigate groundwater, surface water, and seawater processes (Hancock et al., 2000; Porcelli, 2008) and that of ^{210}Po as an atmospheric tracer (Baskaran, 2011).

Alpha spectrometry is commonly used for monitoring of environmental samples for the impact of nuclear activities. Examples include actinide determination on soil samples and analysis of water samples downstream of uranium mining operations for uranium series radionuclides. The technique is also used for internal dosimetry for workers, by means of analysis of biological samples such as urine (Kehagia et al., 2007; Manickam et al., 2010). Alpha spectrometry is a basic technique for the determination of man-made radionuclides in nuclear power

production, nuclear fuel processing and reprocessing, management and storage of radioactive wastes, decommissioning of nuclear facilities, nuclear medicine, nuclear safeguards and forensics, etc.

As a result of development in detector fabrication and source preparation procedures, as well as progress in the technology of multichannel analyzers (MCAs) and spectrum unfolding programs, high-resolution alpha spectrometry (HRAS) became available in the 1980s. Thus, a precise and sensitive technique was developed that is suitable for measurement of nuclear data such as half-life, cross section (Wiltshire, 1984), and emission probabilities (Bortels and Collaer, 1987). Based on development in spectrum interpretation and deconvolution, in situ (nondestructive) alpha spectrometry has become available and has been applied for in-field measurements (Pöllänen, 2016). Recently, attempts have been made to prepare the alpha source directly on the detector surface, thus combining source preparation and detection occasionally as well as chemical separation into a single-step process (Krupp and Scherer, 2018). More recently, cryogenic detectors have dramatically improved the achievable peak resolution, and the application of magnetic spectrometers brought this highly specialized technique closer to routine alpha spectrometry (Hoover et al., 2015).

Some mass spectrometry techniques, which detect the radioactive atom itself rather than the emitted radiation, have shown significant advances in sensitivity for the determination of long-lived alpha particle—emitting radionuclides such as ^{238}U and ^{235}U . These developments have made these techniques rivals to, and in some applications superior to, alpha spectrometry in terms of sensitivity and/or sample throughput. Nevertheless, the advantages of alpha spectrometry, especially for shorter-lived radionuclides, mean that it will remain an important, standard technique for the foreseeable future.

II. Alpha decay and alpha particle—emitting radionuclides

Alpha decay occurs when a nucleus of helium $^4_2\text{He}^{2+}$ called an “alpha particle” is emitted from a heavy nucleus. After the decay, the mass number (A) and the atomic number (Z) of the new nucleus are lower by 4 and 2, respectively.

During the spontaneous decay, the decay energy Q is liberated and shared between the reaction products $^{A-4}_{Z-2}\text{Y}$ and $^4_2\text{He}^{2+}$ according to the law of conservation of momentum. The kinetic energy of the alpha particle (E_α) can be calculated from:

$$E_{\alpha} = Q \left(1 - \frac{1}{1 + m_Y/m_{\alpha}} \right) \quad (5.2)$$

where Q is the disintegration energy, m_Y is the mass of the daughter nuclide Y (also called the recoil atom), and m_{α} is the mass of the alpha particle (α).

Since the masses of the decay products are significantly different, the kinetic energy of the alpha particle is almost equal to the total decay energy Q . The decay energy Q and therefore the energy of the alpha particle E_{α} is in the range of 2–8 MeV. (A more detailed description of alpha decay is given in Chapter 1, Volume 1.)

Alpha decay is the major decay mode of proton-rich and high atomic number nuclides because in heavy nuclides the electrostatic repulsive forces increase more rapidly with atomic number than do the cohesive nuclear forces. Hence,

alpha decay is characteristic for heavy nuclides, predominantly for those with atomic numbers greater than 83 (i.e., beyond Bi). The radionuclide of lowest atomic number that emits alpha particles is $^{144}_{60}\text{Nd}$. There are in total 815 alpha emitters in the Nuclides.net database (NUDAT 2, 2009) (see in Fig. 5.1).

There are relatively few long-lived alpha particle-emitting radionuclides of relevance in the measurement of environmental and nuclear samples. A list of some important long-lived alpha particle-emitting radionuclides and their short-lived progeny is presented in Table 5.1, together with the half life, alpha particle energy (E_{α}), and emission probability (I_{α}) of the most intensive alpha emissions.

A unique feature of the alpha decay process is the strong correlation between alpha particle energy and the half-life of the parent nuclide. It can be clearly seen from Table 5.1 that isotopes of the highest alpha particle energies

FIGURE 5.1 Alpha emitters in the upper right region of the concise chart of the nuclides indicated by yellow (online version) or gray color (printed version). Nuclides are presented by their atomic numbers as a function of neutron number. From Magill and Galy (2005); reprinted by permission of Springer-Verlag © 2005.

have the shortest half-lives (and therefore highest decay constants). For example, within the series of ^{232}Th , ^{230}Th , and ^{228}Th , the half-life is reduced from 10^{10} years to about 2 years, whereas the alpha particle energy is increased from 4 to 5.4 MeV. This illustrates the validity of the law recognized by Geiger–Nuttall in 1911, which can be expressed by the following empirical equation (see Fig. 5.2):

$$\log \lambda = A + B \log E_\alpha \quad (5.3)$$

where λ is the decay constant, E_α is the energy of the alpha particle, and A and B are constants.

Later this process was explained by the quantum mechanical barrier penetration theory of Gamow (see Chapter 1, Volume 1). Typically, alpha particles have energies in a

FIGURE 5.2 Geiger–Nuttall plot: half-life as a function of atomic number $Z = 84–100$ (Loveland et al., 2006). Reprinted by permission of John Wiley and Sons © 2006.

charge carriers: electron–cation pairs, electron–hole pairs, or electrons, respectively. The collection of these charge carriers at the electrodes gives a current, which flows through a resistor producing a voltage pulse. These interactions between the alpha particle and the detector can be utilized in alpha spectrometry where the height of the generated pulse is proportional to the kinetic energy of the alpha particle, and the pulse frequency or count rate is proportional to the activity of the alpha source. Alpha spectra are commonly depicted as the number of counts collected during a given counting time against the channel number, where channel number is a linear function of the pulse height and thus of the energy of the alpha particle.

An example of a typical alpha decay scheme and corresponding alpha particle energy spectrum are presented in Figs. 5.3 and 5.4.

FIGURE 5.3 Simplified decay scheme of ^{241}Am . The relative emission probabilities of alpha particles and the relevant gamma ray emissions are expressed in % (in parenthesis) beside the radiation energy values in MeV. Energy levels of the nuclides are shown as plateaus along the ordinate and are distributed along the abscissa, representing the atomic number. From Chapter 1, Volume 1. The full scheme can be obtained from the website of the Decay Data Evaluation Project, DDEP, <http://www.nucleide.org/DDEP.htm>.

narrow range, between 4 and 8 MeV. If the alpha energy is beyond these values, the half-lives of the nuclides become either too short for the radionuclides to be easily detected or so long that they can be regarded as practically stable. Both cases require special skills and highly sophisticated analytical techniques for successful measurement.

In alpha spectrometry, alpha particles of different kinetic energies are “detected” using various types of nuclear detectors, the most common being gas ionization, semiconductor, and scintillation detectors. When an alpha particle enters the detector, it produces (directly or indirectly)

Alpha decay is characterized by the similarity of the decay schemes of many radionuclides (in particular the even mass number nuclides) in the following sense: Several radionuclides have only a few possible alpha particle transitions involving different alpha particle energies and emission probabilities (see Table 5.1). Direct transformation to the ground state of the daughter results in the emission of alpha particles of the highest energy. For almost all even-mass number and for many odd-mass number alpha particle–emitting radionuclides, this is the emission with the highest intensity. Thus, a series of alpha

FIGURE 5.4 Simulated alpha spectrum of a ^{241}Am source as it appears in a high resolution (full width at half maximum smaller than approximately 20 keV—blue curve) and a low-resolution alpha spectrum (green curve). In high-resolution spectrometry, the alpha peaks at 5.389, 5.443, 5.486, and 5.545 MeV can be identified as partially overlapping peaks, whereas in low-resolution spectrometry, the peaks are strongly overlapping appearing as a single broad peak. Spectra were generated by the AASI simulation software (Siiskonen and Pöllänen, 2004) with estimated resolutions of Si semiconductor detectors of 14 and 40 keV.

particles of slightly different energies and of increasing emission yield with increasing energy can be assigned usually to a single radionuclide.

Each alpha particle energy results in an alpha peak in the spectrum; however, due to the relatively small energy difference between the peaks of the radionuclide, in question, they are more or less overlapping, resulting typically in a single broad asymmetric alpha peak similar to the one shown in Fig. 5.4. Thus, instead of individual peaks, the spectrum may consist of a group of overlapping peaks where the individual peaks can be distinguished only by using HRAS with full width at half maximum (FWHM) of the alpha peaks in the order of 20 keV or less.

For normal analytical purposes, if the group of alpha peaks belonging to a single radionuclide is well separated from those of the other nuclides, then there is no need to analyze the individual peaks for nuclide identification and activity calculation. Rather, each group of peaks is evaluated as a unit, and the total counts assigned to the appropriate radionuclide. This approach may be referred to as conventional alpha spectrometry.

III. Detection systems

The core part of an alpha spectrometer is the detector, where the interaction of the alpha particles with the matter of the detector material takes place. The energy of the alpha particle is transformed to a measurable physical quantity, e.g., electric charge, current, or voltage. In the process of detection, the charge carriers are collected and converted to electric pulses.

In spectrometry, pulses are processed in so-called “pulse mode” where each interacting particle is detected independently. Electric pulse processing units such as preamplifiers and amplifiers attached to the detector output both amplify and form (shape) the pulses. Pulses are then digitalized by an analog-to-digital converter (ADC). From a series of digitalized pulses of different height at the ADC output, the MCA generates a pulse height spectrum by sorting the pulses according to their heights and assigning them to a channel number proportional to the pulse height as illustrated in Fig. 5.5.

A schematic drawing of an alpha spectrometer is shown in Fig. 5.6. An alpha spectrometer usually contains a

FIGURE 5.5 Transformation of digital pulse data into a pulse height spectrum using a multichannel analyzer. The left side of the figure shows the pulses appearing at the detector as a function of time. The right side shows the generated spectrum with the number of pulses as a function of the pulse height.

vacuum chamber surrounding the detector and the source. The vacuum supply unit contains a vacuum pump such as an oil rotation pump, a vacuum gauge, and occasionally a vacuum control system to adjust to the desired pressure.

In spectrometric applications, the basic information of the radiation (i.e., the type of radiation, the energy of the particles, and the activity of the source) is conserved in the form of the shape and height of the electric pulses, and the pulse frequency or count rate.

The components of the alpha spectrometer are discussed in more detail below.

A. Detectors

1. Interaction of alpha radiation with detector materials

Only a few detector types are suitable for the accurate determination of the energy distribution of alpha particles. Of these, silicon semiconductor detectors are the most frequently used at present. Due to instrumental improvements and developments in spectrum analysis software, HRAS using Si detectors became available in the 1980s.

Among gas ionization detectors, ionization chambers and proportional counters have been used in alpha spectrometry, and a special type of gas detector, the gridded ionization chamber, has been developed for the determination of pulse height distribution of the alpha particles.

Although scintillation detectors have, in general, relatively poor energy resolution, the development of “high-resolution” alpha liquid scintillation (LS) spectrometers in

combination with selective chemical procedures offers some advantages in alpha spectrometry.

The process of detection of alpha particles by various nuclear detectors is determined by the interactions between the particle and the detector. The principal characteristics of the interactions have been described in Chapter 1, Volume 1. The most important aspects influencing the detection process in alpha spectrometry are summarized briefly below.

When alpha particles enter the detector, they immediately interact with the atomic electrons of the detector material. The main results of this interaction are **excitation** and **ionization**. In the latter case, electron and positive ion (cation/hole) pairs are formed. Along its path through the detector, the high-energy alpha particle will create a large number (N) of electron–cation pairs. N can be expressed as

$$N = \frac{E_{\alpha}}{\epsilon} \quad (5.4)$$

where E_{α} is the energy of the alpha particle and ϵ is the energy needed to form one electron–cation pair.

Since E_{α} is in the range of a few MeV, and ϵ is—depending on the type of detector—in the range of 1–100 eV, a single alpha particle can produce 10^4 – 10^6 charge carriers, whereas it loses its energy before it is stopped.

The track of the alpha particles in the detector is almost **straight** because the heavy alpha particles are not significantly deflected by the interacting electrons. The specific energy loss of the alpha particle, also called the **stopping**

FIGURE 5.7 The range of alpha particles in silicon and air.

power, is described by the Bethe formula (see in Chapter 1, Volume 1). The alpha particle interaction with the detector is characterized by a **range** or distance beyond which no particles penetrate (Fig. 5.7). This range depends on the energy of the alpha particle and the type of the detector, i.e., its atomic number and density.

Although alpha particle energy loss in the detector material or in other media usually occurs with electromagnetic interactions of the electrons, interactions with the nuclei are also possible. In these cases, the track of the alpha particles is not straightforward and may lead to backscattering from the detector and, thus, may slightly reduce the detection efficiency.

Since alpha energies of radionuclides are not higher than 10 MeV, they are completely absorbed in a Si layer of 100 μm in thickness. Thus, Si detectors should not be significantly thicker, if they are used for the measurement of alpha-emitting radionuclides. Otherwise, other particles such as (conversion) electrons or low-energy photons may produce interfering signals that are in coincidence with the alpha particles and may influence the spectrum analysis (Siiskonen and Pöllänen, 2006). In the case of gas detectors, the detector thickness depends on the type and especially on the pressure of the gas in the detector chamber. Around atmospheric pressure, the range of 10 MeV alpha particles is about 5–10 cm (Fig. 5.7), and so this is the desired detector size.

The very short range of alpha radiation enables the design of detectors, which are able to completely absorb the incident radiation, without requiring large detector volumes. This fact, combined with the large number of charge carriers that are produced, is responsible for the high counting efficiency that is typical of alpha spectrometry.

However, the limited range of alpha radiation is also responsible for the major challenge in alpha particle detection, which is ensuring that alpha particles reach the active volume of the detector without significant losses. This means reduction or elimination of absorption in the source, any absorbent layers between source and detector, and in the detector window. Absorption and self-absorption in the detection process can be reduced by ensuring direct contact between the source and the detector, e.g., by placing the source inside the detector gas chamber or by dissolving the source in a liquid detector, as in the case of liquid scintillation counter (LSC). In the case of silicon detectors, absorption can be reduced by the use of vacuum in the chamber surrounding the detector and the alpha source. In addition, considerable efforts have been made to develop radiochemical procedures for the preparation of “infinitely thin” alpha sources that are almost free of self-absorption (see Section VI).

The interaction of alpha radiation with matter is a statistical process. When monoenergetic alpha particles pass through matter, there is a spread of energies at distances along the beam path, which is called **energy straggling**. The energy distribution of an originally monoenergetic beam becomes wider with penetration depth; however, near the

FIGURE 5.8 Schematic drawing of energy straggling of an alpha particle beam (Knoll, 2010). Reprinted by permission of John Wiley and Sons © 2010.

end of the range, the distribution becomes narrower again due to the reduction of the beam energy (see Fig. 5.8).

Analogously to energy straggling, the fluctuation in the path length of the alpha particles due to the statistical nature of the interactions is known as **range straggling**. Straggling happens in the source, in the media between the source and the detector and in the detector dead layer.

Energy and range straggling are the basic physical processes, which contribute significantly to peak broadening in conventional alpha spectrometry (see the peaks of ^{241}Am in Fig. 5.4). The peak shape in alpha spectrometry is affected by many parameters, including the characteristics of the detector, the absorbers between the detector and the source, and those of the source.

The time required to stop alpha particles in the detector is calculated from its range and average velocity where velocity (v) is a function of the energy (E_α) and the atomic mass of the particle (m_α):

$$v = \sqrt{\frac{2E_\alpha}{m_\alpha}} \quad (5.5)$$

Using typical range values, **stopping times** of alpha particles are a few picoseconds in solids and liquids and a few nanoseconds in gases resulting in the possibility of very fast detector response.

2. Characterization of spectroscopic detectors

To compare various types of detectors, the following parameters are determined:

- energy resolution,
- detection efficiency,

- response time, and
- dead time.

Detector characteristics are not the only important factors that influence the performance of alpha spectrometers. Other major contributors to the overall quality of alpha spectra are other electronic units and the type and quality of the alpha source.

Energy resolution in nuclear spectroscopy is expressed as the FWHM of the peak. In alpha spectrometry, the energy resolution performance of the detector is expressed traditionally as the FWHM in keV at the 5486 keV peak of ^{241}Am .

In alpha spectrometry, the peaks are usually not symmetric (not Gaussian shaped). The asymmetry appears as a low-energy side tailing that can be better characterized by the full width at one-tenth of the peak maximum (FWTM).

The absolute **counting efficiency** (ϵ_{abs}) in nuclear spectroscopy is defined as *the number of pulses recorded over the number of alpha particles emitted by the source* and it equals

$$\epsilon_{abs} = \frac{\Omega}{4\pi} \epsilon_{int} \quad (5.6)$$

where ϵ_{int} is the intrinsic efficiency of the detector that is defined as *the number of pulses recorded over the number of quanta incident on the detector*, Ω is the solid angle of the detector seen from the actual source position, and $\Omega/4\pi$ is the geometry factor.

A special feature of alpha detectors is that their intrinsic efficiency is practically 100%. This means that all alpha particles that reach the active volume of the detector are counted (although only a part of their energy is registered if the detector thickness is smaller than the range of alpha radiation in the detector material or if the alpha particles are backscattered from the detector). In alpha spectrometry, the determination of the absolute counting efficiency can be limited to the determination of the geometry factor, which can be calculated if the geometry parameters such as source and detector area and source-to-detector distance in coaxial arrangement are known exactly (see Section IV.B for more details.)

Response time is the time interval between the arrival of the alpha particle into the detector and the appearance of the response signal at the detector output. New particles entering the detector during the response time period are either not detected or detected together with another pulse causing a deviating pulse height, i.e., a pileup peak. **Dead time** is the minimum length of time that must separate two events that they can be recorded as two separate pulses.

In semiconductor alpha spectrometry, the response time and the dead time are very short, and high count rates may be tolerated without pileup and dead time corrections. Using gas ionization detectors, the dead time is longer and corrections are more likely to be necessary. The dead time

(τ) corrected count rate (i_{cor}) is calculated from the measured count rate (i_{meas}) according to the following equation:

$$i_{cor} = \frac{i_{meas}}{1 - i_{meas}\tau} \quad (5.7)$$

3. Gas ionization detectors

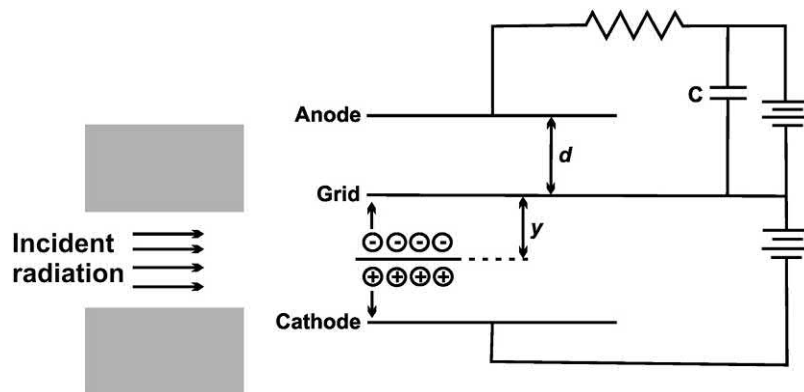

Gas ionization detectors are described in detail in Chapter 2. For alpha spectrometric purposes, ionization chambers and proportional counters can be applied. Geiger–Müller counters are not suitable for measuring the radiation energy because the electron discharge due to the high gas multiplication envelops the entire anode wire independently of the original number of primary electrons produced by the ionizing radiation. Semiconductor detectors have replaced gas detectors in many applications because they are superior in terms of energy resolution, response time, ease of operation, and cost. Gas ionization detectors offer the attractive feature that large alpha sources can be detected, which is often important in the direct analysis of some environmental samples without sample dissolution and chemical separation, such as air samples (Röttger et al., 2001) or the surface of plate glass (Samuelsson, 2011).

Gas ionization detectors usually consist of a gas-filled cylinder that serves as a cathode and an anode wire. The filling gas is usually a noble gas (Ar, He) or a mixture of gases. Alpha particles excite and ionize the gas. In the latter process, positive gas ions and free electrons are created. The average energy needed to form an ion pair is 30–40 eV depending on the type of gas. Therefore, an incident 5 MeV alpha particle creates about 1.5×10^5 ion pairs. In an external electric field, electrostatic forces will move the charges to the electrodes of opposite charge. The mobility of the free electrons is about 1000 times higher than that of the positive gas cations. Therefore, typical collection times for electrons are much shorter (in the range of microseconds) compared with the milliseconds characteristic of cations.

Ionization chambers are operated at low voltage (100–250 V), whereas a somewhat higher voltage (300–600 V) is applied in **proportional counters** where the accelerated electrons generate new charge carriers in collisions with gas molecules. This process is called **gas multiplication**. In proportional counters, the total number of charge carriers is proportional to the primary charge carriers generated by the alpha particle; therefore, the pulse height is also proportional to the particle energy. As a result of gas multiplication (which can be as high as 10^6), the output pulse is much higher than in the case of ionization chambers.

For alpha spectrometry, gas ionization detectors are used in pulse mode. Because of the slow migration of the ions, these detectors are often operated in electron-sensitive mode. By changing the time constant of the electric circuit,

FIGURE 5.9 Operational principle of the gridded ionization chamber according to Knoll (2010). The rise of the pulse results from the drift of the electrons across the grid–anode region d . No signal voltage is generated when electrons move across region y where d and y are the distances between the grid–anode and the interaction position–grid. Reprinted by permission of John Wiley and Sons © 2010.

the amplitude of the detected pulse reflects only the drift of the electrons. However, the amplitude of the pulse becomes sensitive to the position in the chamber where the alpha particle interaction takes place. This drawback can be overcome by the use of gridded ionization chambers.

In the **Frisch grid detector** (Fig. 5.9), the ionization chamber is divided into two parts by the grid, which is maintained at an intermediate potential between the original electrodes. Alpha particles enter only the grid–cathode compartment through the use of a collimator. Only the upward movement of the electrons in the grid–anode compartment is registered by placing the load resistor in the anode–grid circuit. When the electrons move from the grid to the anode, the grid–anode voltage begins to drop and the signal voltage begins to develop across the resistor. The maximum signal voltage ($V = n e^-/C$) is reached when the electrons reach the anode.

The grid is maintained at an intermediate voltage between the cathode and anode, and therefore, the grid becomes almost transparent for the electrons. Increasing the grid voltage will cause losses of electrons, and the detected count rate will be reduced (Fig. 5.10).

In the Frisch grid chamber, a fast and position-independent pulse is generated by detecting the electron drift separated from the drift of positive ions.

Gridded ionization chambers have been successfully used for alpha spectrometric analysis of large area sources up to 80 mm radius by Roos and Roos (1999). An absolute counting efficiency close to 40% was achieved, whereas the energy resolution was acceptably high (FWHM was about 30 keV).

Major characteristics of gas ionization detectors:

- Ionization chambers, preferably gridded chambers, operated as pulse chambers have been used to obtain alpha spectra.
- Pulse amplitudes are usually very small because of the lack of gas amplification; consequently, low-noise pre-amplifiers have to be attached to the ionization chambers.
- Energy resolution of the detector is limited by the relatively high ionization potential (energy needed to create an electron–ion pair) of the gases. Typical resolutions of 35–40 keV have been reported.

FIGURE 5.10 Change in count rate at different grid to anode and anode to cathode voltages (Roos and Roos, 1999).

- Response times are relatively slow, electron collection times are in the range of μs , and ion collection times are in the range of ms. In gridded ionization chambers, only the drift of electrons is detected.
- Absolute counting efficiencies are close to 50% if sources are placed inside the chamber.
- Gridded ionization chambers are superior to Si detectors regarding efficiency when large samples (larger than the size of the Si detector) are measured.

4. Semiconductor silicon detectors

Silicon semiconductor detectors are regarded as analogous to gas ionization, as solid-state ionization detectors. The use of a solid medium has the advantage that the dimensions of the detector can be kept small, whereas the counting efficiency is as high as in the case of gases. In alpha spectrometry, this means that a 100% intrinsic efficiency can be reached with a Si detector of 100 μm in thickness. A major advantage of semiconductors is their high (10–20 keV) energy resolution (only the special application cryogenic detectors described below have a higher energy resolution). Their drawbacks include the limitations on size and their high susceptibility to radiation-induced damage, resulting in spectrum degradation.

There are some differences in the pulse generation processes between gas ionization and semiconductor detectors:

- The mobilities of the charge carriers are different. In gas ionization detectors, the mobilities of the electrons are about 1000 times higher than those of the cations, whereas in semiconductor detectors, the mobilities of the electrons are 2–3 times higher than those of the holes.
- The charge collection times are different. The time needed to collect electron–cation pairs is in the range of milliseconds, whereas that for electron–hole pairs is in the range of microseconds.
- The size of the sensitive volume is constant in gas ionization detectors, whereas it is dependent on the applied voltage in semiconductor detectors.

The properties of semiconductor materials, including the description of the band structure, have been discussed in detail in many good monographs (Knoll, 2010; Gilmore, 2008) and are also described in Chapter 4, Volume 1. Here, we focus our discussion on Si detectors, which are the most frequently used detectors in alpha spectrometry.

In Si semiconductor detectors, p-type and n-type Si are brought together in good contact, and a reverse bias (positive voltage to the n-type Si) is applied. At the junction of the two Si layers, an intrinsic layer depleted in any charge carriers is formed. The reverse biased p-n junction, the so-called p-n diode, is used as an alpha particle detector.

The basic interaction between the ionizing particle and the detector takes place in the depleted/intrinsic region. When the alpha particle passes through a semiconductor, **electron–hole pairs** are created along the track. These charge carriers are collected by the electric field, with changes in the electric field being registered as pulses. Pulse amplitudes are small, being in the range of microamperes. Since the height of the pulse is proportional to the energy deposited by the interacting particle, the detector is suitable for spectrometric measurements.

The average energy expended by the ionizing radiation to produce one electron–hole pair in Si is about 3.6 eV (slightly higher than the 3.0 eV in Ge). This value is also somewhat higher than the width of the bandgap in Si (1.12 eV) or the ionization energy because the energy imparted by the alpha particle is not 100% utilized in electron–hole pair production. This value is about an order of magnitude lower than the 30 eV required to create an electron–cation pair in gas ionization detectors. Therefore, the number of charge carriers is increased by about 10 times, and the statistical fluctuation in number is reduced, resulting in a better energy resolution as well as improved signal-to-noise ratio. The ionization energy depends slightly on temperature; in Si, it is 3% greater at liquid nitrogen temperature compared with room temperature.

The electrical resistance of pure Si is high, and therefore, the leakage current across the junction is small. In spectrometric applications, this must not exceed a few nanoamperes. This low current is a major requirement if electric pulses that generate $\sim \mu\text{A}$ current are to be analyzed.

Electrical charges are collected by two ohmic contacts fitted to the opposite faces of the semiconductor material. The ohmic contacts are connected to a detection circuit, and an electric field is applied to collect the charge carriers. Special blocking electrodes are used where the number of charge carriers is reduced during the application of the electric field to reduce the leakage current of the detector.

According to fabrication technology, silicon semiconductor detectors are of three different types: the diffused junction detector, the surface barrier detector (SBD), and the passivated ion–implanted planar Si (PIPSi) detector. Each detector can be regarded as a reverse-biased compensated detector where n- and p-type Si crystals are brought into contact and a depleted/intrinsic (i) layer is formed as the sensitive volume of the detector.

Diffused junction detectors. These detectors, belonging to the first generation of Si diode detectors, are prepared by diffusion from p-type Si. An n-type impurity, usually P, is evaporated on one surface of the crystal and is diffused into the Si crystal to a depth of 0.1–2 μm . A depleted layer is formed under the surface layer that is relatively thick. The incident radiation must pass this “dead layer” before reaching the sensitive volume. The dead layer

causes losses in production of charge carriers and a reduction in energy resolution.

Surface barrier detectors. By etching the surface of an n-type Si crystal, a p-type layer (oxide) is formed that is coated by a thin gold layer using vacuum evaporation. SBDs can be produced starting from a p-type Si that is evaporated by aluminum to form an n-type contact. Gold or Al serve as electric contacts and entrance window for the radiation. These detectors are characterized by a very thin dead layer, resulting in high-energy resolution and small losses in charge collection. Due to the very thin entrance window, these detectors are sensitive to mechanical or chemical impacts and are permeable also for photons. They can be operated in light tight chambers that usually also serve as vacuum chambers.

Passivated ion-implanted planar Si detector. At present, these are the detectors most frequently used for alpha spectrometry. N-type Si is used as the starting material for the production of PIPSi detectors (PIPS and ULTRA are the registered trade names of the PIPSi detectors of Canberra and Ortec). Accelerators of about 10 kV are used to implant B or P ions as p-type impurities and an As n-type blocking contact.

PIPSi detectors have the following advantages:

- The implanted Al entrance window is thin and even, allowing high-energy resolution and small losses in charge production.
- The implanted Al window is resistant to mechanical effects; it can be cleaned.
- The leakage current is small.

The flowchart of the production of PIPSi detectors is shown in Fig. 5.11.

Silicon detectors, and especially PIPSi detectors, find widespread application in standard alpha spectrometry. Since the 1980s, considerable efforts have gone into improving the detection systems and developing HRAS, which allows the determination of nuclides that emit alpha particles of similar energies.

HRAS is not based on a new detection principle and does not require a new type of instrumentation, but special efforts are made to improve the energy resolution. PIPSi detectors of thin window and small size (20–50 mm²) are often used. The alpha sources are prepared with special care, typically with vacuum sublimation or electrodeposition to obtain an almost infinitely thin and even sample layer after radiochemical processing. The source to detector distance is kept high (several times the diameter of the detector) to have a small solid angle of measurement (<1% of 4 π sr), and so absolute counting efficiencies are typically less than 1% (typically 0.1%–0.2%). High source to detector distance is necessary to minimize the variation of the alpha particle track length in the source and in the dead layer of the detector. Because of the low counting efficiency, a source strength of a few tens of Bq or more are a

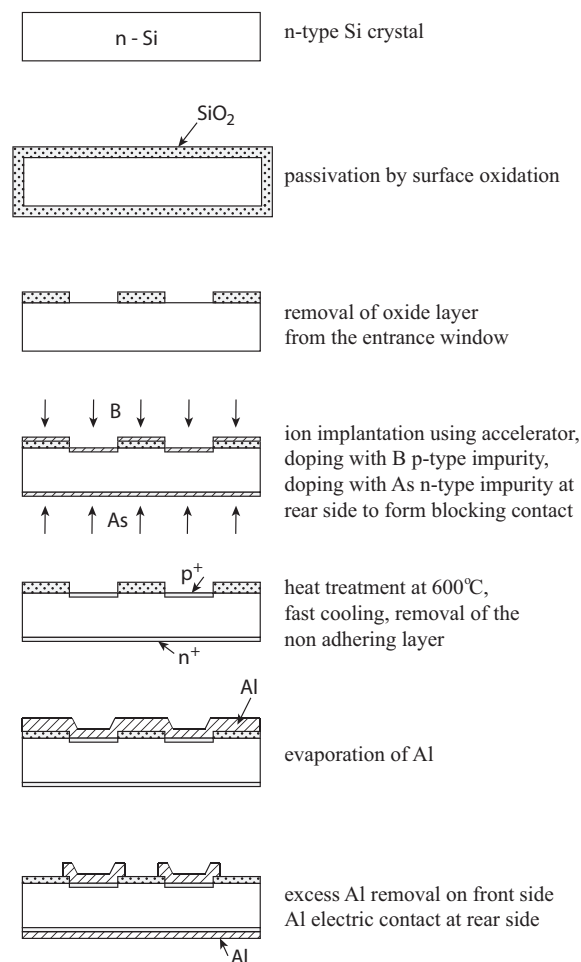

FIGURE 5.11 Steps in PIPSi detector fabrication. PIPSi, passivated ion-implanted planar Si. *Amoudry and Burger (1984), reprinted by permission of Elsevier Ltd. © 1984.*

requisite to avoid a data acquisition time, which is too long. A high vacuum and high stability of the electronic equipment is assured by special technical tools. Temperature control and source collimation might be necessary. Conversion electrons are sometimes deflected by magnetic deflectors to avoid alpha–electron coincidences. The energy resolution of such a system may be even less than 10 keV, which is significantly smaller than the typical values of 30–80 keV for standard alpha spectrometry. HRAS is especially suitable for the analysis of isotope pairs of similar energies such ²³⁹Pu and ²⁴⁰Pu, or ²⁴³Cm and ²⁴⁴Cm, which are spectroscopically separated.

Major characteristics of Si semiconductor detectors are as follows:

- Surface barrier and preferably passivated implanted planar Si detectors are used to obtain alpha spectra.
- Pulse amplitudes are usually very small (in the range of a few microamperes) but well detectable after amplification.

- The typical leakage current of a PIPSi detector is in the range of nanoamperes.
- Energy resolution of the detector is high due to the low ionization energy needed to create an electron–hole pair. Typical resolution of the detector is 10–20 keV depending on detector performance and size.
- Charge collection times for electron–hole pairs are fast, in the range of microsecond. There is a relatively small difference between the collection times of electrons and holes (a factor of 2–3).
- Absolute counting efficiencies are close to 50% if sources are placed close to the detector inside the chamber.
- Si detectors usually have a low background, resulting in a high counting sensitivity.

Semiconductor Si detectors have proved to have more advantages than gas ionization detectors and have replaced them in most applications.

Research and development trends in Si semiconductor detectors:

Efforts have been made recently to obtain in situ, near real-time alpha spectrometry by combining alpha spectrometry with source preparation on the Si detector. Two techniques have been tested, namely, (1) modifying the Si surface by introducing ion-exchange functional groups and (2) electrodepositing analytes on the metal surface that forms a junction with the semiconductor where the junction can be a rectifying (Schottky contact) or a nonrectifying (Ohmic contact) one.

The first of these techniques was tested by Krupp and Scherer (2018). As a result of a two-step surface modification process, a thiol-functionalized silane was grafted on the surface first, and then sulfonic acid groups were obtained by oxidation, thus obtaining a cation exchange functionalized Si detector. The paper demonstrated the feasibility of measuring alpha particles in solution, and a resolution of about 100 keV was obtained using $^{238}\text{U}/^{234}\text{U}$ isotopes.

Stika et al. (2018) electrodeposited Th and U on Ni metal plates from molten LiCl-KCl electrolyte. Real-time determination of actinides is of major importance in electrorefining of radioactive wastes. The technique showed promising results.

5. Scintillation detectors

Detection of ionizing radiation by scintillation detectors is based on the emission of light as a result of the interaction of the radiation with the detector material (called a scintillator) followed by collection of light and its conversion into electrical pulses using photomultiplier tubes (PMTs) or photodiodes. Scintillation detection is one of the oldest techniques in the measurement of radioactivity, having had widespread application for the detection of alpha, beta, and gamma radiation in the past. At present, most of the applications are related to gross counting of alpha, beta, and

gamma radiation due to the typically high counting efficiency and the low cost of the instrumentation, whereas radiation spectroscopy is limited by the insufficient energy resolution of the scintillators to allow the identification of the radionuclides in an isotope mixture. Scintillation gamma spectrometry was a basic tool till about the 1980s, but it was gradually replaced by semiconductor spectrometry of much better energy resolution.

The operation mechanisms and application fields of LS detectors are described in Chapters 6 and 7 of Volume 1, and those of solid scintillators are summarized in Chapter 9, Volume 1. Here, we summarize the principles of operation and describe the alpha spectrometric application, the so-called high-resolution alpha liquid scintillation spectrometry (α -LSC).

Scintillation detectors include solid and liquid scintillators as well as inorganic and organic scintillators. For all these different types, the basic process used for detection is **fluorescence**, which is the prompt emission of visible radiation (light). Good scintillator materials are characterized by

1. high scintillation efficiency in converting the kinetic energy of the particle to light,
2. linearity of conversion that means that the light yield is proportional to the deposited energy, thus allowing spectrometric analysis,
3. good optical properties, including transparency to the emitted light to allow efficient light collection,
4. fast response time with prompt light emission,
5. high density or high atomic number—this is required only for the detection of gamma radiation.

Inorganic alkali halide crystals, such as NaI(Tl) and CsI(Tl), usually meet the requirements of (1), (2), (3), and (5), but are usually slow in response time. Organic scintillators such as solid plastics and liquid scintillators are usually faster, but the light yield is lower and the requirements of high density and atomic number are not fulfilled.

The main parts of a scintillation detector are the **scintillator**, which converts the radiation energy to visible light photons and the **photoelectron multiplier (PM)** tube containing the photocathode, the multistage electron multiplying section made of a series of electron-multiplying dynodes and an anode for collection of the amplified charge situated in a glass vacuum envelope. Photocathodes are responsible for converting the energy of the photons into electrons. If the light appears as a pulse, the photoelectrons produced will also form a pulse of similar time duration. The number of electrons emitted by the cathode is multiplied on the dynodes where the multiplication factor can be as high as 10^6 – 10^8 depending on the applied voltage. The electric pulse at the anode of the PM tube can be directly counted without further amplification by a simple counter, a

single or MCA. Typical tubes have fast response times. When they are illuminated by a short light pulse, an electron pulse will be produced at the anode with a time width of a few nanoseconds after a delay time of 20–50 ns.

The **sensitivity of the scintillation detector** consisting of a scintillator and a PM tube to radiation can be calculated by the following assumptions: The blue light emitted by the scintillator has a wavelength (λ) of about 400 nm. According to Planck's equation, the energy of the photon is therefore about 3 eV. Taking into account that the conversion efficiency of the scintillator is 5%–20%, then the number of photons generated by a particle of 1 MeV energy is about 15,000–60,000. The efficiency of the photocathode to convert photons into electrons is typically 10%. Therefore, the expected number of electrons at the output of the photocathode is 1500–6000. Altogether, about 200–700 eV energy is required to produce a photoelectron. The corresponding "ionization energy" of gas ionization and semiconductor detectors is one and two orders of magnitude lower, respectively. This difference is the basic reason for the poor energy resolution of scintillators compared with gas ionization and especially to semiconductor detectors.

The mechanism of scintillation in inorganic and organic scintillators is different.

Mechanism of scintillation in inorganic crystals with activators. Inorganic scintillators are insulators characterized by a band structure where the lower band (the valence band) represents the electrons that are bound to lattice sites of the crystals and the upper band (the conduction band) represents the electrons that can migrate throughout the crystal. The gap (the forbidden band) between the two bands is wide (above 5 eV). If energy is deposited in the crystal by radiation, electrons in the valence band can be elevated to the conduction band leaving a hole behind. Addition of small amounts of impurity, called an activator, to the pure crystal will create an intermediate energy level within the gap (a luminescence center) through which the excited electron can deexcite back to the valence band while emitting a visible photon with a reduced energy. This photon will serve as the basis of scintillation detection. Deexcitation processes are typically fast with a half-life of about 100 ns.

Beside the luminescence centers, impurities in the crystal can create electron traps. Deexcitation of the electrons from the electron traps either does not result in visible light emission, or the light emission is delayed causing an "afterglow" appearing in an increased background during the measurement.

Detection of alpha particles by solid scintillators. Among the great variety of inorganic scintillators (e.g., NaI(Tl), CsI(Tl), CsI(Na), CaF₂(Eu), LiI(Eu), bismuth germinate), ZnS(Ag) is the one that has been exclusively used for the detection of alpha particles. It has a high

radiation conversion efficiency of about 20%. The maximum wavelength of the emitted photons is 450 nm, close to the maximum sensitivity of the photocathode. The principal decay constant is 0.2 μ s. Its major drawback is that it is crystallized as polycrystalline powder, which is not adequate for spectrometric measurements. Usually, a thin layer of 20–30 mg/cm² thickness is mounted on a glass surface. A thicker layer of ZnS loses transparency.

Mechanism of scintillation in organic crystals, liquids, and gases. In organic scintillators, excitation and deexcitation processes take place in single molecules independent of their physical state, i.e., solid, liquid, or gaseous state, in marked contrast to inorganic scintillators. Scintillation arises from transitions of electrons between the energy levels of the organic molecule.

The energy spacing between the ground and the excited levels is 3–4 eV for many organic scintillators. In both states, there are several vibrational energy levels where the energy spacing is much smaller (about 0.15 eV), these levels can also be occupied. The molecules at room temperature and in the absence of radiation occupy the ground state. When radiation travels through the scintillator, the deposited energy excites the molecule, and this is followed by fast (ps) deexcitation. Deexcitation to the ground level does not result in light emission. Fluorescent light is emitted in those deexcitation processes where the excited molecule goes back to one of the vibrational levels of the ground state. In organic scintillators, delayed light emission (phosphorescence) is also often observed.

In mixtures of organic molecules, the excitation energy undergoes substantial transfer from one molecule to another. This energy transfer plays an important role in liquid scintillators where often a high concentration of nonscintillating solvent is mixed with a small concentration of an efficient scintillator. The primary energy transfer takes place in the solvent, and the excitation energy is finally emitted as photons by the scintillator molecule. Scintillation cocktails often contain a third organic molecule called a wavelength shifter that can change the wavelength of the emission spectrum so that it is better fitted to the absorption maximum of the photocathode. Scintillator molecules usually contain aromatic rings, and oxygen and nitrogen atoms can be included in the aromatic ring structure.

Detection of alpha particles by LSC. Liquid scintillators are frequently used for the detection of alpha particles. Commercial liquid scintillation counters (LSCs) developed for the detection of low energy beta particles can be used to measure alpha particles without self-absorption losses, giving 100% absolute counting efficiency. This advantage is counterbalanced by the limited resolution of the scintillators. A typical energy resolution using commercial LS system is about 20%–25%, so alpha spectrometry is difficult or almost impossible to achieve.

Detection of low-level alpha radiation by a commercial LSC is difficult because the scintillation yield of the alpha particles is lower by about a factor of 10 than that of beta particles. Therefore, the spectra of the alpha radiation of 4–6 MeV appears in the same region as the spectra of beta particles of 400–600 keV.

Furthermore, the response of organic scintillators to alpha or beta radiation is not completely linear; deviation from linearity is found at low energies. The explanation of this behavior was given by Birks (1964). In organic scintillators such as LSC, only a small fraction of the kinetic energy of the alpha particles is converted to light, and the remainder is dissipated in the matter as heat and lattice vibrations. The high ionization density along the track of the alpha particle causes damages to the organic molecules that leads to quenching (absorption) of the fluorescence light created in the interaction. It is expected that the light output (dL/dx) is proportional to the specific energy loss of the particle (dE/dx), if there is no quenching:

$$\frac{dL}{dx} = S \frac{dE}{dx} \quad (5.8)$$

where S is the normal scintillation efficiency.

The Birks' formula expresses the deviation from the normal scintillation due to quenching:

$$\frac{dL}{dx} = \frac{S \frac{dE}{dx}}{1 + kB \frac{dE}{dx}} \quad (5.9)$$

where kB is treated as an adjustable parameter to fit experimental data for a given organic scintillator.

The **reduced scintillation efficiency** is a special feature of the interaction of heavy charged particles with organic scintillators and makes alpha spectrometry using commercial LSC very difficult.

To avoid the interference of alpha and beta LS spectra, a technique of **pulse shape discrimination (PSD)** has been introduced. In organic scintillators, fluorescent light is produced in a very rapid "prompt" process as well as in a slower process corresponding to delayed fluorescence. The response times of the processes are in ns and 100 ns ranges, respectively, as shown by the shape of the pulses depicted as pulse intensity versus time in Fig. 5.12. The slow scintillation component is higher for particles of high specific energy loss (dE/dx), such as alpha particles and heavy charged particles. Based on the differences in the pulse shapes, it is possible to separate pulses due to alpha particles from those originating from beta or gamma radiations. Using special electronic circuits for PSD, alpha and beta spectra are constructed from a single LS spectrum. Using this technique, which is available in modern LS counters, the problems of overlapping alpha and beta spectra due to reduced scintillation efficiency can be eliminated.

FIGURE 5.12 Typical pulse shapes in liquid scintillation spectrometry. Tailing refers to delayed fluorescence. The contribution of the slow component to the pulse is higher for alpha particles than beta particles.

Alpha spectrometry by high-resolution α -LSC. A so-called high-resolution alpha-LSC characterized by an FWHM of 200–400 keV for alpha particles in the energy range of 4–7 MeV has been developed for the measurement of alpha spectra of separated radioelements such as uranium and thorium. A small volume of extracted sample mixed with an organic scintillator is detected by a single PM tube in a special geometry shown in Fig. 5.13.

The differences in fluorescent yields of alpha and beta particles cause troublesome background interference from beta and gamma radiations in the alpha counting. With the selection of an appropriate scintillator, alpha-produced pulses are about 30 ns longer than beta-produced pulses. Based on this difference, beta-produced pulses are

FIGURE 5.13 Schematic drawing of the sample, reflector, and photomultiplier tube arrangement for alpha LSC. McKIveen and McDowell (1984), reprinted by permission of Elsevier Ltd. © 1984.

electronically rejected by a PSD. The system is called photon–electron rejecting alpha liquid scintillation (PERALS) spectrometer. The use of PSD is responsible for rejection of the pulses originating from interfering gamma rays and conversion electrons, which are emitted by many of the alpha-decaying nuclides (see [Table 5.1](#) provided earlier in this chapter.). The improved energy resolution of the PERALS system is a consequence of

- the small sample size,
- the efficient geometric arrangement,
- the rejection of electrons and photons by the use of PSD,
- the use of aqueous immiscible scintillator and organic extractant,
- removal of dissolved O₂ by purging the sample with Ar gas.

Eliminating the presence of water and dissolved O₂ helps reduce quench effects that result in highly variable light production and, as a consequence, poor resolution in a conventional LSC. In the PERALS spectrometer—differing from the commercial LSC instruments dedicated for tritium and ¹⁴C measurements—a single PM tube is applied. To analyze alpha-emitting nuclides with the relatively low-resolution PERALS spectrometer, selective chemical separations have to be performed. For this purpose, a great variety of special extractive scintillators have been developed that serve as solvent extractants and liquid scintillators at the same time. A list of the available extractive scintillators is given in Chapters 6 and 7 of Volume 1. An alpha spectrum evaluation code has been developed to deconvolute PERALS spectra that will be discussed in Section IV.A.3 ([Aupiais, 2004](#)).

Major characteristics of scintillation detectors used for determination of alpha particles:

- Among the great number of activated inorganic scintillators, ZnS(Ag) has been used to detect alpha particles. LS detectors are also used to detect alpha particles. High-resolution alpha LSC is applied for alpha spectrometric measurements.
- Pulse amplitudes are usually directly measurable because amplification is performed by the dynode system of the PM tubes.
- Scintillators are characterized by their light yield or scintillation efficiency, which is usually higher in the case of inorganic than organic scintillators. The total light yield of inorganic scintillators is about 10,000–50,000 photons/MeV.
- The wavelength of the light emitted by organic and inorganic scintillators is in the range of 400–450 nm and 300–550 nm, respectively. This is coupled to the photocathode that has highest sensitivity in the range of 300–600 nm.
- The light yield of organic scintillators is about an order of magnitude lower for alpha particles than for electrons due to quenching caused by radiation-damaged organic molecules.
- Energy resolution of the scintillation detector is poor due to the high energy (a few hundreds of eV) needed to produce a photoelectron. Typical energy resolution of a NaI(Tl) detector for gamma radiation is about 8%–10%. The energy resolution of a commercial LSC for alpha particles is 20%–25%.
- Responses of scintillation detectors are usually fast, in the nanosecond range for organic scintillators and somewhat slower in case of inorganic scintillators (in the ns–μs range). The rise and fall of the light output can be characterized by an FWHM of the light versus time profile, called response time FWHM, analogously to the FWHM of the counts versus energy distribution. The very good time resolution of the scintillators is preserved in pulse processing by PM tubes.
- Absolute counting efficiencies of solid scintillators depend on the counting geometry and the type of radiation to be detected. The counting efficiency of LSC for high-energy beta and alpha particles is 100%; for low energy beta particles such as for ³H, the efficiency is 30%–40%.
- Scintillation counters generally have high background, increasing the detection limit compared with measurements with gas ionization and semiconductor detectors. The most significant source of noise is the spontaneous emission of thermionic electrons by the photocathode. (Various sources of background and the techniques of background reduction are discussed in detail in Section IV.C.)
- The performance of LSC is strongly dependent on quenching (see Chapter 6, Volume 1), which causes losses in the light output of the scintillator either by hindering the light production (chemical quenching) or by absorbing the produced light (color quenching).

Although semiconductor Si detectors proved to have advantages over scintillation detectors in spectrometric measurements, liquid scintillators are used in various fields, including gross alpha/beta counting; absolute activity determination due to high counting efficiency and the high-resolution alpha LS spectrometry (PERALS) has been successfully used for fast spectrometric determination of some alpha emitters.

6. Cryogenic detectors

A measurement technique has been developed, which is based on the thermal detection of alpha particles using very sensitive detectors, called bolometers. The bolometer is a calorimeter operated at very low temperature, typically

below 100 mK. The bolometer has two major parts, an absorber where the energy of the single alpha particle results in a temperature rise and a thermal sensor (thermometer) to measure it. At this very low temperature, the heat capacity of the absorber, which can be a dielectric, a metal, or a semiconductor material, becomes so small that the temperature rise due to the interaction of a single alpha particle becomes detectable (See Chapter 9, Volume 1 for additional information on the operating principle of bolometers).

In the interaction of alpha particles with matter, energy is transferred to electrons by inelastic collisions that induce ionization and excitation. The energy is distributed between the production of charge carriers (in semiconductor materials, electron–hole pairs) and phonons (lattice vibrations, heat). In bolometers, the energy of the phonons is detected. If the electron–hole pairs recombine in the bolometer within the time resolution of the system, their energy is also transferred to phonons that are also detected.

Bolometers have the great advantage that theoretically better energy resolution can be achieved than in the case of Si detectors. Juillard (1999) calculated that the FWHM in a Ge or Si bolometer is in the order of 1 keV for alpha particles of 5 MeV energy. Leblanc et al. (2006) reported 4 keV FWHM for an alpha spectrum measured with a composite copper–germanium bolometer and an external electrodeposited ^{238}Pu source. The detector response was in the range of 10^{-8} – 10^{-7} V/keV, and the pulse rise and decay times were about 1 and 5 ms, respectively. Fig. 5.14 shows the schematic drawing of the Cu-Ge bolometer used for the measurements.

FIGURE 5.14 Bolometer B300 developed by Leblanc et al. (2006). A Cu absorber disk (1) is thermally coupled to a Ge heat diffusing volume (2, 3) coupled to a large thermometer (4). Pure Ge pillars (5) assure a rigid support and the thermal link to the thermal bath (7). The detector frame is fixed on the cold plate of the refrigerator. The bolometer was tested in a 20 mK dilution refrigerator, placed in a Faraday cage and decoupled from ground vibrations. Reprinted by permission of Elsevier Ltd. © 2006.

The development of a new type of microcalorimeter also called magnetic spectrometer has been reported. Magnetic calorimeters are particle detectors operated at low temperatures (typically below 100 mK) where the temperature rise due to absorption of the particle in the sensor is transformed into a measurable magnetic flux change in the superconducting quantum interference device (SQUID). Paramagnetic temperature sensors have been used as detectors. Pabinger et al. (2011) used a sputtered Au:Er paramagnetic temperature sensor attached to a superconducting pickup coil and reported 2.83 keV energy resolution for ^{241}Am . Yoon et al. (2012) reported 1.2 keV resolution for the same nuclide.

Hoover et al. (2015) developed a superconducting transition-edge sensor (TES) with the sample encapsulated inside a gold foil that is used to absorb the decay energy (Q). The TES is based on a superconducting film, the resistance of which is strongly dependent on temperature. Therefore, it can act as a thermometer. The electric current flowing through the TES changes with temperature, and the current change is measured using the SQUID. Modern refrigerator technology assures the necessary low temperature for the detection of the temperature rises due to single alpha decay events. Energy resolution of about 1 keV has been reported for the Q -value spectra.

After further development and optimization, microcalorimeters will probably find application in metrology where extremely HRAS is required for the accurate determination of nuclear data.

B. Electronic units

The basic alpha spectrometric measurement system consists of a detector, electronics to process the signals, a power supply unit, a chamber (light tight chamber in the case of a light-sensitive Si detector and gas-tight chamber in the case of a gas ionization detector) surrounding the detector, a vacuum system to reduce the chamber gas pressure and absorption of alpha radiation, and a software package to analyze the spectra. The signal processing electronics usually contains the preamplifier, the main amplifier, the ADC, and MCA, as illustrated previously in Fig. 5.6.

In semiconductor detectors, the preamplifier is usually a charge sensitive amplifier, whereas in scintillation detectors, it is the PMT. The various types of preamplifiers are described in detail in Chapter 9, Volume 1.

The roles of the main amplifier are (1) to further amplify the signal and (2) to shape the signal from the discharge curve to a signal in pulse shape. In the main amplifier, only the first part with the increase of the discharge curve is used to speed up the signal processing significantly.

The ADC determines the height of the pulse signal supplied from the main amplifier. This pulse height is then converted to a number of channels by the MCA. The MCA counts the number of events per channel and generates the pulse height spectrum.

With the advent of personal computers (PCs) at the beginning of the 1980s, a powerful system of standardized processor, large computing and storage power, and large variety of interfaces became available for spectrometric purposes. At present, there are two types of PC-based MCA systems, PC plug-in cards, and NIM modules under PC control. Spectrum data are stored either in PCs or in stand-alone storage modules. In both cases, setup and control of the MCA is accomplished via a computer program, and spectrum evaluation software is usually also installed in PCs.

With the increasing development of complex digital electronics, the so-called digital amplifiers for spectroscopy were developed, which are not only amplifiers but also analyzers. These systems digitize the signals from the preamplifier directly and then process them digitally. The great advantage of the digital amplifier is the large signal throughput. As a result, extremely high count rates can be processed almost without interference.

The high voltage supply is adapted to the type of detector and provides a very clean and stable signal. Noise of the high voltage power supply has a detrimental effect on the spectra, resulting in degraded energy resolution or deviations in the amplification of the signals, e.g., in case of scintillation detectors.

A detailed description of the electronic units is given in Chapter 4, Volume 1 on gamma spectrometry and in several good monographs (Knoll, 2010).

IV. Characteristics of the alpha spectrum

A. Peak shape and spectrum analysis

The major characteristics of the alpha particle spectra depend on the type and quality of the detector and the electronic units, the geometric arrangement, and the quality of the alpha source. The operating principles and the major characteristics of the various types of detectors have been discussed above. Energy resolution, pulse shape, response times, and intrinsic efficiency are determined by the detector; other factors will contribute to the overall performance but cannot overcome limitations of the detector. A thick alpha source, a thick absorber layer between the source and the detector, or an uneven detector window will negatively affect the energy resolution, whereas electric noise in the signal processing will increase the background. In the present section, the various factors influencing alpha spectra are discussed first based on the example of semiconductor Si alpha spectrometry, followed by a brief discussion of other detector types.

1. Peak shape and spectrum analysis with Si detectors

a. Peak shape

Typical alpha spectra of various resolution and shape are shown in Fig. 5.15. The sources, which were prepared by membrane filtration, contain different amounts of natural U and so have different thicknesses. The measurements were performed using a PIPSi detector.

Fig. 5.15 shows the effect of self-absorption on the peak shape. The spectrum with the highest resolution was

FIGURE 5.15 Alpha spectra of samples composed of natural U with different source thicknesses. The peaks on the left and right correspond to ^{238}U and ^{234}U . Spectra are shifted along the vertical axis to show the differences in peak width (resolution) and tailing. Pöhlänen et al. (2005), reprinted by permission of Elsevier Ltd. © 2005.

obtained using a typical thin alpha source produced by radiochemical sample processing, similar to the spectrum in Fig. 5.4. This source has a thickness of $6.8 \mu\text{g}/\text{cm}^2$. By increasing the source thickness to a few mg/cm^2 , the self-absorption of alpha radiation is increased, and peaks become wider causing poor energy resolution and the low-energy tailing increases.

Energy resolution (FWHM). Alpha peaks are characterized in routine analytical practice by the FWHM value, which can be easily determined from the spectrum as the peak width in keV at the half of the peak height. The FWHM values of alpha peaks are usually larger than the specified values for the detector. While typical FWHM values of PIPSi detectors are 17–19 keV and 30–37 keV for detectors of 300 and 1200 mm^2 in active area, respectively, those of alpha spectra in routine analytical work may be in the range of 30–80 keV depending on the source quality.

The statistical fluctuation in the number of the electron–hole pairs produced in the detector determines the theoretically achievable energy resolution of an alpha spectrometer. The number of electron–hole pairs varies due to the presence of impurities, due to crystal defects that can trap the charge carriers, and due to possible recombination of the charge carriers. Various secondary processes (such as crystal damage and lattice vibration) may also have an effect. A significant part of the energy deposited in the detector does not create electron–hole pairs but appears as heat and vibrations (phonons). According to theoretical calculations, the limit of the energy resolution in Si detectors (when processes taking place outside the detector such as absorption and self-absorption are neglected) is about 7–10 keV (Steinbauer et al., 1994; Amoudry, 1990). The measured FWHM depends on many other parameters of the detection system, the geometric arrangement of the source and the detector (Fig. 5.16), and the properties of the alpha source itself. Each process causes peak broadening.

FIGURE 5.16 Paths of alpha particles (a to e) in the source–detector system.

The final FWHM can be calculated from the individual contributions as

$$\text{FWHM}^2 = \text{FWHM}_d^2 + \text{FWHM}_s^2 + \text{FWHM}_a^2 \quad (5.10)$$

where d, s, and a refer to detector, source, and absorber effects, respectively.

The effect of the geometric arrangement on the energy resolution is illustrated in Fig. 5.16.

Alpha particles emitted by the radionuclides embedded in the source material can have different paths before entering the Si detector. They can deposit energy in the source such as particles b and c in Fig. 5.16. All particles (a to e) will deposit energy in the air gap between the source and the detector and in the detector window. The first process represents self-absorption, and the latter ones represent absorption. The role of absorption in air can be neglected if high vacuum is present in the detector chamber, but very often it is desirable to attain a low air pressure to protect the detector from recoil particles (see below). Altogether, the contributions of absorption in the source (“self-absorption”), in the detector dead layer, and in any other absorbent will mutually contribute to the total absorption. Each process causes reduction of the total energy deposited in the Si detector, and each process results in a range and energy straggling of the monoenergetic alpha particles. The lengths of the arrows in the Si material (Fig. 5.16) represent the paths of the alpha particles and the energy deposited by each particle in the active volume of the detector. Variation in these individual energy depositions results in peak broadening.

Absorption and self-absorption have different effects on the alpha spectrum, although from the physics point of view both processes are basically the same. If only absorption has a significant contribution to energy losses (thin source but thick absorber between the source and the detector), then the spectrum is shifted to lower energies because all alpha particles lose part of their energy in interactions outside the detector (Fig. 5.17). It also causes peak broadening due to the variation in energy loss outside of the detector due to varied angles of incidence and to the reduction in number of charge carriers produced in the detector. If only self-absorption has a significant contribution to energy losses (as in the case of thick sources), then the peak is broadened, but the spectrum is not shifted (Fig. 5.18). This is because alpha particles originating from the surface layer of the source can reach the detector without loss of energy.

Absorption and self-absorption depend on the composition, density, homogeneity, and surface roughness of the absorber and the source. All these parameters can be adjusted in the Monte Carlo simulation program known as AASI (<https://www.stuk.fi/web/en/services/aasi-program-for-simulating-energy-spectra-in-alpha-spectrometry>).

FIGURE 5.17 Simulated alpha spectra of a source containing equal activities of ^{238}U and ^{234}U by assuming different absorber thicknesses (0, 20, and 40 μm). Detector full width at half maximum (here 14 keV) and source thickness (0.4 μm , 6.8 $\mu\text{g}/\text{cm}^2$) do not influence the peak shapes significantly. Spectra were generated by the AASI simulation software (Siiskonen and Pöllänen, 2004).

FIGURE 5.18 Simulated alpha spectra of a source containing equal activities of ^{238}U and ^{234}U with varying source thickness (0.4, 20, and 40 μm with source surface densities of 6.4, 320, and 640 $\mu\text{g}/\text{cm}^2$). Detector full width at half maximum and absorber thickness are assumed to be 14 keV and 0 μm (0 $\mu\text{g}/\text{cm}^2$), not influencing the peak shape significantly. Spectra were generated by the AASI simulation software (Siiskonen and Pöllänen, 2004).

The resolution of semiconductor alpha detectors depends on the detector size. The reason is that large detectors cannot be prepared with a completely even thickness of the front face contact and without dead layer inhomogeneity. *Inhomogeneity and surface roughness* in the source, the detector dead layer, or even the absorber will result in increased FWHM values.

The peak resolution depends on the measuring geometry, i.e., the source–detector distance, dimensions of the source and the detector, and their relative positions. When the source is placed parallel to and in line with the detector, peak broadening is observed when the source is moved toward the detector. This phenomenon can be easily interpreted as the increased angle under which the alpha particles can reach the detector, resulting in an increased path in the detector dead layer and, thus, a reduction of energy deposited in the effective volume of the detector (see Fig. 5.16). This effect on FWHM is especially

significant in the case of thick detector windows (e.g., in case of DJDs).

Alpha spectra measured with Si detectors are characterized not only by the FWHM but also by the **asymmetric peak shape**. Peaks usually have a Gaussian shape on the high energy side and a low-energy tailing as shown in Figs. 5.15, 5.17 and 5.18.

Due to the complexity of the processes resulting in peak tailing, the FWHM parameter is not enough to describe the peak shape, unlike other spectrometric methods such as gamma ray spectrometry and LSC. In a simplified case, the FWTM parameter is used together with FWHM, but in more detailed studies, the whole peak shape has to be described by peak fitting algorithms. Systematic studies have in recent years revealed the physical processes responsible for the asymmetric shape of alpha peaks.

High-energy tailing originates from pulses that are detected as the sum (coincidence) of the alpha pulses and

the pulses due to conversion electrons (or to a lesser extent to low energy gamma radiation) emitted by the same radionuclide if the pulses are detected within the resolution time of the detector. For example, ^{241}Am emits alpha particles and photons with several different energies. Instead of gamma emission, the deexcitation can also occur by the emission of conversion electrons of discrete energies. These relatively low-energy electrons are detected with high efficiency by the Si detector. Thus, pulses on the high energy side of the alpha peak originate basically from the true coincidences of alpha particles and conversion electrons/photons. No true coincidences exist in the case when the alpha decay leads to the ground state of the daughter nuclide. The effects of coincident emissions may be notable if the deexcitation leads to the excited state of the daughter nuclide as pointed out by Siiskonen and Pöllänen (2006).

The origin of **peak broadening and low-energy tailing** is a complex process that can be observed in all types of alpha spectra produced by Si detectors including low- and high-resolution spectra, spectra of isotopes emitting either a single alpha particle or different alpha particles with or without the emission of gamma photons.

Alpha peaks have an asymmetric shape with low-energy tailing in both high- and low-resolution alpha spectrometry, but the physical phenomena responsible for this shape are different. In high-resolution alpha spectrometry, where absorption and self-absorption are reduced to a minimum, the physical processes have been studied in detail by several authors (Steinbauer et al., 1994; L'Hoir, 1984; Bland, 1998). In addition to the (small) variation of the alpha particle track length in the absorbing materials (mainly dead layer of the detector and remaining air in the vacuum chamber), the peak broadening originates from energy straggling in the absorbing material and the electronic noise (e.g., in the detector, the amplifier), which cannot be totally eliminated. This peak broadening can be described by a Gaussian function. The low-energy tailing arises from the processes where the deposited energy of the alpha particles in the Si detector does not result in the production of electron–hole pairs. Such processes are collisions of the alpha particles with the Si nuclei and further interactions of the knocked-on Si ions in the crystal. Stopping of these ions (such as by recoil, heat, and phonon generation) results in pulse height defect that can appear as tailing in the spectrum. Low-energy tailing can be described by exponential functions.

In low-resolution alpha spectrometry, these fundamental processes are overshadowed by other types of interaction of alpha particles usually taking place outside the detector. Low-energy tailing and peak broadening are explained by **absorption and self-absorption** of the alpha particles, such as

- absorption in gases (air) present in the vacuum chamber,

- absorption in the entrance window, and
- self-absorption in the source.

Absorption results in peak shifting, peak broadening, and peak tailing. In the case of self-absorption, there is no peak shifting (as measured at the upper limit of the peak), but there is peak broadening and increased tailing, as discussed above (see Figs. 5.17 and 5.18). Ideally, sources should be infinitely thin to avoid self-absorption. Significant peak deterioration for uranium sources was observed above a source density of $100\text{ }\mu\text{g}/\text{cm}^2$ by Martin and Hancock (2004a), although the significance will depend on the homogeneity of the sources and on the energy difference for the lines of interest.

The processes influencing alpha peak shape in the case of thick sources have been investigated by Monte Carlo simulation (e.g., Ziegler et al., 1996; Pöllänen et al., 2007). Pöllänen found that in thick sources the peak shape distortion is influenced by source thickness, source density, source inhomogeneities, and elemental composition of the source (see Figs. 5.15, 5.17 and 5.18). The AASI software uses Monte Carlo simulations to generate alpha spectra from sources of different characteristics. It was shown by Pöllänen et al. (2005) how the properties of the alpha source (such as inhomogeneities) affect the peak shape. Simulated and measured spectra agreed well when source inhomogeneities were also taken into account.

b. Peak fitting functions

A prerequisite for successful alpha spectrum unfolding is the knowledge of the peak shapes to be used in the analysis. Other relevant points are calibration of the detector (section VII) and how to use decay-related information, i.e., the fitting process peak based or peak family based. Depending on the application, there are other constraints, such as the emission probabilities (Martin Sanchez and Rubio Montero, 1999), and the effects of true coincidences, which may also be taken into account.

Various mathematical models have been proposed to describe the shape of monoenergetic alpha peaks, and these are used for fitting the alpha peaks in spectrum analysis software. The fitting procedure involves

- the selection of the peak shape model that depends on a number of parameters,
- selection of the optimization criteria for fitting the model to the measured data, and
- the choice of the numerical optimization procedure.

As a result of fitting, measured data are compared with calculated values, the goodness of fit is described, and peak areas and peak positions are calculated together with their uncertainties.

To describe the asymmetry of the alpha peaks, **modified Gaussian functions** were used from the end of the 1960s,

but these functions failed to describe the peak tailing (García-Toraño et al., 1999). Later, the use of a combination of **Gaussian and exponential functions** was proposed. The analytical function consisting of a Gaussian and a one-sided exponential function was first proposed by L'Hoir (1975), and it has been used for the analysis of alpha peaks in HRAS by several authors (Watzig and Westmeier, 1978; Bortels and Collaers, 1987; Bortels et al., 1995; Martin Sanchez et al., 1996).

Bortels and Collaers (1987) used a Gaussian and one or two exponential functions. In certain cases, a step function had to be subtracted from the spectrum before data processing. In the peak shape model, two random variables (x , y) are considered where x has a normalized Gaussian probability density function $p_x(x)$ with σ resolution:

$$p_x(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{x^2}{2\sigma^2}\right) \quad (5.11)$$

and y has a normalized left-sided exponential with parameter τ

$$p_y(y) = \frac{1}{\tau} \exp\left(\frac{y}{\tau}\right) H(-y) \quad (5.12)$$

where $H(-y)$ is the left-sided unit-step function where $H(x) = 1$ for $-\infty < x < 0$, otherwise $H(x) = 0$.

$$f(u) = A \cdot p_u(u) = \frac{A}{2\tau} \exp\left(\frac{u-\mu}{\tau} + \frac{\sigma^2}{2\tau^2}\right) \operatorname{erfc}\left[\frac{1}{\sqrt{2}}\left(\frac{u}{\sigma} + \frac{\sigma}{\tau}\right)\right] \quad (5.15)$$

This fitting function obtained from a Gaussian and one exponential function can describe the asymmetric peak shape relatively well. It has two shape parameters σ and τ and two parameters characterizing the peak area A and the peak position μ . For a measured spectrum composed of several peaks, the sum of fitting functions $F(u)$ is calculated by addition of the individual $f(u)$ functions.

However, it was found that the fitting function (Eq. 5.15) does not describe well the tailing (especially long tailing). Therefore, instead of one exponential, two or three exponential functions or occasionally two exponentials and a constant were included in the fitting functions. It was found useful first to subtract the constant and then use the following fitting function $F(u)$ that comprises a Gaussian function to describe the peak region and two exponential functions to describe the tailing as convolution of two exponential of steeper and a less steep functions. The explicit form of the fitting function is as follows:

$$F(u) = \sum_{i=1}^m \frac{A_i}{2} \left[\frac{1-\eta}{\tau_1} \exp\left(\frac{u-\mu_i}{\tau_1} + \frac{\sigma^2}{2\tau_1^2}\right) \operatorname{erfc}\left[\frac{1}{\sqrt{2}}\left(\frac{u-\mu_i}{\sigma} + \frac{\sigma}{\tau_1}\right)\right] + \frac{\eta}{\tau_2} \exp\left(\frac{u-\mu_i}{\tau_2} + \frac{\sigma^2}{2\tau_2^2}\right) \operatorname{erfc}\left[\frac{1}{\sqrt{2}}\left(\frac{u-\mu_i}{\sigma} + \frac{\sigma}{\tau_2}\right)\right] \right] \quad (5.16)$$

The random variable $u = x + y$ (the energy variable) is characterized by a joint probability density function $p_u(u)$:

$$p_u(u) = \int_{-\infty}^0 p_y(y) p_x(u-y) dy \quad (5.13)$$

The normalized function after integration is:

$$p_u(u) = \frac{1}{2\tau} \exp\left(\frac{u}{\tau} + \frac{\sigma^2}{2\tau^2}\right) \operatorname{erfc}\left[\frac{1}{\sqrt{2}}\left(\frac{u}{\sigma} + \frac{\sigma}{\tau}\right)\right] \quad (5.14)$$

in which erfc is the complementary error function. Taking into account the actual peak area A that is different from unity and the position of the peak center μ in the Gaussian function, one obtains the expression of the fitting function $f(u)$ for a single alpha peak:

This fitting function, consisting of one Gaussian and two exponential functions, has four shape parameters, i.e., σ , τ_1 , τ_2 , and η , which are the same for all peaks and two parameters, i.e., A_i (peak area) and μ_i (peak position) that are specific for each peak.

The peak fitting model involved in a spectrum analysis software was used successfully for the deconvolution of spectra acquired by HRAS. The method allows even the identification of the strongly overlapping peaks of ^{239}Pu and ^{240}Pu , and it is adequate for the determination of exact emission probabilities of alpha-emitting nuclides. The major drawbacks of the method are the following:

- Relatively high source activities (sometimes 10 Bq) are required even with very long counting times to have acceptable statistics, whereas the energy resolution is

also kept excellent (in alpha spectrometry, the requirement toward high resolution is contradicting the requirements toward high efficiency).

- Many fitting parameters are used, which makes the fitting more accurate, but the numerical optimization becomes more complicated.

Other models to fit the alpha spectra have been developed by Koskelo et al. (1996), García-Toraño (1997, 2003), and Lozano et al. (2000). As an example, the results of deconvolution of the spectrum of ^{239}Pu and ^{240}Pu using the ALPACA code developed at the Spanish institute CIEMAT (García-Toraño, 2006) are shown in Fig. 5.19. The spectrum consists of the five strongly overlapping peaks at energies of 5105 keV (^{239}Pu line), 5124 keV (^{240}Pu line), 5144 keV (^{239}Pu line), 5157 keV (^{239}Pu line), and 5168 keV (^{240}Pu line). These isotopes are known as the ones that cannot be determined by routine alpha spectrometry because the five lines lie within a very narrow energy range of 65 keV. (Routinely used alpha spectrometers require about 200 keV peak-to-peak separation to avoid peak overlapping.) Nonetheless, the determination can be done by HRAS using a spectrum deconvolution software.

Bortels et al. (1995) extended the method for the analysis of **alpha spectra of low statistics**. These sources usually have a finite source thickness and a source diameter of a few centimeters; the detector diameter is increased ($>100\text{ mm}^2$), whereas the source to detector distance is reduced increasing the solid angle—all factors resulting in a reduced energy resolution. It was shown that the fitting functions developed for infinitely thin sources with high resolution ($<10\text{ keV}$) cannot be used directly for sources of lower resolution ($>10\text{ keV}$).

It was shown that in low-statistics alpha spectra, there is insufficient information on the spectrum tailing to use the fitting function in Eq. (5.16); therefore, the simpler model

using a single exponential function (Eq. 5.15) was used for spectrum deconvolution. Furthermore, it was found that the peak deconvolution is successful only if single isotope spectra are used as constraints when spectra of mixed sources are evaluated. In Pu analysis, pure ^{239}Pu standard was used as a single isotope source. The use of statistical weights in the fitting of low-activity samples has been proposed by García-Toraño (1994).

Bortels et al. (1995) fitted triplets or quadruplets in the common region to the nuclide ^{239}Pu and ^{240}Pu depending on the actual resolution. Besides the activities, the activity ratio of $^{239}\text{Pu}/^{240}\text{Pu}$ could be calculated. The deviation from the target value was about 2% when equally large peaks having a separation of about one FWHM are analyzed (Fig. 5.20).

For relatively low statistics alpha spectra from measurements at a relatively high solid angle, $^{239}\text{Pu}/^{240}\text{Pu}$ activity ratios in the range of 1.4 down to 0.1 could be determined in the above example. The $^{239,240}\text{Pu}$ peak should be >100 to obtain reliable values for the $^{239}\text{Pu}/^{240}\text{Pu}$ isotopic ratio (Ihantola et al., 2011b).

In low activity samples, several other functions have been used to describe the low-energy side peak tailing, whereas the peak center and the high-energy side of the peak has been described usually by Gaussian function. Fitting models developed by LaMont et al. (1998), Leon et al. (1996), and Mitchell et al. (1998) are much simpler than the models developed for HRAS.

LaMont et al. (1998) also used a modified Gaussian function to model the tailing (See Fig. 5.21). The Gaussian portion of the peak is fitted by Eq. (5.17) when $x > c - t$:

$$f(x) = h \cdot e^{-\frac{(x-c)^2}{w^2}} \quad (5.17)$$

The modified Gaussian portion of the peak tailing is fitted by Eq. (5.18) when $x < c - t$:

$$f(x) = h \cdot e^{-\frac{t(2x-2c+t)^2}{w^2}} \quad (5.18)$$

FIGURE 5.19 Graphical presentation of a deconvolution of the multiplet containing the alpha peaks of ^{239}Pu and ^{240}Pu by high-resolution alpha spectrometry. Fitting was done by the ALPACA code. Smooth lines represent the fitted peaks and the sum spectrum, whereas the histogram represents the measured points. The goodness of the fit is shown by plotting the residuals in the upper curve. FIGURE 5.20 Fitted spectrum and residuals (relative deviation of measured and fitted values) of a mixed ^{239}Pu and ^{240}Pu source prepared by drop deposition. Peak full width at half maximum is 12.4 keV. Source activity was 17.5 Bq and the activity ratio of $^{239}\text{Pu}/^{240}\text{Pu}$ was 0.67. Spectra were measured with a 300 mm² PIPS detector in a solid angle of about 13% of 4π sr. Quadruplets were used in the fits. (The peaks not labeled in the figure belong to ^{240}Pu .) Bortels et al. (1995), reprinted by permission of Elsevier Ltd. © 1995.

where x is the energy variable at which to compute $f(x)$, h is the peak height, c is the center of the peak, t is the distance

FIGURE 5.21 Alpha peak fitting by a Gaussian and a modified Gaussian function according to LaMont et al. (1998). Reprinted by permission of Springer-Verlag © 1998.

below c where shape deviates from Gaussian, and $w = \text{FWHM} \cdot 0.60056$.

The method was used for the determination of $^{239}\text{Pu}/^{240}\text{Pu}$ activity ratios using a commercially available alpha spectrometer with ULTRA detector of 50 mm² in area. Sources were prepared by electrodeposition. Source–detector distance was 1.8 cm, and the resulting resolution was 16 keV FWHM. Peak heights and centroid energies were constrained. An acceptable agreement was found between calculated ^{239}Pu and ^{240}Pu activities and the target values.

MicroSAMPO, a commercially available software originally developed for gamma spectrometry (Aarnio et al., 1987), was used to fit the alpha peaks of low activity samples by Leon et al. (1996) and Mitchell et al. (1998). The fitting model is a modified Gaussian with left- and right-handed exponential tails. The fitting function does not take into account the long-range tailing, but it still was used successfully for deconvolution of ^{239}Pu and ^{240}Pu , as well as ^{243}Cm and ^{244}Cm peaks. The latter issue is especially important because the relatively short-lived Cm isotopes cannot be analyzed by mass spectrometric techniques. To perform spectrum deconvolution of these nuclides in environmental samples, a relatively good energy resolution is required. In the case of the analysis of Cm nuclides, the FWHM value was 13–15 keV, a PIPS detector of 100 mm² was used, the source to detector distance was 15 mm, and the sources of about 10 mBq activity were counted for an extremely long time (5×10^6 s).

The **WinALPHA code**, which is freely available from the Physics Section of the IAEA (Capote Noy et al., 2004), uses the following analytical model (García-Toraño, 2003). To describe the peak, a pure Gaussian is used above the peak center, and a second Gaussian with a wider resolution (σ) is used below the peak maximum:

$$f(x) = A \cdot e^{-\frac{(x-c)^2}{2\sigma_{l,r}^2}} \quad (5.19)$$

where $f(x)$ is the value for the channel x , A is the peak amplitude, c is the channel number at peak maximum, and $\sigma_{l,r}$ is the resolution on the left or right side of the peak describing the asymmetry.

The low-energy tailing is described by the following equation:

$$f(x) = B \exp \left[-C \left(\frac{x-c}{\sigma_d} \right)^{0.5} \right] \quad (5.20)$$

where B and C are parameters obtained from the shape parameter n as follows:

$$B = A \frac{\exp(-n^2/2)}{\exp(-2n^2)} \quad (5.21)$$

$$C = 2n^{3/2} \quad (5.22)$$

Thus, the set of shape parameters (n , σ_l , σ_r) are constant within one spectrum, and a fitting function containing relatively few parameters has been obtained. The accurate

description of the tailing outside the vicinity of the peak center is not possible.

c. Alpha spectrum analysis software

In the alpha spectrum evaluation process, defined analytical functions containing several shape parameters are fitted to the measured spectrum data. To solve the nonlinear fitting problem, initial parameter values have to be provided, and then optimization procedures are used to solve the nonlinear least squares fitting problem by one of the methods such as the Newton–Raphson, the Levenberg–Marquart, or the simplex method. The goodness of fitting can be characterized by various techniques, e.g., calculating the goodness of fitting (R^2), the chi-square value (χ^2), and/or the fitting residuals. A summary of the mathematical procedures for least squares fitting is given by [García-Toraño et al. \(1999; García-Toraño 2006\)](#).

As a result of fitting, the unknown parameters of the algorithm are determined. Using the fitted function with the known parameters, spectra can be deconvoluted into the individual peaks that contribute to the final measured spectrum. The convoluted spectrum is the simple sum of the individual reconstructed peaks of the given nuclide.

Computerized **spectrum evaluation programs** can be used for the analysis of overlapping peaks of one or more nuclides or also for the analysis of complicated spectra containing several radionuclides. At present, there are several software programs in use, which allow the fitting of alpha spectra with different levels of complexity, from simple peak integration to nonlinear fitting algorithms.

An intercomparison exercise of four commercially available alpha software programs was carried out under the auspices of the IAEA in 1997 ([Blaauw et al., 1999; IAEA TECDOC-1104, 1999; García-Toraño et al., 1999](#)). All of these programs are general-purpose, commercial codes, not dedicated for the analysis of high-resolution alpha spectra. **AlphaVision (EG&G Ortec, USA)** uses a Gaussian function with one low-energy exponential function that is fitted to the peaks with the simplex method. The code can be operated in peak search and fit as well as library search and fit mode. The code is operated in selected regions in peak search mode. The **Alps program (Westmeier GmbH, GE)** is based on the fitting of a Gaussian with one or two folded exponentials with a linear least squares algorithm in three passes. By the alpha analysis software of Genie 2000 (**Canberra Industries Inc., USA**), the line shape model is a modified Gaussian function (see [Eqs. 5.17 and 5.18](#)) and peak areas can be determined either by summation of singlets or by nonlinear least squares fitting of singlets and multiplets using a modified Marquardt algorithm for fast convergence. Peak search is performed using either a library driven routine or by the generalized second differential method. In **Winner Alpha (Eurisy Mesures, FR)**, the peak areas are determined either by summation of singlets or by nonlinear least squares fitting of singlets or multiplets using a modified Marquardt algorithm for fast convergence. Peak search is performed using either a library-driven routine or

by the generalized second differential method. Comparison was done in terms of the determination of peak area, peak position, deconvolution capabilities, uncertainty calculation, nuclide identification in case of large and small peaks, and doublets. All programs had difficulties with the analysis of small peaks. It was clear that the results left room for improvement, e.g., in the uncertainty calculation.

[Hurtado et al. \(2008\)](#) made a comparison of the Genie 2000 and the **WinALPHA programs**. Both are general-purpose codes using a relatively small number of fitting parameters. WinALPHA uses the line shape algorithm described in [Eqs. \(5.19\)–\(5.22\)](#), and it performs a nonlinear fit of the spectra with the Levenberg–Marquardt optimization method. WinALPHA has two modes of operation: library-driven and automatic peak search modes. The basic properties of Genie 2000 are described in the previous section. The programs were compared in terms of accuracy and precision in the analyses of environmental samples. Both programs provide correct peak areas and peak search results. WinALPHA performs a full uncertainty calculation and a better peak deconvolution than Genie 2000. Nonetheless, Genie 2000 Alpha Analysis and Interactive Peak Fitting software packages were also used for the determination of $^{233}\text{U}/^{234}\text{U}$ ratios in groundwater samples ([Harrison et al., 2016](#)).

The WinALPHA program was successfully used for the determination of the $^{240}\text{Pu}/^{239}\text{Pu}$ activity ratio in samples from a reprocessing plant and a heavy water reactor by [Srinivasan et al. \(2005\)](#) and [Aggarwal and Alamelu \(2007\)](#), respectively. Electrodeposited Pu sources were measured with Si detectors of 25 mm² in area by using HRAS. (The FWHM value was 15 keV in the latter case.) Good agreement was found between measured and targeted activity ratios. [Alamelu and Aggarwal \(2012\)](#) used the WinALPHA program for the determination of the isotopic composition of uranium (^{232}U , ^{233}U , ^{234}U) in irradiated thorium in the presence of ^{228}Th .

Examples of other alpha spectrum evaluation programs are ALFAS by [Babelovswsky and Bortels \(1993\)](#), ALPACA by [García-Toraño \(1994\)](#), FITBOR by [Martin Sanchez et al. \(1996\)](#), Sigma-Plot by Jandel Scientific Inc. (1998), Colegram by [Dayras \(2002\)](#), and ALFITeX by [Caro Marroyo et al. \(2013, 2014\)](#). An improved peak shape fitting was attained by applying a convolution of the Gaussian with more exponential tailing functions (up to 10 on the low- and 4 on the high-energy side) in the BEST algorithm ([Pommé and Caro Marroyo, 2015](#)). The method was tested by fitting high-resolution spectra of ^{240}Pu and ^{236}U as well as a thick source of ^{238}U .

While many spectrum unfolding codes have been developed for the analysis of high- and ultrahigh-resolution alpha spectra of thin alpha sources, less attention has been paid to the analysis of thick sources. As discussed above, peak resolution and the peak shape for thick sources are basically determined by self-absorption. **ADAM** (advanced deconvolution of alpha multiplets, [Ihantola et al., 2011](#)) is a general-purpose program for alpha spectrometry using Si detectors. The peak shape model in ADAM is convolution of a Gaussian distribution (characterized by FWHM) with

low-energy side exponential tail. Up to three exponential functions characterized by the slopes of the exponentials $1/\lambda$, $1/\mu$, $1/\nu$ (in keV), and their area ratios R1 and R2 are possible. Up to three different peak shapes are possible, and the software can also take into account the coincidences between alpha particles and electrons or low-energy photons. The AASI computer program (Siiskonen and Pöllänen, 2006) provides coincidence information for ADAM to be included in the fitting. Using the ADAM software, the $^{239}\text{Pu}/^{240}\text{Pu}$ multiplet in chemically processed samples could be successfully deconvoluted. The method gave good results for the $^{239}\text{Pu}/^{240}\text{Pu}$ activity ratio using Si detectors as large as 1200 mm^2 (FWHM 21 keV) (Pöllänen et al., 2011).

Recently, more attention has been paid to the high-energy tailing of peaks, and beside software development, magnet systems have been installed in the spectrometers for the suppression of conversion electrons and their coincidences with alpha particles. By applying HRAS with this technique, the emission probabilities of various alpha particle-emitting radionuclides such as ^{236}U and ^{238}U have been determined with higher accuracy (Marouli et al., 2014; Pomme et al., 2014; Paepen et al., 2014).

2. Peak shape and spectrum analysis with gas ionization detectors

Properties of alpha spectra obtained with gridded ionization chambers are not basically different from the spectra from PIPSi detectors.

Fig. 5.22 shows an example of the asymmetric peak shape with low-energy tailing that is similar to those of the peaks obtained by semiconductor alpha spectrometry. Typical resolutions are somewhat poorer than in the case of PIPSi detectors; the FWHM is not smaller than 30 keV. Spectra obtained with gridded ionization chambers can be evaluated by the same method as for low-resolution alpha spectra using PIPSi detectors.

3. Peak shape and spectrum analysis with liquid scintillation detectors

Peak shapes in LS spectrometry are different from those measured with gas ionization and semiconductor detectors. A typical alpha spectrum of ^{226}Ra and progeny measured with a PERALS spectrometer is shown in Fig. 5.23.

The peaks in the spectrum are symmetric and can be modeled by a Gaussian function. The main reason for the symmetric shape is the lack of absorption and self-absorption in LSC where samples are mixed with the scintillation cocktail. (Absorption and self-absorption are the major reasons for peak broadening and low-energy tailing when “thick” sources are measured with semiconductor detectors.)

LS spectra are characterized by relatively poor resolution even in the case of so-called high-resolution alpha LSC using the PERALS spectrometer. The FWHM is typically a few hundred keV (Fig. 5.24), and the variation of the resolution as a function of energy is more pronounced than in semiconductor alpha spectrometry. This resolution does not allow the detection of the individual alpha lines belonging to many alpha-emitting isotopes. For example, in Fig. 5.23, the alpha radiation of ^{226}Ra at 4.601 and 4.783 MeV appears as a single common peak and cannot be resolved. The Rn and Po isotopes shown in the same spectrum emit monoenergetic alpha particles.

Alpha peaks in LS spectra may also have tailing, but this appears on the high-energy side of the peaks as shown in Fig. 5.24.

This high-energy tailing can be observed in the case of those nuclides that emit several alpha particles of different energies, and the daughter nuclides deexcite to the ground state by internal conversion or the emission of gamma radiation. Internal conversion produces electrons that cause scintillation in the cocktail. Since the scintillation efficiency

FIGURE 5.22 Schematic drawing of an alpha spectrum of a mixed source measured by a gridded ionization chamber.

FIGURE 5.23 Schematic drawing of an alpha spectrum of ^{226}Ra and progeny measured by a PERALS spectrometer.

of electrons is about 10 times higher than that of the alpha particles (Section III.A.5), a sum peak resulting from the true coincidence of the alpha particle and conversion electron will appear at a higher energy than the alpha peak itself. This phenomenon was taken into account to better describe the alpha peak shape in LSC by Aupiais (2004), and the spectra successfully deconvoluted by fitting several Gaussian functions to both the direct alpha peaks and the pileup peaks of alpha particles and conversion electrons as shown in Fig. 5.24. The method was successfully used for the determination of U and Th nuclides in water by alpha LSC.

4. Peak shape with cryogenic detectors

The energy resolution of the alpha spectrum using bolometers is extremely high. Measured FWHM values below 5 keV have been reported (Leblanc et al., 2006). The alpha spectrum of a ^{241}Am source is shown in Fig. 5.25.

The superior resolution of alpha spectra using bolometers compared with that of Si detectors is explained by differences in the nature of the interaction of the alpha particle with the detector. In the case of Si detectors, alpha particles have to pass the detector window (the electric contact), whereas there is no detector window in bolometers. Inside the Si detector, there is a relatively large statistical fluctuation in the number of generated and detected electron–hole pairs due to the presence of impurities, crystal defects that can trap the charge carriers, and possible recombination and secondary processes (e.g., crystal damage, lattice vibration). All of these intrinsic processes as well as the instability of the electronic units contribute to degradation in the energy resolution (see Eq. 5.10). Thermal detectors are less sensitive to the fluctuations in the number of electron–hole pairs because the total energy of the phonons (heat, lattice vibrations) is detected. If electron–hole pairs recombine within the time constant of the bolometer, they will be

FIGURE 5.24 Schematic drawing of high-resolution alpha LSC (PERALS) spectrum of a mixed source showing spectrum deconvolution. The calculated positions of the α peaks, and the pileup peaks originating from the coincidences of the α peaks and the conversion electrons, are also indicated.

FIGURE 5.25 Alpha spectrum of an external sputtered ^{241}Am source measured with the bolometer B306. Data acquisition time was 12 h. The individual peaks at 5443 and 5486 keV are completely separated. *Leblanc et al. (2006), reprinted by permission of Elsevier Ltd. © 2004.*

detected also as phonons. However, as in the case of Si detectors, energy losses due to secondary emission processes cannot be avoided in bolometers.

According to the calculations of *Amoudry (1990)* and *Steinbauer et al. (1994)*, the theoretical contribution of the basic processes of detection to the energy resolution of Si detectors is 10.5 and 7.4 keV, respectively, and *Juillard (1999)* obtained FWHM less than 3 keV for Si and Cu bolometers.

By the development and use of the new types of magnetic microcalorimeters for Q spectrometry, much improved resolution values have been reported. Energy resolutions below 3 keV at the alpha energies of ^{241}Am and Pu isotopes are reported by several research groups (*Pabinger et al., 2011*; *Yoon et al., 2012*; *Hoover et al., 2015*) (See Section A.6.).

B. Counting efficiency

In radiochemical determinations, radioactive tracers are added to the sample, and the activity of the radionuclides present in the sample is determined from the relative number of counts in the analyte and tracer peaks. In this case, a knowledge of the absolute counting efficiency is not necessary to calculate the results (see below). However, it is necessary to determine the chemical recovery, which is an important quality control check. In addition, in cases where the tracer is determined by a separate measurement, the counting efficiency must be known. An example of the latter case is the use of ^{133}Ba as a tracer for Ra determination, where the activity concentration of ^{133}Ba is measured using gamma ray spectrometry.

Since the intrinsic counting efficiency of the Si semiconductor detectors is in practice 100%, the determination of the counting efficiency can be performed by calculating the solid angle presented by the radioactive source to the detector (see Section III.A.2), provided the activity on the source is evenly distributed. A schematic drawing of the source–detector geometrical arrangement is shown in *Fig. 5.26*.

In the case of a point source placed a distance of H in front of an alpha detector of radius R_D , the following equation can be used to calculate the absolute counting efficiency:

$$\epsilon_{\text{abs}} = \frac{1}{2} \left(1 - \frac{H}{\sqrt{H^2 + 4R_D^2}} \right) \quad (5.23)$$

The solid angle (the absolute counting efficiency) of various source–detector arrangements can be calculated by Monte Carlo computations. *Gascon and Munoz (2003)* developed two theoretical formulas to calculate the efficiency of extended sources where R_S is the radius of the source and D is given in *Fig. 5.26*. The simplified geometry formula obtained by an approximation with an infinite series is given below:

$$\epsilon_{\text{abs}} = \frac{1}{2} \left[\frac{R_D^2}{D(D+H)} \right] - \frac{3}{16} \frac{R_S^2 R_D^2 H}{D^5} + \frac{5}{32} \frac{R_S^4 R_D^2 H}{D^9} \left[H^2 - \frac{3}{4} R_D^2 \right] \quad (5.24)$$

FIGURE 5.26 Geometrical arrangement of the alpha source and the detector used for calculation of the counting efficiency according to *Gascon and Munoz (2003)*.

The calculated efficiencies were compared with each other and with experimentally determined values, and a good agreement was found. Therefore, the use of the above simplified formula can be recommended. Efficiencies are often determined by measurements when standard alpha sources of known activity concentration and the same geometry (same size of the active source area, same distance from detector) are available.

Geometrical detection efficiencies are often calculated by Monte Carlo simulations when the sizes of the source and the detector window and the exact geometric arrangement are known. The AASI simulation software available through the Internet (Siiskonen and Pöllänen, 2004) can calculate the efficiency. Calculated efficiencies as a function of source–detector distance, source diameter, and detector diameter are given in Fig. 5.27.

Typical counting efficiencies for a small source ($R_S < R_D$), close (5–10 mm) to a Si detector of 300–600 mm² in area are about 20–40%. The efficiency decreases significantly as the source–detector distance increases.

Calculated efficiencies can be used for a source–detector system if absorption and self-absorption are not high (i.e., not resulting in counting losses) and if radionuclides on the source plate are homogeneously distributed. Counting efficiencies can also be affected (increased/decreased) by backscattering of the alpha particles from the sample holder/detector entrance window.

C. Background and contamination in alpha spectrometry

Semiconductor alpha spectrometers usually have a low background, originating mainly from electronic noise of the instrument. Since alpha pulses have a high energy and electronic noise is usually in the low-energy region, they can be easily discriminated (i.e., separated by pulse height). The typical background of a new spectrometer in the region of a single alpha-emitting isotope can be as low as 1 count per a couple of days (10^{-5} – 10^{-6} cps). This low background is responsible for the extremely high sensitivity of alpha spectrometry. **Detection limits** as low as 1 mBq per sample are easily achievable, provided contamination of the detector, the detection chamber, and the source is avoided.

Contamination of the detector can take place when particles from sources are sputtered or splashed onto the detector or the chamber surface. This can happen when the radionuclides do not adhere strongly to the source support. The vacuum can help remove loosely bound particles from the source. This type of contamination can usually be removed by careful cleaning of the detector (PIPSi detectors are washable) or the chamber walls.

Recoil contamination takes place if recoil causes products of alpha decay to sputter from the source onto the chamber walls or (in the worst case) the surface of the detector. If the recoil atoms or their short-lived progeny are

themselves alpha emitters, this will raise the background. Recoil atoms, like other accelerated or implanted particles, adhere strongly to the surfaces and are almost impossible to remove. For example, when measuring natural Th, the alpha particle–emitting ²²⁴Ra, as the decay/recoil product of ²²⁸Th, can contaminate the detector. Since ²²⁴Ra has several short-lived progeny, they can all accumulate in the detector window creating a background that contains the following alpha peaks: ²²⁴Ra, ²²⁰Rn, ²¹⁶Po, ²¹²Bi, and ²¹²Po. This contamination will “decay” by the half-life of ²²⁴Ra (3.7 days). A typical ²²⁸Th spectrum is shown in Fig. 5.28. After measurement of the Th source, the background spectrum may contain all these radionuclides except ²²⁸Th.

Three techniques have been used to avoid recoil contamination in alpha spectrometry:

- operation of the spectrometer with an air barrier;
- covering the source with a thin even foil (Van der Wijk et al., 1987; Vainblat et al., 2004; Inn et al., 2008); and
- applying a voltage between the source and the detector where the source is negatively biased by a few volts (Sill and Olson, 1970).

The idea behind the first two protective measures is that a properly selected absorber can stop the recoil particles of high mass and low kinetic energy, whereas alpha particles of low mass and high kinetic energy pass through the absorber. An absorber layer of about 12 mg/cm² thickness can reduce the recoil contamination by a factor of 1000. Nonetheless, using any type of absorber between the source and detector will increase energy straggling and reduce the energy resolution. It will also slightly shift the spectrum to a lower energy region. Applying a negative bias to the source can retain the positively charged recoil atoms on the source, although a small chamber pressure (at least 12 μg/cm²) is still required to prevent recoiling atoms from reaching the detector before they are attracted back to the source (Sill and Olson, 1970).

Alpha spectrometers have to be protected from contamination due to **oil vapors** that can be released into the vacuum system if rotary vacuum pumps are applied to evacuate the alpha chamber. Oil contamination is a real danger if the vacuum pump fails, as oil particles can backstream due to the prevailing vacuum. To avoid oil contamination, a vacuum trap or filter can be installed between the pump and the chamber.

D. Stability of the alpha spectrometer

System stability is very important in alpha spectrometry when long measurements of low activity samples lasting for several days are performed (Pommé and Sibbens, 2004).

Long-term stability is affected by environmental conditions with special respect to the detector junction. Surface barrier detectors fail when the encapsulation of the detector

FIGURE 5.27 Counting efficiencies as a function of (A) source–detector distance (H) by assuming point source or extended source of constant diameter and constant detector diameter; (B) detector diameter (Φ_D) by assuming point source or extended source of constant diameter and constant source–detector distance; (C) source diameter (Φ_S) by assuming constant detector diameter and source–detector distance. Efficiencies were calculated by the AASI program according to [Siiskonen and Pöllänen \(2004\)](#) in case of extended sources and according to [Eq. \(5.23\)](#) in case of point sources.

FIGURE 5.28 Alpha spectrum of a ^{228}Th source with ingrown progeny. From *Mietelski (2011)*.

is damaged. The junction of the PIPSi detector is implanted in the Si matrix assuring higher intrinsic stability.

Alpha detectors are sensitive to **temperature changes**. The leakage current of a Si diode doubles for every 5.5–7.5°C change. The current change results in a change of the detector voltage, which can affect the overall gain of the preamplifier and cause a spectrum shift.

V. In situ alpha spectrometry with Si detectors

In alpha spectrometry, the chain of sampling, sample processing, data acquisition, spectrum analysis, and reporting and interpreting the results is usually time-consuming and requires appropriate laboratory infrastructure and expertise. However, in some cases, the performance of rapid measurements, while still retaining a fit-for-purpose quality of the spectra, may be of utmost importance; examples include response to a nuclear incident (*Dilbeck et al., 2006*) and nuclear forensics (*Hoffman et al., 2011*). In general, the equipment and software can be designed in such a way that makes it possible to shorten sample processing and to simplify processes in the data acquisition and spectrum analysis, allowing the performance of measurements outside of a fixed laboratory and even in the field.

There are several independent approaches to simplifying the abovementioned components of the chain:

- Sampling can be developed so that the samples can be measured as such, i.e., without radiochemical or other sample processing.
- Sample processing can be simplified, enabling a rapid start to the measurements.
- Data acquisition can be made in situ (e.g., at ambient air pressure) without substantial deterioration in the energy resolution or loss of the detection efficiency.
- The processes of spectrum analysis and reporting can be developed and automated in a similar way to those used in gamma ray spectrometry.

Each of these approaches has advantages and disadvantages, which are discussed in the following sections.

A. Sampling and simplified sample processing

In an ideal case, it would be advantageous to analyze the samples by alpha spectrometry without sample processing (*Sill, 1995*). Unfortunately, this is only rarely possible because of prominent energy absorption of the alpha particles in the source material. Thin, flat, and homogeneous samples with minimum surface roughness are optimal for quantitative alpha spectrometry, but environmental samples seldom have these characteristics. However, there is a group of samples/objects, such as air filters, wipe samples (swipes), wire screens, sheets of solid material, or other smooth surfaces that can be used as such in the measurements.

Applications of continuous aerosol monitors include environmental monitoring outside nuclear facilities or outside hot cells, to give alarm signals in case of a possible release. The monitors are equipped with filters that are counted by an alpha spectrometer operating at ambient air pressure (*Moore et al., 1993; Monsanglant-Louvet et al., 2012*). Use of an optimized distance between the filter and the detector is important to reduce variation of the alpha particle track length in air and in the filter material. The aim is to minimize the peak tailing and achieve good energy resolution while retaining an acceptable detection efficiency.

Characteristics of the filter are of relevance to the energy resolution and especially peak tailing. The energy resolution achievable with membrane filters is superior to that for glass fiber filters (*Fig. 5.29*). In the case of glass fiber filters, the radioactive aerosol particles may penetrate the filter, causing notable tailing of the alpha peaks. Optimization is also necessary when a filter material is selected, because the flow rate through membrane filters is usually much smaller than that for glass fiber filters. In addition, collection efficiencies as a function of aerosol particle size are different for various types of filter. The procedures of

FIGURE 5.29 Alpha particle energy spectra of indoor air radon progeny collected in a glass fibre (top) and membrane filter (bottom) measured in a vacuum (Pöllänen and Siiskonen, 2005). Counts below 1 MeV are originating from beta particles and, to a lesser extent, photons. Most of the transuranium nuclides (TRUs) that might be present in the source in a hypothetical nuclear incident would locate between 4–6 MeV.

wiping and air filtration can be fine-tuned to facilitate measurements in a vacuum by taking into account the requirements needed, especially in the field or other challenging environments.

There are a number of applications in which nondestructive alpha spectrometry is used to detect alpha particle-emitting radon progeny in air or in soil gas (Goliás et al., 2005). The samples are usually obtained by filtration. Measurement of the activity size distribution of short-lived radon decay progeny is another example for special applications in alpha spectrometry. Porstendörfer (2000) used a multistage impactor equipped with alpha detectors for this purpose. Another approach is to use the diffusion of ultrafine particles from an air stream passing through wire screens; in this case, the alpha detectors either face the screen or a backup filter placed behind the screen (Solomon and Ren, 1992; Solomon, 2001).

Nondestructive alpha spectrometry allows the measurement of alpha spectra without sample processing, which may facilitate subsequent analysis techniques (Fig. 5.30). Sometimes, minor sample processing, such as evaporation of

water from the sample (Semkow et al., 2009; Vesterbacka and Pöllänen, 2011; Parsa et al., 2011; Pöllänen and Klemla, 2016; Pöllänen et al., 2016), is necessary to allow direct measurement of the spectra. However, the energy resolution may be relatively poor due to the thickness of the evaporation residue, as evidenced in Fig. 5.31.

Rapid activity determination can be achieved by use of a simplified radioelement separation procedure, for example, separation of all actinides together from the sample (see Section VI). However, this may pose special challenges in the spectrum unfolding because radionuclides of different elements may be present in the source.

B. Data acquisition

The presence of several alpha particle-emitting radionuclides does not necessarily prevent radionuclide identification in the source. For thin sources producing sharp peaks in the spectra, such as presented in Figs. 5.29 and 5.30, the detection efficiency can be determined by the AASI software, which enables activity determination without tracers

FIGURE 5.30 Unfolded alpha particle energy spectrum (screen snapshot of the ADAM program (Ihantola et al., 2011) measured in a vacuum from a membrane air filter where nuclides of radon progeny are collected. See Pöllänen and Siiskonen (2014), reprinted by permission of Elsevier Ltd. © 2018, for the details of the spectrum analysis.

FIGURE 5.31 Schematic representation of the evaporation of drilled well water under an infrared lamp (left) and respective alpha particle energy spectrum measured in a vacuum from the residue containing radon and its progeny (right, screen snapshot of the ADAM program). Stressed alpha peak tailing and poor energy resolution does not prohibit spectrum unfolding.

in the case of in situ spectrometry (Pöllänen et al., 2011), avoiding the necessity of radiochemical processing of the samples. However, for the case of thick sources, although radionuclide identification is still possible, a tracer would need to be present to enable activity determination.

Portable equipment mounted in a mobile platform exist that allow the performance of alpha spectrometry in the same way as in a fixed laboratory (Smolander and Toivonen, 2004; Hoffman et al., 2011). However, in such a laboratory, only simplified sample processing is usually possible. In an optimal case, the energy resolution may be practically as good as in a fixed laboratory (Fig. 5.30; FWHM for the main alpha peaks is 21–23 keV). Simple portable equipment for field measurements have also been developed (Lidström and Tjärnhage, 2001; Martín Sánchez and de la Torre Pérez, 2012).

The data acquisition can also be performed with fairly good energy resolution at ambient air pressure, i.e., without using a vacuum chamber. Except for the thickness of the dead layer, the detectors operating at normal air pressure are basically similar to those operating in a vacuum. The entrance window is covered by aluminum and varnish layers with thickness of approximately 1.5 μm Si equivalent (Pöllänen et al., 2012a,b). These layers are needed to protect the active volume of the detector against daylight, which may

cause a large number of background counts. In addition, the layers facilitate decontamination of the detector.

The extra thickness of the dead layer causes worsening of the energy resolution, especially at small source–detector distances. This is because the variation of the alpha particle track length in the dead layer is greater at short distances compared with that at large distances. However, when the data acquisition is performed using large source–detector distances, the detection efficiency will be lower and may be unacceptable for low-activity sources. In addition, at large enough distances at ambient air pressure, the energy loss of the alpha particles in air may become too large to detect alpha particles. For example, if the emission energy of the alpha particles is 5.2 MeV (representing ^{239}Pu and ^{240}Pu), the detected energy at the source–detector distance of 3 cm in air is only around 1 MeV, which is in practice too low an energy to be exploited in detecting alpha particles.

When there is air between the detector and the source, the alpha particles entering the detector on the slant do not contain as much useful information as those entering perpendicularly. Alpha particles α_1 and α_2 in Fig. 5.32 (left) lose substantial and different amounts of energy in air causing wide tails in the alpha spectrum. Their presence does not facilitate spectrum analysis. The variation of the energy loss of alpha particles α_3 and α_4 is much smaller, and

FIGURE 5.32 Detection of alpha particle-emitting radionuclides on a surface below a PIPSi detector at ambient air pressure. The alphas will be detected unless their energy is not fully absorbed in air (figure in the left). A honeycomb collimator placed in front of the detector stops those alphas (α_1 and α_2 in the right), which have an entering angle to the detector too acute to reach the detector. PIPSi, passivated ion-implanted planar Si. See Pöllänen et al. (2012a,b), reprinted by permission of Elsevier Ltd. © 2018.

this energy loss only causes a shift of the peak position. This phenomenon can be utilized by using collimation.

Collimation techniques (Park et al., 2015) are widely applied in detecting ionizing radiation, but the question arises how to apply them to alpha spectrometry at ambient air pressure while minimizing loss of detection efficiency. A honeycomb collimator inserted between the source and the detector provides a solution for this problem; the principle of the technique is illustrated in Fig. 5.32 (right). From the efficiency point of view, the cell size of the collimator should not be too small. The smaller the cell size, the better the energy resolution, but the lower the efficiency; the detection efficiency is reduced by a factor of 10 by using a cell size of 3.2 mm, assuming a homogeneous surface contamination (Pöllänen, 2016). Fig. 5.33 shows the improvement in resolution using a honeycomb collimator with a cell diameter of 1.5 mm, demonstrating that it is mainly the alpha particle path length variation in the inactive layers that causes peak widening at small source–detector distances.

A novel equipment was recently developed for alpha spectrometry at ambient air pressure (Pöllänen et al., 2014). The equipment enables alpha spectrometry from smooth and flat sources basically in the same way as for in situ gamma ray spectrometry. Alpha radiation is detected using similar procedures to those used for an alpha counter, but a fixed measurement geometry (including possible alpha particle collimation) is required for radionuclide identification. Because the measured spectra may be extremely complex, sophisticated analysis tools are needed in the activity determination. This may be difficult in the field, but real-time data transmission to a reachback center is included to ensure rapid analysis of the spectra and correct interpretation of the results in a remote location.

C. Spectrum analysis tools

An ideal spectrum unfolding tool should be able to analyze different types of alpha spectra. As shown in Section IV.A, a number of analysis programs have been developed that can be used for radiochemically processed sources, if the resolution is good enough, if the peak shapes can be characterized by an analytical function with appropriate tailing, and if the measurement conditions are stable. These programs may also be used for the spectra obtained by nondestructive alpha spectrometry (see Figs. 5.30 and 5.31). Nevertheless, there are cases for which the presently available spectrum analysis programs are not appropriate. For example, peak shapes in the spectra of Fig. 5.33 deviate from the Gaussian-based shapes, and a good-quality peak fit cannot be obtained.

A method has been developed based on iterative Monte Carlo simulations and subsequent fitting for unfolding of complex alpha spectra. If some characteristics of the source (such as source thickness, particle size, or other relevant properties) are tentatively known, an appropriate alpha peak shape can be obtained by simulations (Pöllänen et al., 2007). This simulated peak shape can be used by a fitting program to perform peak area fitting. The shape simulation with a slightly different input value with subsequent fitting to the measured spectrum is repeated as many times as necessary to obtain acceptable values for the goodness-of-fit indicators (Pöllänen et al., 2009a). An example of the method is presented in Fig. 5.34 in which the peak shapes of the alpha spectrum from particles composed of U are simulated by the AASI program and then fitted by its supplemented version known as AASIFIT.

FIGURE 5.33 Alpha particle energy spectra from a thin radiochemically processed source measured at source–detector distance of 9 mm at ambient air conditions, NTP (normal temperature and pressure, spectra at the top and bottom), and in a vacuum (spectrum in the middle). The PIPSi detector used in the measurements was similar to those used in continuous aerosol monitors, having a thick entrance window. The source contains ^{239}Pu , ^{241}Am , and ^{244}Cm , and the energies are calibrated to the nominal emission energy of the alpha particles. Spectrum at the bottom was obtained by using a honeycomb collimator with the cell diameter of 1.5 mm. PIPSi, passivated ion–implanted planar Si. The relative residual in terms of standard deviations is presented at the top. *Ranebo et al. (2010)*, reprinted by permission of Elsevier Ltd. © 2018.

D. Alpha spectrometry combined with other analysis techniques

Although alpha spectrometry alone is a powerful tool for detecting, identifying, and quantifying alpha particle-emitting radionuclides present in a sample, it can be combined with other analysis methods to get information that is not accessible if the techniques are used independently. In addition to alpha spectrometry, radiochemically processed samples are used for supplementary analysis techniques such as inductively coupled plasma mass spectrometry (Farmer et al., 2003), neutron activation analysis (Montoya et al., 2012), and gamma ray spectrometry (Bem et al., 2002). In combination with X-ray spectrometry, which is an element-based method, it is possible to determine the isotopic ratio of $^{239}\text{Pu}/^{240}\text{Pu}$ even if the resolution in the alpha spectrum is similar to that presented in Fig. 5.35 (Komura et al., 1984; Arnold, 2006). Parus and Raab (1996) used the combined method of gamma spectrometry with a multigroup analysis (MGA) program

(Gunnink et al., 1990) and isotope dilution alpha spectrometry for the determination of plutonium concentration in various nuclear materials.

Alpha spectrometry can also be used in coincidence with gamma ray spectrometry. This technique can be applied, e.g., for checking alpha decay schemes (Martín Sánchez and Caro Marroyo, 2012), analysis of individual radioactive particles (Peräjärvi et al., 2011), or investigations of Rn progeny behavior in filters (Turunen et al., 2011). In connection with event-mode data acquisition (Fig. 5.36), the technique is a powerful tool for determining alpha particle-emitting radionuclides in a sample. Recently, coincidence techniques were also applied for alpha conversion electron measurements (Dion et al., 2016).

VI. Radiochemical processing

To obtain high-energy resolution, “good quality” alpha sources have to be prepared. Prerequisites for good-quality sources are that the deposit be thin and homogeneous with

FIGURE 5.35 Alpha (right) and X-ray (left) spectra from a nuclear bomb particle containing Pu isotopes and ^{241}Am . U L-X-ray peaks following the decay of Pu isotopes are denoted in the X-ray spectrum as well as the 26 and 59 keV gamma rays. In the X-ray spectrum, no gamma ray peaks of Pu isotopes are visible. See Pöllänen et al. (2009b), reprinted by permission of Elsevier Ltd. © 2018) for the details of isotopic ratio calculation.

FIGURE 5.36 Part of the gamma ray spectrum from a nuclear bomb particle gated by alpha particles (Fig. 5.35). Inset: scanning electron microscopy image. *Peräjärvi et al. (2009), reprinted by permission of ACS © 2018.*

a smooth flat surface. Since the range of alpha radiation from the alpha-emitting radionuclides is less than 100 μm in typical condensed phases, the source thickness should be desirably much less than this value. Taking into account that the source diameter should not exceed that of the detector, alpha sources should contain less than 10 mg/cm^2 material or less than 50 mg material on a source of 2.5 cm diameter.

To meet this requirement,

- samples are prepared and pretreated by mechanical and physicochemical operations,
- chemical separations are performed to separate the analyte from the matrix components and any interferences of the sample, and
- thin sources are prepared for alpha spectrometry.

The steps involved in standard radiochemical analysis by alpha spectrometry are shown in Fig. 5.37. The full procedure as shown is time-consuming, and recently some of the individual steps have been combined to accelerate the process. Chemical separation has been combined with source preparation by preparing selective PLFs, and efforts have been made to combine chemical separation with deposition and counting by modifying the detector surface with selective ligand.

Sample **preparation and pretreatment** covers all operations that are performed before the chemical separation of the analyte, e.g., drying, homogenization, sieving, destruction of the sample, and preconcentration of the analyte. A short discussion of the methods is given in Section V.A.

Radiochemical processing includes, beside sample preparation and preconcentration, the **chemical separation** of elements using various separation techniques, the most common being precipitation, coprecipitation, distillation, ion exchange, solvent extraction (also called liquid–liquid

FIGURE 5.37 Steps involved in radiochemical analysis by alpha spectrometry. *Martin and Hancock (2004b), reprinted by permission of Supervising Scientist Division © 2004.*

extraction [LLE]) and extraction chromatography (EC) (also called solid phase extraction), and the source preparation.

In the case of environmental samples, several grams of matrix material are usually removed to obtain thin alpha sources. It is not always necessary to separate all of the alpha-emitting radionuclides from the element to be determined, but there are several nuclide couples whose peaks cannot be resolved by means of standard alpha spectrometry. Examples of well-known **interferences** are the following: ^{238}Pu and ^{241}Am ; ^{237}Np , ^{230}Th , and ^{234}U ; ^{239}Pu and ^{209}Po . If the radioelements such as Pu and Am, or Np,

Th and U, or Pu and Po, respectively, are chemically separated, the interference issue can be overcome and the originally interfering nuclides can be determined in separate alpha sources. If interferences of the radioisotopes of the same element occur, such as in case of ^{239}Pu and ^{240}Pu , or ^{243}Cm and ^{244}Cm , chemical separations will not solve the problem. In some cases, the ingrowth of short-lived alpha-emitting progeny on the source can be used (e.g., in the case of ^{223}Ra and ^{224}Ra). However, in general, HRAS or other analytical techniques such as mass spectrometry or microcalorimetry have to be introduced in such cases.

Whenever chemical separations are performed, losses of the analytes can appear almost unexpectedly in different parts of the procedure. For example, losses may occur during sample destruction due to volatility or sample splashing. They may also occur during separations due to absorption on the walls of the beakers or on the surfaces of undissolved residues: this is because typically trace or ultratrace amounts of the analytes are processed. To process such small amounts, special methods are used to minimize losses and to determine the **chemical recovery** based on the application of radioactive tracers or chemical carriers.

Tracers are those radionuclides that are added to the sample to quantify the chemical recovery. Either they are not present in the sample or the activity added to the sample is much larger than the amount present in the sample. Tracers are assumed to behave in the same way as the radionuclide(s) to be determined. Tracers are typically but not exclusively the isotopes of the same element as the analyte nuclides. The use of yield tracers was described in detail by [Harvey and Lovett \(1984\)](#). A few examples of frequently used tracers are listed in [Table 5.2](#). The best tracers are relatively long-lived alpha-emitting isotopes that emit alpha radiation of different energy from the analyte nuclides.

Carriers are stable elements showing similar chemical properties to the analyte(s). Unfortunately, many of the alpha-emitting nuclides do not have stable isotopes, but sometimes stable elements belonging to the same group of the Periodic Table can be used as carriers. For example, stable Ba is often used as a carrier for Ra. The mass of the stable carrier before and after separation can be determined by various analytical techniques such as gravimetry, atomic absorption spectrometry, optical emission spectrometry, or mass spectrometry (MS).

As the final step of radiochemical processing, **alpha sources are prepared**. The most frequently used techniques are electrodeposition and microcoprecipitation. Occasionally, drop deposition methods (evaporation) are also used with or without the addition of surface-active agent. The first two techniques have been described in detail in the ASTM Standard Practices C1284-10 and C1163-08, respectively. An overview of alpha source preparation methods is given in Section V.C.

Chemical separations are discussed using as examples the most important alpha-emitting radioelements/radionuclides, including artificial (Pu, Np, Am, Cm) and naturally occurring (U, Pa, Th, Ra, Po) radionuclides in environmental radioactivity measurements in Section V.B. Alpha spectrometry is a measurement method routinely used for the determination of radionuclides of these elements.

To reveal the principle of the radiochemical processes, the basic chemical properties of actinides (Th, Pa, U, Np, Pu, Am, Cm) and Po and Ra relevant for the chemical separations are briefly summarized below. Several monographs and review papers have been published about the radiochemical processing of samples to determine Th ([Hyde, 1960](#)), Pa ([Kirby, 1959](#)), U ([Roberts et al. 1986](#)), Np ([Burney and Harbor, 1974](#)), Pu ([Coleman, 1965](#); [Cleveland, 1970](#); [Hoffmann, 2001](#)), Am and Cm ([Penneman and](#)

TABLE 5.2 Frequently used tracers and analytes in alpha spectrometry.

Analytes	Tracers	Decay mode of tracer
$^{239,240}\text{Pu}$, ^{238}Pu	^{242}Pu , ^{236}Pu	Alpha
^{237}Np	^{239}Np	Beta, gamma
^{241}Am , ^{243}Cm , ^{244}Cm , ^{242}Cm	^{243}Am	Alpha
^{238}U , ^{235}U , ^{234}U	^{232}U , ^{233}U	Alpha
^{232}Th , ^{230}Th , ^{228}Th	^{229}Th	Alpha
^{226}Ra , ^{224}Ra , ^{223}Ra , $^{228}\text{Ra}(\text{beta})$	^{225}Ra	Beta (alpha particle—emitting progeny)
^{226}Ra , ^{224}Ra	^{133}Ba	Beta, gamma
^{210}Po	^{208}Po , ^{209}Po	Alpha
^{227}Ac	^{225}Ac	Beta (alpha particle—emitting progeny)

^{243}Am and ^{133}Ba are nonisotopic tracers for the determination of Cm and Ra nuclides.

Keenan, 1960; Warwick et al., 1996), Po (Matthews et al., 2007; Henricsson et al., 2011), and Ra (IAEA, 2010a) using both old and new separation procedures, and good books and book chapters are also available that deal with groups of these radioelements (Bagnall, 1957, 1966; Katz et al., 1986; Wolf, 2006; Nash et al., 2006; Hou and Roos, 2007; Vajda and Kim, 2011; Lehto and Hou, 2011). A list of recently published standards and procedures is given in Table 5.3.

Th, Pa, U, Np, and Pu are the first, second, third, fourth, and fifth members of the actinide group, respectively. In aqueous solutions, they exist in various (+3, +4, +5, and +6) oxidation states with the exception of Th, which has only one stable form in solution, Th(IV). The most stable forms of Pa, U, Np, and Pu are Pa(V), U(VI), Np(V), and Pu(IV). In alkaline solutions, U(VII) and Np(VII) are also stable. Because the standard electrode potentials of the various Pu and Np species in acidic solutions are only

slightly different, the several various forms can coexist in solutions. Since the oxidation states of Pa, U, Np, and Pu can be changed by the addition of oxidizing or reducing agents, the separation processes can be controlled. According to the actinide theory of Choppin et al. (1997), differences among the various oxidation states of a single actinide are greater than those of different actinides in the same oxidation state.

The formation of complex ions in aqueous solutions with inorganic ions or organic compounds is an important feature of the chemistry of the actinides. The relative complex forming tendency of actinide (An) species is the following:

The stability series of the inorganic complexes of tri-, tetra-, and hexavalent actinides are the same:

There are small differences among the stability constants of the different actinides in the same oxidation state.

Oxidation state adjustment and complex forming conditions have been discussed in many papers, and the conditions of oxidation–reduction reactions as well as stability constants of a great number of complexes have been measured. Formation of the given species is influenced by many parameters (composition of the sample, presence of oxidative/reductive agents, amount and stability of the reagents, kinetics of the process, etc.), and it is an especially challenging job if several actinides are present in the same solution.

Since tetravalent actinides have the highest complexing power, the adjustment of this valence state has formed the crucial part of many separation procedures. In many applications, it would be desirable to keep Th, U, Np, and Pu in the tetravalent oxidation state in the same solution, but this is impossible. Thus, oxidation state adjustment is a kind of compromise among various possibilities.

Np(IV) is easily formed by the addition of various reducing agents, e.g., ferrous ions, iodide ions, to hydrochloric or dilute nitric acid solutions. Strong reducing agents generating Fe^{2+} in situ by the reduction of Fe^{3+} , e.g., hydrazine, hydroxylamine, are adequate for the adjustment of Np(IV) and U(IV) oxidation states. These agents reduce Pu to Pu(III). Trivalent Pu can be oxidized back to tetravalent species by various oxidizing agents. To stabilize the Pu(IV) state without further oxidizing it to Pu(V) or Pu(VI), only a few moderately strong oxidizing agents can be used, e.g., NaNO_2 can be added to nitric acid solutions to oxidize Fe^{2+} , and consequently, Pu to Pu(IV) or H_2O_2 can be added to hydrochloric acid solutions, whereas Np still remains tetravalent and U is oxidized back to U(VI). NaNO_2 and H_2O_2 are much less effective if Pu in higher oxidation states has to be reduced to the tetravalent form.

Besides tetravalent species, hexavalent ones can often form strong complexes. Hexavalent states of Pu, Np, and U can be obtained using strong oxidizing agents, e.g., HBrO_3 , KMnO_4 , $\text{K}_2\text{S}_2\text{O}_8$. Redox conditions of actinides have been studied by many authors, and several reviews are also available.

Am and Cm are the sixth and seventh members of the actinide group. In aqueous solutions, Am can exist in the +3, +4, +5, and +6 oxidation states. Although Am(III) can be oxidized theoretically to Am(IV), that form exists only in basic solutions in the presence of strong complexing agents such as phosphates, but the species is unstable and will be reduced back to the trivalent state easily. Although Am can be oxidized in aqueous solutions to penta- and

hexavalent states with a strong oxidizing agent, e.g., Ag catalyzed $\text{K}_2\text{S}_2\text{O}_8$ forming oxo cations Am(VI)O_2^{2+} and Am(V)O_2^+ , the most stable form is the trivalent one (Osváth et al., 2009). Curium has only exclusively trivalent species in aqueous solutions.

The relative complex forming tendency of Am species depending on the charge density is the same as those of other actinides:

The lack of the tetravalent Am and Cm species of the highest complex forming power and the chemical similarity of Am to Cm, as well as to the lanthanides, badly influence the separation possibilities. This is the main reason why Am and Cm chemistry is still the most challenging part of actinide analysis.

The stability series of the inorganic complexes of Am(III) and Cm(III) are the same as those of other actinides:

Thiocyanate (SCN) complexes of Am and Cm do not have high stability, but because of their relatively high separation factors toward lanthanides, they play an important role in Am and Cm purification.

Ra: Within Group 2, Ca, Sr, Ba, and Ra form a series of closely related elements. All are highly electropositive metals existing in the +2 oxidation state in solution. The chemical properties of these elements vary in a reasonably systematic manner down the group. For example, all form insoluble sulfates, with the solubility product following the series $\text{CaSO}_4 > \text{SrSO}_4 > \text{BaSO}_4 > \text{RaSO}_4$. When Ra is coprecipitated with other group 2 sulfates, or with PbSO_4 , the insolubility of RaSO_4 causes Ra to be enriched in the sulfate lattice relative to the primary precipitate cation (Langmuir and Riese, 1985).

The similarity in their chemical properties means that Ca, Sr, and, especially, Ba are very effective carriers for Ra. It also means that separation of Ra from the other group 2 elements is the primary challenge for HRAS of Ra. For samples with a high Ca content, such as bone, separation of Ra from the bulk Ca may present difficulties (Yamamoto et al., 1991). However, for most samples, it is the separation of Ra from Ba, which is the main problem, due to their very similar chemistries.

There are two basic approaches to the difficulty of separation of Ra and Ba. One of these is to separate the group 2 elements from the bulk matrix and then to carry out a final Ra-Ba separation. This can result in a high-resolution source, but it is time-consuming. The alternative approach is to coprecipitate Ra with BaSO_4 following the bulk matrix separation and to filter this precipitate for

use as the alpha source (e.g., Sill, 1987b). The precipitation and filtration steps are relatively fast, and high recoveries can be expected. However, the poorer peak resolution will generally preclude the use of ^{225}Ra as a tracer. It may also preclude the determination of ^{223}Ra and ^{224}Ra , although the use of microprecipitation techniques may allow this (Nour et al., 2004). In addition, the tracer commonly used, ^{133}Ba , is not an isotope of Ra, and so there is the potential for differences in recoveries between tracer and analyte.

Po: The chemistry of the group 6 elements (O, S, Se, Te, and Po) varies in a more or less regular manner down the series. Due to increased atomic radius, electronegativities decrease down the group, and the elements exhibit increasing metallic character. Hence, whereas O, S, and Se are nonmetals and form covalent bonds, Te shows some metallic character and cationic properties, and Po is essentially a metallic element. There is evidence for the formation of -2 , $+2$, $+4$, and $+6$ oxidation states for Po; however, $+4$ is the most stable state in solution (Figgins, 1961).

The S to Po members of group 6 have d orbitals available for use in bonding, and hexacoordinate compounds are most common for Te and Po. Complexes of the form $(\text{PoX}_5)^-$ or $\text{PoX}_5(\text{H}_2\text{O})^-$ are formed in dilute halide solution, whereas $(\text{PoX}_6)^{-2}$ is formed in more concentrated acid solutions ($\text{X} = \text{Cl}, \text{Br}, \text{or I}$) (Bagnall, 1983). In the absence of more strongly complexing organic agents, halide complexes can be extracted into some organic solvents.

One important feature of Po is its volatility. This varies with chemical form (Mabuchi, 1963). Po has been shown to be partly volatilized from some samples above 100°C (Martin and Blanchard, 1969). Polonium halides have been reported to be volatile above 150°C , but this may depend on the conditions, as only minimal losses were reported by Svetlik et al. (2010) at 350°C for deposits dried from HCl solution. Po volatility is important for potential losses during sample preparation, digestion, and chemical separation. It also means that Po can migrate from the alpha source in the counting chamber and contaminate the detector. This latter problem seems to be reduced by a period of exposure to air before counting (Bagnall, 1957, 1966).

Po spontaneously autodeposits onto the surfaces of several metals, including Ag, Cu, and Ni from dilute acid solution. Autodeposition onto metal discs (usually Ag) is the most common source preparation technique for Po due to its simplicity and the fact that it results in separation from other metal ions, including other alpha emitters (Smith and Hamilton, 1984; Matthews et al., 2007). This being the case, the preceding chemical separation techniques required are generally less extensive than for other alpha emitters. Some published methods rely only on autodeposition for separation, and for simpler sample matrices, this may be sufficient. However, the presence of

interfering elements, especially Fe, can result in lowered recoveries and spectral degradation. Consequently, for general applicability, a separation step is recommended (Lin and Wu, 2009).

A. Sample preparation and pretreatment

The objectives of sample preparation and pretreatment are to obtain a solution that

- is homogenous, is free of any insoluble residues that would interfere during the subsequent chemical processing, and could retain the analyte,
- is free of any organic material that could form complexes with the analyte or the reagents resulting in poor recovery,
- is of relatively small volume to achieve significant volume reduction for large-volume liquid samples,
- contains the analyte preconcentrated usually due to semiselective group separation.

1. Preparation of solid samples

For soil, sediment, and minerals, sample preparation and pretreatment usually mean drying in an oven, homogenizing and sieving (optional), and removing organic material by ashing followed by wet chemical destruction.

a. Sample ashing

In the case of actinide determination, samples are usually ashed at $450\text{--}600^\circ\text{C}$ for a couple of hours or days. Elevated temperatures are not desirable because of the formation of refractory particles. In case of volatile elements such as Po, dry ashing should be replaced by wet ashing.

b. Sample dissolution

For sample dissolution, several methods have been used, including acid **leaching** with mineral acids (most frequently with 8 M HNO_3 in the case of actinide determination or aqua regia) and **complete destruction** by a mixture of mineral acids, typically including nitric, hydrochloric, and hydrofluoric acids and hydrogen peroxide. Kenna (2009) studied the leachability of Pu and Np from sediment samples by applying a series of extractants. If hydrofluoric acid is used to volatilize silica as SiF_4 , then boric acid is added afterward to the final solubilization to complex any fluorides. Actinides such as Pa and Th often form very refractory materials, e.g., the complete dissolution of Pa oxides requires hydrofluoric, sulfuric, or oxalic acids. **Wet acid decomposition** can be carried out in open systems such as in Teflon beakers on a hot plate or in closed systems such as in a microwave oven or pressure bombs. The higher the pressure and the temperature, the faster is the chemical reaction.

Significantly higher temperatures than the boiling points of the aqueous systems can be attained by **fusion** with a variety of salts, thus speeding up the destruction process. Several good monographs and papers have been published on sample decomposition methods (Bock, 1979; Sill and Sill, 1995; Chiu et al., 1984; Claisse, 1995), which can be applied to the analysis of actinides. Fusion is a very effective way of rapid and complete sample decomposition. It is the best technique to destroy refractory materials, such as Th, Pa, U, and Ra embedded in soil and sediment particles. Unfortunately, large amounts of salts often together with impurities are transferred to the sample solution, which may create problems in the course of subsequent chemical separations. The other disadvantages of fusion are that usually only relatively small samples can be treated and that it is inappropriate for Po determinations due to the large losses that occur at the high fusion temperatures. NaOH, Li borate, and mixed carbonate–borate have been used for fusion in actinide chemistry. Sill et al. (1979) and Sill (1980) proposed a very efficient potassium fluoride/pyrosulfate fusion to treat refractory material. Maxwell and coworkers proposed NaOH as a cheap and efficient chemical for fusion of a variety of samples (up to 100 g soil, 1 g concrete or asphalt, 5 kg rice) for the rapid determination of actinides (Maxwell, 2008; Maxwell et al., 2011c, 2013, 2014). They usually used coprecipitation with hydroxide, phosphates, and fluorides to remove the excess NaOH and the interfering elements.

Several standards on sample decomposition are available. Standard ASTM C1342-96 deals with fusion decomposition of solid materials, standard ASTM D1971-95 describes hotplate and convection oven digestion of water and solid samples with nitric and hydrochloric acids, standard ASTM D4309-91 refers to microwave digestion with hydrochloric and nitric acids for the determination of metals and groundwater, and the U.S. EPA Method 3052 (1996) discusses microwave-heated, closed-vessel decomposition of ashes, biological tissues, oils, oil-contaminated soils, sediments, sludges, and soils.

In the case of biological samples, complete destruction is preferred and carried out usually by the combination of dry and wet chemical ashing. Because of the lack of silicates and refractory components, the use of HF can be omitted. Microwave digestion is a preferred way of decomposition of smaller samples. An efficient way of decomposition of organic materials is the Fenton's reaction using hydrogen peroxide and Fe^{2+} catalyst.

2. Preconcentration of liquid samples and sample solutions

a. Preconcentration of actinides

Preconcentration of actinides by coprecipitation is a frequently used method for large volumes of water samples

as well as for sample solutions obtained after destruction of solid samples. A well-selected coprecipitant concentrates the analyte in a small volume, removes most of the cationic and anionic interferences, and helps increase the decontamination factor (DF) for the whole radiochemical procedure.

Bismuth phosphate (BiPO_4) was the first precipitate applied in large-scale processing of Pu; as BiPO_4 carries Pu(III) and Pu(IV), it was used to separate Pu from U and fission products in both technology and analyses (Kimura, 1990). The coprecipitation of Am with BiPO_4 was studied by Mathew et al. (1981), who found that below 0.3 M acid concentration, Am is carried with the precipitate.

The most frequently used carriers of actinides are the following: ferric and ferrous hydroxides, lanthanide fluorides and hydroxides, alkaline earth oxalates, phosphates and fluorides, some other phosphates and oxalates, barium sulfate, and manganese dioxide. The coprecipitation behavior of actinides is discussed in detail in the compilation of Katz et al. (1986).

Hydroxide precipitates, e.g., ferrous and ferric hydroxides, lanthanide hydroxides, and calcium phosphate and calcium/magnesium carbonates, are formed in neutral or basic solutions. Hydroxide, phosphate and carbonate precipitates are usually easily dissolved with acids. Ferric hydroxide is known to coprecipitate actinides in all oxidation states, but sometimes recoveries are low, which is why ferrous hydroxide as a reducing agent is preferred. Coprecipitations taking place in acidic media (e.g., fluorides) are usually more selective than those formed in basic solutions (e.g., hydroxides).

Calcium fluoride and especially lanthanide fluorides of low solubility form precipitates in 4–5 M HF solution. Fluoride precipitates can be dissolved as borate complexes and carry only tri- and tetravalent actinides. The separation of actinides by coprecipitations usually takes advantage of the oxidation and reduction cycles.

Barium sulfate carries only tri- and tetravalent actinides. It can be dissolved either with EDTA or with HClO_4 . The use of EDTA is beneficial if samples have Ca, Mg, and Al content that forms strong complexes and can be separated from actinides during a succeeding lanthanide hydroxide precipitation. Sill and Willis (1966) developed a method for the separation of Np from Ce, Ba, and La based on its coprecipitation with barium sulfate under strict oxidation state control. The oxidation state of Np is adjusted with H_2O_2 to Np(IV), which is coprecipitated with barium sulfate from a sulfuric acid solution containing potassium sulfate. Then, Np is oxidized with chromic acid to Np(VI) and separated from fission products that cannot be oxidized and form precipitate with a next barium sulfate. The Np alpha source is also prepared by coprecipitation with microcrystals of barium sulfate. Sill and Willis (1966) adopted this method for the simultaneous determination of Np, Pu, and U based on a series of barium

sulfate coprecipitations. Coprecipitation of Th with BaSO₄ may be enhanced by the addition of K⁺ to the solution (Burk and Wiles, 1983) or alternatively prevented by use of a La³⁺ holdback carrier (deJong and Wiles, 1984).

Moore (1963) developed a procedure that was later improved by Sill (1984) for the simple separation of Am from many elements, including actinides and lanthanides. Americium was oxidized to its hexavalent state with ammonium peroxydisulfate in a dilute nitric acid solution. The nonoxidizable lanthanides and actinides were then precipitated as fluorides and filtered off. The Am was then reduced and coprecipitated with LaF₃. In the improved method of Sill, the nonoxidized rare earths were coprecipitated with BaSO₄ or NdF₃ whereas oxidized Am(VI) was kept in solution. After reduction with H₂O₂, Am(III) was coprecipitated with a small amount of NdF₃ allowing direct detection of the alpha source (discussed subsequently in source preparation). By this method, Am can be separated also from the nonoxidized Cm isotopes.

MnO₂ precipitated from KMnO₄ and MnCl₂ at pH 8–9 is used for the preconcentration of Am, Pu, and Np from seawater samples at the IAEA's Marine Environmental Laboratory (LaRosa et al., 2005). MnO₂ is dissolved with HNO₃-H₂O₂. Protactinium can be coprecipitated with MnO₂ from siliceous cake after fusion (Dalvi and Verma, 2017).

The pH dependence of the precipitation of metal oxalates was studied by Yamato (1982), who found that calcium oxalate formed at pH ≥ 1.5 carries Am almost quantitatively. Oxalate precipitates are easily decomposed by ashing or wet chemical oxidation.

The following precipitates have been recently used to preconcentrate actinides from various samples: ferric hydroxide, ferrous hydroxide, calcium oxalate, ferric hydroxide and calcium oxalate, calcium phosphate, calcium fluoride, lanthanum fluoride, manganese dioxide, manganese dioxide, and ferric hydroxide. For the concentration of actinides from a large volume of water or solutions of biological origin, special EC materials of extremely high distribution coefficients have also been developed and applied, e.g., TEVA, TRU, DIPHONIX, and DIPEX resins (see in detail in the next section). Smith et al. (1998) developed a method for the preconcentration of Am and Pu from waste waters using a synthetic water-soluble metal-binding, i.e., phosphonic acid polymer that was removed from the waste by ultrafiltration. Chemical yields over 90% have been achieved.

b. Preconcentration of Po and Ra

Coprecipitation with iron hydroxide (Narita et al., 1989; Jia et al., 2001; Zikovsky, 2002) or MnO₂ (Carvalho, 1997; Peck and Smith, 2000; Martin and Hancock, 2004b; Bojanowski et al., 2005) have commonly been used for the preconcentration of Po and Ra, particularly from bulk water samples. Coprecipitation with Ca₃(PO₄)₂ has also been

used for Ra and Pb (Nonova et al., 2009). Coprecipitation with MnO₂ is very commonly used for processing seawater and other saline waters (e.g., Towler et al., 1996; Grabowski and Bem, 2010). Direct adsorption from water samples of Ra onto MnO₂-coated discs for alpha spectrometry has also been used (Eikenberg et al., 2004).

Iron tends to interfere with subsequent chemical separation and autodeposition of Po. Consequently, for Po determinations following coprecipitation with iron hydroxide, an Fe removal step, such as solvent extraction with diisopropyl ether, may be required.

Coprecipitation with PbSO₄ is commonly used for the preconcentration of Ra and separation from the bulk matrix (Sill, 1987b; Kehagia et al., 2007). Radioisotopes of Pb and Ra have also been coprecipitated with Pb(NO₃)₂, with U and Th remaining in solution (Lozano et al., 2010).

Coprecipitation with BaSO₄ is also commonly used for preconcentration and separation of Ra, often as an extra step after coprecipitation with PbSO₄. Yamamoto et al. (1989) used coprecipitation with barium chromate and performed a subsequent Ra/Ba separation. Commercial salts of Ba may contain traces of Ra, and so the reagent used should be pretested, and the amount used minimized. Use of a Ba salt coprecipitation usually means that a Ra/Ba separation will not be carried out, although it may be possible to do so if only small amounts of Ba are present. Alternatively, LS spectrometry may be performed.

For Po preconcentration, coprecipitation with cobalt–ammonium pyrrolidine dithiocarbamate (Co-APDC) chelate has been used (Gascó et al., 2002; Wildgust et al., 1998). Po(IV) also coprecipitates with BiPO₄ at low pH (Hölgye, 2007).

B. Chemical separation

Actinides are amenable to a variety of chemical separation procedures, including precipitation/coprecipitation (see above), LLE, ion exchange chromatography, EC, and the combination of two or more of these methods.

1. Separations by liquid–liquid extraction

Three types of extractants can be distinguished:

- i) neutral extractants that form neutral (ion association) complexes with the actinide ions involving the counterions, very often nitrates or chlorides and the organic molecule forming chemical bonding via electron donor atoms of the organic molecules (oxygen, phosphoryloxygen, sulfur, nitrogen),
- ii) amine extractants where positively charged organic amines form complexes with anions via Coulomb forces, and anions in the complexes can be replaced by anionic actinide complexes in a manner analogous to anion exchange; amine extractants are long-chain

alkyl or aryl quaternary amines or primary, secondary, and tertiary amines that form organic cations with acidic hydrogen,

- iii) acidic extractants that form chelate complexes with the actinide cations replacing the H^+ in the organic compound.

Groups (i) and (ii) can be regarded together simply as ion association complexes. Ion association complexes have the advantage of being applied in acidic media. In general, distribution coefficients are increased when acid concentration increases. On the contrary, chelates are used in media of low acidity because H^+ ions are competitors of the cations for the binding sites.

a. Chemical separation of actinides by liquid-liquid extraction

Many of the LLE procedures for actinides have been developed for the large-scale separation of U and Pu for the nuclear industry. Procedures for the separation of minor actinides (Np, Am, Cm) are under investigation. Solvent extraction offers usually moderate selectivity, but the extraction efficiency can be increased by performing the process in a continuous technological system.

Traditional extractants. Originally, the LLE of Pu and U was accomplished with a wide range of *organic acids, ketones, esters, alcohols, and ether*; the most well-known being **tributyl phosphate** (TBP) used in the PUREX process. Both Pu and U nitrate complexes have acceptable high (but still relatively low) distribution coefficients for technological purposes. Neptunium follows Pu in the extraction processes whenever the oxidation states are the same, but adjustment often fails. The nitrate complexes are even less retained by TBP (Nash et al., 2006).

Methyl-*i*-butyl ketone (MIBK) and TBP were used for analytical purposes for the determination of Pu in the 1950s and 1960s. At present, TBP is used in a mixture with carbamoylmethyl-phosphine oxide (CMPO) for EC (discussed subsequently).

While tetra- and hexavalent actinides are readily extracted by organic acids, ketones, esters, alcohols, and ethers, neither of these organic compounds nor tributyl phosphate can extract the trivalent Am. Trivalent Am^{3+} cations do not form stable ion association complexes with simple monofunctional organic compounds; they can be complexed with bifunctional compounds and do not have the affinity to form anions, but they can be extracted/retained by chelates.

Chelate extractants. Among the ketones, **tenoyl-trifluor acetone** (TTA) has quite significant analytical applications. It is a diketone with a sulfur-containing aromatic ring and a fluorine-substituted methyl group that exists mainly in enol form, thus acting as a chelate. TTA has been used for analytical purposes to separate Pu from various

samples in the past and recently for the separation and purification of Pu in combination with anion exchangers from marine sediment samples, and extremely high DFs were achieved while Pu recovery was 56% (Donard et al., 2007).

TTA proved to be one of the most selective reagents for the separation of Np(IV) when Pu is kept in the trivalent Pu(III) oxidation state. TTA was used as early as 1947 by Magnusson (Coleman, 1965). Neptunium was reduced and then retained from 1 M HNO_3 or HCl on about 0.5M TTA in xylene, and finally stripped with 8–10 M HNO_3 . TTA has also been used for speciation studies where “TTA extractable” species are regarded as tetravalent ones (Wolf, 2006).

The trivalent Am and Cm cations can form stable chelates with TTA but only at relatively high pH. Sekine et al. (1987) used 0.5 M TTA in xylene to purify Am from a solution at $pH \geq 4$.

1-Phenyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP) is an N-containing ketone that also forms chelates in the enol form and has gained application in Am separations. It extracts several elements from more acidic media than TTA. Distribution coefficients for Am and the separation factor of lanthanides are slightly higher than in TTA. Jia et al. (1997) extracted Am from a 0.1 M HNO_3 solution into a mixture of 0.05 M PMBP and 0.025 M trioctylphosphine oxide (TOPO) in cyclohexane. Americium was backextracted with 5 M HNO_3 . Jia et al. (1998) used PMBP/TOPO extraction to purify Am before preparation of alpha sources. Am was extracted from a DTPA/lactic acid solution directly into 0.05 M PMBP + 0.025 M TOPO in cyclohexane. Extraction maximum (about 90%) was in the pH range 1–2.

Bis-2-ethylhexyl-phosphoric acid (HDEHP) as a chelate shows selectivity for cations of higher charges against those of lower charges; thus, HDEHP is a frequently used extractant in Am and Cm separations and is a good choice for the separation of tetravalent actinides.

The distribution coefficients (D) for Am in HDEHP solution strongly depend on the acidity of the aqueous phase, e.g., $\lg(D) = 1$ for Am extraction by 0.5 M HDEHP in *i*-octane if the HNO_3 concentration is 0.1 and $\lg(D) = 4$ in 0.01 M HNO_3 solution (Myasoedov et al., 1974). The separation of trivalent actinides from lanthanides is only possible if strong complexants, e.g., lactic acid, DTPA, are added to the aqueous phase. HDEHP has been used for the separation of Am together with Cm and the lanthanides. It was observed that Fe severely interferes with the extraction. Bernabee et al. (1980) extracted Am from 72% $HClO_4$ solution into 15% HDEHP in *n*-heptane. Americium was backextracted with 4 M HNO_3 . Holm et al. (1979) extracted Am from 0.01 to 0.001 M HNO_3 and backextracted it with 4 M HCl.

In the standard test method ASTM C 1205-07 for “The Radiochemical Determination of Americium-241 in Soil by Alpha Spectrometry,” ^{241}Am is determined in soil samples up to 10 g. The soil is completely dissolved by the use of pyrosulfate fusion. After the initial separation on barium

sulfate, Am together with other actinides and lanthanides is extracted from concentrated HClO_4 solution with 15% HDEHP in n-heptane and backextracted with 5 M HNO_3 . Americium is separated from other trivalent actinides and lanthanides by oxidation of Am and precipitation of the interferences with LaF_3 . The standard test method is based on the procedure developed by Sill and Willis (1966).

In the procedure of Jia et al. (1998), Am was extracted from 0.1 M HNO_3 on a supported KF-HDEHP column, followed by its stripping with 6 M HNO_3 . Am was separated from lanthanides on a second KF-HDEHP column using 0.07 M DTPA—1 M lactic acid solution. The average chemical yield for the whole procedure, including Pu and Sr removal and purification of the Am fraction with PMBP/TOPO extraction (see above), was 58%.

Ramebäck and Skillberg (1998) extracted Pu and Np after oxidation with bromate as Pu(IV), Pu(VI), and Np(VI) together with U, Am, and Cm from 0.1 M HNO_3 solution using HDEHP and then stripped Am and Cm with 5 M HNO_3 , followed by the backextraction of Np with 1 M HNO_3 /hydroxyl amine and Pu(III) with 3 M HCl/TiCl_3 . Chemical recoveries for Pu, Np, and Am were high, 91%, 82%, and 97%, respectively.

In the recently issued standard test method ASTM D6239-09, uranium is separated from drinking water with an extractive scintillator that contains HDEHP as extractant. Uranium is extracted from a 0.01 M DTPA solution at pH 2.5 and 3.0, whereas extraction of undesired ions is masked by forming strong DTPA complexes. Uranium isotopes are determined by high-resolution alpha liquid scintillation spectrometry.

Ion association complexes. Later attention of scientists was turned to other *organo phosphorous compounds* than phosphates, including phosphonates, phosphinates, and phosphine oxides, which showed higher selectivities for many actinides from acidic media. Beside TBP, TOPO is the most well-known representative of the neutral organophosphorous compounds. Pimpl and Higgy (2000), Ayr-anov et al. (2005), Lujanienė and Sapolaite (2005) used TOPO as solvent extractant for preconcentration of Pu and Am from acidic leach solutions. By reducing the acidity, TOPO can also extract trivalent actinides. Pu together with Th, U was extracted from 4–6 M HNO_3 to TOPO in cyclohexane. Then, the acidity was reduced, the pH of the solution was adjusted to 1, and Am was also extracted with TOPO and backextracted with 2 M HNO_3 . Kalmykov et al. (2004) extracted Pu and Np together from 5 M HCl with TOPO and selectively backextracted Pu as Pu(III) with 1 M HCl and ascorbic acid. Np(IV) remaining in the organic phase was irradiated after evaporation to determine ^{237}Np by neutron activation analysis.

Dibutyl-N,N-diethylcarbamyolphosphonate (DDCP) as a bifunctional organophosphorous compound is one of the first representatives of a new group of extractants,

which was applied in acidic solutions. DDCP has been used to extract Am (and Cm) from 12 M HNO_3 by Ballestra and Fukai (1983). Lanthanides followed Am in the procedure. Americium was backextracted into 2 M HNO_3 . Significant improvement was recorded in the Am recovery (69–79%) for the overall procedure, including coprecipitations, anion exchange separations, and source preparation compared with the procedure using HDEHP. DDCP extraction became the basis of the method for Am determination in seawater at the IAEA's Marine Environmental Laboratory (IAEA, 1989). Actinides were preconcentrated by coprecipitation with MnO_2 and ferric hydroxide; Pu, Np, and Th were separated by anion exchange chromatography; Am was coprecipitated with Ca oxalate and passed through an anion and a cation exchanger. Americium was extracted with DDCP. Finally, Am-lanthanide separation was performed on an anion exchange resin column. Later, DDCP was replaced by a new and more effective bifunctional organophosphorous extractant, the CMPO.

CMPO is **octyl(phenyl)-N,N-di-i-butylcarbamoylethylphosphine oxide**, a neutral organophosphorous extractant used in conjunction with t-butyl phosphate as a process solvent (Horwitz et al. 1986). The CMPO/TBP extractant was used in the TRUEX (TRAnsUranium EXtraction) process for the separation of tri-, tetra-, and hexavalent actinides from nitric acid solution, i.e., from the high-level waste (HLW) produced in the PUREX process. The attractive feature of the process is that it allows for the extraction of Am and its separation from tetra- and hexavalent actinides by using different strip solutions. The pitfall of the procedure is that Am is not separated from Cm and lanthanides. The distribution ratios of tri-, tetra-, and hexavalent actinides and nonactinide elements, the mechanism of extraction, were determined in nitric and hydrochloric acids by Horwitz et al. (1987). In the analytical practice, the EC version of the CMPO/TBP extractant called TRU resin has had widespread use (discussed below in the paragraph on Extraction Chromatography).

The higher oxidation states of Am (preferably the complex forming hexavalent state) are not stable in the presence of organic materials.

Amine extractants. Tertiary amines act as strong base anion exchangers and strongly retain the nitrate or chloride complexes of tetravalent Pu and Np, e.g., $[\text{Pu}(\text{NO}_3)_6]^{2-}$, $[\text{Pu}(\text{Cl})_6]^{2-}$ formed in concentrated acidic solutions. **Tri-octyl amine** (TOA) is the most frequently used liquid amine extractant. **Alamine 336** also called tricapryl amine is a mixture of n-octyl and n-decyl amines. **Aliquat 336** is a quaternary ammonium salt that contains a mixture of methyl, n-octyl, and n-decyl ammonium salts. The use of amine extractants for Pu analysis has a long tradition, and TOA still has a widespread analytical application, especially as supported liquid extractant (see later under Extraction Chromatography). Jia et al. (1998) separated Pu

as Pu(IV) from the leachate of soil samples by extraction with TOA and achieved a Pu recovery of 85%. In the experiment, TOA was fixed to microthene particles. Sill and Willis (1966) used Aliquat 336 to extract Np(IV) from environmental samples. Vance et al. (1998) used amine extraction from 0.25 M H₂SO₄ to separate U from Np. Neptunium was not extracted and could be detected directly from the aqueous phase using ICP-MS.

Chen et al. (2001a) developed a method for the determination of ²³⁷Np in soil and sediment samples up to 10 g and seawater up to 100 L using both alpha spectrometry and ICP-MS. Neptunium separation consists of a pre-concentration with mixed Fe oxides precipitated in the presence of K₂S₂O₅ reducing agent, extraction with TOA from 8–10 M HCl, repeated coprecipitation with Fe(OH)₂, and purification of Np(IV) by anion exchange from 8 M HNO₃. An overall recovery of 74%–93% was achieved while DFs for U, Th, and Pu were also high (>10⁴). The method was extended for the simultaneous determination of ^{239,240}Pu, ²⁴¹Am, ²³⁷Np, ²³⁴U, ²³⁸U, ²²⁸Th, ²³⁰Th, ²³²Th, ⁹⁹Tc, and ²¹⁰Pb–²¹⁰Po in environmental materials (Chen et al., 2001b). Aliquat 336 was used for the separation of Pa from HCl/HF mixtures by Dinkar et al. (2017). Protactinium was stripped by a mixture of HNO₃/HF.

Alcohol extractant. The extraction of actinides Th, Pa, U, Np, and Am by aliphatic alcohols was investigated by Knight et al. (2016). The selective extraction of Pa from HCl and HNO₃ by 1-octanol was demonstrated.

Trivalent actinides are not well retained by any of the amine extractants from acidic solutions. Amine extractants as well as anion exchangers have found an application in the field of americium chemistry; they have been used for the separation of trivalent actinides from lanthanides.

Separation of Am from lanthanides. For the separation of trivalent actinides from lanthanides, new extraction systems containing a soft donor atom (N, S, Cl) have been proposed based on the experience that actinides form slightly stronger complexes with ligands containing soft donor atoms than lanthanides. The soft donor atom may be present as free ion (SCN[−] or Cl[−]) or in a water-soluble complexant or in a lipophilic organic extractant. This idea formed the basis for the separations from the early 1940s. Solvent extraction, ion exchange, and EC techniques fit prominently in these processes.

The extractability of tervalent actinides is increased by adding special complexants or high amounts of salts to the aqueous phase. In HLW technology, i.e., in the TAL-SPEAK (Actinide-Lanthanide Separation by Phosphorous reagent Extraction from Aqueous Komplexes) process, DTPA containing the soft donor N atom and lactic acid were added to the aqueous solution to form stronger complexes with Am than with lanthanides, thus allowing their separation using HDEHP (see above). The procedure of Jia et al. (1998) is based on the same principle.

SCN[−] complexant containing the soft donor S and N atoms can help increase the separation factor between Am, Cm, and lanthanides. Moore (1964) first applied quaternary amines to lanthanide/actinide group separations examining the system Aliquat 336/xylene/H₂SO₄-NH₄SCN.

Quaternary amines (0.6 M Alamine 336 in diethylbenzene) are used to selectively extract Am from 11 M LiCl in 0.2 M HCl solution, whereas lanthanides remain in the raffinate. The actinides are subsequently backextracted with 5 M HCl. The separation factor between Am and Eu was 108 (Nash et al., 2006).

Research into the development of new extraction systems to achieve better extractability of Am and higher separation factors for americium–lanthanide separations has been continued.

Comparative evaluation of traditional extractants in LLEs. Acid dependence of the distribution coefficients for all elements, including actinides, were determined by many researchers, and data were compiled in the form of periodic tables. An example of such a data collection was published as the Table of Chromatographers (Lederer, 1992). Among the extractants discussed above, the distribution coefficients (*D*) for tetravalent actinides such as Pu(IV) are increasing in the following order: TBP/7 M HNO₃ < TTA/0.5 M HNO₃ < TOPO/1 M HNO₃ < TOA/4 M HNO₃ < HDEHP/1 M HNO₃ starting from ~20 for the TBP and ending at ~2000 for the HDEHP system (Myasoedov et al., 1974). The retention sequence of the various extractants is the same for other tetravalent species such as Np(IV) and Th. Bigger differences in *D* values exist for different oxidation states. The distribution coefficients (*D*) for trivalent actinides (Am and Cm) are increasing in the following order: TTA/pH ≥ 4 < PMBP/0.1 M HNO₃ < TOPO/0.1 M HNO₃ < HDEHP/0.1 M HNO₃ < DDCEP/12 M HNO₃ < CMPO-TBP/2M HNO₃ starting from ~1 for the TTA and ending at ~100 for the CMPO system (Myasoedov et al., 1974). For the hexavalent U(VI) species, the following order of *D* has been reported: TTA/1 M HNO₃ < TBP/4M HNO₃ < TOA/4 M HNO₃ < HDEHP/8 M HNO₃ < TOPO/1 M HNO₃ with the highest value of 800 in the latter case (Myasoedov et al., 1974). In the case of ion association complexes, *D* values can be increased by the addition of salting-out agents.

Although in many analytical applications, LLE has been replaced by more efficient chromatographic techniques. Solvent extraction is most appropriately applied to measurements by LS. Extractive scintillators containing solvent extractants discussed above and scintillation cocktails have been developed for the PERALS alpha LS spectrometers (Ensor, 1998; PERALS homepage). In the ETRAC procedure, Pu is extracted by a high-molecular-weight tertiary amine converted to nitrate form. The ALPHAEX system based on HDEHP extractant can be applied for the separation of Am. Uranium can also be extracted with HDEHP

containing extractive scintillator (see above). [Dazhu et al. \(1991\)](#) used the extractive scintillator containing TOPO extractant in PPO—naphthalene—toluene scintillator cocktail for the rapid determination of U, Pu, Am, and Cm in the nuclear fuel cycle and in environmental samples. A detailed list of extractive scintillators is found in Chapter 6, Volume 1 of this book.

New extractants. New extractants of high distribution coefficient for trivalent actinides and lanthanides ([Nash et al., 2006](#)) are under extensive investigation for the purposes of HLW treatment. **Malonamides** are the non-phosphorous-containing alternatives of CMPO. In the DIAMEX (DIAMide EXtraction) process, dimethyldibutyltetradecylmalonamide (DMDBTDMA) is used for the extraction of Am, Cm, and lanthanides from HLW solutions. In the modified DIAMEX process, a new malonamide, i.e., dimethyldioctylhexylethoxy-malonamide (DMDOHEMA) was used. **Diglycolamides**, i.e., N,N,N',N'-tetradecyl-3-oxapentanediamide (TODGA) and N,N,N',N'-tetradecyl-3-oxapentanediamide (TDDGA), were found to have extremely high distribution coefficients for Am nitrate complexes from concentrated nitric acid solutions. TODGA has also been successfully used for the separation of trivalent actinides and lanthanides from HLW process solutions.

For the selective extraction of trivalent actinides from lanthanides, N-donor and S-donor extractants have been developed. With the N-donor molecule bis(5,6-dialkyl-1,2,4-triazine-3-yl)pyridine (**BTP derivative**), high Am/Eu separation factor (>100) from concentrated HNO_3 solution was achieved. The SANEX (Selective ActiNide EXtraction) process is based on the selective separation of trivalent actinides from lanthanides using BTP derivatives. Research into the development of other BTP derivatives and modified SANEX processes is in progress. In the GANEX (Group ActiNide Extraction) process, the majority of U is separated first with a monoamide extractant, and then minor actinides are extracted together by a combined DIAMEX-SANEX process.

The most well-known S-donor compound is bis-(2,4,4-trimethyl)pentylidithiophosphinic acid, also called **Cyanex 301**. [Zhu et al. \(1996\)](#) received a separation factor for the extraction of Am(III)/Eu(III) from HNO_3 solution over 5000. The technological application of Cyanex 301 is in progress.

At present, these extractants exhibit the greatest affinity for trivalent actinides. Crown ethers and calixarene compounds are also under investigation.

Methods have been developed for the separation of Am from Cm for partitioning of radioactive wastes. This is the most difficult separation within spent fuel reprocessing because of the high similarity of the two elements. Theoretically, Am can be oxidized to Am(VI), whereas Cm remains tervalent, and then they could be easily separated,

but in practice Am(VI) is very unstable. The Am/Cm separation factor in the DIAMEX process using DMDOHEMA is small (1.6) for effective separation. The highest separation factor for Am/Cm (6–10) has been achieved with a dithiophosphinic acid (bis(chlorophenyl)dithiophosphinic acid), and the separation was in the LUCA (Lanthaniden Und Curium Americium Trennung) process successfully tested at the Forschungszentrum Jülich ([Modolo, 2014](#)).

In analytical practice, anion exchange resins and EC materials are favored over solvent extraction. New EC materials often contain the selective reagents developed for technological purposes (e.g., TEVA, TRU, DGA resins), but unfortunately, many of the extractants of high selectivity (malonamides, BTPs) have not found analytical applications.

b. Chemical separation of Po by liquid–liquid extraction

Po can be extracted into tributyl phosphate from strong HCl solutions ([Figgins, 1961](#)). Other organic agents forming complexes include EDTA and diethyldithiocarbamate (DDTC). When complexed with DDTC, Po can be extracted into chlorinated hydrocarbons, such as chloroform from HCl solution over a wide range of acid strengths. This is useful for the separation of Po from Pb and Bi, as Po is extracted from HCl solutions of higher acid concentration than either Bi or Pb ([Smithson et al., 1979](#); [Wai and Lo, 1982](#); [Kim et al., 2009](#)). ^{210}Po can be effectively separated from lead samples using a DDTC–toluene extraction with EDTA and citrate as masking agents for the Pb ions ([Uesugi et al., 2010](#)).

Other extractants reported in the literature include TOPO in toluene ([Jia et al., 2004](#)), di-n-octyl sulfide ([Johansson and Skarnemark, 2001](#)), triisooctylamine (TIOA) in xylene solution ([Chen et al., 2001c](#)), APDC in MIBK ([Shannon and Orren, 1970](#)), “Aliquot 336” ([Ibrahim and Whicker, 1987](#)), and trilaurylamine (TLA) into xylenes ([Roseberry and Scott, 1985](#)).

2. Separations by ion exchange

The most frequently used **cation exchange resins** are the strongly acidic sulfonated resins containing SO_3^- groups. Less acidic phosphorylated and carboxylated resins are also available. The positively charged counterions can be replaced by any other cations. The ion exchange affinity of the cations increases with increasing charge and decreasing hydrated ion radius. All actinide species, i.e., An^{4+} , An^{3+} , AnO_2^{2+} , AnO_2^+ especially the tetra- and trivalent species, are retained well (high D) at low acidities, and they are removed from the resin by concentrated acids, but no special selectivity against other cations was observed. Ion exchangers are typically used in the form of

chromatographic columns assuring much better separation than batch techniques.

Cation exchangers have been used for the preconcentration of actinides from high-volume dilute acidic solutions. Fjeld et al. (2005) used a cation resin column for the preconcentration of actinides from groundwater and liquid radioactive wastes. Cation exchangers have also been used for the chromatographic separation of actinides in ion chromatographs (IC) either alone or together with anion exchangers as mixed-bed resins. IC separation fits well to the purposes of separation of actinides prior to ICP-MS, but it is less adequate for alpha spectrometry due to small sample masses. Pu(III) and Am(III) were successfully separated on a cation exchange column TCC-II by Jernström (2006) using different complex forming eluents and detecting the sources by alpha spectrometry. Samples were loaded from dilute HCl solution, Pu was stripped with dipicolinic acid, and Am eluted with oxalic acid. Jernström (2006) also used mixed-bed ion exchanger CSA5-CGA5 column for IC of Pu and Am.

Separation of Am from lanthanides using cation exchangers. Trivalent Am^{3+} cations are usually retained well (high D) at low acidities. Several other elements coadsorb with Am, including lanthanides. As the concentration of HCl increases, the distribution coefficient for Am declines, whereas those for lanthanides is smaller, which is revealed by increasing separation factors.

One of the oldest techniques for the separation of Am from lanthanides is based on cation exchange chromatography using complexing agents, e.g., hydroxycarboxylic acids. Ammonium citrate and ammonium lactate have been used, and α -hydroxy- i -butyric acid (α -HIBA) proved to be the most effective eluent for the selective separation of Am. Choppin and Silva (1956) separated Am from the lanthanides on a jacketed (temperature controlled) cation exchange column using α -HIBA. Aminopolycarboxylic acids (e.g., EDTA and DTPA) have also been used as eluents. The disadvantages of their use are the low solubility and the slow establishment of the equilibrium.

Ageyev et al. (2005a,b) separated Am and Cm from lanthanides by cation exchange chromatography with gradient elution using 0.16–0.4 M α -HIBA after removal of Pu with anion exchange. Yields of Pu and Am were in the ranges of 60%–80%, 50%–70%, respectively, when 100–200 g of environmental samples exposed to the emissions from the Chernobyl accident were analyzed. A similar technique has been used for the purification of the Am fraction by Berlioz et al. (2005).

In **anion exchangers**, the functional groups are various amines. Strong basic anion exchangers with substituted quaternary amines strongly retain tetra- and hexavalent actinides from concentrated nitric and hydrochloric acid solutions. The selectivity of the anion resin for actinides is high because only a few other cations (e.g., Fe in HCl) are

able to form strong anionic complexes in acids. For example, the distribution coefficient (D) for Pu(IV) is as high as 10^4 . Fig. 5.38 shows the distribution coefficient (D) for various elements in nitric and hydrochloric acids.

Uranium and thorium. Thorium can be strongly retained on an anion resin from 8 M HNO_3 whereas U as U(VI) is better retained from 9 M HCl with an acceptable high distribution coefficient (D). Uranium can be easily separated from Th with anion resins, but U and Th cannot be retained well from the same solution. These properties have been utilized in the analysis of uranium isotopes in water, urine, and soil samples according to the ASTM standard test methods **D3972-09**, **C1473-11**, and **C1000-11**, respectively. Uranium is retained on a strongly basic anion exchanger from 8 to 9 M HCl solution after sample destruction and preconcentration with ferrous hydroxide precipitate. Uranium can be stripped from the column with 0.1–1 M HCl. In case of soil samples, Fe is removed from the load solution before separation by extraction of the chloride complexes with di- i -propylether. The retention of Pa from HCl or HF solutions on anion exchange resins is not quantitative (Dalvi and Verma, 2017).

Plutonium. A convenient way to separate Pu selectively from other ions is to load tetravalent Pu(IV) from 8 M HNO_3 on an anion resin and remove the possible interferences, primarily Th, by washing the column with 9 M HCl, because this does not form chloride complexes. Plutonium can be stripping as Pu(III) with 9 M HCl using a reducing agent, e.g., iodide. This is the procedure that became the basis of many methods. Because of the high selectivity of the resin for Pu(IV), very often a single chromatographic separation provides sufficient purity for the analysis. Basically the same procedure was already used in the 1960s (Coleman, 1965) and has been used by many authors recently (Moreno et al., 1997; Qu et al., 1998; Pilviö, 1998; Michel et al., 2008; Komosa and Chibowski, 2002; Solatie, 2002; Hrnccek et al., 2002; Vioque et al., 2002; Berlioz et al. 2005; LaRosa et al., 2005; Ageyev et al., 2005a,b; Giardina et al., 2006; Lee et al., 2000; Jakopic et al., 2007; Michel et al., 2008, 2008).

The standard procedures for Pu analysis by α -spectrometry are usually also based on anion exchange separation. According to the **ASTM C 1001-05 (2005)** standard (Standard Test Method for Radiochemical Determination of Plutonium in Soil by Alpha Spectroscopy), 10–50 g of soil is destructed with a mixture of nitric, hydrofluoric, and hydrochloric acids. Pu is isolated by anion exchange, followed by alpha source preparation. According to the standard **ASTM D3865-02 (2002)** “Test Method for Pu in Water”, Pu is coprecipitated with iron as ferric hydroxide, the coprecipitated Pu is dissolved, and the solution is adjusted to 8 M in HNO_3 for anion exchange separation, and then the alpha source is prepared. The recommended procedures of the International Atomic Energy Agency

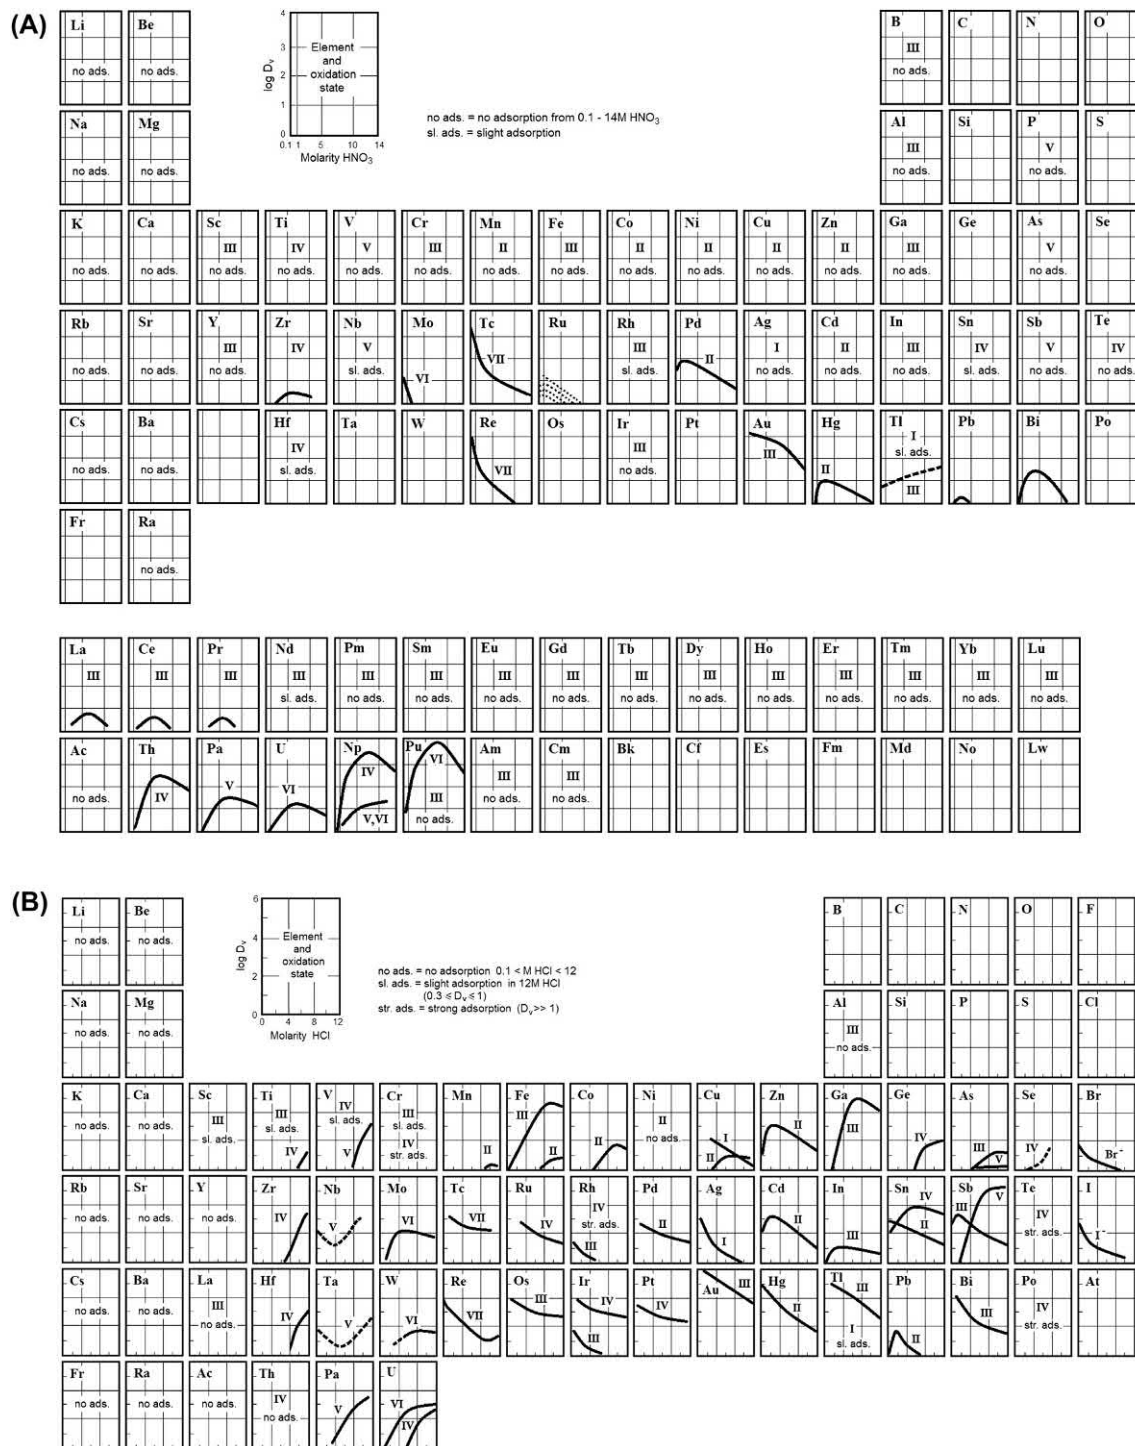

FIGURE 5.38 Distribution coefficient (D) for various elements of the periodic chart on a strong basic anion exchange resin in (A) nitric and (B) hydrochloric acids. Lederer (1992), reprinted by permission of John Wiley and Sons © 1992.

described in the Technical Report Series 295 from 1989 and in the most recent publication from 2012 (IAEA, 2012) are also based on the separation of Pu by anion exchange chromatography. The latest ISO standard **ISO 18589-4** and **BS 07/30047016 DC** (April 2007) on “Measurement of

Radioactivity in the Environment Soil Part 4. Measurement of Pu Isotopes by α -Spectrometry” recommends the optional use of HDEHP extraction, strong basic anion resin chromatography, and EC using TRU resin (see later) for Pu determination.

Many examples exist on the use of anion exchange resins for Pu separation from HCl solution. Samples containing Pu(IV) are loaded from 9 M HCl on the column, and after washing, Pu is stripped using a reducing agent. This procedure has the disadvantage that the anionic ferric chloride complex is also retained by the anion resin. Similar procedures were used from the 1960s up to the present. Lee et al. (2008) studied the oxidation states of Pu in HCl solutions and carried out Pu separation from 9 M HCl solution in the presence of NaNO₂. Pu was stripped with 0.36 M HCl + 0.01 M HF, and the Pu recovery as a mixture of Pu(IV) and Pu(VI) was >75%.

Neptunium. Anion resins, from both nitric and hydrochloric acid solutions, are used for the selective separation of Np. In reducing media, when Np is turned to the tetravalent form and Pu is reduced to the trivalent state, the separation of Np from Pu is easily accomplished. This is the most common method of selective ²³⁷Np separation. Np was retained as Np(IV) together with Th on anion resin from 8 M HNO₃ in reducing media in the procedures of Niese and Niese (1985) and Germian and Pinte (1990). According to the procedures of Koyoma et al. (1998), Michel et al. (1999), Moreno et al. (1997), and La Rosa et al. (2005), Np(IV), Pu(IV), and Th were retained also from 8 M HNO₃ followed by the selective stripping of the actinides. The tetravalent oxidation states were adjusted by applying reduction/oxidation cycles with or without the addition of NaNO₂ or H₂O₂. Np(IV) and Pu(IV) together with U can be retained on anion resin from 9–10 M HCl load solution. Then, Pu is stripped selectively with 9–10 M HCl/0.1 M NH₄I followed by stripping of Np with more dilute 1–4 M HCl. In the procedure of Rosner et al. (1993), fractionation of Np between the wash and the Np strip solutions was observed. Sumiya et al. (1994) and, more recently, Joe et al. (2007) successfully used similar procedures. To achieve higher DFs, the anion exchange procedures are sometimes repeated (Beasley et al., 1998), or additional purification steps using TTA, TEVA, TOPO extraction (see later) are included. Anion exchange resin has been used to separate Np from U from 4 M acetic acid solution when Np is released while U is retained (Winkel et al., 1971).

If Np and Pu are to be detected in the same fraction, they can be loaded as tetravalent species and stripped also together (Kim et al., 1992; Qiao et al., 2011).

Americium. Am(III) does not form strong complexes with nitrate or chloride ions and is not well retained on anion resins. In concentrated HCl solutions (>11 M), there is an increase in the retention of Am on anion exchangers, whereas lanthanides are adsorbed less. However, the difference is not as high as in the case of cation exchangers. Thus, the separation of Am from lanthanides is less successful under these conditions.

Separation of Am from lanthanides using anion exchangers. The presence of alcohol in the media enhances the anion exchange of Am especially in nitric and sulfuric

acids. Guseva et al. (1976) measured distribution coefficients as high as 5000 from 0.5 M HNO₃ in 95% methanol. Lighter lanthanides also have high distribution coefficients, whereas heavy lanthanides do not. In a HCl-methanol system, the anionic complexes of Am together with the heavy lanthanides are well retained by the resin, whereas light lanthanides are less retained. Both the HNO₃–methanol and the HCl–methanol systems, and preferably, the combination of the two systems, can be used for Am–lanthanide separation. A mixture of 0.5–1.0 M HNO₃ and 90–96% methanol was reported as the load and wash solutions by many authors (Holm and Fukai, 1976; Ballestra and Fukai, 1983, etc.) followed by stripping of the best retained Am with a mixture of 0.5–1.5 M HNO₃ and 70–86% methanol (Jernström, 2006) or simply with HCl (Livens and Singleton, 1989) or HNO₃ (Bains and Warwick, 1993). Methanol has been replaced with ethanol with similarly good results.

Kraus et al. (1955) found that many elements have higher distribution coefficients in LiCl solutions than in HCl. The sorption of Am on anion exchangers increases with increase in LiCl concentration, whereas the sorption of lanthanides varies only slightly favoring Am–lanthanide separation. The separation is further improved if alcohol is added to the LiCl solution, e.g., a good separation was achieved with 8 M LiCl and 40% methanol on Dowex 1 × 8 anion exchange resin by Guseva et al. (1976).

The group separation of trivalent actinides and lanthanides can be carried out with concentrated (>8 M) NH₄SCN solution as eluent (Surls and Choppin, 1957). Lanthanides are less strongly retained on an anion column in the SCN form than Am. The Am can be stripped with 4 M HCl. Bojanowski et al. (2005) and Lovett et al. (1990) applied this method successfully for the analysis of marine environmental samples.

Guseva and Tikhomirova (1968) showed that the best separation can be achieved with 1–2 M NH₄SCN solution containing 50–70% methanol, ethanol, or propanol. This procedure became the basis of many methods where Am–lanthanide separation was necessary. Holm et al. (1979) used this procedure for the final purification of the Am fraction from large amounts of environmental samples (200 L seawater, 100 g sediment, 500 g biological material) after the removal of the interfering components. The final residue containing Am and lanthanides was dissolved in a few milliliters of 1 M HNO₃–93% methanol and was loaded on an anion exchange resin column. The column was washed with dilute HCl–NH₄SCN–methanol solution to remove lanthanides, and Am together with Cm was stripped using 1.5 M HCl–80% methanol. The overall chemical recovery varied between 40% and 80%. A similar procedure was followed by Yamato (1982) to determine Pu and Am from 50 g of soil. In the final purification of Am, 1 M HNO₃–93% methanol, 0.1 M HCl–0.5 M NH₄SCN–80% methanol, and 1.5 M HCl–86% methanol

solutions were used as load, wash, and strip solutions, respectively, and 75%–92% chemical recoveries for Am were reported for the whole combined procedure.

The procedure has been successfully applied by many laboratories for Am–lanthanide separation. It is the recommended procedure in the laboratories of the IAEA, both in Monaco and in Seibersdorf (LaRosa et al., 1989, 2005). It has been used by Jakopic et al. (2007) for the analysis of environmental samples.

Polonium. Ion exchange resins are less commonly used nowadays for Po separations than methods based on LLE or EC. Polonium is strongly adsorbed onto anion exchange resin across a wide range of acid concentrations. Although this can be used for effective separation, the approach requires large elution volumes (Reischmann et al., 1984; Skwarzec et al., 2001). Cation exchange resins have been used to adsorb Po from dilute acid solutions, with elution by 7M HCl (Reischmann et al., 1984).

Radium. Strong basic anion exchange resins do not retain the group 2 elements (Fig. 5.38) but may be used to remove other alpha emitters, major cations, and/or anions, such as sulfate (Gleason, 1980) or chromate (Yamamoto et al., 1989). Hence, use of anion exchange resins may be preparatory to a final cleanup step for Ra.

Cation exchange resins may be used for preconcentration of Ra and separation from the bulk matrix for sample digests or aqueous samples. The digest is taken up in dilute HCl or HNO₃ for loading onto the resin and washed with dilute acid before eluting Ra with higher concentrations of these acids (e.g., Volpe et al., 1991; Lawrie et al., 2000; Crespo, 2000). However, to effectively separate Ra from Ba and Sr on a cation exchange resin, it is generally necessary to use complexing agents.

Gleason (1980) developed a separation method using cyclohexane-diaminetetraacetic acid (CyDTA), which has been a basis for several methods reported since then (Yamamoto et al., 1989; Rodriguez-Alvarez and Sanchez, 1995; Jia et al., 2006). Hancock and Martin (1991) used EDTA and ammonium acetate on 50WX12 cation exchange resin before washing and elution of Ra. Volpe et al. (1991) also used EDTA solution with cation exchange resin columns.

3. Separations by extraction chromatography

In EC, also called solid-state extraction and reversed-phase partition chromatography, liquid extractants are adsorbed onto the surface of inert solid support material. The theory of EC was described more than 30 years ago in the book of Braun and Ghersemi (1975). EC has the following advantages compared with solvent extraction and ion exchange:

- the extraction process takes place in the thin surface layer allowing good contact of the reagents and fast exchange kinetics compared with ion exchangers,

- as a result of the chromatographic technique, more effective separation is achieved than in the batch technique in which LLE is performed,
- less reagents and chemicals are used than in ion exchange or LLC;
- less hazardous waste is produced, and
- the whole process is more economic.

Attempts have been made to replace solvent extraction by EC from the end of the 1960s.

a. Extraction chromatography of actinides

The chelating extractant, **HDEHP** showing high distribution coefficient for Am from dilute acid solutions, has been prepared as a solid EC material on various supports to serve as stationary phase. HDEHP was prepared on hydrophobic support by Horwitz and Bloomquist (1975). Jia et al. (1997) used microporous polythene support. The 0.01 M HNO₃ load solution containing Am was passed through the column and washed with 0.1 M HNO₃, and Am was stripped with 0.07 M DTPA–1 M lactic acid. Pu and Po were separated before using supported TOA columns. Jia et al. (1998) determined Pu, Sr, and Am in a sequential separation procedure. First Pu and Sr were separated by EC, after which Am was concentrated on an HDEHP column. Americium was eluted with a 0.07 M DTPA–1 M lactic acid solution to separate it from lanthanides. The Am fraction was purified by an extraction with PMBP/TOPO. The chemical recovery for Am was 58%, and the source was free from Fe, Po, and lanthanide contamination. Desideri et al. (2002) determined actinides in depleted uranium. After EC separation of the actinides using supported TOA columns, the Am fraction was cleaned using a supported HDEHP column (pH 2.4). Arginelli et al. (2005) prepared HDEHP on polythene support and loaded the pretreated urine sample from dilute acidic solution (pH 2) on the column; Am was stripped with 4 M HCl. Supported HDEHP has become commercially available as Ln resin produced by Eichrom Co. McAlister and Horwitz (2007) characterized the Ln resin by measuring the capacity factors k' of various elements (see Fig. 5.39).

Gleisberg and Köhler (2002) separated Np from uranyl nitrate solution using Ln resin column. Np and Pu species were retained from 10 M HCl load while U entered into the effluent.

Meanwhile, the interest for Am separation by HDEHP has declined due to the development of more efficient EC materials (see TRU resin later).

Supported TOPO on microthene (microporous polyethylene) and TOA on icorene (microporous polyethylene) were prepared by Jia et al. (1998) from the 1970s.

Supported TOPO on Kieselgur was used by Afsar and Schüttelkopt (1988). Americium was loaded onto the column from 0.1 M HNO₃, washed with 0.1 M HNO₃, and

FIGURE 5.39 Uptake of various elements by Ln resin from HNO_3 solutions. *McAlister and Horwitz (2007)*, reprinted by permission of Eichrom Technologies LLC © 2007.

stripped with 8 M HNO_3 . The supported TOPO was applied for the separation and purification of U and Pu in safeguard samples (ISO 15366-1 and ISO 15366-2). *Solatie et al. (2001)* investigated the separation/purification methods for the determination of ^{232}U and ^{236}Pu in spent nuclear fuels by combining TOPO, anion exchange resin, and UTEVA EC.

Delle Site et al. (1973) separated actinides from urine samples on microthene-supported TOPO loaded from 4–6 M HNO_3 . Actinides were stripped consecutively with 0.3 M H_2SO_4 (Th), 6 M HCl –0.2 M HF (Pa), 1 M HF (U), 6 M HCl + Cl_2 (Np), and 6 M HCl + 0.1 M HI (Pu). Americium was separated on a microthene-supported HDEHP column. Acceptable high recoveries (>70%) were obtained with the exception of Am even in the presence of DTPA complexing agent.

EC using supported TOPO was successfully applied for Pu determination by *Cozzella et al. (2002)*.

Supported liquid anion exchangers were used for the separation of Np from environmental samples in the procedure of *Yan-Qin et al. (2001)*. Neptunium was retained on a Teflon-coated TOA from 2 M HNO_3 and stripped with hot 0.02 M oxalic acid/0.16 M HNO_3 . High recovery (>80%) and high DF against U (> 10^4) were obtained. In

the most recent work of *Desideri et al. (2011)*, Am, Cm, Pu, Np, and U were separated from small volumes of water samples and determined by alpha spectrometry. Samples were loaded onto macroporous PE-supported TOA from 9 M HCl solution, and Am, Pu, Np, and U were sequentially stripped. Recoveries higher than 74% were reported for each actinide.

Horwitz et al. (1966) reported a method that can separate Am from Cm on a supported (hydrophobic diatomaceous earth) Aliquat 336 column using 8 M LiNO_3 –0.01 M HNO_3 for loading and 3.5 M LiNO_3 –0.01 M HNO_3 solution to separate Am from Cm. More than 99% of Am and Cm were recovered in a radiochemically pure state (<0.1% impurity). The method was also applied to separate milligram quantities of Am and Cm (*Horwitz et al., 1967*).

Giardina et al. (2006) used microthene-supported TOPO, icorene-supported TOA, anion exchange resin, and TRU resin (see later) for the separation of Pu from urine samples followed by alpha spectrometric determination. Methods were compared with the standard procedure based on anion exchange chromatography. All methods gave good Pu recoveries (>80%), and DFs were acceptably high for naturally occurring radionuclides. Smaller DFs were obtained by TRU resin (discussed subsequently).

From the 1990s, a family of EC materials has been developed for the separation of actinides by Horwitz and colleagues at the Argonne National Laboratory, USA, and later, these materials became commercially available from EiChrom Co. and Triskem SAS. The EC materials have been carefully characterized by measuring the physical and chemical properties, distribution coefficients, extraction kinetics, and elution behavior and by developing separation procedures for special purposes. If a single resin is not capable of the separation of all the desired radionuclides because of limited selectivity, the use of tandem column arrangements is recommended, in which the effluent of one column serves as the load solution for the subsequent one. Because kinetics of the extraction is fast, the columns can be operated at higher flow rates than gravity flow; for this purpose, vacuum boxes have been proposed.

TEVA resin (*Horwitz et al., 1995*) dedicated to the separation of TEtraValent actinides is a supported quaternary amine-based (Aliquat 336) liquid anion exchanger where the support material is Amberchrom CG-71 ms. TEVA as an analog of strong basic anion exchangers is expected to be an excellent chromatographic material for the retention of Pu(IV) and Np(IV). The resin capacity factors (k') that are directly proportional to the distribution coefficients for Pu(IV) and Np(IV) in 6 M HNO_3 are 3×10^4 and 4×10^3 , respectively, and are superior to other actinides. This is the reason why the TEVA resin has received widespread application in Pu and Np analysis since the first report of Horwitz in 1995 (see in Fig. 5.40).

FIGURE 5.40 Capacity factors k' of various actinides on TEVA resin from HNO_3 and HCl solutions. www.eichrom.com, reprinted by permission of Eichrom Technologies LLC©2012.

Uranium and thorium: Capacity factors for Th and U(VI) on TEVA resin from HNO_3 solutions as shown in Fig. 5.40 are relatively low, and the selectivity for U and Th in concentrated HCl solutions is limited.

Plutonium: Varga et al. (2007c) used TEVA resin for the separation of Pu from environmental samples of 1–5 g after a CaF_2 coprecipitation. NaNO_2 was used to adjust the oxidation state of Pu(IV). The sample was loaded in 3 M HNO_3 and eluted with 6 M HCl , and Pu was stripped with 0.1 M HNO_3 /0.1 M HF . The Pu recovery for the whole procedure, including alpha source preparation, was 72%–93%, and the DF for U was $>10^5$, which was also sufficient for ICP-MS measurement. Chamizo et al. (2008) determined Pu in environmental samples without preconcentration using TEVA chromatography. Pu(IV) was loaded on the column in 3 M HNO_3 /Al(NO_3)₃, followed by washing with 6 M HCl and stripping with 0.5 M HCl . Recovery of Pu ($>60\%$) and DF for U (>100) was somewhat poorer than in the previous method, probably due to the lack of a selective preconcentration. Several authors used TEVA successfully for the separation of Pu for ICP-MS measurements (see the review of Kim et al., 2004). The standard procedures for the determination of actinides in water (ACW13VBS, ACW16, ACW17) developed by EiChrom Technologies, Inc (available from www.eichrom.com) are based on the use of different column sets where Pu is separated by TEVA EC.

Neptunium: For the individual determination of ^{237}Np , samples are usually loaded on TEVA column from 2 to 3 M HNO_3 after reduction of Np to Np(IV), whereas Pu is in the nonretainable Pu(III) oxidation state. Neptunium can be stripped with dilute HNO_3 – HF mixture. High Np yields were obtained in the procedures of Anton et al. (2006), Ayranov et al. (2005) and Maxwell and Jones (1998) analyzing soil, sediment, and nuclear materials, respectively.

If Np and Pu are to be determined together, the sample has to be loaded on TEVA after adjusting the Np(IV) and Pu(IV) oxidation states (see earlier). Kenna et al. (2002, 2009) obtained high yields for both elements analyzing sediment samples, whereas Np recoveries varied between 19% and 54% in the procedure of LaRosa et al. (2008). In the rapid separation procedure for the determination of ^{237}Np and Pu isotopes in large soil samples, Maxwell et al. (2011b) also found that Np recoveries were reduced when the matrix content increased (sample masses were higher than 30 g). Plutonium recoveries were high ($>82\%$) and independent of matrix effect. In the standard procedure for the determination of Th and Np in water (ACW08) developed by EiChrom Technologies (1995), quantitative recoveries have been attained using the simple TEVA procedure.

The standard procedure for the determination of ^{237}Np in soil (ASTM C 1475-05) is based on the use of TEVA column. The Np(IV) oxidation state is adjusted using ferrous sulfamate and NaNO_2 . Sample is loaded from 2.5 M HNO_3 /0.5 M Al(NO_3)₃, and Np is stripped with 0.02 M HNO_3 /0.02 M HF .

Americium: Am(III) is only slightly retained on TEVA resin from nitric or hydrochloric acid solutions. The maximum of the distribution coefficient is 0.1. However, TEVA resin, analog to anion exchange resins, can be used for the separation of Am from lanthanides, which was performed by loading the sample in a 2 M NH_4SCN –0.1 M formic acid solution followed by the elution of lanthanides with 1 M NH_4SCN –0.1 M HCOOH and stripping Am (together with Cm) with 0.25–2 M HCl (Horwitz et al., 1995). Good separation was achieved. A pitfall in the procedure is the same as in case of the classical Am–lanthanide separation using anion exchanger, i.e., it is difficult to dissolve larger sample amounts in a small volume of load solution. The method is applied after the separation of Am from most of the sample components. The same method was applied by Berne (1995) in the standard procedure of the Environmental Measurement Laboratory (EML), USA, for the determination of Am in soil after leaching the actinides, removal of Pu and Th with anion exchange resin, concentrating Am from the effluent with Ca oxalate coprecipitation and separating Am from most of the interferences on a TRU column (see later). The procedure was applied for the purification of the Am

fraction by Michel et al. (2008) and Maxwell (2008). Jernström (2006) separated Pu(III) and Am(III) on TEVA resin, whereby plutonium was adsorbed quantitatively (98.5%–99.1%) by the resin when loaded and washed with a mixture of 2 M ammonium thiocyanate in 0.1 M formic acid. Quantitative elution of Pu(III) from the resin was achieved with 0.25 M HCl. Sorption of Am(III) on TEVA resin was quantitative in the same mixture, and americium was eluted from the resin with 0.25 M HCl.

UTEVA resin (Horwitz, 1992) is a dipentyl-pentyl phosphonate impregnated Amberlite XAD-7 EC material that was designed to separate U and TEtraVAleNT actinides. Because the resin contains a phosphonate compound, actinides are retained at higher distribution coefficients than on phosphates, e.g., TBP. The k' capacity factor for Pu(IV), Np(IV), U(VI), and Th(IV) are about 10^3 , 4×10^2 , 4×10^2 , and 2×10^2 respectively, in 8 M HNO₃, which assures acceptable retention and easy removal of the tetra- and also the hexavalent actinides (see the capacity factors of actinides on UTEVA from HNO₃ and HCl solutions in Fig. 5.41).

Apostolidis et al. (1998) developed a procedure for the determination of Pu and U from reprocessing solution using a single UTEVA column. The oxidation state of Pu was adjusted with H₂O₂, and the sample in 4M HNO₃ was loaded on the column, and Pu was subsequently eluted with dilute HNO₃ containing hydroxyl amine and ascorbic acid as reducing agents. Finally, U was stripped with bioxalate solution. A high recovery (>95%) was achieved for Pu with a DF for U of about 10^4 .

FIGURE 5.41 Capacity factors k' of various actinides on UTEVA resin from HNO₃ and HCl solutions. www.eichrom.com, reprinted by permission of Eichrom Technologies LLC©2012.

Pu and Np were determined by UTEVA EC in a combined procedure with the analysis of Th and U from environmental and nuclear waste samples by Vajda et al. (2003) after preconcentration of the actinides in reduced form with ferrous hydroxide. The sample solution was loaded in 8 M HNO₃, which contained ferric nitrate as salting-out agent. Pu was stripped with 9 M HCl/0.1 M NH₄I, as Pu(III), Th, and Np were stripped together with 4 M HCl, and U was eluted finally with dilute acid. Pu recoveries varied in the range of 69%–92%, and the DF was high enough to obtain Pu alpha sources without interferences. Osvath et al. (2009, 2010) improved the procedure by using a strong oxidizing agent to form Np(VI) and Pu(VI), which are retained by the resin together with U, and they purified the Np–Th strip solution by EC separation on a second UTEVA column from 9 M HCl solution. In the modified procedure, Pu and Np recoveries were 65%–82% and 66%–93%, respectively, and the Np source could be analyzed by ICP-MS, whereas Pu and U sources were measured by alpha spectrometry.

Guerin et al. (2010) determined the k' values of Np(VI) on various EC materials, including TEVA, UTEVA, TRU, and DGA from HNO₃ and HCl solutions. The Np oxidation state was adjusted with KBrO₃, KMnO₄, K₂S₂O₈, Ag₂O, and O₃. A simple method using two UTEVA columns was used to detect Np in soil and sediment samples. Np recovery was 70%.

In the rapid procedure of Ohtsuka et al. (2006), UTEVA is used in an ion chromatograph directly connected to ICP-MS. The authors claim that the complete analysis of an environmental sample (1 g), including destruction by fusion, is performed within 60 min. Morgenstern et al. (2002) used UTEVA for the separation of U, Pu, Np, and Am for the determination of U and Pu in safeguarding nuclear materials.

TRU resin (Horwitz et al., 1993; Berne, 1995) is a chromatographic material comprised of a tri-n-butyl phosphate (TBP) solution of the bifunctional organophosphorous extractant octyl(phenyl)-N,N-di(iso-butyl)-carbamoyl-methyl-phosphine oxide (CMPO) adsorbed on an inert polymeric substrate (Amberlite XAD-7). It was designed to separate all transuranium nuclides, including trivalent Am and Cm besides the tetra- and hexavalent species. Extremely high capacity factors were measured on TRU resin in concentrated nitric acid solutions, k' is higher than 10^5 , 5×10^4 , 10^4 , and 10^3 for Pu(IV), Np(IV), Th, and U(VI), respectively, at HNO₃ concentrations above 1 M, and for Am, the k' is about 100. Unfortunately, Fe³⁺ present in the sample is also retained and competes for actinide-bonding sites, especially for those occupied by the less strongly retained Am (Cm). Reduction of Fe to Fe²⁺ helps decrease the interference. The capacity factors of actinides on TRU from HNO₃ and HCl solutions are shown in Fig. 5.42.

FIGURE 5.42 Capacity factors k' of various actinides on TRU resin from HNO_3 and HCl solutions. TRU, transuranium nuclide. www.eichrom.com, reprinted by permission of Eichrom Technologies LLC©2012.

TRU resin has recently become a popular tool for the separation of Am, but it can be used also for the retention of other actinides either for preconcentration or also for analytical separations. It seems to be an ideal material for the simultaneous separation of all actinides. TRU resin replaced almost exclusively all the methods used for concentration of Am in the past, i.e., chelating extractants and cation exchangers. Recently, several new molecules have been synthesized and have proven to be superior to TRU material regarding the distribution coefficient for Am or even separation factors, but the development of analytical procedures has a time-lag and applications are scarce, yet. Due to the moderately high distribution coefficient for Am on TRU and the various interferences from trivalent ions, e.g., Fe and lanthanides, and from matrix components, the separation procedures cannot avoid adequate preconcentration of Am.

Berne (1995) determined Am, Pu, and U in air filter and water samples. The sample was loaded in 8 M HNO_3 / NaNO_2 . The Am was eluted with 0.025 M HNO_3 , and Pu and U together with bioxalate. Because of cross-contaminations, it was recommended to separate Pu first on an anion exchange resin and use the TRU resin for the purification of Am only. This procedure was followed by many laboratories later, including the Environmental Measurements Laboratory, at the IAEA Laboratories at Seibersdorf and Monaco (Moreno et al., 1997, 1998; IAEA, 2012; LaRosa et al., 1989, 2001, 2005).

Horwitz et al. (1993) recommended a procedure for the sequential separation of actinides using a single TRU column. Actinides were loaded in 2 M HNO_3 after reduction when Pu was present as Pu(III). The Am was eluted with

4 M HCl , and Pu was eluted with 4 M HCl /0.1 M hydroquinone, followed by stripping of Th, Np, and U with 1.5 M HCl , 1 M HCl /0.03 M oxalic acid, and 0.1 M ammonium bioxalate, respectively. This procedure was slightly modified and applied for the rapid determination of Am, Pu, Th, and U in small environmental samples (1g) by Vajda et al. (2009). After LiBO_2 fusion and CaF_2 coprecipitation, the oxidation state was adjusted with NaNO_2 turning Pu to Pu(IV). The sample was loaded in 2 M HNO_2 . Am was stripped with 4 M HCl . Pu was eluted after fast on-column reduction with 4 M HCl /0.1 M TiCl_3 . High recoveries were obtained both for Am (96%) and for Pu (85%), and no traces of contamination were detected in the Am and Pu alpha sources. The behavior of Np on TRU resin was also tested; however, a good separation from U was not attained. A sequential separation procedure for the determination of the actinides in power plant effluents was developed by Spry et al. (2000). In the 3 M HNO_3 load solution, Pu was present as Pu(III), and it was oxidized after retention on-column with NaNO_2 . Am was stripped as above, Th was eluted with 4 M HCl /0.01 M HF , and Pu with 0.1 M bioxalate. Am and Pu recoveries were acceptably high (52% and 56%, respectively). The robust procedure for the determination of plutonium and americium in seawater developed by Sidhu (2003) is based on MnO_2 / $\text{Fe}(\text{OH})_3$ preconcentration of the actinides and their separation using a TRU column. Pu as trivalent ion was loaded together with other actinides from 3 M HNO_3 , and it was stripped after Am with 4 M HCl /0.02 M TiCl_3 . High recoveries were achieved for both nuclides (Pu: 78%, Am: 85%). Similar procedures were applied by Olahova et al. (2005) and Gogorova and Matel (2007).

In the ASTM standard guide C1561-10 for the determination of Pu and Np in uranium hexafluoride and U-rich matrix, two TRU columns are used. U is separated by retention on the first column from a 0.1 M oxalic acid–2 M HNO₃ solution, and then other actinides are retained on the second column from 3 M HNO₃. Americium, Th, and Pu are selectively stripped with 4 M HCl, 1.5 M HCl, and 1 M HCl–0.1 M oxalic acid, respectively.

Separations using UTEVA-TRU tandem resin columns: Several multistage EC methods were proposed for the simultaneous separation of actinides, but the one that became the most frequently used is based on the tandem column set of UTEVA-TRU. [Thakkar \(2001, 2002\)](#) described the detailed procedure in 2001, as the rapid sequential separation of U, Th, Pu, and Am. Actinides were preconcentrated with calcium phosphate (pH = 9) and then dissolved in 3 M HNO₃/1 M Al(NO₃)₃. Pu was reduced to Pu(III) with ferrous sulfamate and ascorbic acid. The sample was loaded on the tandem column where UTEVA was the first column and TRU was the second. After loading and washing, the columns were separated. Th and U were removed from the UTEVA column eluting them subsequently with 5 M HCl/0.05 M oxalic acid, respectively. On the TRU column, Pu was oxidized to Pu(IV) with 2 M HNO₃/0.1 M NaNO₂, and then Am and Pu were stripped after each other with 4 M HCl and 0.1 M ammonium bioxalate, respectively. This procedure resulted in high recoveries for Pu (>80%) and Am (>72%) as well as for U (>79%), and also relatively high DFs (in the Pu fraction DF for U > 104). This simple and fast procedure was frequently used with minor changes in different laboratories ([LaRosa et al., 2001](#); [Varga et al., 2007a, 2007b](#); [Jakopic et al., 2007](#) and [Mellado et al., 2001](#)).

DIPEX resin ([Horwitz et al., 1997](#)), also called *actinide* resin, is a neutral, bifunctional organophosphorous extractant, consisting of bis(2-ethylhexyl)methanediphosphonic acid supported on an inert polymeric substrate. It has extraordinary affinity for actinides from dilute acids. The capacity factor for Pu(IV) and Np(IV) from 0.1 M HCl solution is about 2×10^7 and 10^7 , respectively, and the same for Am, the traditionally least extractable actinide is even one order of magnitude higher (2×10^8). Actinides together with the extractant can be recovered from the resin by alcohol stripping and wet oxidation. These properties can be exploited in the preconcentration of actinides from large volume samples or complex matrices. The direct analytical application of the resin may be limited by the incomplete removal of the actinides from the resin. [Burnett et al. \(1997\)](#) used DIPEX resin for the preconcentration of actinides from soil solutions and large-volume water samples. Actinides from soil samples after NaOH fusion, dissolution, and ferrous hydroxide scavenge were concentrated on a DIPEX column. Isopropanol was used to solubilize the extractant that retained the actinides followed by

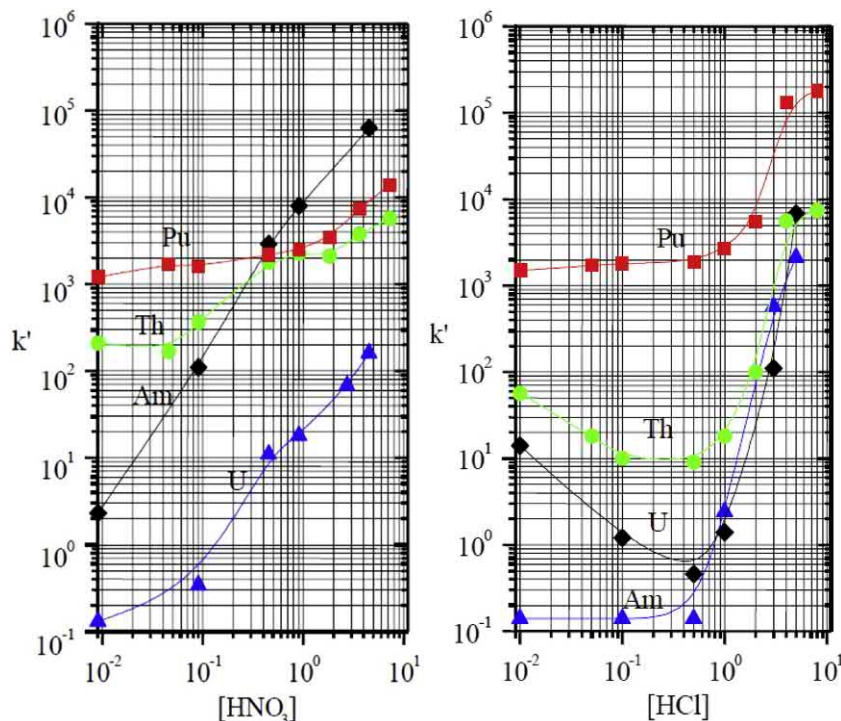

the oxidation of the organic component. Basic calcium phosphate was used to scavenge the actinides repeatedly, and the final separation was performed on a UTEVA-TRU tandem column setup as described below. Recoveries of Pu, Am, and U varied in a wide range (31%–91%, 22%–99%, 60%–85%, respectively). *Actinide* resin was used for the preconcentration of Pu and Am from human tissue followed by the separation of Pu with anion exchange resin by [Qu et al. \(1998\)](#). The overall recovery for Pu was high (>80%) assuring the adequacy of the preconcentration, as well. An interesting application of *actinide* resin for the determination of Pu has been proposed by [Labrecque et al. \(2013\)](#). In the cloud point extraction, the selective ligand extracting Pu is enclosed in a micelle shielding that was formed from ionic and nonionic surfactants in the presence of bromine. The method represents a green alternative to conventional LLE. The *actinide* resin was used for the extraction of ²³¹Pa from concentrated HCl solution in the presence of its daughter products ([Sankhe et al., 2017](#)).

DIPHONIX resin ([Chiarizia et al., 2011](#)) can be regarded as the chelating ion exchange resin analog of the DIPEX EC material. It contains geminally substituted diphosphonic acid groups chemically bound to a styrenic-based polymer matrix. It also contains strongly hydrophilic sulfonic acid groups in the same polymer network. Also, extremely high capacity factors were observed for the retention of all actinides, close to those of DIPEX from dilute acid, but several transition metals (e.g., Cr, Ni, Cu, Zn) are also retained. The removal of the actinides is more problematic due to the massive resin structure. Strong complexing agents can remove the actinides that have to be decomposed or the resin itself has to be destroyed. Analytical procedures have been proposed by the authors, but because of the difficulties in removing the actinides from the resin, they have not been applied in practice. [Rosskopfova and Holkova \(2005\)](#) reported the use of DIPHONIX resin for the preconcentration of actinides from large soil samples followed by their separation using different eluents, i.e., Am was stripped with 6 M HNO₃ and Pu with 4 M HCl/0.015 M TiCl₃. Recoveries for Am were high (70%, 78%) but varied for Pu (37%, 93%).

DGA resin ([Horwitz et al., 2005](#)) consists of N,N,N',N'-tetraoctyldiglycolamide adsorbed onto Amberchrom CG-71 resin. DGA is known for its high selectivity for trivalent actinides and lanthanides from HLW technology. Like the DIPEX resin, DGA retains Am strongly; in concentrated HNO₃ solutions (>1M), the capacity factor of Am is higher than 10^4 . High capacity factors were found also for Pu (> 10^3) at high HNO₃ concentrations, but they were not significantly smaller at low acidities. DGA resin can be used advantageously for the separation and purification of Am without losses from various matrices, e.g., soil and water.

The capacity factors of actinides on DGA resin are shown in [Fig. 5.43](#).

FIGURE 5.43 Capacity factors k' of various actinides on DGA resin from HNO_3 and HCl solutions. www.eichrom.com, reprinted by permission of Eichrom Technologies LLC©2012.

In many applications, DGA resin has been used for the separation of Am (together with lanthanides). Maxwell and Culligan (2006) and Maxwell (2008) developed a very promising rapid method for the determination of actinides in large soil samples up to 200 g. Samples are fused with NaOH, and actinides are preconcentrated with $\text{Ce}(\text{OH})_3$ and CeF_3 coprecipitation. Stacked TEVA–TRU–DGA cartridges are loaded with 8 M HNO_3 . TEVA serves for the separation of Th and Pu(IV), whereas Am (and Cm) are separated with the TRU–DGA multistage column. Americium originally retained on TRU was eluted with 4 M HCl and transferred to the DGA column. Americium was stripped from DGA with dilute (0.25 M) HCl solution. Am and Pu recoveries for the whole procedure were high, varying between 76% and 98% and between 61% and 92%, respectively. The method was adopted for the analysis of water samples (Maxwell, 2006) up to 1 L and extended for the determination of Sr radionuclides using Sr resin. The procedure combined the advantages offered by the rapid and effective destruction with NaOH fusion, the selective preconcentration of actinides with $\text{Ce}(\text{OH})_3$ and CeF_3 , and the EC separation using highly specific resins, i.e., TEVA for Pu and TRU–DGA for Am.

Maxwell et al. (2011a) developed a rapid simplified method for the determination of Pu and Np in water samples using a stacked column set of TEVA and DGA resins. In the combined procedure, Pu(IV) and Np(IV) were retained on a TEVA column first, and then Pu was reduced

and retained as Pu(III) on the DGA column together with U. From the DGA, U was eluted with 0.1 M HNO_3 , and Pu(III) was stripped with 0.02 M HCl /0.005 M HF /0.0005 M Ti^{3+} . High recoveries and DFs for U (higher than 10^6 and 10^4 in case of Pu and Np, respectively) were reported. The resulting source quality met the requirements of both alpha spectrometry and ICP-MS.

Since the DGA resin became commercially available, many analytical applications have been reported, but most of them apply DGA resin only for Am separation (Dulanska et al., 2015; Gorietti et al., 2017; Yoon et al., 2018; Luo et al., 2018; Wang et al., 2018). There are a few other examples for the retention of various actinides on DGA.

Groska et al. (2016) developed a procedure for the simultaneous separation and determination of all actinides (U, Th, Np, Pu, Am, Cm isotopes) from low-level waste samples. A single DGA resin column is used to retain actinides from a reductive media. Individual actinides were stripped after adjusting the oxidation states on-column and the concentration of the acids and the oxalic acid complexes. Acceptable high recoveries and decontamination factors were obtained in the alpha spectra.

A new type of DGA resin where DGA is covalently bound to silica has been prepared and tested for the separation of Th, Pa, and U by Hopkins et al. (2018). Th and Pa were separated from U. By using a sulfur-based DGA derivative, the diglycothioamide (DGTA) Pa could be selectively separated from Th and U. The radiochemical purity

of ^{231}Pa is an important issue in targeted alpha therapy (Mastren et al., 2018).

1-Octanol impregnated resin, commercialized as TK400 resin (TRISKEM SAS), proved to be a selective EC material for the retention of Pa from HCl solution. High Pa recoveries have been reported by Knight et al. (2016b) for the separation from Np, by Jerome et al. (2018). Protactinium was successfully separated from Th and U in marine sediments with TK400 resin after a preliminary removal of matrix components using an anion exchange resin (Süfke et al., 2017).

b. Extraction Chromatography of Radium and polonium

Sr resin is an EC material particularly useful for separation of group 2 elements, with an especially high affinity for Sr. In nitric acid solutions, uptake of Ra is lower than Pb, Sr, and Ba but higher than Ca. Radium and Ba uptake are highest at approximately 2–3M HNO_3 , whereas Sr uptake increases monotonically with HNO_3 concentration. Lawrie et al. (2000) used 3 M HNO_3 on Sr Spec resin as a final cleanup step to separate Ra and Ba prior to alpha spectrometry. Although the main reported applications to date have been for separations preparatory to mass spectrometry (e.g., Yokoyama and Nakamura, 2004), the material shows promise for expanding the application to alpha spectrometry for Ra isotope analysis.

Vajda et al. (1997) developed a method for the separation of Po using Sr Spec resin. The digest is loaded on the column in 2 M HCl. Bismuth and several other matrix components, including Fe, are eluted with the 2 M HCl wash, whereas Po and Pb are retained. Po may then be eluted with 6 M HNO_3 , and Pb subsequently eluted with 6 M HCl. The column may be reused one or two times after the first extraction (Vreček et al., 2004; Kim et al., 2009).

3M Empore Radium Rad Disks are a filter-like membrane on which a Ra ion-selective crown ether is embedded. They are especially useful for preconcentration and separation of Ra from water samples and other aqueous solutions. The disks are commonly analyzed using gamma spectrometry, as little further sample preparation is required. However, the Ra may be eluted (for example, with alkaline EDTA) and a source for alpha spectrometry prepared (Durecová, 1997; Purkl and Eisenhauer, 2003).

c. Combined procedures

Combined procedures are often used for chemical separations of a single element to have high decontamination factors for one element or for the simultaneous determination of several elements. It is a rare case when an element can be separated adequately for alpha spectrometry by a single procedure. There is a huge variety of combined procedures that cannot be discussed in the frame of this

chapter (see the reviews and books referred to at the beginning of this section). The following combinations have been reported recently (Vajda and Kim, 2011):

anion exchange resin—anion exchange resin,
anion exchange resin—TEVA resin,
anion exchange resin—UTEVA resin,
anion exchange resin—TRU resin (—TEVA resin),
anion exchange resin—cation exchange resin (ion chromatography),
anion exchange resin—TEVA-DGA,
LLE with TOPO—UTEVA-TRU,
LLE with TOPO—TRU-TEVA,
LLE with TOPO—TEVA—TRU—TEVA,
LLE with TOPO—HDEHP,
UTEVA—TRU,
UTEVA—DGA,
TEVA—TRU,
TEVA—UTEVA,
TEVA—DGA,
TEVA—UTEVA—TRU,
TEVA—TRU—UTEVA,
TEVA—TRU—DGA,
Sr resin—TEVA—UTEVA (IAEA, 2014a,b).

Remark: Other chromatographic materials have been reported also to be efficient for actinide analysis, but because of lack of information about their composition, they have not been discussed in this review (e.g., molecular recognition materials such as AnaLig-Pu, product of IBC Advanced Technology).

C. Alpha source preparation

Following chemical separation from the sample matrix, the analytes must be prepared as a thin, flat, uniform source suitable for alpha spectrometric analysis. The basic characteristics of a high-quality source are that the alpha particles lose only a small and consistent amount of energy while exiting the source (minimizing energy straggling), the geometry of the source—detector arrangement results in a high counting efficiency, this efficiency is consistent between sources, the deposit is robust, the deposited activity is relatively homogeneous across the deposit, and the source is easy to handle and store.

There are three main methods of source preparation: evaporation, coprecipitation with a microcrystalline precipitate, and electrodeposition. In the ASTM standard D3084–05 on “Standard Practice for Alpha-Particle Spectrometry of Water,” all three methods are described.

The **evaporation technique** involves depositing the solution onto a stainless steel or platinum disk or a porcelain disc and evaporating the solution in such a way that a uniformly covered surface is obtained. This method is quick and ensures a very high recovery. A difficulty is

ensuring that the source deposit is uniform, and for that purpose, a wetting or spreading agent is usually used (Lally and Glover, 1984). A further disadvantage is that deposits do not always adhere tenaciously to the substrate.

Microcoprecipitation of actinides on a rare earth fluoride, often NdF_3 , followed by filtration on a smooth surface membrane filter of small pore size (0.1–0.2 μm), produces a good-quality alpha source (ASTM Test Method C 1163, Sill, 1987a). For Ra, the most commonly used coprecipitation method for source preparation is with BaSO_4 as described by Sill (1987b). Coprecipitation and filtration is more rapid than electrodeposition; however, a disadvantage is that the resulting filter is flexible and may require adhesion to a backing to prevent curling.

In **electrodeposition**, metallic radionuclides are electrochemically plated with high yield from an electrolyte solution onto a metal cathode surface. Most commonly, a polished stainless steel cathode planchet is used, although a metal-coated plastic film may be used for specialized applications, such as coincident photon and alpha spectrometry (Johnston et al., 1991). The anode is typically Pt wire or gauze. The anode is often rotated to stir the solution, although bubbling by gas formed at the anode may provide sufficient mixing. A variety of electrolytes have been used to close the electric circuit, including sulfate, oxalate, and acetate buffers.

In most cases, metallic elements are deposited with high yield in a relatively nonselective manner, with the exception of group 1 and 2 elements. For the widely used method of Hallstadius (1983), deposition yields were reported to be between 90% and 99% for Cm, Am, Pu, Np, U, Th, Pb, and Po and <1% for Ra.

An aqueous/alcohol electrolyte solution (e.g., 1 mL 0.1M HNO_3 and 9 mL propanol) may be used to electrodeposit Ra (Smith and Mercer, 1970; Hancock and Martin, 1991). Alternatively, Ra may be deposited from an aqueous solution of ammonium acetate and nitric acid, or ammonium oxalate and HCl, usually with the addition of a small amount of Pt in solution (Roman, 1984; Orlandini et al., 1991; Hamilton et al., 1994).

Electrodeposition is often performed at a constant current density (0.5–1 A/cm^2) and low voltage (<10 V) for about half an hour to 2 hours. A standard procedure for electroplating actinides from a solution of ammonium sulfate was published in 2000 and reapproved in 2005 (ASTM C1284-00, 2000b). For alpha spectrometric purposes, the last two procedures are routinely used.

Polonium spontaneously autodeposits onto the surfaces of several metals, including Ag, Cu, and Ni from dilute acid solution. **Autodeposition** onto metal discs (usually Ag) is the most common source preparation technique for Po due to its simplicity and the fact that it results in separation from other metal ions, including other alpha emitters (Smith and Hamilton, 1984; Matthews et al., 2007). Electrodeposition can also be used for Po source preparation (Uesugi et al., 2010).

A review of electrodeposition methods for the preparation of alpha sources has been prepared by Crespo (2012). Evaluation of procedures for the electrodeposition of uranium, plutonium, and americium has been performed by Oh et al. (2014).

Ultrathin Am, Cm, and Th sources may be prepared by the adsorption of insoluble compounds onto a substrate (Wyllie and Lowenthal, 1984; Martin and Hancock, 2004b). The alpha peak resolution for these sources is very high. However, the recoveries obtained are relatively low, and although useful for the preparation of high-quality test sources, the technique has not been used for routine analysis. Energy resolution of alpha peaks has been improved by the unique technique of ion implantation using ICP-MS device for the preparation of implanted alpha source (Dion et al., 2015). Separation of isotopes by mass with a quadrupole mass spectrometer assures not only high-quality (thin and even) alpha source but also an effective purification.

Whichever method is used for source preparation, perfect homogeneity of the deposited activity across the source cannot be expected. With careful design of the deposition system, a reasonably even and consistent deposit can be attained (Klemenčič and Benedik, 2010). Nevertheless, on a small scale, it can be expected that the activity and source thickness will show some “graininess,” which will mean that the effect of the deposit on peak resolution will be greater than that expected purely from the deposited mass per unit area (Martin and Hancock, 2004a).

For the rapid preparation of alpha sources, a new technique has been introduced, the **ligand film technique**. Selective extractive ligands are immobilized in a support that is counted directly after extraction of the alpha-emitting nuclide by alpha spectrometry. The technique combines radiochemical separation with alpha source preparation.

For the rapid extraction of Pu and Am from water and urine, a PLF was prepared from Dipex and polystyrene (Gonzales and Peterson, 2009). Recoveries were poor, but FWHM values were as low as 20 keV. Rim et al. (2013) prepared an HDEHP-based polymer (polystyrene) ligand film for the extraction of Pu, but its distribution in the film was uneven. A Klaui-type tripodal oxygen donor ligand film was prepared by spin-casting solutions onto glass substrate for the rapid analysis of Pu by Hanson et al. (2014). High recoveries and low FWHM values (33 keV) were obtained. Paul et al. (2014, 2015) prepared self-supported and membrane-supported polymer-containing phosphate and sulfonic acid groups for the extraction of Pu and U. Acceptable high recoveries were obtained for both isotopes using the bifunctional polymer layer grafted on poly(ethersulfone) membrane. Ultrathin films of quaternary amine anion exchange polymers on glass and silicon were prepared by dip coating by Mannion et al. (2016).

and successfully used for Pu extraction. Recently, ultrafiltration membranes were grafted with uranium-selective polymer and used for analysis of U isotopes. The great number of publications on PLFs reflects the need for rapid determination of alpha-emitting nuclides in liquid samples.

VII. Determination of activity and recovery

To determine alpha particle—emitting radionuclides conventionally, the following procedure is performed: alpha sources are prepared by radiochemical separation; the alpha spectrometer is calibrated; sample, background, and blank sources are counted with the alpha spectrometer for adequate counting times; the spectra are analyzed (i.e., peaks are identified and peak areas are calculated); and the activities of the identified nuclides are calculated. In this chapter, the major steps of activity determination are discussed using examples from standard semiconductor alpha spectrometry. The same method can be used in the case of gas ionization detectors without significant changes. High-resolution alpha spectra and high-resolution LS spectra are usually evaluated by using computer programs that have been briefly discussed above.

A. Calibration

Calibration of the instrument comprises energy, resolution, and efficiency calibration that may be established from the same source, most likely a calibration source (CS) containing known quantities of at least two radionuclides emitting alpha radiation. The CS should have activities

such that instrumental dead time resulting in lost counts can be avoided. The limitation of approximately 1000 Bq is a typical value. The CS is placed in the detector chamber at a distance from the source that is larger than the detector diameter to reduce the geometric effect on FWHM value, and then the counting chamber is evacuated and the system bias is adjusted to the factory given value. The source is counted during a measurement period that produces a relatively low counting uncertainty. A typical alpha spectrum of a CS is shown in Fig. 5.44.

Energy calibration is carried out by plotting the known energies (E) of the peaks belonging to highest alpha abundance against the peak location channel numbers (ch) referring to the peak center position. Usually, a straight line is fitted to the points as

$$E = b + m \cdot ch \quad (5.25)$$

where m is the slope and b is the intercept of the line. Because the energy response of the detector is reasonably linear, the measurement of two points is sufficient for routine analytical purposes. However, modern spectrometry software packages perform calculations based on the measurement of several peaks and may include cubic or quadratic terms to account for minor nonlinearity.

Calibration of the energy resolution is performed by measuring the peak width at channels corresponding to the half of the maximum counts and expressing the width in energy units (see Fig. 5.44). The stability of FWHM values is an important indicator of good system performance.

In principle, **efficiency calibration** can be performed according to the following equation from the measurement

FIGURE 5.44 Alpha spectrum of a commercially available calibration source containing ²³⁹Pu, ²⁴¹Am, and ²⁴⁴Cm. The source was prepared by vacuum evaporation and counted with a PIPSi detector with 300 mm² surface area at a distance of 5 cm from the detector. PIPSi, passivated ion-implanted planar Si.

of the same CS, if the calibration standard is measured in the same geometry as the sample source:

$$\varepsilon = \frac{r_{CS} - r_{BG}}{A_{CS} \cdot I_{\alpha} \cdot D} \quad (5.26)$$

where ε is the counting efficiency, r_{CS} is the gross count rate of the calibration source (cps), r_{BG} is the background count rate (cps), A_{CS} is the activity of the calibration source at the reference date (Bq), I_{α} is the alpha abundance, and

$$D = e^{-\lambda_{CS} \cdot t_{CS}}$$

is the decay factor for the calibration source from the reference date to the measurement date, where λ_{CS} is the decay constant of the calibration source (s^{-1}) and t_{CS} is the time from the reference date of the calibration source to the measurement date (s).

The law of uncertainty propagation for a single measurement according to the equation above or preferably the standard deviation of multiple measurements can be used to express the standard uncertainty of ε .

In practice, calibration sources rarely have the same geometry as those for the sources prepared from the sample for analysis. Therefore, calibration sources of the required geometry have to be prepared from standard solutions. These sources are used to determine the counting efficiency as described above.

Since the intrinsic detection efficiency of a PIPSi detector has practically a value of 1, the activity determination is possible without using tracers in the sample processing (Pöllänen et al., 2011). If the processed sample is thin, i.e., there is no alpha particle self-absorption, the geometric detection efficiency can be used in the activity determination. Geometric detection efficiency can be calculated by using appropriate computer programs such as AASI (Siiskonen and Pöllänen, 2005).

The efficiency of a solid-state alpha spectrometry detector is not a function of energy over the typical energy range of emitted alpha particles due to the high stopping power of alpha particles in Si. Therefore, the average of the efficiencies of multiple alpha peaks can be calculated to obtain a more accurate efficiency value.

When a sample is analyzed by using an alpha particle-emitting tracer as an internal standard, the efficiency does not affect the result of analysis because the count rates of the analytes are directly related to the count rate of the tracer. Therefore, an exact knowledge of the efficiency is only necessary to calculate the chemical recovery. However, when a sample source is analyzed without an alpha-emitting tracer, then the efficiency is used to calculate the activity of the analyte.

The standard practice of calibration of alpha spectrometers is described in ASTM D7282-06 standard.

B. Measurement procedure

The samples to be analyzed are placed in the vacuum chamber. The selection of the distance of the source from the detector is always a kind of optimization between efficiency and resolution, and it depends on the source activity. The chamber is pumped until a vacuum of about 15 mbar is achieved, if it is desirable to protect the detector from the recoil contamination or of about 0.01 mbar and if high resolution is of major concern. Then the detector voltage is set to the value recommended by the detector manufacturer. Counting times are selected according to the activity of the source and the required counting uncertainty. Low-activity environmental samples are typically counted for several days.

C. Alpha spectrum evaluation

1. Principle of evaluation

The activity of the analyte is determined from the known activity of the tracer that was added to the sample and the ratio of the peak areas belonging to the analyte and the tracer. The method is called **isotope dilution alpha spectrometry** and has the advantage that the calculated activity is inherently corrected for chemical losses because losses of the analyte are taken to be equal to those of the tracer. This is a very realistic assumption whenever the tracer and the analyte are isotopes of the same chemical element in the same chemical form, but the procedure should be used with care if this is not the case.

2. Nuclide identification

In isotope dilution alpha spectrometry, chemical separation is designed to favor one element or a group of elements. Therefore, only a limited number of isotopes are expected in the alpha source, and identification of the nuclides simply means comparing the peak energy in the spectrum with the alpha energies of the expected nuclides and possible contaminants, which could be present due to failure of separation. For example, after chemical separation of Pu from an environmental sample, one can expect the peaks of ^{238}Pu , the common peak of ^{239}Pu and ^{240}Pu , and the peak of the tracer ^{242}Pu or ^{236}Pu (Fig. 5.45).

A very important quality control procedure in alpha spectrometry involves checking the spectrum for the presence of alpha peaks from elements other than the one of interest. This may be due to the failure of the chemical procedure to achieve high separation efficiency due to matrix effects or the presence in the sample of a relatively high activity of the contaminating radionuclide. As examples, possible interferences in the Pu spectrum are Th isotopes, if anion exchange separation of Pu is performed from nitric acid solution, or traces of U isotopes in the Pu source,

FIGURE 5.45 Setting regions of interest of equal width for the evaluation of the well-separated peaks of Pu nuclides.

if anion exchange separation of Pu has been performed from hydrochloric acid solution.

3. Peak area determination for nonoverlapping peaks

The number of counts in the peak corresponding to the analyte are integrated, and the counts of the tracer nuclide in the channel region of the same width are also integrated. Blank samples are also processed and analyzed to determine the background contribution to the counts in the regions of interest (ROIs).

4. Peak area determination with correction for overlapping peaks

In the case of overlapping peaks, there are basically two different approaches for the peak area determination. The areas can be determined by using computer programs presented in Section IV.A. Accurate results can be obtained

provided that correct peak shapes are used in the peak area fitting. Another option for the area determination is to use methods described below. The advantage is that no sophisticated computer programs are necessary.

Due to the asymmetric character and significant low-energy tailing of alpha peaks, the low-energy peaks are sitting on the tails of all the peaks of higher energies. This tailing has to be corrected for, and this correction is especially important, if the peaks are close to each other or if the count rate in the higher energy peak is much greater than that in the lower energy peak.

In Fig. 5.46, partially overlapping peaks of $^{239,240}\text{Pu}$ and ^{238}Pu are shown according to the ISO 11,483:2005 standard. The exact activity ratio of $^{238}\text{Pu}/^{239,240}\text{Pu}$ can be determined after tailing correction. There are two standardized methods for the determination of peak area of overlapping peaks, the so-called geometric progression decrease (GPD) method and the exponential decrease (ED) method that have been described in detail in the standard.

The basic idea in the GPD method is that the counts in the tail of a peak decrease in geometric progression. It is assumed that the shapes of the different peaks in the same spectrum are the same, therefore, in the flat portion of tail, peak tailing contributions are proportional to the corresponding peak areas, and the tails are the sum of all single peaks of higher energies.

According to Fig. 5.46, four regions of interest (A, B, C, D) of equal channel numbers are selected. The high-energy end of ROI A is selected as the center energy of the second peak plus the half of its FWHM. The low-energy end of ROI A is fixed so that the region is not extending into the region of the first peak. The high-energy end of ROI B is selected similarly to ROI A as the center energy of the first peak plus the half of its FWHM. The width of ROI B is the same as that of ROI A. ROI C and ROI D are selected so

FIGURE 5.46 Tailing correction for partially overlapping peaks according to standard ISO 11483(2005).

that the difference between the two neighboring peaks and the width of each ROI are the same. The constant ROI width is selected so that the ROIs should not extend to the regions of any other peaks. The sum of the counts in ROIs A, B, C, and D are calculated and identified as a , b , c , and d , respectively. The corrected ratio of the peak areas (R_{cor}) is calculated according to the geometric progression decrease as follows:

$$R_{cor} = \frac{a}{b_{corrected}} = \frac{a}{b - \frac{ac}{b + \frac{ad}{c}}} \quad (5.27)$$

Thus, the values of a and the tailing corrected $b_{corrected}$ are obtained for the calculation of the exact activity or activity concentration. The complicated uncertainty calculation is described in the ISO standard.

The basic idea in the ED method is that the decrease of counts in the tailing region can be described by an exponential function. The ROIs A and B are selected as described above. An exponential function is fitted to the points in the region between ROI A and ROI B:

$$Y_i = A' \cdot e^{B' \cdot X_i} \quad (5.28)$$

where Y_i and X_i are the number of counts and the number of channels belonging to the measured spectrum data point, and A' and B' are the fitted parameters of the exponential function.

Then the area under the assumed tailing curve in ROI B is calculated as the sum of counts $\sum Y_i$ using the parameters of the fitted curve. The corrected area of the first peak is obtained as $b - \sum Y_i$, and the corrected ratio of the peak areas (R_{cor}) is calculated as

$$R_{cor} = \frac{a}{b - \sum_{i \in \text{ROI-B}} \Sigma Y_i} \quad (5.29)$$

The uncertainty calculation of the corrected peak area is given in the ISO standard.

Both methods of tailing correction have limitations in applications: Spectra of relatively high energy resolution and high counts are required, and the peaks have to be relatively well separated so that the regions can be selected without interferences from other peaks. Both methods have been successfully used for the accurate determination of $^{238}\text{Pu}/^{239,240}\text{Pu}$ isotope ratios in nuclear fuel samples by alpha spectrometry.

5. Calculation of results

The calculation of results comprises calculation of the activity per unit mass (or per other quantity in question) of the radionuclide and its standard uncertainty. The latter can be occasionally replaced by the calculation of the standard deviation of repeated measurements. Additionally, chemical recoveries and decision thresholds as well as detection limits should be calculated.

The ratio of the net counts of the peaks belonging to the analyte and the tracer (n/n_T) is used to calculate the activity concentration of the analyte in the sample on the date of chemical separation (a_1) taking into account the activity concentration of the tracer solution (C_T), the masses of the sample (m_s) and the tracer solution (m_T) used, and the decay of the tracer between its calibration date and counting (f_T). The decay of the analyte between separation and counting can be neglected, if the nuclides are long lived. The method of calculation of the results has been described by Kanisch (2004).

The activity concentration of the analyte (a_1 , Bq kg⁻¹, dry) at the separation time can be calculated by the following formula:

$$a_1 = \frac{C_T \cdot n}{m_s \cdot n_T} \cdot m_T \cdot f_T \quad (5.30)$$

where the decay correction factor is calculated as follows:

$$f_T = \exp(-\lambda_T \cdot t_T) \quad (5.31)$$

where λ_T is the decay constant of the tracer (years⁻¹) and t_T is the time interval between the reference date of the tracer and the separation time (years).

Finally, the activity concentration of the analyte in the sample is calculated back to the date of sample collection (a_0).

$$a_0 = a_1 \exp(\lambda_A t_1) \quad (5.32)$$

where λ_A is the decay constant of the analyte (years⁻¹) and t_1 is the time interval between the sampling date and the separation time (year).

The detection efficiency (ϵ) is not needed directly for the calculation of the activity concentration in isotope dilution alpha spectrometry. However, it allows one to calculate the chemical recovery (R) from the activity of the tracer added and the net counts in the corresponding peak:

$$R = \frac{n_T}{C_T \cdot m_T \cdot \epsilon \cdot t_m} \cdot \exp(\lambda_T \cdot t_T) \quad (5.33)$$

The detection efficiency is determined from the activity of a calibration source and the net count rate measured in the same geometry as the sample (see Eq. 5.26).

Calculation of the activities of all analyte isotopes (e.g., ^{238}Pu and $^{239,240}\text{Pu}$) is performed in the same way replacing the relevant analyte data in the equation and using the same tracer data (e.g., ^{242}Pu).

6. Calculation of the combined standard uncertainty

Activities in the source and **activities** per unit mass of the analytes in the sample are determined according to Eq. (5.30).

Calculation of the **combined standard uncertainty** can be performed according to the ISO Guide to the Expression

of Uncertainty in Measurement (1995) or according to the IAEA (2004) publication on Quantifying Uncertainty in Nuclear Analytical Measurements. First, the individual uncertainties of the input parameters are calculated or estimated, and then the uncertainty of the activity concentration $u(a_0)$ is calculated according to the law of uncertainty propagation.

a. Individual uncertainty components

Uncertainty in weighing of sample mass. The uncertainty associated with the mass of sample is estimated using the data from the calibration certificate of the analytical balance and the manufacturer's recommendations on the uncertainty estimation of the balance. If it is assumed that the balance with 0.1 mg of uncertainty is used for weighing the sample and the linearity distribution is assumed to show a rectangular distribution, the standard uncertainty in weighing of the sample mass can be calculated by the following formula:

$$\frac{0.1}{\sqrt{3}} = 0.058 \text{ mg} \quad (5.34)$$

The contribution for the linearity has to be accounted for twice, once for the tare and once for the gross mass (tare + sample), leading to an uncertainty $u(m_s)$ of

$$u(m_s) = \sqrt{2 \times (0.058)^2} = 0.082 \text{ mg} \quad (5.35)$$

Uncertainty in the mass of the tracer solution is calculated similarly.

Uncertainty of the activity concentration of the tracer solution. The uncertainty of the certified concentration of the tracer solution on a calibration, $u(C_T)$, is provided by the producer.

Uncertainty of net count rates of analyte and tracer. Since

$$u(n) = \sqrt{n}, \text{ and } r = \frac{n}{t_m} \text{ therefore} \quad (5.36)$$

$$u(r)^2 = \frac{n}{t_m^2} = \frac{r}{t_m}$$

Thus, the uncertainty of count rates for analyte and analogously for tracer in alpha spectra can be calculated according to the equation below:

$$u(r_g)^2 = \frac{n_g}{t_m^2} = \frac{r_g}{t_m} \quad (5.37)$$

$$u(r_{gT})^2 = \frac{n_{gT}}{t_m^2} = \frac{r_{gT}}{t_m} \quad (5.38)$$

In the case of background, the number of counts is usually small, and the $u(n) = \sqrt{n}$ equation is not valid; therefore, background uncertainties are calculated from the

average and standard deviation of several long-time background measurements according to

$$\bar{r}_0 = \frac{\sum_i r_{0i}}{n_b} \quad (5.39)$$

where \bar{r}_0 is the average of n_b measurements each resulting in a r_{0i} background count rate,

$$u(r_0) = \frac{\sum_i (r_{0i} - \bar{r}_0)^2}{n_b - 1} \quad (5.40)$$

where $u(r_0)$ is the standard deviations of the n_b repeated background measurements.

The average value for \bar{r}_{0T} and the standard deviation $u(r_{0T})$ are derived similarly.

1. The uncertainties for decay correction factor, $u(f_T)$, can be calculated as follows:

$$u(f_T) = f_T \cdot t_T \cdot u(\lambda_T) \quad (5.41)$$

where uncertainties of the decay constants are obtained from nuclear tables.

The uncertainty of measuring time is neglected: $u(t) = 0$.

b. Combined uncertainty

Combined uncertainty in the determination of the massic activity of the analyte (a_1) is calculated according to the general formula:

$$u(a_1) = \sqrt{\sum_i \left(\frac{\partial a_i}{\partial x_i} \right)^2 u(x_i)^2} \quad (5.42)$$

where x_i are the individual parameters of the result a_1 . In the basic Eq. (5.30), net counts are replaced by net count rates expressed as the difference of gross and background count rates to take into account that counting times of sample and background are usually different. The basic equation for the calculation of the result is therefore

$$a_1 = \frac{C_T \cdot (r_g - r_0)}{m_s \cdot (r_{gT} - r_{0T})} \cdot m_T \cdot f_T \quad (5.43)$$

and a_1 is dependent on the parameters $a_1 = f(r_g, r_0, r_T, r_{0T}, C_T, m_s, m_T, f_T)$. Thus, partial derivatives of a_1 are calculated for each parameter as follows:

$$\frac{\partial a_1}{\partial r_g} = \frac{a_1}{(r_g - r_0)} \quad (5.44)$$

$$\frac{\partial a_1}{\partial r_0} = - \frac{a_1}{(r_g - r_0)} \quad (5.45)$$

$$\frac{\partial a_1}{\partial r_{gT}} = -\frac{a_1}{(r_{gT} - r_{0T})} \quad (5.46)$$

$$\frac{\partial a_1}{\partial r_{0T}} = \frac{a_1}{(r_{gT} - r_{0T})} \quad (5.47)$$

$$\frac{\partial a_1}{\partial C_T} = \frac{a_1}{C_T} \quad (5.48)$$

$$\frac{\partial a_1}{\partial m_s} = -\frac{a_1}{m_s} \quad (5.49)$$

$$\frac{\partial a_1}{\partial m_T} = -\frac{a_1}{m_T} \quad (5.50)$$

$$\frac{\partial a_1}{\partial f_T} = -\frac{a_1}{f_T} \quad (5.51)$$

where

$$\frac{\partial a_1}{\partial \lambda_T} = -t_T a_1 \text{ and } \frac{\partial a_1}{\partial t_T} = 0 \quad (5.52)$$

The uncertainty of the analyte concentration on the separation time $u(a_1)$ can be calculated as follows:

$$\frac{\partial a_0}{\partial a_1} = \frac{a_0}{a_1} \quad (5.55)$$

$$\frac{\partial a_0}{\partial \lambda_A} = a_0 t_1 \quad (5.56)$$

Therefore, the combined relative uncertainty of the basic activity of the analyte (Bq kg^{-1} , dry) on the sampling date ($\mu(a_0)$) can be calculated by the formula

$$\left(\frac{u(a_0)}{a_0}\right)^2 = \left(\frac{u(a_1)}{a_1}\right)^2 + t_1^2 \cdot u(\lambda_A)^2 \quad (5.57)$$

Calculation of the relative uncertainty of the chemical recovery is made based on Eq. (5.33) that can be expressed with count rates instead of counts:

$$R = \frac{r_{gT} - r_{0T}}{C_T \cdot m_T \cdot \varepsilon} \cdot \exp(\lambda_T \cdot t_T) \quad (5.58)$$

$$u_{rel}(R_{cal})^2 = u_{rel}(r_T)^2 + u_{rel}(C_T)^2 + u_{rel}(\varepsilon)^2 + u_{rel}(m_P)^2 + u_{rel}(f_T)^2 \quad (5.59)$$

$$u(a_1)^2 = \left(\frac{a_1}{r_g - r_0}\right)^2 \cdot u(r_g)^2 + \left(-\frac{a_1}{r_g - r_0}\right)^2 \cdot u(r_0)^2 + \left(\frac{a_1}{r_{gT} - r_{0T}}\right)^2 \cdot u(r_{gT})^2 + \left(\frac{a_1}{r_{gT} - r_{0T}}\right)^2 \cdot u(r_{0T})^2 + \left(\frac{a_1}{C_T}\right)^2 \cdot u(C_T)^2 + \left(-\frac{a_1}{m_s}\right)^2 \cdot u(m_s)^2 + \left(\frac{a_1}{m_T}\right)^2 \cdot u(m_T)^2 + (-t_T a_1)^2 \cdot u(\lambda_T)^2 \quad (5.53)$$

and $u(r_g)$ and $u(r_{gT})$ can be replaced by Eqs. (5.37) and (5.38) to get the final expression for the measurement uncertainty:

$$\text{Since } u(r_T)^2 = \frac{n_{gT}}{t_m^2} + \frac{n_{0T}}{t_0^2} = \frac{r_{gT}}{t_m} + \frac{r_{0T}}{t_0} \text{ and } \quad (5.60)$$

$$u(a_1)^2 = \left(\frac{a_1}{r_g - r_0}\right)^2 \cdot \frac{r_g}{t_m} + \left(-\frac{a_1}{r_g - r_0}\right)^2 \cdot u(r_0)^2 + \left(\frac{a_1}{r_{gT} - r_{0T}}\right)^2 \frac{r_{gT}}{t_m} + \left(\frac{a_1}{r_{gT} - r_{0T}}\right)^2 \cdot u(r_{0T})^2 + \left(\frac{a_1}{C_T}\right)^2 \cdot u(C_T)^2 + \left(-\frac{a_1}{m_s}\right)^2 \cdot u(m_s)^2 + \left(\frac{a_1}{m_T}\right)^2 \cdot u(m_T)^2 + (-t_T a_1)^2 \cdot u(\lambda_T)^2 \quad (5.54)$$

Combined uncertainty in the determination of the analyte on the sampling date, $u(a_0)$ can be derived from the uncertainty on the separation time $u(a_1)$ by differentiating Eq. (5.32). Each partial derivative can be calculated as follows:

$$u_{rel}(f_T)^2 = t_T^2 \cdot u(\lambda_T)^2 \quad (5.61)$$

the following equation is obtained:

$$u_{rel}(R_{cal})^2 = \left(\frac{r_{gT}}{t_m} + \frac{r_{0T}}{t_0} \right) \cdot \left(\frac{1}{r_{gT} - r_{0T}} \right)^2 + u_{rel}(C_T)^2 + u_{rel}(\varepsilon)^2 + u_{rel}(m_p)^2 + t_T^2 u(\lambda_T)^2 \quad (5.62)$$

Similarly, the relative uncertainty of the counting efficiency is calculated from Eq. (5.26):

$$u_{rel}(\varepsilon)^2 = \left(\frac{r_{CS}}{t_{CS}} + \frac{r_{BG}}{t_{BG}} \right) \cdot \left(\frac{1}{r_{CS} - r_{BG}} \right)^2 + u_{rel}(A_{CS})^2 + u_{rel}(I)^2 + t_{CS}^2 u(\lambda_{CS})^2 \quad (5.63)$$

where the indexes *CS* and *BG* refer to the calibration source and the background in the peak of the calibration source, A_{CS} is the known activity of the calibration source, I is its alpha decay probability/abundance, t_{CS} is the time elapsed from source calibration to measurement, and λ_{CS} is the decay constant of the calibration source. Holmes (2004) proposed the spreadsheet approach for the calculation of combined uncertainty in alpha spectrometry, which has the advantage of avoiding having to solve complicated differential equations and identifying how much individual uncertainty components contribute to the combined uncertainty.

Kim et al. (2008b) identified and quantified all uncertainty sources, which can appear in the measurement of ^{210}Pb and ^{210}Po by liquid scintillation counting and alpha particle spectrometry, including correction to the sampling date. The paper also presented how the combined uncertainty in the calculation of ^{210}Po activity on the sampling date depends on the ratio of $^{210}\text{Po}/^{210}\text{Pb}$ specific activities on the sampling date (or the reference date in the particular case of analysis of a reference material).

7. Calculation of the decision threshold and the detection limit

a. Decision threshold

In accordance with ISO 11929 (2010), the decision threshold, a^* , is obtained from the following equation:

$$a^* = k_{1-\alpha} u(0) \quad (5.64)$$

where $k_{1-\alpha} = 1.65$ is often chosen as default, and $u(0)$ can be calculated from Eqs. (5.54) and (5.57) by substituting the value of r_0 background instead of r_g , the measured value of the analyte. The decision threshold is obtained as activity concentration expressed in Bq kg^{-1} .

b. Detection limit

In accordance with ISO 11929 (2010), the detection limit, $a^\#$, is calculated by iteration according to the following equation:

$$a^\# = k_{1-\alpha} u(0) + k_{1-\beta} u(a^\#) \quad (5.65)$$

Assuming $\alpha = \beta$, then $k_{1-\alpha} = k_{1-\beta} = k$. The detection limit is obtained as activity concentration expressed in Bq kg^{-1} (IAEA, 2017).

VIII. Quality control

General requirements for the competence of testing and calibration laboratories are summarized in the ISO/IEC 17025 (2017) standard. Here, we discuss specific issues of QC of alpha spectrometers and validation of alpha spectrometric methods.

A. Quality control for alpha spectrometers

Instrument performance is regularly monitored by counting check sources. The same alpha source containing at least two alpha emitting radionuclides can be used to check the energy, the FWHM and the efficiency calibration of the detector/alpha spectrometer. The check source is counted under fixed conditions similar to those used for samples. The parameters characterizing the stability of the system are the **peak location, the FWHM, and the counting efficiency** of a selected radionuclide present in the check source. The measured values are plotted in a control chart as a function of counting date/time. It is desirable to set the control limits for mean chart and range chart according to ISO standard (ISO 7870-2, 2013). The coverage factors for the control limits of mean chart and range chart are decided based on the observations in subgroups of size. When measured values are out of the warning level range, the instrument has to be checked or repaired, and it may be that the detector has to be replaced. If the measured values are out of the control limit range, measurements are suspended until the cause analysis for outliers in the control charts has been completed. The frequency of control measurements is regulated in the Quality Manual of the laboratory, but it is desirable to perform QC measurements before each series of analysis. Additionally, **background measurements** are performed on a regular basis to check detector contamination.

As an example, the efficiency control chart of an alpha spectrometer is shown in Fig. 5.47 together with the average value of the measurements and the warning and control levels that were established by the first seven data points.

B. Validation of the procedure

Methods that have been developed at the laboratory, which are nonstandard methods or amplifications and modifications of standard methods, have to be validated to

FIGURE 5.47 Control chart of an alpha spectrometer showing the efficiency data and their uncertainty (1σ) as well as the average values, warning levels ($\pm 2\sigma$ deviation from the average) and control levels ($\pm 3\sigma$ deviation from the average).

demonstrate that they fit the purposes of application. According to the [ISO/IEC 17025 \(2005\)](#) standard, the techniques used for the determination of the performance of a method are one of, or a combination of, the following:

1. calibration using reference standards or reference materials,
2. comparison of results achieved with other methods,
3. interlaboratory comparisons (intercomparison exercises or proficiency tests),
4. systematic assessment of the factors influencing the result,
5. assessment of the uncertainty of the result based on scientific understanding of the theoretical principles of the method and practical experience.

Whenever standards and reference materials with known concentrations of the analytes are available, it is recommended that measurements be carried out using these materials. Reference materials are provided for a great variety of alpha-emitting nuclides by the IAEA, IRMM, and NIST, among others. Results obtained by alpha spectrometry can often be compared with those obtained by other techniques such as mass spectrometry, gamma spectrometry, and liquid scintillation counting. An increasing number of interlaboratory comparisons have been organized by national and international institutes, and network laboratories (e.g., [IAEA, 2010b](#)).

Although systematic assessment of the factors influencing the result (point 4 above) and evaluation of the uncertainty components (point 5) are extremely important, method validation should not be based exclusively on one of these validation techniques. It is desirable to apply—whenever it is possible—the combination of the validation techniques (points 1–3). For example, the recommended procedure of the IAEA for the simultaneous determination of Pu and Am nuclides in environmental samples was

validated by preparing the uncertainty budget, by the measurement of six different reference materials by the proposed procedure, and by an interlaboratory comparison with two participating expert laboratories. In the course of the validation procedure, the performance parameters of the method including accuracy, uncertainty, detection limit, range of results, selectivity, linearity, repeatability and reproducibility, robustness against external influences, or cross-sensitivity against interferences have to be assessed ([IAEA, 2012](#)). It is recommended to follow the EURACHEM guide ([EURACHEM Guide, 2014](#)) for the method validation, which describes the validation procedure in detail.

IX. Conclusions

In recent years, the position of alpha spectrometry as the technique of choice when reliable isotopic analysis of very low activity levels is required has been challenged somewhat by improvements in other radioanalytical techniques, especially mass spectrometry. This is particularly the case for very long-lived radionuclides such as ^{238}U and ^{235}U . However, for shorter-lived alpha emitters such as ^{210}Po , the sensitivity of alpha spectrometry remains unchallenged due to a combination of low background and high detection efficiency.

The need for sample digestion and lengthy chemical separations remains the main drawback for standard alpha spectrometry analysis. The use of microwave digestion and the development of methods for fusion of solid samples or coprecipitation from water are increasingly common approaches for sample preparation and digestion. The development of methods utilizing EC is a major step forward for chemical separation, particularly for actinides. Some progress has also been made in automated chemical separations.

With increasing requirements on laboratories for traceability of results and for accreditation, the existence of standard, validated methods and of proficiency tests is becoming more important. Several methods have been published by ASTM, IAEA, and ISO, partially fulfilling this need. However, the large matrix of analytes and sample types, which can be analyzed by alpha spectrometry, means that a complete and up-to-date set of such methods is unlikely to materialize, and laboratories will continue to develop methods based on their specific needs. A wide variety of proficiency tests and reference materials would also be desirable for a similar reason.

Recently, in situ alpha spectrometry and use of other analytical methods in combination with alpha spectrometry have been under investigation. Coincidence techniques and list mode data acquisition are among the novel methods applied in alpha spectrometry. Special attention has also been paid to the development of spectrum analysis programs. The use of spectrum deconvolution software in conjunction with high- and medium-resolution alpha spectrometry is a promising tool to analyze overlapping peaks and alpha sources of “poor quality.” Developments in spectrum evaluation can help replace or at least simplify chemical sample processing and the analysis of those nuclides whose spectra could not be evaluated with conventional alpha spectrometry.

Despite the challenges, alpha spectrometry remains important as a workhorse for many applications, as an essential tool in a number of important specialist applications and as a reliable and high-sensitivity technique for research and other investigative work.

Terms and definitions, symbols, and abbreviations

$a^{\#}$ detection limit (Bq kg^{-1})
 a^* decision threshold (Bq kg^{-1})
 a_0 the activity concentration of the analyte on the sampling date (Bq kg^{-1})
 a_1 the activity concentration of the analyte at the separation time (Bq kg^{-1})
 C_T the certified concentration of the tracer on the reference date (Bq g^{-1})
 f_T the correction factor for the decay of the tracer during elapsed time (days) between the reference date of tracer and the beginning of the measurement
 m_s the mass of sample (L)
 m_T the mass of the tracer taken (g)
 n and n_T net counts in ROIs (region of interest) of analyte and tracer (counts), respectively,
 n_0 and n_{0T} blank or background counts in ROIs (region of interest) of analyte and tracer (counts), respectively,
 n_g and n_{gT} gross counts in ROIs (region of interest) of analyte and tracer (counts), respectively,
 R the chemical recovery of the analyte

r and r_T net count rates in ROIs (regions of interest) of analyte and tracer (counts), respectively,
 r_0 and r_{0T} blank or background count rates in ROIs (regions of interest) of analyte and tracer (counts), respectively,
 r_g and r_{gT} gross count rates in ROIs (regions of interest) of analyte and tracer (counts), respectively,
 t_0 the counting time of blank (s)
 t_1 the time interval between the sampling date and the separation time (year)
 t_m the sample counting time (s)
 t_T the time interval between the reference date of the tracer and the separation time (years)
 $u(C_T)$ the uncertainty of the certified concentration of the tracer solution according to the calibration (Bq g^{-1})
 $u(f_T)$ the uncertainty of correction factor for decay of the tracer during elapsed time (years) between the reference date of tracer and the separation time
 $u(m_s)$ the uncertainty of mass of sample (kg)
 $u(m_T)$ the uncertainty of mass of the tracer (g)
 $u(n)$, $u(n_T)$ the uncertainty of the net counts in the ROIs of the analyte and the tracer, respectively
 $u(\lambda_A)$ the uncertainty of the decay constant of the analyte (year^{-1})
 $u_c(a_0)$ combined uncertainty of the activity concentration of the analyte on sampling date (Bq kg^{-1})
 λ_A the decay constant of the analyte (years^{-1})
 λ_T the decay constant of the tracer (years^{-1})

Dr. Nóra Vajda

Dr. Nóra Vajda is radiochemist and professor of the Hungarian Academy of Sciences. She has been the head of RADANAL Ltd. for the last 10 years and had been working at the Budapest University of Technology and Economics as an associate professor. Her main research area is radiation measurements, especially radiochemical alpha, beta, and gamma ray spectrometry and neutron activation. Other areas of interest are the determination of difficult-to-measure radionuclides in radioactive wastes, technological water of nuclear power plants, and the environment. During her 40-year career, she has published more than 100 scientific papers, was the supervisor of several PhD, MSc, and BSc students, and participated in missions to Member States on peaceful applications of nuclear energy organized by the International Atomic Energy Agency.

Dr. Roy Pöllänen

Dr. Roy Pöllänen is an adjunct professor in the physics department of the University of Helsinki. He works in the Radiation and Nuclear Safety Authority (STUK) of Finland as a senior inspector. His main research area is radiation measurements, especially nondestructive alpha spectrometry and gamma ray spectrometry. Other areas of interest are environmental radiation monitoring and in particular air monitoring, atmospheric transport calculations, determination of radioactive particle characteristics, dose calculations, radiation hazard estimation, radiation detection methods in general, and in-field measurements. Radiation measurements by using unmanned aerial vehicles, emergency preparedness, and organizing training and radiation detection exercises are other topics of interest. During his 30-year career in STUK, Roy Pöllänen has published more than 100 scientific papers and reports. He represents STUK

in the International Committee for Radionuclide Metrology, ICRM, and he is active in various (inter)national research projects.

Paul Martin

Dr. Paul Martin has 35 years of experience in radioactivity measurements, with a special emphasis on the determination of the natural series radionuclides in environmental samples by alpha and gamma spectrometry. Particular areas of his professional activity have been uranium mining-related environmental and radiological impact studies, behavior of radionuclides in the tropical environment, radon and radon progeny in the atmosphere, airborne gamma spectrometry as a site assessment tool, sample analysis for nuclear safeguards, and reference material production and interlaboratory comparison exercises for analytical quality assurance. From 2012 to 2017, Paul was an associate editor for the Journal of Environmental Radioactivity.

Chang-Kyu Kim

Chang-Kyu Kim studied chemistry at the University of Tsukuba (Japan), where he received a PhD degree in 1990. From 1990 to 1998, Mr. Kim worked as a principal researcher for the Environmental Radiation Assessment Unit, Korea Institute of Nuclear Safety, Korea. Mr. Kim was in charge as project manager for the project on the development of advanced analytical techniques for ultratrace-level long-lived radionuclides in environmental samples using high-resolution ICP-MS. From 2004 to 2010, Mr. Kim worked as a radiochemist specialist at the Terrestrial Environment Laboratory, IAEA Environment Laboratories, Seibersdorf, Austria. From 2011 to 2012, Mr. Kim worked as a senior radiochemist for the Forensic Scientific Services, Health Physics, Queensland Health, Australia. He has more than 30 years of working experience in the field of radioanalytical chemistry, and he has published more than 150 papers and reports. Since 2013, Mr. Kim has worked as a nuclear safeguards inspector and quality manager at the On-Site Laboratory team, Office of Safeguards Analytical Services, IAEA.

Liquid scintillation analysis: principles and practice*

Michael F. L'Annunziata¹, Alex Tarancón², Héctor Bagán² and José F. García²

¹The Montague Group, Oceanside, CA, United States; ²Department of Chemical Engineering and Analytical Chemistry, University of Barcelona, Barcelona, Spain

Chapter outline

I. Introduction	576		
II. Basic theory	577		
A. Scintillation process	577		
B. Alpha-, beta-, and gamma-ray interactions in the LSC	579		
C. Cherenkov photon counting	581		
III. Liquid scintillation counter (LSC) or analyzer (LSA)	581		
IV. Quench in liquid scintillation counting	584		
V. Methods of quench correction in liquid scintillation counting	588		
A. Internal standard (IS) method	588		
B. Sample spectrum characterization methods	589		
1. Sample channels ratio (SCR)	589		
2. Combined internal standard and sample channels ratio (IS-SCR)	590		
3. Sample spectrum quench indicating parameters	591		
C. External standard quench indicating parameters	595		
1. External standard (source) channels ratio (ESCR)	596		
2. H-number (H#)	597		
3. Relative pulse height (RPH) and external standard pulse (ESP)	599		
4. Spectral quench parameter of the external standard or SQP(E)	600		
5. Transformed spectral index of the external standard (tSIE)	601		
6. G-number (G#)	604		
D. Preparation and use of quenched standards and quench correction curves	606		
1. Preparation of quenched standards	606		
2. Preparation of a quench correction curve	608		
3. Use of a quench correction curve	609		
E. Combined chemical and color quench correction	609		
F. Direct DPM methods	611		
1. Conventional integral counting method (CICM)	611		
		2. Modified integral counting method (MICM)	612
		3. Efficiency tracing (ET) with ¹⁴ C	613
		4. Multivariate calibration	617
		VI. Analysis of X-ray, gamma-ray, atomic electron, and positron emitters	618
		VII. Common interferences in liquid scintillation counting	623
		A. Background	623
		B. Quench	624
		C. Radionuclide mixtures	624
		D. Luminescence	625
		1. Bioluminescence	625
		2. Photoluminescence and chemiluminescence	625
		3. Luminescence control, compensation, and elimination	626
		E. Static	628
		F. Wall effect	629
		VIII. Multiple radionuclide analysis	630
		A. Conventional dual- and triple-radionuclide analysis	630
		1. Exclusion method	630
		2. Inclusion method	631
		B. Three-over-two fitting and digital overlay technique (DOT)	641
		C. Full spectrum DPM (FS-DPM)	641
		D. Recommendations for multiple radionuclide analysis	644
		E. Complex spectral analysis	644
		1. Most-probable-value theory	645
		2. Spectral fitting, unfolding, and interpolation	648
		3. Spectral fitting and subtraction	651
		4. Modeling from spectral library	654
		5. Spectral unfolding by region count ratios	655
		6. Multivariate calibration	657
		IX. Radionuclide standardization via LSA	658

I. Introduction

Liquid scintillation counting (LSC) or liquid scintillation analysis (LSA) has been a very popular technique for the detection and quantitative measurement of radioactivity since the early 1950s. The technique has been most useful in studies of the life sciences and the environment, and it is

also a powerful tool in the chemical and physical sciences. Many of the principles of liquid scintillation analysis overlap into the fields of low-level environmental radioactivity monitoring, the detection of singular decay events in basic nuclear physics, and the measurement of higher levels of radioactivity used in research, radioisotope applications, and nuclear power. However, the techniques and

principles used in the LSA of environmental radioactivity per se will not be covered in detail in this chapter. The reader is directed to Chapter 2 of Volume 2 of this book for additional information on the use of LSA for the measurement of either natural levels of radionuclides or low-levels of man-made radionuclides found in the environment.

Applications of liquid scintillation analysis to the measurement of radionuclides used as tracers in research has led to a large number of cutting edge and Nobel prize-winning discoveries in the life sciences over the past 50 years. The LSA technique in scientific research remains one of the most popular experimental tools used for the quantitative analysis of radionuclides. These include principally the analysis of alpha and beta particle-emitting nuclides, but may also include nuclides that emit gamma radiation, as well as atoms that decay with the emission of x radiation, and those that emit Auger and internal-conversion electrons. Included in this chapter are also advances that continue to be made in the application of liquid scintillation to the analysis of neutrons, and the discrimination of neutron and gamma radiation, the analysis of high-energy charged particles, and the detection and measurement of unique events, such as π^+ decay, μ^+ decay, $\beta\beta$ decay, and the detection of neutrinos.

Some advances in the use of liquid scintillation analysis in the standardization of radionuclides will be included in this chapter. A more comprehensive treatment of radionuclide standardization by means of all available radiation detection and measurement methods will be included in Chapter 7, Volume 2 of this book.

The wide popularity of liquid scintillation analysis is a consequence of numerous advantages, which may include high efficiencies of detection, improvements in sample preparation techniques, automation including computer data processing, and the spectrometer capability of liquid scintillation analyzers permitting the simultaneous assay of different radionuclides.

II. Basic theory

A. Scintillation process

The discovery of scintillation in organic compounds was documented in a thesis by Herforth (1948) under the leadership of Hartmut Kallmann, which is related in a historical account by Niese (2003, 1999). In her thesis presented on September 13, 1948, at the Technical University Berlin — Charlottenburg, Herforth reported that aromatic compounds could convert absorbed energy of nuclear radiation into light photons. Herforth coauthored a subsequent publication with Kallmann and Immanuel Broser, another student of Kallmann, on the scintillation process in naphthalene (Broser et al., 1948) as well as a

paper on fluorescence from liquid (molten) naphthalene, diphenyl, and phenanthrene as a consequence of interaction with alpha particles, fast electrons, and gamma rays (Herforth and Kallmann, 1948). Both Herforth and Broser were fellow students, who had researched radioactivity counters under Hans Geiger. Herforth's thesis and publications with Kallmann were followed by papers authored by Kallmann (1950) and Reynolds et al. (1950) on liquid scintillation counting that demonstrated certain organic compounds in solution-emitted fluorescent light when bombarded by nuclear radiation. The origin of liquid scintillation analysis as a technique for the quantification of radioactivity is attributed to the original papers by Kallmann and Reynolds in 1950. The fluorescence or emission of photons by organic compounds (fluors) as a result of excitation can be readily converted to a burst of electrons with the use of a photomultiplier tube (PMT), and subsequently measured as an electric pulse.

The technique of liquid scintillation counting involves placing the sample containing the radioactivity into a glass or plastic container, called a scintillation vial, and adding a special scintillation cocktail containing organic fluors dissolved into suitable solvents. Common capacities of scintillation vials that can be accommodated easily in conventional automatic liquid scintillation analyzers vary from 4 to 20 mL; however, microfuge tubes of 0.5–1.5 mL capacity can also be counted directly in a conventional LSA with the use of special microtube holders. Samples may also be analyzed by high-sample-throughput LSA in plastic microplates containing 24, 96, or 384 sample wells per microplate, which accept sample-fluor cocktail volumes in the range of 20–150 μ L. High-sample-throughput microplate liquid scintillation counting is described in Section XIII of this chapter.

Both plastic and glass liquid scintillation counting vials have certain advantages and disadvantages in terms of background, solvent permeability, fragility, and transparency, etc. Polyethylene plastic vials are permeable when stored containing fluor solvents such as benzene, toluene, and xylene; however, these vials do not display solvent diffusion when more environmentally safe commercial fluor cocktails are used (e.g., Ultima Gold, Pico-fluor, Opti-fluor, etc.), which use diisopropylnaphthalene (DIN), pseudocumene, or linear alkylbenzene solvents. The plastic vials are also unbreakable, less expensive, and display lower backgrounds than the glass vials. Glass vials, however, provide the advantage of transparency to visualize the sample and fluor cocktail solution to permit inspection for undesirable properties such as color, residue, or sample inhomogeneity.

The scintillation cocktail may be composed of a solvent such as DIN, or a linear alkylbenzene together with a fluor solute such as 2,5-diphenyloxazole (PPO) dissolved in a concentration of approximately 2–10 g/L. Many liquid

fluor cocktails are available commercially, and these are made to be compatible and mixable with radioactive samples dissolved in either organic solvents or aqueous media. When samples are dissolved in aqueous media, three different chemical components are required in the fluor cocktail solution: the organic solvent, organic scintillator, and a surfactant (emulsifier). The choice of solvent, scintillator, and surfactant for the preparation of contemporary fluor cocktails is dictated by the need for efficient energy transfer and light output in the scintillation process even under very high aqueous sample loads exceeding 50% water as well as the need for environmentally safe solutions with low toxicity, high flash point, and low disposal costs. To meet these needs, some commercially available formulations use diisopropylnaphthalene or a linear alkylbenzene solvent. A few of these commercial fluor cocktails were noted in the previous paragraph. The properties and performance of the modern environmentally safe solvents and some of the commercially available cocktails made from these solvents have been reviewed and tested by Feng et al. (2015), Ruano Sánchez et al. (2013), Verzezen et al. (2008), Medeiros et al. (2003), DeVol et al. (1996), Neuman et al. (1991), Thomson (1991), and a comprehensive review with recommendations is provided in Chapter 7, Volume 1 of this book. The findings of these studies, as summarized by Verzezen et al. (2008), are that no specific liquid scintillation cocktail can be identified to fit all radio-analytical needs, and cocktail formulations are designed to compromise between a performance aspect (*e.g.*, high sample load or sample compatibility) at the expense of another (*e.g.*, counting efficiency or stability). Chapter 7 of Volume 1 of this book provides detailed information on the composition and performance of many liquid scintillation fluor cocktails and sample preparation techniques.

Unique scintillation cocktails may be prepared to meet special detection needs, such as the detection of neutrinos, neutron/gamma discrimination, alpha/beta discrimination, and the detection of neutrinos or unique decay events, such as muon-, pion-, and double-beta decay. The characteristics of the liquid scintillation media or cocktails used for these specific detection needs are noted within the chapter.

A sample, which is to be analyzed for its radioactivity or disintegration rate, is placed into the scintillation cocktail to form a homogeneous counting solution. The liquid scintillation process that occurs in a scintillation cocktail is shown in Fig. 6.1. The first step in the process is the interaction of the nuclear radiation or particle under analysis with the solvent molecules of the liquid scintillation cocktail. These solvent molecules, as depicted in Fig. 6.1, are organic in nature and contain at least one aromatic ring. Because the solvent molecules are in greater concentration than the solute fluor molecules in the fluor cocktail, the solvent molecules will absorb the major portion of the nuclear radiation energy emitted by the radionuclides in the cocktail solution. The

The Basic Liquid Scintillation Process

FIGURE 6.1 An illustration of the sequence of events in the basic liquid scintillation process. A radionuclide will dissipate its energy of decay (*e.g.*, β^- -particle energy) in the liquid scintillation cocktail containing solvent and fluor (scintillator). The aromatic solvent absorbs most of the energy of the beta particle. The energy of excitation of the solvent is then transferred to the scintillator (fluor) molecules, which upon deexcitation emit photons of visible light. The intensity of the light photons are detected by a photomultiplier tube (PMT), which converts the light photons into a flow of electrons and further amplifies the current pulse. Points of interference caused by chemical, ionization, and color quenching are also indicated.

result is the formation of activated organic solvent molecules followed by a transfer of energy to the organic scintillator or fluor, as illustrated in Fig. 6.1. Organic scintillators are chosen because they are soluble in the organic solvent, they can easily accept the energy from the activated solvent molecule, and they produce an activated or excited scintillator molecule. These excited scintillator molecules rapidly lose their energy and return to their original ground state by way of a fluorescence mechanism. The energy is released as photon emissions in the wavelength range of 375–430 nm for each radioactive decay process occurring in the fluor cocktail. The wavelength of emission depends on the scintillator dissolved in the fluor cocktail. The photon emission intensity is a function of the energy and the type of nuclear decay.

The scintillation cocktail converts the original nuclear decay energy to photons of light by way of the process shown in Fig. 6.1. The intensity of the photon emission is directly proportional to the original nuclear energy dissipated in the fluor cocktail. The higher the energy absorbed by the fluor cocktail, the greater is the intensity of the photon emission. For example, tritium, which is a low-energy beta-particle emitter ($E_{\max} = 18.6$ keV), would produce relatively very low intensity photon emissions for each beta particle absorbed in the fluor cocktail. However, ^{32}P , which is a high-energy beta-particle emitter ($E_{\max} = 1710$ keV), would produce a light intensity approximately 100 times greater in the fluor cocktail. Thus, the light intensity emitted by a scintillation fluor cocktail reflects the original nuclear decay energy, and the photon emissions per unit time is proportional to the number of nuclear decays in that time period or, in other words, the sample radioactivity (*e.g.*, disintegrations per minute or DPM).

A liquid scintillation analyzer may also be used to measure the photon emissions produced when radioactive nuclides are adsorbed onto or in close proximity to the

surface of a plastic or glass scintillator (solid scintillator) located within a conventional liquid scintillation counting vial or well of a microplate scintillation analyzer. The solid scintillation counting process uses a solid inorganic scintillator (e.g., yttrium silicate) to produce the light emissions, which are quantified by the liquid scintillation counter. The photon emissions are produced directly by the interaction of the decaying nuclear event with the inorganic scintillator. The photon emission intensities produced are proportional to the energies of the radiation emitted from the nuclear decay that are absorbed by the scintillator, similar to that for the liquid scintillation process. This technique, known as scintillation proximity assay (SPA), is used to measure binding reactions, commonly studied in the fields of medicine, biochemistry, and molecular biology, without the need to separate bound from free fractions. It uses glass or plastic solid scintillation microspheres together with a low-energy-emitting isotope-labeled (^3H or ^{125}I) ligand. The method is described briefly in Section XIII.B of this chapter and in more detail in Chapter 9, “Solid Scintillation Analysis”, in Volume 1 of this book, as it is a solid scintillation technique, which utilizes a liquid scintillation counter.

B. Alpha-, beta-, and gamma-ray interactions in the LSC

The scintillation process and light output are different for the alpha, beta, and gamma decay. These decay processes are described in detail in Chapter 1, Volume 1. Only a brief treatment is provided here. The alpha decay process is illustrated by Eq. (1.154) and Fig. 1.40 of Chapter 1. During the alpha decay process, a helium nucleus, which is composed of two protons and two neutrons, is released with a specific energy (monoenergetic) from the atomic nucleus. The general decay energy range for alpha particles is 2–8 MeV. When alpha decay occurs in a liquid scintillation cocktail, the alpha particles interact with the fluor cocktail to produce photons of light (approximately 1 photon/keV of original decay energy). The photon intensity is converted into an electric pulse of magnitude proportional to the photon intensity via a photomultiplier tube described in Section III of this chapter.

If we compare the linear range (R_{cm}) in centimeters of a 5.5 MeV alpha particle from ^{241}Am in water ($R_{\text{cm}} = 0.0048$ cm) to the range of a 0.55 MeV beta particle from ^{10}Be in water ($R_{\text{cm}} = 0.178$ cm), we see that the alpha particle travels a much shorter distance, only 2.7 hundredths (0.0048/0.178) that of the beta particle, regardless of the fact that the alpha particle possessed 10 times the energy of the beta particle (See Chapter 1 for calculations of range and energy for alpha and beta particles). The higher charge and mass of the alpha particle compared with the beta particle are responsible for the reduced range of the

alpha particle (See Chapter 1) and less efficient excitation energy transfer to solvent and fluor. Alpha particles produce photons of light in the liquid scintillation cocktail at about one-tenth the intensity per unit of particle energy of beta particles (Horrocks, 1974). Therefore, in the case of alpha particles, which are monoenergetic, a single pulse height peak is seen for each alpha decay, at a pulse height equivalent to approximately one-tenth its original nuclear decay energy. A 5-MeV alpha particle, therefore, would be detected by a pulse height equivalent to approximately 500 keV in a liquid scintillation cocktail. Consequently, the pulse heights of alpha particles and beta particles in the same sample often overlap even when the alpha particles emitted from certain radioactive nuclides are of energy about 10 times greater than the E_{max} of beta particles emitted by other radionuclides in the same sample. The overlapping liquid scintillation pulse height spectra of ^{210}Po and ^{90}Sr (^{90}Y) in the same sample are illustrated in Fig. 6.2.

The pulse decay times of the photon emissions produced in liquid scintillator from alpha and beta events are also different. A pulse in the scintillation process produced by an alpha particle can be about 35–40 nsec longer than a pulse event produced by a beta particle. Using this characteristic, simultaneous analysis of alphas and betas in the same pulse height energy range can be performed. The discrimination of alpha and beta particles, which produce overlapping pulse height intensities, is described in Section XV of this chapter.

The counting efficiency (i.e., how efficiently the nuclear decay is detected) is approximately 100% for almost all alpha decays using a liquid scintillation cocktail. Because of the unique pulse height spectral characteristics of alpha detection in a liquid scintillation counter (See Fig. 6.2) and their slower pulse decay times, alpha particles can be distinguished easily from most other nuclear decay radiations with the liquid scintillation analyzer.

A very common radionuclide decay process is the production and emission of beta particles. Beta decay can take place by either negatron (β^-) or positron (β^+) emission. The production of a negative beta particle (negatron) is described by Eqs. (1.173) and (1.174) of Chapter 1. During the beta decay process with negatron emission, a neutron is converted to a proton and an electron (negative beta particle) and an antineutrino. The beta particle (negatron) is equivalent to an electron in property, and the antineutrino is a particle of zero charge and near zero mass. The total decay energy that is released in the beta decay process is shared between the beta particle and the antineutrino. This total decay energy is usually expressed as the E_{max} , which is the maximum energy that is released in the decay process. The decay energy is shared between the beta particle and antineutrino, but only the beta particle can be detected directly by the scintillation process. Thus, the

FIGURE 6.2 The overlapping pulse height spectra produced by a mixture of the 5.30 MeV alpha particles of ^{210}Po and the 0.55 MeV energy maximum of the beta particles of ^{90}Sr and 2.28 MeV energy maximum of the beta particles of ^{90}Y in a PerkinElmer 2750 TR liquid scintillation analyzer. The sample contains a mixture of $^{210}\text{Po} + ^{90}\text{Sr}(^{90}\text{Y})$ in a scintillation cocktail of 50% water (1:1 mixture of water and Ultima Gold AB fluor cocktail) and displayed a tSIE quench indicating parameter of 277. Notice the relatively sharp peak of the 5.3 MeV alpha-particle pulse height spectrum of ^{210}Po overlapping with the 0.55 MeV energy maximum beta-particle pulse height spectrum of ^{90}Sr and 2.28 MeV maximum beta-particle pulse height spectrum of ^{90}Y . The ^{90}Y daughter is in secular equilibrium with its parent ^{90}Sr . The α -peak of ^{210}Po and the β peaks of $^{90}\text{Sr}(^{90}\text{Y})$ appear in a separate α -MCA and β -MCA. The two pulse height spectra of the MCAs are overlapped to demonstrate the overlapping pulse heights produced by the ^{210}Po and ^{90}Sr . (L'Annunziata, M. F. 1997, unpublished work of the writer.)

resultant spectrum for all beta decays starts at zero and goes to the maximum decay energy (E_{max}) as illustrated in Fig. 1.45 of Chapter 1. Approximately 10 photons of light per keV of beta-particle decay energy are produced in the liquid scintillation process. Because of the broad spectrum of beta-particle energies emitted by a given radionuclide sample, beta decays can easily be recognized by this distinct broad spectral pattern as illustrated in Fig. 1.45 of Chapter 1 on the linear energy scale or in Fig. 6.2 of this chapter illustrating the pulse height spectra of $^{90}\text{Sr}(^{90}\text{Y})$ on a logarithmic energy scale.

Another type of beta decay produces a positron or positive beta particle. This beta decay process converts a proton to a neutron and a positively charged electron (positron) accompanied by the emission of a neutrino. Positron emission is described by Eqs. (1.202) and (1.203) of Chapter 1. The positron is an antiparticle of an electron; it possesses an opposite charge and a spin in the opposite direction to that of the electron. The total energy released in the positron decay process is shared between the positron and the neutrino. The positron will lose its kinetic energy in matter via ionization. When it comes to a near stop, it comes into contact with an electron, its antiparticle, and is annihilated with the simultaneous production of two gamma-ray photons of 0.51 MeV energy equivalent to the two annihilated electron rest masses. See Chapter 1 for more detailed information on both the negatron and positron decay processes.

The liquid scintillation counting efficiency for beta particles (negatrons or positrons) is dependent on the original energy of the beta decay. For most beta particles with a decay energy above 100 keV, the counting efficiency is 80%–100%, but for lower energy beta decays (e.g., ^3H , $E_{\text{max}} = 18.6$ keV) the counting efficiency is normally in the range of 10%–60% depending upon the

degree of quench in the sample. The phenomenon of quench and its effect on liquid scintillation counting efficiency are described in Sections IV and V of this chapter.

Another common nuclear decay process is gamma-ray emission. In this process, a gamma ray is emitted from the nucleus of the decaying atom. The gamma ray is electromagnetic radiation or, in other respects, a photon particle. The general energy range for gamma rays is 50–1500 keV. Gamma-ray emission often accompanies alpha-emission, beta-emission, or electron capture (EC) decay processes. Bremsstrahlung or X-radiation, which is electromagnetic radiation originating from electron energy transitions, also accompanies the EC decay process. When gamma-emitting radionuclides are detected by the liquid scintillation counter, it is not the gamma ray that is detected to a very significant degree, but rather the alpha particles, beta particles, or atomic electrons (Auger and internal-conversion electrons) that may be produced during decay processes occurring in the liquid scintillation fluor cocktail. Gamma rays from sample radionuclides in the scintillation cocktail can produce Compton electrons, although these interactions are less significant in magnitude in the liquid fluors. In general, electromagnetic radiation makes only a minor contribution to excitation in liquid scintillation fluor compared to charged-particle radiation. For example, if we consider the liquid scintillation analysis of ^{125}I , which decays by electron capture with the emission of gamma rays and daughter X-radiation, liquid scintillation counting efficiencies as high as 85% are reported. However, the excitations in the liquid scintillation fluor are due mainly to the absorption of Auger and internal-conversion electrons and only a minor contribution ($\sim 8\%$) is the result of X-rays produced during the decay process (L'Annunziata, 1987).

C. Cherenkov photon counting

Beta particles of energy in excess of the threshold energy of 263 keV can be detected and quantified in water using the liquid scintillation analyzer without the use of scintillation fluor cocktail. Other threshold energies exist for media other than water, and these are described in Chapter 6, Volume 2 of this book. The sample is simply placed in a clear liquid solution (often aqueous) and detected by the photons of light produced by the Cherenkov Effect. Charged particles, such as beta particles, that possess sufficient energy can travel at a velocity exceeding the speed of light in transparent media such as water, organic solvents, plastic, and glass. When this occurs, the charged particle will produce Cherenkov photons, which extend from the ultraviolet into the visible wavelengths. The light, which is produced, is of low intensity, and it is detected in the low-energy counting region of a liquid scintillation analyzer with pulse heights equivalent to those produced by beta particles of 0–50 keV. High-energy beta-particle emitters, which emit a significant number of beta particles in water in excess of 263 keV, can be analyzed by counting the Cherenkov photons in the liquid scintillation analyzer without fluor cocktail. Some examples are ^{32}P ($E_{\text{max}} = 1710$ keV), $^{90}\text{Sr}/^{90}\text{Y}$ where the E_{max} of ^{90}Y beta particles is 2280 keV, ^{86}Rb ($E_{\text{max}} = 1770$ keV occurring at an 88% intensity (probability per decay) or 680 keV at a 12% intensity), and ^{89}Sr ($E_{\text{max}} = 1490$ keV). The Cherenkov counting efficiency of these radionuclides in water is in the range of approximately 35%–70% depending on color quench of the sample and E_{max} of the beta-particle emissions. The process of Cherenkov counting is treated in detail in Chapter 6, Volume 2 of this book, and a thorough treatment of the origin, principles, and theory of Cherenkov radiation and the Cherenkov Effect is provided in previous books by the writer (L'Annunziata, 2007, 2016). In general, it is important to remember that when quantifying radionuclides by Cherenkov counting, the counting region should be set to encompass only the low pulse height spectra produced by Cherenkov photons, which is equivalent to the pulse heights produced by

low-energy (0–50 keV) beta particles, and no fluor cocktail is required.

III. Liquid scintillation counter (LSC) or analyzer (LSA)

As described previously, the scintillation process involves the conversion of nuclear decay energy into photons of light. Therefore, to quantify the nuclear decay event and to satisfy needs for automation and multiple user programs, a liquid scintillation counter must be able to perform the following functions: (1) it must be able to detect photon emissions that occur in the scintillation vial containing fluor cocktail or solid scintillator (SPA) and be able to determine the number of photon emissions and their intensity; (2) it must be able to hold a large number of scintillation vials (>400) of various sizes (e.g., 20 mL, 8 mL, 7 mL, 4 mL, and microfuge or Eppendorf tubes); (3) it must have the ability to process automatically various types of samples using different counting conditions and counting programs (e.g., single radionuclides, multiple radionuclides, quench corrections, direct DPM, or Cherenkov counting) using programmable counting setups or counting protocols; (4) it must be able to process the data from photon emissions per unit time (e.g., photons per minute) to counts per minute (CPM) and then convert these count rates to actual nuclear disintegration rates or nuclear decay events per unit time (e.g., disintegrations per minute or DPM) using a quench correction method or direct DPM method; and (5) it must perform data analysis and reduction, special computer-managed data application programs, and instrument performance assessment.

The first and most important task of the liquid scintillation analyzer is the detection and quantification of the number of photon emissions and their corresponding intensities. This is accomplished by the heart of the LSC, the light detection, and quantification components. A simple block diagram of a conventional LSC with two photomultiplier tubes is illustrated in Fig. 6.3. Three basic components are found in this part of the LSC, namely, the

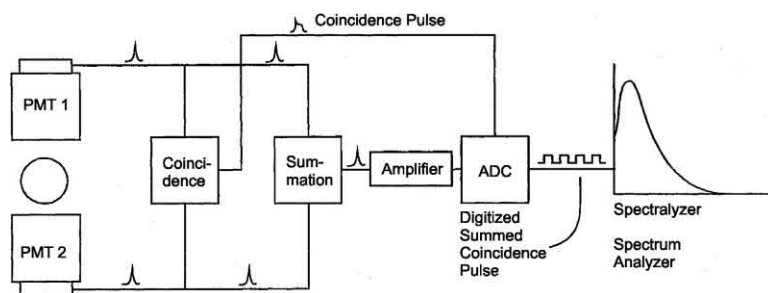

FIGURE 6.3 Schematic diagram of the components of a basic liquid scintillation analyzer. The circle between photomultiplier tubes PMT 1 and PMT 2 represents a vial containing the sample and scintillation fluor cocktail. From Kessler (1989), ©1998–2018, PerkinElmer, Inc. Printed with permission. See also Cook and van der Plicht (2007).

detector(s), a counting circuit, and a sorting circuit. Liquid scintillation analyzers with three photomultiplier tubes (PMTs) are also available, but yet less common. LSAs operating with three PMTs provide unique methods of activity analysis, and these are discussed in Section IX.C of this chapter.

In order to quantify the radioactivity in the sample, the sample is loaded into the counting chamber using either an up- or downloading elevator mechanism. The downloading mechanism is able to prevent any external light from entering the counting chamber by using a double light seal mechanism. The double light seal is implemented by automatic loading of the sample vial from the sample chamber deck to a holding area, where the sample is sealed from external light. The sample is mechanically moved into the counting chamber, which is below the holding area. Because of this unique downloading mechanism, the photomultiplier tube (PMT) high voltage can remain on at all times and the PMT background stabilized. Once the sample has been loaded into a light-tight chamber, the photons of light emitted from the vial are detected using two photomultiplier tubes (PMT 1 and PMT 2 of Fig. 6.3).

The photomultiplier tubes (PMTs) convert the photons of light emitted from the liquid scintillation vial to electrons when the photons hit a bialkali photocathode located inside the face of the PMT, as illustrated in Fig. 6.4. The photoelectrons produced at the PMT photocathode are amplified through a series of positively charged dynodes, each dynode having an increasing positive voltage along the series. The increasing voltage accelerates the initial photoelectrons produced at the PMT photocathode to yield an avalanche of secondary electrons, resulting in a pulse amplification. A photon, which is produced in the

scintillation vial, is thereby converted to a corresponding electronic signal. Because the amount of light produced in the scintillation vial is normally very low (~ 10 photons per keV energy absorbed in the liquid fluor cocktail), the PMT must be able to amplify the pulse resulting from secondary electrons produced by a single photon of light by a large factor. This pulse amplification factor or gain is $> 10^6$ for the standard PMT used in the LSC.

As illustrated in the block diagram of Fig. 6.3, two PMTs are used for the measurement of the light intensity from the nuclear decay processes in the sample vial. The two PMTs permit coincidence light detection and coincidence pulse summation required for the LSC to be able to detect low-energy radionuclides such as tritium ($E_{\max} = 18.6$ keV) and to distinguish instrument background from true nuclear events. If only a single PMT were used in the LSC, the background level would be approximately 10,000 CPM for a 0–2000 keV counting region. This high background is normally due to the large amplification factor from the PMT. This high background count rate mainly occurs in the 0–10 keV region (thermal and electronic background noise). In the LSC, two PMTs and a coincidence circuit are used to help differentiate background signals from true nuclear decay events in the scintillation vial, which is referred to as coincidence counting. The principle behind coincidence counting is based upon the fact that, when a nuclear decay event occurs in the scintillation vial, light is produced which is isotropic (*i.e.*, is emitted equally in all directions). Since the decay process and resultant scintillation process produce multiphoton events (about 10 photons per keV of nuclear energy dissipated in a liquid scintillation cocktail), light is emitted in all directions from the scintillation vial. The decay

FIGURE 6.4 Schematic of a photomultiplier tube. The drawing is based on schematics by Itaya et al. (2004) and Polyakov (2013). A photon of visible light emitted from a liquid scintillation vial collides with a bialkali photocathode producing a photoelectron. The trajectory of the photoelectron is focused and accelerated toward a positive dynode (Dy1). The impact of the photoelectron onto the first dynode (Dy1) produces secondary electrons that are accelerated toward a second dynode (Dy2) of higher positive voltage. The secondary electrons are accelerated sequentially toward dynodes of increasing potential difference (Dy3 to Dy10), which result in an avalanche of secondary electrons. The avalanche of electrons (not illustrated with dynodes Dy6 to Dy10) are collected at the anode, yielding a pulse amplification $> 10^6$ with a typical rise time of ~ 2 ns. The rise time is the time for the anode output pulse to rise from 10% to 90% of the peak amplitude. The faceplate is made generally of borosilicate glass with a diameter of ~ 5 cm.

process and resultant scintillation are very rapid (approximate light decay time is 2–10 ns). Because the scintillation process produces multiphoton events and the events decay rapidly, we can distinguish most background from true nuclear decay in the scintillation vial. If light is produced in the scintillation vial inside the analyzer detection area, it will be emitted in all directions and be detected by the two PMTs in the very short pulse decay time of 2–10 ns. When a signal is detected in both the PMTs within a coincidence resolving time of 18 ns, it is accepted as a true nuclear decay event. If on the other hand, a background event occurs in one of the PMTs or in the electronic circuitry (*e.g.*, thermal or electronic noise), it will produce a single event, which will be detected by only one of the two PMTs in the 18 ns time frame. Such a single event is rejected as occurring external to the sample or, in other words, a background event. By using two PMTs and the coincidence circuit, the instrument background can be reduced from 10,000 CPM with a single PMT to about 30 CPM with two PMTs for a wide-open 0–2000 keV pulse height counting region. The PMT signal that is sent to the coincident circuit is an analog signal with a pulse height that reflects and is proportional to the original nuclear decay energy.

The next part of the detection area, illustrated in Fig. 6.3, is the summation circuit. This circuit has a dual purpose. The first is to reassemble the original two coincident signals into an individual signal with the summed intensity. This helps to optimize the signal-to-noise ratio in the instrument. The second purpose is to compensate for the light intensity variations due to the position of the nuclear decay in the vial that would occur when samples containing color are counted. If only one of the two PMT signals were used in counting a colored sample, the signal height would be dependent on where in the scintillation vial the light was produced. If the light was produced near the edge of the scintillation vial closer to the face of the PMT, a more intense emission of light would be detected by the PMT due to its closer proximity to that edge of the vial. However, with two PMTs and a summed signal, the final pulse height produced by the PMT is not affected by the position of the nuclear decay in the presence of color in the sample counting vial.

Subsequent to pulse summation in the LSC, the signal is further amplified and sent to the analog-to-digital converter (ADC). The ADC converts the signal from an analog signal, which is a pulse with a certain height, to a single number that represents its pulse height or intensity. The digital pulses are finally sorted on the basis of their magnitude or pulse height number. The sorting can be accomplished by one of two methods: pulse height analysis (PHA) or multichannel analysis.

PHA, which is the older of the two methods, utilizes only two discriminators, an upper- and a lower-energy discriminator. An upper-level discriminator is set such

that all of the pulses with a certain energy of interest are always lower than this upper level. A lower-level discriminator is also set to reject pulse magnitudes that are below the lower-level discriminator setting thereby reducing background and other counting interferences of low pulse height. When an event is detected, its pulse height is measured, and if it has an intensity lower than the upper discriminator and higher than the lower discriminator, it is accepted as a true nuclear event. If any of the pulses fall outside this range, they are rejected and lost by the counting circuitry. All of the pulses that fall into the accepted range are counted, hence the term liquid scintillation counting (LSC).

The second and more contemporary method of sorting pulses is MCA. The multichannel analyzer is a series of bins or slots, where different pulse height magnitudes are placed once they have been detected. Two types of MCAs are commonly used: linear and logarithmic. The linear MCA provides data with pulse heights calibrated to represent decay energy in keV on a linear scale. For a common 4000 channel linear MCA, each channel may represent approximately 0.5 keV of energy. The logarithmic MCA displays the pulse heights in channels plotted along a logarithmic scale as illustrated in Fig. 6.2.

All of the pulses collected in MCAs are not only counted but analyzed in terms of their number and pulse height; therefore, the liquid scintillation counter is now more often referred to as the liquid scintillation analyzer (LSA). A linear MCA output with a typical beta-particle pulse height spectrum is illustrated in Fig. 6.5.

The second function of the modern LSA is to count automatically various types and sizes of samples in vials containing scintillation fluor cocktail. Most modern LSAs

FIGURE 6.5 Illustration of a typical liquid scintillation beta-particle pulse height spectrum collected in the many channels of a multichannel analyzer (MCA). A typical linear MCA will have as many as 4000 channels within which pulses of certain heights are collected and counted. The channels are calibrated over the energy range of 0–2000 keV. ©1998–2018, PerkinElmer, Inc. Printed with permission.

are cassette based. This means that sample vials are placed in racks holding between 12 and 18 individual scintillation vials or samples. Specific cassettes are available for holding scintillation vials of different volumes up to 20 mL.

Many persons can use the same instrument by establishing counting protocols set up via computer to analyze different radionuclides under different counting conditions and sample sizes. The key functions of the LSA—analyzing sample data by determining sample quench levels, converting count rate (*e.g.*, counts per minute or CPM) to disintegration rate (*e.g.*, disintegrations per minute or DPM) for unknown samples, and automatic monitoring of the performance of the instrument (instrument performance assessment)—will be described in detail further on in this chapter.

The majority of liquid scintillation analyzers in use today contain two photomultipliers, and these are installed with large-capacity sample changers as nonportable equipment in laboratories around the world. Portable and very compact liquid scintillation analyzers with multi-channel analysis have been developed, which is very applicable to mobile laboratories (Capogni and De Felice, 2014; Johansson et al., 2014; Kossert et al., 2014a,b,c; Gudjónsson et al., 2009; Theodórsson, 2006; Theodórsson and Jónsson, 2006; Theodórsson et al., 2006; Jónsson et al., 2006). In some portable single-photomultiplier-tube liquid scintillation analyzers, the single PMT measures the scintillation photons from the bottom of the counting vial. Such a small portable liquid scintillation analyzer can find numerous applications in mobile-laboratory on-site monitoring of radionuclides. The application of the single-photomultiplier LSA for the monitoring of environmental tritium and radon has been demonstrated (Theodórsson and Skripkin, 2003; Theodórsson and Gudjónsson, 2003; Gudjónsson et al., 2009). An example of such a portable liquid scintillation analyzer and luminescence counter is the Triathler (Hidex, Inc., Turku, Finland) described by Santiago et al. (2014).

IV. Quench in liquid scintillation counting

In scintillation counting, the sample is either dissolved in a liquid scintillation cocktail or adsorbed onto a solid scintillator in a sample vial or microplate well. In order to quantify the nuclear events as activity in terms of disintegrations per minute (DPM), the LSA counts the number of photon emissions in a preselected time period to provide a count rate (CPM) of the sample. The sample count rate is dependent on how efficiently the nuclear decay events are converted to photons of visible light that are detected and quantified by the LSA. Because the sample solution is always present, it can absorb nuclear decay energy thereby

preventing this energy from being absorbed by the solvent and chemical fluor molecules, or the solution can absorb photons of light emitted by the fluor molecules, thus reducing the photon intensity measured by the PMT. This causes the phenomenon called quench. We can define quench as interference in the conversion of nuclear decay energy to photons of light emitted from the sample vial. Quenching can be the result of three phenomena, namely, (1) chemical quenching, (2) ionization quenching, and (3) color quenching. These interference phenomena are discussed in more detail in the subsequent paragraph. Many texts refer only to chemical and color quench phenomena as mechanisms to be considered for the determination of radionuclide detection efficiency with little or no reference to ionization quenching. This may be due to the much smaller effect that ionization quenching has compared to chemical and color quenching in liquid scintillation counting, and the attention to this phenomenon has been demonstrated to be relevant only in the application of liquid scintillation analysis to the standardization of radionuclides (Grau Carles et al., 2004, 2006a,b, Kossert and Grau Carles, 2006, Grau Malonda and Grau Carles, 2008, Bagán et al., 2008, 2009, Bignell et al., 2010a,b, Cassette et al., 2010b, Thiam et al., 2012, van Wyngaardt et al., 2012, Kossert et al., 2014b, and Altitzoglou and Rožkov, 2016). Radionuclide standardization is carried out only by specialized laboratories such as those found in national institutes of standards. The application of liquid scintillation analysis (LSA) to the standardization of radionuclide samples, as a specialized application of LSA, is discussed in Section IX of this chapter. The points of interference of chemical, ionization, and color quenching in the liquid scintillation process are illustrated in Fig. 6.1.

The three quenching phenomena, which interfere with the liquid scintillation measurement of radionuclides, are described in more detail as follows:

1. *Chemical quenching.* This is the most common quench mechanism and the one that generally can have the most deleterious effect on the liquid scintillation detection efficiency. Chemical quench is caused by the presence of chemical substances in the sample, including the sample solution, that absorbs nuclear decay energy in the scintillation process, thereby obstructing to a certain degree the transfer of nuclear decay energy to the scintillation cocktail solvent. A chemical quenching agent can be thought of as a sponge that absorbs energy before it can produce light in the scintillation process. In addition to reducing the number of photon emissions resulting in a loss of radiation counts, the quenching process can, and often does, decrease the light intensity and thereby reduce the pulse heights as measured by the scintillation process. Chemical quenching occurs to some degree in most liquid scintillation counting samples.

2. Ionization quenching. The second mechanism of quench, ionization quenching, as described by [Grau Carles et al. \(2004\)](#), is related to the density of excited solvent molecules in the scintillation fluor cocktail. The response of a liquid scintillator to the interaction of charged particles is not linear with the energy deposited. The nonlinearity of the photon intensity output by the scintillator and the energy deposited by the charged particles increases with the mass of the particle, and the nonlinearity is a function of the linear energy transfer (LET) of the particle. Also, as defined by [Bignell et al. \(2010a\)](#), ionization quenching in scintillators is the reduction of luminosity associated with a high density of excited molecules caused by a large LET to the scintillant. Thus, low-energy beta particles, such as those emitted from ^3H , exhibit a greater nonlinearity of light output versus energy deposited than high-energy beta particles or electrons, because the LET of low-energy beta particles or electrons is higher than the LET of high-energy beta particle or electrons (See Tables 1.29 and 1.30 of Chapter 1). The cause of this nonlinearity is ionization quenching, which is a consequence of the density of excited solvent molecules in the scintillation fluor cocktail. Charged particles, which exhibit a high LET, will create a higher number of excited solvent molecules. When the concentration of the excited molecules is high, there is a higher probability of interaction between two excited molecules whereby one molecule can lose its energy of excitation to the other resulting in one molecule becoming superexcited. The superexcited molecule has a high probability of reaching the state of ionization. The overall outcome of this process is two solvent molecules, originally excited by the charged particle (e.g., β -particle or electron), which lose their energy of excitation and thereby do not transfer this energy to the fluor molecules or transfer only a diminished portion of that excitation energy. This results in a loss of excitation energy and a reduction of the photon intensity from the scintillation fluor, which may manifest itself by a reduced count rate or a reduction in the magnitude of the pulse height measured by the photomultiplier from the photon intensity output. [Grau Carles et al. \(2004\)](#) explain that this process is observed clearly in the interaction of α -particles with liquid scintillator. Also, radionuclides decaying by low-energy β transitions, such as ^3H , as well as those decaying by electron capture with the emission of Auger or Coster-Kronig electrons, are those that display this ionization quenching, that is, the nonlinearity between the intensity of the photon emissions from the scintillation counting vial and the energy deposited by the β particle or electron. Electron-capture decay results in the emission of X-rays from subsequent atomic electron rearrangements following EC decay,

which can produce X-ray Compton electrons and photoionization, all of which are low-energy electrons exhibiting a relative high LET compared to the higher-energy beta particles from most beta-emitting radionuclides. This mechanism of quench is relevant only in the specialized application of liquid scintillation analysis to the standardization of radionuclides (See Section IX of this chapter).

- 3. Color quenching.** The phenomenon of color quench occurs when color is visible in the sample that is being counted. The color quench phenomenon normally acts by absorbing photons of light in the scintillation vial before they can be detected and quantified by the PMT. This is similar to what happens when a colored filter is used on a camera to filter out certain wavelengths of light. Chemical quench absorbs nuclear decay energy and color quench absorbs photons of light. Color quenching is often less a problem than chemical quenching, because samples most often can be decolorized easily with minute quantities of bleaching agent or other means (See Chapter 7 of Volume 1 on Sample Preparation Techniques for Liquid Scintillation Counting).

The quenching phenomena reduce the photon intensities emitted from scintillation counting vials and consequently reduce the magnitudes of the pulse heights measured by the liquid scintillation analyzer; in addition, the quenching phenomena can also reduce the count rate of a sample measured by the liquid scintillation analyzer (*i.e.*, counts per minute, CPM). To compensate for the count rate loss due to quench and to determine the sample activity or DPM (nuclear decay rate), it is necessary to know the counting efficiency, defined by the following equation:

$$\% \text{ efficiency} = \text{CPM} / \text{DPM} \times 100. \quad (6.1)$$

where CPM is the count rate of the sample determined by the LSA, and DPM is the actual disintegration rate of the sample. The relationship between CPM and DPM of the sample varies according to the energy of the nuclear decay at a given degree of quench. The lower the energy of the decay, the greater is the effect of quench on the counting efficiency for beta-emitting radionuclides. This is illustrated in [Fig. 6.6](#), which shows the liquid scintillation pulse height spectra of seven tritium samples ($E_{\text{max}} = 18.6 \text{ keV}$) that were prepared with the same activity (DPM), but with different amounts of 5.0 M HNO_3 , which acts as a chemical quenching agent. The liquid scintillation analyzer determined the CPM for each sample by summing the area under the pulse height spectrum of each sample. As illustrated in [Fig. 6.6](#), the least quenched sample is that which contains no HNO_3 . The area under the pulse height spectrum of the first sample had 126,287 CPM and the highest pulse heights with a maximum equivalent to approximately

FIGURE 6.6 Pulse height spectra of seven samples of ^3H of equal activity containing varying amounts of 0.5M HNO_3 quenching agent. The pulse height spectra are plotted on a logarithmic scale with pulse heights calibrated to equivalence in keV energy. The liquid scintillation counting (detection) efficiencies for each sample are listed as percentages. ©1998–2018, PerkinElmer, Inc. Printed with permission.

18.6 keV. The counting efficiency for this sample is calculated as 126,287 CPM/210,000 DPM or 60.1%. The second sample is quenched by the added 0.05 mL of HNO_3 , and as a result, (1) the CPM is reduced to 115,834, (2) the endpoint or maximum intensity of the pulse height spectrum of this sample is reduced, and (3) the counting efficiency of the sample is reduced to 55.1%. As illustrated in Fig. 6.6, when the sample is quenched more and more, the maximum observed pulse height is reduced further and the CPM collected under the pulse height spectrum is reduced. For example, the last sample listed, which contains the highest amount of quenching agent, gave the lowest count rate of 16,091 CPM and a calculated counting efficiency of only 7.7%. Thus, as the quench increases for tritium, both the maximum pulse height and the total CPM

are reduced significantly. Chemical quenching agents, although dilute and small in quantity, can have a significant effect on the counting efficiency of tritium.

On the other hand, an isotope such as carbon-14, which emits beta particles of energy almost 10 times higher ($E_{\text{max}} = 156 \text{ keV}$) than tritium, quenching agents cause a significant reduction in the maximum pulse heights but have a less significant effect on the pulse counts collected than was observed in the case of tritium. Table 6.1 shows the effect of the quenching agent on five samples of carbon-14. The five samples contained the same activity (100,000 DPM), but increasing amounts of quenching agent. The quenching agent is not given here, but a common quenching agent used for these studies is nitromethane over the range of 0–100 μL per 20 mL of fluor cocktail. The endpoint of the pulse height spectra (maximum pulse height expressed in keV) of each sample listed in Table 6.1 changed significantly from sample 1 to sample 5 as chemical quench increased; however, the sample count rates (total counts collected under the pulse height spectra per given period of time) did not change as drastically as for tritium. As can be seen from Table 6.1, pulse height spectral intensity (maximum pulse height) changes as the sample is quenched, but the efficiency or CPM value (area of energy spectrum) changes only slightly. The overall conclusion is that for beta-particle emitters, the lower the energy (E_{max}) of the beta decay, the greater is the effect of quench on the counting efficiency of the radionuclide.

For alpha-emitting radionuclides the phenomenon of quench does not significantly affect the counting efficiency as shown in Fig. 6.7. As the quench of the sample is increased, the monoenergetic alpha peak is simply shifted to lower pulse heights, but the total area under the pulse height spectrum or detection efficiency (equivalent to counting efficiency) is not changed significantly. Also, as illustrated in Fig. 6.7, the alpha-particle pulse height spectrum in the LSA undergoes some peak broadening (reduced resolution) proportional to the level of quench; although this will have no significant effect on detection efficiency. The resolution is determined by the percent full width at half maximum (FWHM), as described in Chapter 9

TABLE 6.1 Effect of quench on carbon-14 counting efficiency in liquid scintillation analysis.

Sample	Maximum pulse height (keV)	CPM	DPM	Efficiency (%)
1	156	95,000	100,000	95.0
2	112	94,500	100,000	94.5

of Volume 1 of this book. Vera Tomé et al. (2002) and Bhade et al. (2017) studied alterations in alpha-peak shape in liquid scintillation with the potential of utilizing LSA for alpha spectrometry. Bhade et al. (2017) measured the liquid scintillation detection efficiencies and alpha spectra resolution of several alpha emitting radionuclides. They demonstrated the shifting of the alpha-particle pulse height spectra to lower level pulse heights and a linear decrease in alpha spectra resolution according to the quench level of the sample, as illustrated in Figs. 6.8 and 6.9, respectively. In addition, they found no significant reduction in the counting efficiencies for alpha particles over a wide range of quench levels. In an early work, by Horrocks (1974a) he reported “alpha particles are counted with 100% efficiency even when the sample is highly quenched.” This conclusion was based on the work of several researchers including Horrocks (1974a, 1968, 1966), Seidel and Volf (1972), Joshima and Matsuoka (1970), Scott and Good (1967), Wright et al. (1961), Seliger (1960), Basson and Steyn (1954), who demonstrated detection efficiencies of 98%

FIGURE 6.8 The shifting of alpha pulse spectra over a wide range of quench from lower levels of quench with a quench indicating parameter SQP(E) = 720 to higher levels of quench at a quench indicating parameter SQP(E) = 407. The broadening of the alpha peaks is visible as the quench level increases. The measurement of quench indicating parameters is discussed further on in this chapter. From Bhade et al. (2017), reprinted with permission from Elsevier © 2017.

—100% for alpha emitters over a wide range of quench levels.

For gamma emitting radionuclides, the quenching phenomenon is very similar to that observed with beta-particle interactions in liquid scintillation fluor cocktails (Ishikawa and Takiue, 1973), as Compton-electrons produced by γ -photon interactions in scintillation fluor cocktail will undergo similar quenching effects as beta particles. See Section VI of this chapter for a treatment on the liquid scintillation analysis of gamma-emitting radionuclides.

The effect of quench when solid scintillators are used in a liquid scintillation analyzer is described in Chapter 9 on Solid Scintillation Analysis of Volume 1. When using solid

scintillators, the sample is normally placed directly on the solid scintillator and dried or the sample is counted adsorbed onto the solid scintillator as in a scintillation proximity assay (SPA). See Chapter 9 for more detailed information on SPA. When scintillation proximity analysis is undertaken, the sample is in direct intimate contact with the solid scintillator, and therefore no chemical quenching exists for these types of samples. Under these circumstances, color quench can occur with colored samples.

For the Cherenkov counting of samples containing high-energy beta-emitting radionuclides, color quench can occur; however, neither chemical quench nor ionization quench are possible. See Chapter 6, Volume 2 for a detailed treatment of Cherenkov counting with conventional liquid scintillation analyzers.

All chemical substances that either dilute the solvent of the fluor cocktail or compete with it for nuclear decay energy will cause quench. Even dissolved oxygen from the air is a chemical quenching agent (Takiue and Ishikawa, 1974); its effect can be seen in the LSA of weak (low-energy) beta particle-emitting radionuclides such as tritium. More information on chemical quenching agents and their classifications can be obtained in a previous book (L'Annunziata, 1987). As chemical quenching agents in samples generally cannot be avoided and the effect of quench on detection efficiency is significant with many radionuclides, it is important to correct for quench when necessary. This will permit accurate measurement of sample activities in disintegration rate (*e.g.*, DPM).

V. Methods of quench correction in liquid scintillation counting

Some degree of quenching exists in almost all samples, which are quantified by the liquid scintillation counting process. It is consequently important to utilize a method that can be used to correct for quench. The quench correction methods allow us to determine the detection efficiency of a particular sample and convert the count rate (CPM) to the actual number of nuclear decays or disintegration rate (DPM) of a sample. Quench correction can be accomplished by one of the following techniques: (1) an internal standard method, (2) a sample spectrum method, (3) an external standard method, and (4) a direct DPM method. These techniques can be used for quench correction and DPM determination. Each may have distinct advantages for various sample types, instrument model utilized and/or radionuclides to be analyzed. These methods will be discussed subsequently together with explanations of the when and why of using these techniques.

A. Internal standard (IS) method

The internal standard (IS) method is the oldest and most tedious, and it can be the most accurate method if great care

is taken in its implementation. The technique involves a series of steps for each sample. The first step is to count each sample and obtain an accurate count rate (CPM) value for each. Then the samples are removed from the liquid scintillation counter, and a known activity (DPM) of a radionuclide standard is added to each sample; hence, the term internal standard is applied to this technique. After the addition of the internal standard and thorough mixing of the standard and sample, the samples are recounted to obtain the CPM of the sample with its internal standard. Once the CPM of the sample and the CPM of the sample with internal standard are obtained, the following equation is applied to determine the counting efficiency of the sample:

$$E = \frac{C_{s+i} - C_s}{D_i} \quad (6.2)$$

where C_{s+i} is the sample count rate after the addition of the internal standard, C_s is the sample count rate before the addition of the internal standard, and D_i is the disintegration rate of the added aliquot of internal standard. The disintegration rate of the sample, D_s , may then be calculated as follows:

$$D_s = C_s/E \quad (6.3)$$

For example, if the counting efficiency for a given sample was found to be 0.25 according to Eq. (6.2) and the sample count rate was found to be 25,000 CPM, the activity of the sample can be calculated to be 25,000 CPM/0.25 = 100,000 DPM.

Several assumptions and restrictions are made for the internal standard method, some of which may be intuitively obvious. These are described as follows: (1) The same radionuclide must be used for the internal standard as the sample radionuclide; for example, a tritium-labeled standard must be used with samples containing tritium. Hendee et al. (1972) showed that [^3H]toluene and [^3H]hexadecane are good internal standards for organic-compatible fluor cocktails and [^3H]water or [^3H]hexadecane serve well for aqueous-compatible fluor cocktails when assaying for tritium. The organic standards labeled with ^{14}C are good internal standards for counting efficiency determinations of samples containing ^{14}C . (2) The internal standard added to the sample must have a count rate at least 100 times that of the sample. (3) The addition of the internal standard to the sample must not alter the quench in the sample to any significant degree. (4) The activity (DPM) of the internal standard must be accurately known, as with a National Institute of Standards and Technology (NIST) traceable standard. (Commercially available ^3H and ^{14}C standards, as well as mixtures of the two radionuclides, designed specifically for application in the internal standard quench correction technique for either aqueous or organic solutions are available from PerkinElmer, Inc. as well as other standard radionuclide sources. (5) This method of determining sample activities requires accurate sample transfer

procedures, which can be tedious when working with many samples and small volumes of internal standard. Dobbs (1965) and Thomas et al. (1965) have investigated syringe dispensing techniques for the addition of internal standards to samples in scintillation counting vials.

This method, if performed properly, can provide accurate activity measurements. Some examples of the internal standard quench correction technique applied to the analysis of ^3H may be obtained from the works of Alongi et al. (2003), Sweet et al. (2004), Batistoni et al. (2005, 2007), Klin et al. (2010), Eikenberg et al. (2011), Osman et al. (2016) and Vagner et al. (2016), to the analysis of ^{14}C from the works of Alongi et al. (2003), Martins and Boekel (2003), TenBrook and Tjeerdema (2006), Eikenberg et al. (2011) and Osman et al. (2016), and to the analysis of ^{226}Ra from the work of Godoy et al. (2016). The major disadvantages of this technique are the time and the number of sample-handling steps required for each sample.

B. Sample spectrum characterization methods

Sample spectrum characterization methods of quench correction involve the use of some characteristic of the sample spectrum as a measure of quench in the sample. Some of these methods are described subsequently.

1. Sample channels ratio (SCR)

The sample channels ratio (SCR) method was applied often during the early generations of liquid scintillation counters that were equipped with only the pulse height analysis (PHA) or single channel analyzer for data storage and analysis. Nevertheless, the method is applicable with most commercial liquid scintillation analyzers today. It also remains a useful method for modern liquid scintillation analyzers not equipped with external standards, and the SCR method has other applications described further on in this

chapter. The method involves counting the sample in two counting regions defined by lower-level (LL) and upper-level (UL) pulse height discriminator settings. The count rate in each counting region varies according to the level of quench in the sample due to the pulse height spectral shift from higher to lower magnitudes caused by sample quench. An example of the pulse height shift according to quench level is illustrated in Fig. 6.10. As illustrated, a sample that is more highly quenched will produce pulse events of lower magnitude (height) than a sample that is lesser quenched.

The SCR quench correction method requires firstly defining the widths of two counting regions also referred to as counting channels or windows. The lower and upper discriminator levels of one region are selected so as to provide a narrow counting region, which can register pulses of only low magnitude (e.g., Channel 1, 0–300 of Fig. 6.10). The discriminator levels of the second counting region are set to provide a wider counting region, which can register most of the pulses of both low and high magnitude (e.g., Channel 2, 0–700 of Fig. 6.10).

A shift in pulse height due to quenching produces a change in the ratio of the pulses registered (counts) by the two regions. The degree of spectral shift and magnitude of change in the sample channels ratio (SCR), such as $\text{CPM}_1/\text{CPM}_2$ or sample count rate in Channel 1 over the sample count rate in Channel 2, are dependent on the severity of quench. Consequently, if a series of quenched standards consisting of scintillation vials each containing the same amount of radioactive standard but increasing amounts of quenching agent were counted, they would show a variation in the channels ratio and counting efficiency, such as that illustrated in Fig. 6.11. The procedures used to prepare sets of quenched standards are described in Section V.D. of this chapter and in Chapter 7 on “Sample Preparation Techniques for LSC” of Volume 1 of this book. The quench correction curve, once prepared for a given

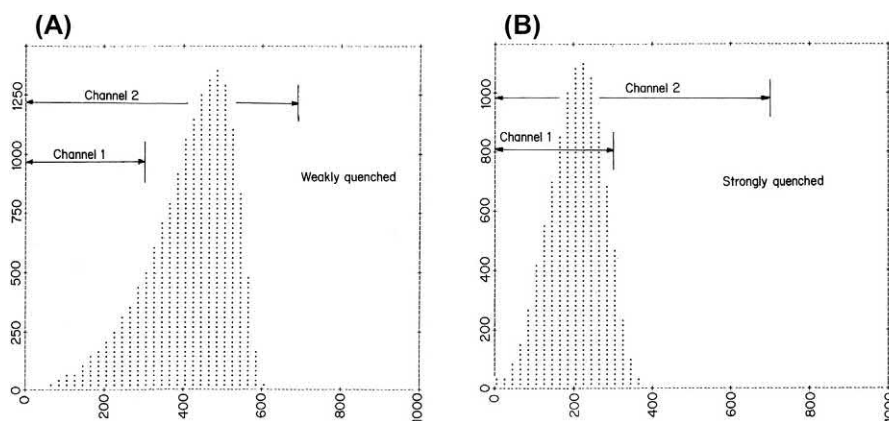

FIGURE 6.10 (A): Weakly-quenched and (B): Strongly-quenched pulse height spectra produced by ^{33}P in relation to two overlapping counting regions (Channels 1 and 2) of a Beckman LQ 7800 liquid scintillation analyzer. The counting channels 1 and 2 are defined by lower- and upper-level discriminator settings of 0–300 and 0–700, respectively. (L’Annunziata, M. F. 1986, unpublished work of the writer.)

FIGURE 6.11 Typical channels ratio quench correction curve. The channels ratio (I/II) represents the count rate of ^{33}P from Channel I divided by the count rate from channel II. The discriminator and gain settings for each channel are given. The data were obtained from six samples each containing 15 mL of commercial scintillation cocktail (Insta Gel) and 1.0 mL of [^{33}P]orthophosphate of known activity (0.103 μCi equivalent to 3.81 kBq). Each sample contained increasing amounts of CCl_4 as quenching agent. (L'Annunziata, M. F. 1986, unpublished work of the writer.)

radionuclide and fluor cocktail, may be used as a standard curve for determining the counting efficiency of a sample from its channels ratio. The values of counting efficiency for the standard curve are calculated according to

$$E = C_{\text{std}}/D_{\text{std}} \quad (6.4)$$

where E is the counting or detection efficiency with values between 0 and 1.0, C_{std} is the count rate of the quenched standard in units of counts per minute (CPM) or counts per second (CPS) in the wider Channel 2, and D_{std} is the disintegration rate of the quenched standard in units of disintegrations per minute (DPM) or disintegrations per second (DPS). The activities of the unknown samples are determined from the count rate of the sample in the wider Channel 2 divided by the detection efficiency obtained from the SCR quench correction curve or

$$D_s = C_s/E \quad (6.5)$$

where D_s is the disintegration rate of the sample, C_s is the count rate of the sample in the wide-open channel (i.e., the wider channel from which the detection efficiencies of the quenched standards were determined), and E is the detection efficiency obtained from the SCR quench correction curve, as illustrated in Fig. 6.11.

A more detailed treatment of this method can be found in reviews by L'Annunziata (1984a,b, 1987 and Bagán et al., 2008). The method is less often used with modern

liquid scintillation analyzers due to the advent of multi-channel analyzers (MCAs) in commercial LSA instrumentation, which utilize sample spectrum quench indicating parameters or external standard quench correction methods. Tarancón et al. (2004) used the SCR quench measurement technique as well as an external standard quench measurement in the evaluation of plastic scintillation beads in a conventional liquid scintillation analyzer. The application of the SCR technique in Cherenkov counting is useful with commercial liquid scintillation analyzers, which are not equipped with an external standard suitable for the production of Cherenkov photons (Todorović et al., 2017). The application of the SCR method to Cherenkov counting is described in detail in Chapter 6 of Volume 2 of this book. The SCR technique is generally not useful with samples of low count rate or high quench, because the counts in one or both of the channels may be so low that a channels ratio becomes meaningless, or long periods of counting time would be required to achieve acceptable levels of statistical accuracy.

A variant of the SCR technique is the Self Constant Channel Ratio (SCCR) method, which is utilized by Hitachi Aloka liquid scintillation analyzers. The SCCR technique utilizes the sample pulse height spectrum to measure a quench indicating parameter. The magnitudes and intensities of the pulse heights produced by the beta particles will depend on the energy of the beta emissions and the quench level of the sample. A multichannel analyzer measures the entire sample pulse height spectrum and the channel equivalent to 75% of the pulse heights measured from a lower level discriminator to 75% of the pulse heights. The pulse height at the 75% cut-off of the sample pulse height spectrum is taken as the quench indicating parameter of a sample. Quench standards are counted and the SCCR quench indicating parameter is measured for each sample. Excellent quench correction curves of % E versus SCCR are obtained, which is evidenced by the strong correlation of a broad range of SCCR values for tritium counting efficiencies ranging from 5% to 60% (Hitachi Aloka, 2014).

2. Combined internal standard and sample channels ratio (IS-SCR)

Dahlberg (1982) devised a combination of the IS and SCR methods (IS-SCR), which ameliorates the disadvantages of the two techniques. The high dependence on accurate dispensing of internal standards in the IS technique and the high errors encountered at low count rates in the SCR technique have been eliminated in the combined IS-SCR method for quench correction. In the combined IS-SCR method, the disadvantage of the SCR method at low count rates is avoided by the addition of internal standard

(IS) to low radioactivity samples. The SCR values are then taken for quench correction, instead of calculating the efficiency by the 'classical' IS method of measuring the contribution to count rate by the known amount of standard added. As only an SCR value is required after adding an internal standard, the dependence of the 'classical' IS method on accurate dispensing of standard to sample is also eliminated.

A similar combined IS-SCR technique was devised by McQuarrie and Noujaim (1983) for the counting efficiency determinations of either ^3H , ^{14}C , or both nuclides as a mixture. The unique characteristic of this method is the use of ^{67}Ga as the internal standard for either ^3H , ^{14}C , or the dual nuclide mixture. The liquid scintillation pulse-height spectrum of ^{67}Ga is characterized by two peaks (Fig. 6.12) corresponding to 8 keV Auger electrons and 93 keV conversion electrons, which are similar in energy to the average beta-particle energy of 5.7 keV for ^3H and 49 keV for ^{14}C . A ratio of the measured activity of the two ^{67}Ga peaks is used to reflect the degree of quenching in the sample. The sample is easily recovered after the internal standard ^{67}Ga decays ($t_{1/2} = 78$ hours) and accurate dispensing of the internal standard to sample is not required, because only the ratio of activity between the two peaks is used to monitor quench.

3. Sample spectrum quench indicating parameters

With the development of the multichannel analyzer (MCA), sample spectrum quench indicating parameters (QIPs) have become more sophisticated, as all of the channels of the MCA can be used simultaneously to measure quench. Examples of quench indicating parameters that measure quench by sample spectrum characterization are the spectral index of the sample (SIS), the spectral quench parameter of the isotope, SQP(I), and the asymmetric quench parameter of the isotope, AQP(I).

FIGURE 6.12 Liquid scintillation spectra of ^3H , ^{14}C , and ^{67}Ga . From McQuarrie and Noujaim (1983). Reprinted with permission from Faculty of Pharmacy and Pharmaceutical Sciences © 1983 University of Alberta, Edmonton.

a. Spectral index of the sample (SIS)

The SIS is a measure of the mean pulse height or center of gravity of the sample pulse height spectrum, which is utilized in the Tri-Carb liquid scintillation analyzers of PerkinElmer, Inc. The pulses produced from photon events are linearly amplified, digitized, and stored in a multichannel analyzer to produce a complete sample pulse height spectrum in a region of pulse heights calibrated to represent the energy scale from 0 to 2000 keV. The SIS is a measure of the first moment of the pulse height spectrum proportional to the average energy of the beta spectrum times a factor K or

$$\text{SIS} = K \frac{\sum_{x=L}^U X \cdot n(x)}{\sum_{x=L}^U n(x)} \quad (6.6)$$

where X is the channel number (see the beta-particle pulse height spectrum with respect to the numerous channels of the MCA in Fig. 6.5), $n(x)$ is the number of counts in Channel X , L , and U are the lowest and uppermost limits of the pulse height spectrum, and K is a factor, which fixes the SIS of unquenched ^3H and ^{14}C at 18.6 and 156, respectively, corresponding to the respective maximum beta-particle energies of ^3H and ^{14}C in keV. Therefore, the SIS reflects the endpoint or maximum energy of the sample pulse height spectrum as well as the magnitude and shape of the spectrum. From Eq. (6.6) we see that the value of SIS is (1) unitless, (2) always greater than 1.0, (3) becomes smaller in magnitude as quench increases for a given radionuclide, and (4) at a given level of quench, beta-emitters of higher E_{max} will produce higher values of SIS.

An example of count rate (CPM) and quench indicating parameter (SIS) data collected for a series of 10 quenched tritium standards is given in Table 6.2. This data was collected by the liquid scintillation analyzer when the instrument counted each tritium quenched standard to provide a count rate (CPM) for each standard, which is listed in column 2 of Table 6.2. After the count rate of each standard is obtained, the LSA measures the QIP of each standard, in this case SIS, according to Eq. (6.6). The next step required for the preparation of the quench correction curve is the calculation of the percentage counting efficiency for each standard according to Eq. (6.1). The instrument makes this calculation by taking the CPM (column 2) and dividing by the DPM (column 3) of each quenched standard and multiplying by 100 to obtain the percent counting efficiency.

The data of counting efficiency and quench indicating parameter, SIS, listed in Table 6.2 is then taken automatically by the instrument to plot the quench correction curve for tritium illustrated in Fig. 6.13. Another quench correction curve, that for ^{14}C , is also plotted in Fig. 6.13. The ^{14}C

TABLE 6.2 Data collected for the preparation of a ^3H quench correction curve of counting efficiency versus the quench indicating parameter SIS (© 1998–2018 PerkinElmer, Inc. Printed with permission.).

Standard	CPM	DPM	Efficiency (%) ^a	SIS
1	68,000	100,000	68	18.6
2	64,000	100,000	64	16.0
3	58,000	100,000	58	14.8
4	52,000	100,000	52	13.6
5	48,000	100,000	48	12.0
6	38,000	100,000	38	11.0
7	29,000	100,000	29	10.5
8	23,000	100,000	23	9.2
9	18,000	100,000	18	8.5
10	13,000	100,000	13	8.0

^aThe % efficiency here refers to the % counting efficiency calculated according to Eq. (6.1). For the calculation of sample activities from count rate the decimal equivalent of percent counting efficiency is used (e.g., 0.68 for 68%).

**FIGURE 6.13** Quench correction curves for ^3H and ^{14}C based on the quench indicating parameter SIS, a sample pulse height spectrum characterization method. © 1998–2018 PerkinElmer, Inc. Printed with permission.

quench correction curve was prepared in a fashion similar to the procedure described above for ^3H with the exception that ^{14}C quenched standards were used. Fig. 6.13, therefore, illustrates plots of the quench correction curves for two radionuclides on the same graph. Several observations can be made from these two curves. The first observation is that for ^{14}C , which is a beta-particle-emitting radionuclide of intermediate energy ($E_{\text{max}} = 156 \text{ keV}$), quench has a marked effect on the endpoint or maximum spectral pulse height, as the SIS decreases from 156 to 25). However, the count rate (area under the pulse height spectrum of each standard) or counting efficiency (CPM/DPM) decreases only slightly (0.95–0.83) as illustrated in Fig. 6.13. Therefore, for midrange to higher-energy beta particle-emitting radionuclides, quench does not have as marked

effect on the counting efficiency of the sample as on the apparent endpoint of the spectral pulse height. The second observation is related to the tritium quench correction curve. In the case of tritium, both the pulse height spectrum endpoint and the counting efficiency are dramatically reduced as a result of quench. The curve of percent counting efficiency versus SIS is very steep for tritium. This dramatic slope can result in a rather large error in DPM values, if accurate SIS values are not obtained. Also, it is intuitively obvious that the spectrum characterization method of determining the quench indicating parameter is dependent on the counts in the sample. The larger the number of counts, the more accurate is the measurement of sample spectrum quench parameter (e.g., SIS). From these observations, it is clear that the sample spectrum

characterization method of determining the QIP should be used only when mid-to high-energy radionuclides are being quantified and when the count rate of the sample is well above background ($> \sim 1000$ CPM). We shall see further on in this chapter that quench indicating parameters derived from an external standard are more versatile and applicable to samples of both low and high activity (See Section IV.C.). However, quench indicating parameters derived from the sample spectrum are particularly useful when external standards cannot be applied such as in color quench correction for Cherenkov counting as demonstrated by L'Annunziata and coworkers (see Noor et al., 1996a). The SIS parameter was used by Vincze et al. (2007) in tests on the applicability of plastic scintillator beads in lieu of scintillation cocktail in a conventional liquid scintillation analyzer. The SIS is also a valuable tool in spectrum unfolding for the analysis of a mixture of two beta-particle-emitting radionuclides (L'Annunziata, 1997b, Lee et al., 2002a,b and Reddy et al., 2009) described further on in this chapter.

Once a quench correction curve is plotted by the liquid scintillation analyzer (LSA) and stored in its memory, it can be applied by the instrument computer to calculate the activity (DPM) of an unknown sample. For example, a sample of ^3H of unknown activity, prepared in the same fluor cocktail as the tritium standards used for the preparation of the quench correction curve, is counted and the LSA provides a count rate of 36,000 CPM and a SIS value of 12. A tritium quench curve of percent efficiency versus SIS, as illustrated in Fig. 6.13, is used by the LSA to determine the percent counting efficiency of that unknown sample. The instrument is programmed to read the stored quench curve and obtains the percent counting efficiency of 48% from the curve. The sample activity is calculated by the LSA according to the equation

$$DPM_s = \frac{CPM_{net}}{E} \quad (6.7)$$

Where DPM_s is the sample activity in disintegrations per minute, CPM_{net} is the net count rate (i.e., background-subtracted count rate) of the unknown sample, and E is the counting efficiency obtained from the quench correction curve as a decimal, not as a percent. The value of E should be generally in the range between 0 and 1.0, as the decimal representation of the percent counting efficiency over the range of 0%–100%. Therefore, in this example, the instrument calculates the activity of the unknown sample as $36,000 \text{ CPM} / 0.48$ and the resultant value of 75,000 DPM is obtained. The LSA can perform this type of analysis for all samples of unknown activities.

b. Spectral quench parameter of the isotope spectrum or SQP(I)

The spectral quench parameter of the isotope or SQP(I) is also referred to as the mean pulse height of the isotope spectrum (Rundt, 1991; Warrick and Croudace, 2013;

Croudace et al., 2016). It is utilized as a sample quench indicating parameter with some liquid scintillation analyzers of Wallac Oy such as the LKB Rackbeta liquid scintillation analyzer. The SQP(I) is measured by the liquid scintillation analyzer in a similar fashion as the previously described quench indicating parameter SIS. As described by Grau Malonda (1999), the SIS provides a value for the center of gravity of the sample pulse height spectrum plotted on a linear pulse height scale, while the SQP(I) is a calculation of the sample pulse height spectrum plotted on a logarithmic scale according to the equation

$$SQP(I) = \frac{\sum_{i=L}^U iN_i}{\sum_{i=L}^U N_i} \quad (6.8)$$

where i is the channel number of the MCA (see Fig. 6.5), N_i is the number of counts in channel i , and L and U are lowest and uppermost limits, respectively of the sample pulse height spectrum. By comparing Eqs. (6.6) and (6.8), we can see the close similarities of the sample spectrum quench indicating parameters, SIS and SQP(I).

The sample spectrum quench indicating parameter SQP(I) has the same applications and limitations as SIS previously described. All methods of characterizing the sample spectrum to define the degree of quench in a sample require the use of quenched standards for the preparation of a standard quench correction curve of counting efficiency plotted against the QIP. The procedures used to prepare a standard quench correction curve are described in Section V.D of this chapter.

A relatively new and unique application of the SQP(I) quench indicating parameter to the rapid screening of unknown radionuclides in drinking waters and samples under analysis for emergency response and nuclear forensics are described by Warrick and Croudace (2013) and Croudace et al. (2016). The method involves utilization of the SQP(I) to determine the asymmetry of the peak characteristic of the sample pulse height spectrum, which provides a rapid screening of samples to indicate the presence of multiple radionuclides as well as distinguish between alpha- and beta-emitters. As described by Croudace et al. (2016), a quench parameter SQPI(x) is measured from the sample spectrum and defined in terms of the spectrum channel number below which a percentage area (x) of the spectrum lies. Two values of the SQPI(x) are chosen to define a peak shape factor (PSF), which is the ratio of the SQPI values calculated for 95% of the spectrum and 50% of the spectrum where

$$PSF = \frac{SQPI(95)}{SQPI(50)} \quad (6.9)$$

Croudace et al. (2016) recognize that the deconvolution of alpha and beta emitting radionuclides can be achieved using techniques such as pulse decay discrimination

described in Section XV of this chapter; however, they point out that specific pulse processing capability is not available on all commercial liquid scintillation counters and that such discrimination is also quench dependent. The first report of the development of the use of the peak shape factor (PSF) with SQP(I) to discriminate between alpha and beta emitting radionuclides and to screen rapidly samples for the presence of multiple radionuclides was provided by Warrick and Croudace (2013). An example of the potential of this method to screen water samples and other media for radionuclides of interest in emergency response and nuclear forensics is provided by Fig. 6.14, which is a plot of the sample PSF versus its SQP(I) calculated for 95% of the spectrum. Warrick and Croudace (2013) report that the method has been tested on contaminated drinking waters and pipeline scales with radionuclide compositions typical of those that could be encountered in a real case. The method has been demonstrated to be highly effective in the identification and quantification of the radionuclides present, and it is being incorporated into an integrated analytical system for emergency response with a rapid and effective analytical system to monitor the accidental or intentional radionuclide contamination of drinking water supplies. The identification of beta-emitting radionuclides at different quench levels was demonstrated with various beta emitting radionuclide standards with their characteristic beta-particle maximum energies (E_{\max}). The

radionuclide identification is due to the fact that the sample peak position at SQPI(95) and the external standard quench parameter SQPE varies depending on the beta particle E_{\max} . Thus, the ratio of SQPE/SQPI(95) was a function of the radionuclide E_{\max} irrespective of a range of sample quench levels as illustrated in Fig. 6.15. The external standard quench parameter SQPE is described in Section V.C.4 of this chapter.

c. Asymmetric quench parameter of the isotope or AQP(I)

The asymmetric quench parameter of the isotope [AQP(I)] is a sample spectrum quench indicating parameter employed with certain microplate scintillation counters of PerkinElmer, Inc (Hughes et al., 2001). Quench correction curves based on AQP(I) provide an improvement over the SQP(I) sample spectrum quench correction curves for low-energy beta-emitters such as tritium. The previously described SQP(I) is a quench indicating parameter that provides an MCA channel number equating the midpoint of the isotope spectrum. When quench occurs in tritium samples, the shift in the MCA channel number according to quench is limited because of the small (low-energy range) of the tritium beta-particle pulse height spectrum. The AQP(I) makes use of two multichannel analyzers, MCA₁ and MCA₂ providing two pulse height spectra of the sample. The MCA₁ produces a pulse height spectrum of the

FIGURE 6.14 Identification of radionuclides using a peak shape factor (SQPI(95)/SQPI(50)). S1–S4 represents test samples spiked with an unknown radionuclide that are superimposed on standards data. The radionuclide present in each sample was identified by its position on the plot along with data from the combined internal/external quench ratio. Reproduced with permission from Warwick et al. (2013), © 2013, American Chemical Society.

FIGURE 6.15 Relationship between beta E_{\max} and SQPE/SQPI(95) over two quench ranges and between three Quantulus LS counters (Q1, Q2, and Q3). Reproduced with permission from Warwick et al. (2013), © 2013, American Chemical Society.

sample of beta events detected by the two photomultiplier tubes in coincidence. The MCA₂ records the beta events from only one MCA where pulse events of low height (*e.g.*, below channel number 150) are discarded. The setting of the channel discriminator setting can be adjusted to optimize quench correction curves. The AQP(I) is then calculated from the ratio of the counts in the two MCAs or $AQP(I) = MCA_1/MCA_2$. Since the pulse height spectrum of MCA₁ is always greater than that of MCA₂, the value of the quench indicating parameter is greater than one, and its value reduces in magnitude as quench increases.

A major advantage of the AQP(I) quench indicating parameter is a very broad range of QIP values over a broad range of quench levels providing more accurate determination of detection efficiencies for low-energy beta-emitters, such as tritium. For example, ³H samples with counting efficiencies over the range of approximately 2.5%–35% will yield AQP(I) values over the broad range of approximately 5–120, respectively. Therefore, a tritium quench correction curve based on a plot of % counting efficiency of ³H versus AQP(I) can be used to provide more accurate measurements of counting efficiency as a function of AQP(I).

C. External standard quench indicating parameters

A method of quench correction more popular than the aforementioned sample spectral methods is the measurement of a quench indicating parameter based on an external

standard or external radiation source. This method uses an external source of gamma radiation to create a Compton spectrum in the scintillation cocktail as a tool to facilitate the measurement of quench in the sample. The sample with fluor cocktail in its scintillation counting vial is counted first in the absence and subsequently in the presence of the external gamma-ray source. This external gamma-ray source is located within the instrument, and it is positioned into close proximity of the counting vial when needed. The general interaction of the gamma rays with the scintillation vial material and cocktail is mainly via the Compton effect (See Chapter 1). The external gamma radiation produces Compton electrons with a wide spectrum of energies within the scintillation cocktail. The Compton electrons produce a scintillation effect in the fluor cocktail and a characteristic pulse height spectrum. The pulse height spectrum produced by the external standard is used to create a quench indicating parameter (QIP) for the measurement of quench in homogeneous samples in fluor cocktail. A series of radionuclide quenched standards are prepared generally as described in Section V.D, and a quench correction curve of percent counting efficiency versus a QIP created by the external gamma-ray source is plotted. Once the quench correction curve is prepared, the quench levels and activities of experimental samples are determined automatically by the LSA. The instrument determines the count rate of the sample and then uses the external standard gamma-ray source to measure the QIP of the sample. The value of the QIP is then used to obtain the radionuclide counting efficiency from the quench

correction curve. The counting efficiency, in turn, is used to convert the sample count rate to disintegration rate according to Eq. (6.7).

Some external standard gamma-ray sources used in liquid scintillation analyzers are ^{133}Ba ($t_{1/2} = 10.6$ y), ^{137}Cs ($t_{1/2} = 30$ y), ^{152}Eu ($t_{1/2} = 13.2$ y), ^{226}Ra ($t_{1/2} = 1559$ y), and ^{241}Am ($t_{1/2} = 432$ y). The QIPs that are measured against the ^{133}Ba , ^{137}Cs , and ^{152}Eu external standards are defined as the tSIE (transformed spectral index of the external standard), H# (Horrock's number), and SQP(E) (*i.e.*, spectral quench parameter of the external standard), respectively. The various quench indicating parameters (QIPs) are determined differently and with different gamma sources. These will be described subsequently in addition to a quench indicating parameter common to all external standard sources, namely, the external standard channels ratio (ESCR) technique.

1. External standard (source) channels ratio (ESCR)

The external standard channels ratio (ESCR) technique, which may also be referred to as the external source channels ratio technique, for the determination of counting efficiencies is similar to the SCR method described previously. The principal difference is that the channels ratio produced by the external standard Compton pulse height spectrum is utilized rather than that produced by the sample pulse height spectrum.

The ESCR remains a very popular quench indicating parameter. The ESCR technique offers the advantage that the optimum channel widths (*i.e.*, counting regions) and gains for the channels ratio determinations are often factory set to monitor the scintillation events produced by Compton electrons that result from the interaction of gamma rays of the external standard with the scintillation cocktail and vial wall. In the previously described SCR technique, the channel widths and gain settings, which produce the best (most linear) quench correction curve, must be determined experimentally and will differ from radionuclide to radionuclide. Nevertheless, some researchers opt to define the widths of channels for the measurement of the ESCR (Hofmann et al., 1990; Tsroya et al., 2012).

In practice, the ESCR quench correction curve is prepared firstly by counting a series of variably-quenched radionuclide standards in a preselected counting region from which counting efficiency values are obtained. The standards are prepared as described in Section V.D of this chapter. Each standard will contain a known activity (DPM) of a standard of the radionuclide under analysis with different amounts of quenching agent in scintillation fluor cocktail. The % detection efficiency of the radionuclide in each of the quenched standards will differ, and the values are calculated from the count rates of each quenched

standard in the preselected counting region and the known activity of the radionuclide in the quenched standards (*i.e.*, $\%E = \text{CPM/DPM} \times 100$). After each of the standards are counted in a preferred counting region, an additional count is made for each of the variably-quenched standards exposed to the external gamma-ray source; however, the external standard counts are collected in two other preselected or factory set counting channels, and the net count rate in these two channels due to the external standard is computed by subtracting from both channels those pulses or counts contributed by the radionuclide standards. The ratio of the counts due to the Compton spectrum produced by the external standard source in the two counting channels provides a channels ratio (ESCR) for each of the radionuclide standards. The detection efficiency of the radionuclide standards is then plotted against the ESCR (% detection efficiency vs. ESCR) as illustrated in Fig. 6.16. A radionuclide sample of unknown activity prepared in the same scintillation fluor cocktail is counted in the same counting region used to measure the detection efficiencies of the radionuclide standards, and the ESCR for that sample is measured by the liquid scintillation analyzer. From the value of the ESCR of a sample of unknown activity, the detection efficiency of that sample is then found from the relationship (*i.e.*, curve) of % detection efficiency versus ESCR (Feng et al., 2017; Nakayama et al., 2017; Kanisch, 2016; Yang et al., 2006; Liu et al., 2005; Zimmerman and Collé, 1997b; L'Annunziata, 1987; Takiue et al., 1983).

Fig. 6.16 illustrates three quench correction curves with three sets of ^{14}C quenched standards provided by three suppliers, namely Hitachi Aloka, Packard Bioscience (now

FIGURE 6.16 Quench correction curves based on the external standard channels ratio (ESCR) for three sets of ^{14}C quenched standards measured by an ALOKA LSC-5100 liquid scintillation counter equipped with a 4096-channel pulse-height analyzer. The ^{14}C quenched standards were provided by ALOKA, PACKARD, and PerkinElmer. From Nakayama, M., Hara, M., Matsuyama, M., Hirokami, K. 2017. Modified integral counting method with various quenched samples for different scintillators. Radiat. Safety Manag. 16, 1–7; printed with permission from the Japanese Society of Radiation Safety Management.

a part of PerkinElmer), and PerkinElmer. The three quench correction curves are quite similar; however, they do illustrate differences by a small but not insignificant extent. The quenched standards provided by suppliers are not identical, as reported by Nakayama et al. (2017); they can vary in solvent (e.g., toluene, diisopropylnaphthalene) or quantity and type of scintillation fluor (PPO, POPOP, bis-MSB). Thus, Fig. 6.16 illustrates that for more accurate determinations of sample activities, it is best to analyze samples in the same liquid scintillation cocktail as used for the preparation of quenched standards. The detailed procedure for the preparation of quenched standards is provided in Section V.D of this chapter and Chapter 7, Volume 1. If one prefers not to prepare quenched standards, there remains the possibility of using a direct DPM method of analysis as described by Nakayama et al. (2017) and expounded on in Part V.F of this chapter.

Because the channels ratio in the ESCR method arises from counts produced by an external source, the ratio determination does not suffer from poor statistical accuracy for samples with low count rates, as does the SCR method. The quench correction curves may display a greater difference for color and chemical quenching; although decolorization of samples is often an easy task as described in Chapter 7 of Volume 1 of this book. Wigfield and Cousineau (1978) found excellent agreement between counting efficiencies and various combinations of chemical and color quenching. The ESCR method remains a common method of quench correction. It has been used with a wide variety of commercial liquid scintillation analyzers including Wallac LKB, PerkinElmer, and Hitachi Aloka instruments, as reported by Feng et al. (2017) and Al-Haddad et al. (1999) for the measurement of ^3H , Nakayama et al. (2017) in the measurement of ^{14}C and ^{35}S , Kanisch (2016) in general environmental radionuclide analysis, van Wyngaardt et al. (2014) in the measurement of ^{99}Tc ,

Lin et al. (2008), Yang et al. (2006) and Liu et al. (2005) for the measurement of ^{45}Ca , Wells et al. (2001) for the measurement of ^{32}P , and Hofmann et al. (1990) in the measurement of ^{32}Si and ^{32}P .

2. *H-number (H#)*

The *H-number (H#)*, as a quench indicating parameter, was first proposed by Horrocks (1976a, 1976b, 1977, 1978a), and it remains a versatile method for quench correction in liquid scintillation analysis with Beckman Instruments (Huang et al. (2016); Collé et al., 2016 and Huang et al. (2016), Hui et al., 2012, Laureano-Perez et al., 2010, Ray et al., 2009, Bonardi et al., 2004, Zimmerman et al., 1998, Zimmerman and Collé, 1997a,b, Sinor et al., 1997, Samuels and Scott, 1995, Newell and Krambeck, 1995, and L'Annunziata, 1987).

The technique involves the irradiation of liquid scintillation counting vials containing radionuclide standards in scintillation cocktail, varying in their degree of quench, with an external radionuclide source ^{137}Cs ($^{137\text{m}}\text{Ba}$) emitting monoenergetic gamma radiation. The radiation reaching the scintillation vials and samples consists exclusively of 0.662 MeV gamma rays, as the 0.032 MeV X-rays from $^{137\text{m}}\text{Ba}$ are absorbed by the source container. Via the Compton effect, the gamma radiation produces a spectrum of Compton scatter electrons of varying energies between zero and an energy maximum (E_{max}) in the scintillation fluor cocktail.

The spectrum of energies of the Compton electrons are constant from sample to sample. However, the scintillation photon intensities and concomitant pulse heights produced by the Compton electrons will vary depending on the amount and type of quenching agent in each sample. The Compton scatter electrons produce a spectrum of pulse events as illustrated in Fig. 6.17. If only those Compton

FIGURE 6.17 Effect of quenching on the inflection point (I_q) of the external standard ^{137}Cs Compton edge for (A) a weakly-quenched sample ($H\# = 19$) and (B) a strongly-quenched sample ($H\# = 339$) in comparison to the inflection point of a nonquenched sample (I_{nq}) factory set at 870 in a Beckman LS 7800 liquid scintillation analyzer (L'Annunziata, M. F. 1986, unpublished work of the writer.).

scatter electrons with energy E_{\max} are considered, these would produce pulse heights of maximum magnitude as a peak referred to as the Compton edge. The magnitude of the pulse height spectrum at the Compton edge is maximum for a sample free of quenching agents and saturated with nitrogen gas (nonquenched sample). The Compton edge of quenched samples is encountered at lower pulse heights than that of the nonquenched sample, and the degree of spectral shift is a function of the amount of quench in the sample. A measure of the degree of spectral shift or difference in E_{\max} pulse response is called the $H\#$, and it is a measure of the amount of quench in a sample.

In practice, the $H\#$ concept is applied to the quench correction of samples counted with liquid scintillation analyzers with logarithmic pulse height conversion. Such systems convert the initial pulse-height response to the logarithm of the pulse height. Thus, initial pulse responses, which may differ by a factor of 1000, may be handled by a single amplifier and pulse-height analyzer and, as reported by Horrocks (1978b), there is a constant logarithmic difference between response relationships at different quench levels. For example, a 50% reduction in photon yield or an increase in quench by a factor of two represents a constant difference of 0.301 or the logarithm of two between the logarithmic response relationships of different quench levels. This is illustrated in Fig. 6.18.

With logarithmic response relationships, the measured pulse height, H , may be defined using the notation of Horrocks as

$$H = a + b \log E \quad (6.10)$$

where H is commonly expressed in a discriminator division, a is the pulse height response for a 1 keV electron, and b is the slope of the energy response curve. For different levels of quench, the slope b will remain constant, but the value a will differ. For a nonquenched sample, the measured pulse height, H_o , may be defined as

$$H_o = a_o + b \log E \quad (6.11)$$

Likewise, for a quenched system the measured pulse height, H_q , may be written as

$$H_q = a_q + b \log E \quad (6.12)$$

The difference between the measured pulse-height responses for electrons of the same energy (e.g., E_{\max} from ^{137}Cs Compton edge) in nonquenched and quenched systems is defined as the $H\#$ or

$$H\# = H_o - H_q \quad (6.13)$$

$$= a_o - a_q + b \log E - b \log E \quad (6.14)$$

$$= a_o - a_q \quad (6.15)$$

FIGURE 6.18 Relative quench effect on the logarithmic response for different electron energies. Curves are marked to indicate logarithmic response at quench levels of 50, 25, and 10% compared to the pulse-height response from nonquenched scintillation media. Curves marked '25%', '50%', and 'nonquenched' are separated by a constant value of 0.301 relative pulse height. From Horrocks (1980). Reprinted with permission from Elsevier © 1980.

The $H\#$ is determined by taking the difference between the relative pulse heights at the inflection points of the ^{137}Cs Compton spectra of nonquenched and quenched samples, as illustrated in Fig. 6.17. In the examples presented in Fig. 6.17, $H\#$ values of 19, and 339 are illustrated. Greater and lesser degrees of quench will result in a corresponding variation in the magnitude of the $H\#$. The inflection points of the quenched and nonquenched samples are determined automatically by multichannel analysis while exposing the samples to an external ^{137}Cs ($^{137\text{m}}\text{Ba}$) source. The multichannel analyzer divides the pulse height scale into narrow channels and accumulates the counts in each channel over a given period of time. A microprocessor then compares the counts in each channel to define the Compton spectra and precisely locate the inflection points.

With certain liquid scintillation spectrometers, for example, those of Beckman Instruments, the inflection point of the external standard Compton edge produced by a nonquenched fluor cocktail is factory set at 870 discriminator units. Quenched samples produce Compton edges

with inflection points at lower discriminator levels, and the magnitude of the difference defines the $H\#$ (see the examples in Fig. 6.17).

In practice, a standard curve is prepared to relate counting efficiency to $H\#$. This requires the preparation of a set of standards in liquid scintillation vials containing the same and known activity (DPM) of radionuclide and increasing amounts of quenching agent in scintillation fluor cocktail (see Section V.D for procedures for preparing quenched standards). These standards are then counted in optimal region settings (LL and UL discriminator settings) and the counting efficiency ($E = \text{cpm/dpm}$ or cps/Bq) for each quenched standard is plotted against the $H\#$ as illustrated in Fig. 6.19. The counting efficiency of specific radionuclide samples of unknown activity are determined from their $H\#$ and the standard curve for that radionuclide. Fig. 6.19 illustrates the magnitude of quench as a function of the E_{max} of the beta-particle emitting nuclide. Quenching agents in the liquid scintillation fluor cocktail have a greater effect on the detection efficiency of beta-emitters of lower E_{max} . The four radionuclides illustrated in Fig. 6.19 emit beta particles with the following values of E_{max} included in parenthesis: ^3H (0.018 MeV), ^{14}C (0.15 MeV), ^{33}P (0.25 MeV), and ^{32}P (1.71 MeV). The quench correction curve for ^3H in Fig. 6.19 shows a linear relationship between detection or counting efficiency and $H\#$ over the $H\#$ range from ~ 50 to ~ 200 where most experimental samples would be found. This is confirmed by Colle et al. (2016) as illustrated in Fig. 6.20. A linear quench correction curve may be the most desirable, but it not necessary provided a good correlation between detection efficiency and quench indicating parameter is established.

The $H\#$ technique offers certain advantages over the 'classical' quench correction methods such as SCR and

FIGURE 6.19 Quench correction curves for ^3H , ^{14}C , ^{33}P , and ^{32}P based on the quench indicating parameter $H\#$. The ^3H and ^{14}C plots were obtained from commercially obtained quenched standards. Those of ^{33}P and ^{32}P were obtained from standards prepared with Insta Gel scintillation cocktail and increasing amounts of CCl_4 as quenching agent. From L'Annunziata, M. F. (1986), unpublished work of the writer.

FIGURE 6.20 A typical quench curve in terms of the ^3H efficiency ϵ_3 as a function of the quench indicating parameter $H\#$ for a Beckman counter. The open diamonds and closed circles represent data from two ^3H sources. From Collé et al. (2016) reprinted with permission from Elsevier © 2016.

ESCR. These advantages are (1) any sample can have only one $H\#$ value, contrary to channels ratio techniques, (2) the $H\#$ technique results in less variable quench correction curves over a wider range of counting efficiency, (3) if the $H\#$ of a nonquenched standard is properly calibrated, the $H\#$ of any given sample would be constant from instrument to instrument, although the counting efficiency may not necessarily be constant.

3. Relative pulse height (RPH) and external standard pulse (ESP)

The relative pulse height (RPH) and external standard pulse (ESP) quench correction techniques are similar in concept to the previously described $H\#$ quench monitor procedure.

In the ESP technique, reported by Laney (1976, 1977) and evaluated by McQuarrie et al. (1980), the liquid scintillation spectrometer measures the degree of quench in a sample by the shift in the average pulse height, P_s , originating from Compton electrons produced by an external ^{133}Ba gamma-ray source as compared to the average pulse height, P_r , produced in a sealed nonquenched reference vial stored in the elevator mechanism of the counter. The shift in the average pulse heights is defined by the ratio

$$\text{ESP} = \frac{P_r - P_\infty}{P_s - P_\infty}, \quad (6.16)$$

where P_∞ is a correction term corresponding to Compton electrons produced by the external gamma-ray source under 'infinite' quenching. In ESP determinations, the entire external standard pulse-height spectrum of quenched and nonquenched samples is stored in a multichannel analyzer from which the average pulse height is determined.

As described in the case of $H\#$, a quench correction curve is prepared relating counting efficiency with ESP, using a set of quenched standards containing the same

FIGURE 6.21 Variations in counting efficiency with ESP using quenched ^{14}C standards. Plotted from data of McQuarrie et al. (1980).

activity of radionuclide and varying amounts of quenching agent in fluor cocktail. A quench correction curve is obtained by plotting counting efficiency against ESP as illustrated in Fig. 6.21. Laney (1976) defined the relative pulse height (RPH) as the reciprocal of the ESP. Both can serve as quench indicating parameters, but ESP produces quench correction curves with more linearity (Grau Malonda, 1999).

4. Spectral quench parameter of the external standard or SQP(E)

The quench indicating parameter SQP(E) is measured with ^{226}Ra or ^{152}Eu (Günther, 1998) as the external standard source in liquid scintillation analyzers of the LKB and Wallac (now PerkinElmer) instruments (Kouru, 1991; Grau Malonda, 1999). A multichannel analyzer with 1024 logarithmic channels is used to determine the position of 99.5% of the endpoint of the external standard Compton spectrum to define the value of the SQP(E). As described by Grau Carles (2006b) the endpoint of the Compton spectrum is a well-defined point for spectrometers with logarithmic amplifiers. The SQP(E) parameter, like all quench indicating parameters (QIPs), is a relative number, and it is a meaningful number when compared to other SQP(E) values. As a QIP in liquid scintillation analysis, SQP(E) remains a robust and widely used parameter to monitor and correct for sample quench levels for the determination of detection efficiencies (Fons-Castells et al., 2017d; Jiang et al., 2017; Kossert et al., 2017a,b; Kristof and Logar, 2017, 2013; Stojković et al., 2017a,b,c; 2016, 2015; Collé et al., 2016; Feng et al., 2015, 2013; 2012; Chmeleff et al., 2010; Jörg et al., 2010; Kossert and Grau Carles, 2010, 2008; 2006; Wanke et al., 2010; Kossert et al., 2009a,b; Krajcar Bronić et al., 2009; Varlam et al., 2009; Kossert et al., 2009a,b; Werth and Kuzyakov, 2008;

Laureano-Pérez et al., 2007; Tarancón et al., 2007; Grau Carles et al., 2006; Grau Malonda et al., 2006; Hou, 2005; and Hou et al., 2005).

The gamma source for the SQP(E) determination is positioned below the counting vial containing scintillation fluor cocktail. The SQP(E) defines the uppermost channel number (endpoint) that comprises 99.5% of the total counts of the external standard pulse height spectrum. Only a small portion of the endpoint, the remaining 0.5% of the total counts or area under the pulse height spectrum are excluded (Kessler, 1989). As described by Grau Malonda (1999), the SQP(E) for a nonquenched sample is defined as

$$\text{SQP(E)} = P - 400 \quad (6.17)$$

where SQP(E) corresponds to the i value of the equation

$$\sum_{j=1}^n N_j \geq (1-r) \sum_{j=400}^n N_j > \sum_{j=i+1}^n N_j \quad (6.18)$$

where N_j is the total number of external standard counts in channel j , $r = 0.995$, n = the total number of channels = 1024, and $\sum_{j=400}^n N_j = N_{\text{tot}}$ is the total number

of external standard counts or area under the external standard pulse height spectrum above channel 400. The above formula indicates that the first 400 channels of the external standard pulse height spectrum are excluded from the calculations. The 400 channels at the lower end of the pulse height spectrum correspond to approximately 0–20 keV events, and the objective of the exclusion is to reduce that portion of the spectrum that could vary from any ‘wall effect’ that would occur whenever scintillation fluor solvent penetrates into the plastic wall of the counting vial. The wall effect is enhanced scintillation resulting from organic solvents such as benzene or toluene penetrating into the plastic vial wall. However, this effect generally does not occur to any appreciable extent with the modern solvents based on linear alkylbenzene and diisopropylnaphthalene (See Chapter 7, Volume 1). In the elucidation by Grau Malonda (1999), the value of P is obtained from the equation

$$P = i + \frac{1}{N_i} \left[\sum_{j=i}^n N_j - (1-r)N_{\text{tot}} \right] \quad (6.19)$$

where N_i is obtained from the equation

$$N_i = \frac{1}{3} \left[\sum_{j=i-1}^{i+1} N_j \right] \quad (6.20)$$

As required with other quench indicating parameters, it is necessary to count a set of quenched standards all having a known and constant activity of radionuclide but varying levels of quench. From the count rates of each standard and SQP(E) value measured by the liquid scintillation analyzer, a standard curve of counting efficiency for a given

FIGURE 6.22 Quench correction curves for ^3H and ^{14}C with SQP(E) as the quench indicating parameter measured with a Quantulus 1220 liquid scintillation counter. From Hou (2005), reprinted with permission from Elsevier © 2005.

radionuclide versus SQP(E) is plotted, such as illustrated in Fig. 6.22 for the radionuclides ^3H and ^{14}C . When a sample of unknown activity of a given radionuclide is analyzed in the liquid scintillation analyzer, the instrument will determine the SQP(E) value of the sample, and subsequently extract the counting efficiency of that radionuclide from the standard curve. It is important that the samples of unknown activity be prepared in the same fluor cocktail formula as the radionuclide standards used to prepare the quench correction curve.

The quench correction curve for ^3H , illustrated in Fig. 6.22, appears to be near linear over the SQP(E) range of ~ 700 – ~ 800 , which is a range of quench level in samples generally counted. Collé et al. (2016) determined a similar near linearity in a quench curve, illustrated in Fig. 6.23, determined with two different ^3H radionuclide standards, which can illustrate the robustness of this QIP.

FIGURE 6.23 Typical quench curve in terms of the ^3H efficiency ϵ_3 as a function of the quench indicating parameter SQPE for a Wallac counter. The open diamonds and closed circles represent data from two ^3H sources. From Collé et al. (2016) reprinted with permission from Elsevier © 2016.

Quench correction curves need not be linear provided there is a good correlation between detection efficiency and quench indicating parameter.

5. Transformed spectral index of the external standard (tSIE)

The external standard quench correction methods previously described define specific characteristics of the external standard pulse height spectrum as quench indicating parameters such as, (1) the magnitude of the average pulse heights of the external standard Compton spectrum (e.g., ESP and RPH), (2) the inflection point at the Compton edge (e.g., $H\#$), and (3) the endpoint of the external standard pulse height spectrum [e.g., SQP(E)]. Another popular external standard quench indicating parameter was first reported by Everett et al. (1980) and Ring et al. (1980) under the designation of spectral index of the external standard (SIE). The SIE is similar to the SIS previously described with the exception that the SIE characterizes the external standard pulse height spectrum in the same fashion as the SIS characterizes the sample pulse height spectrum (Kessler, 1989). The objective of SIE is to characterize the external standard pulse height spectrum to the extent of quantifying the various features of the pulse height distribution (i.e., pulse height spectral shape) and any changes in these features, which could occur as a result of quench. Features such as the spectral peak, slope at various points of the spectrum, and maximum pulse height will govern the center of gravity of the pulse height spectrum, which will obviously change according to quench level (L'Annunziata, 1987). The SIE is calculated as

$$\text{SIE} = k \frac{\sum_{x=L}^U X \cdot n(x)}{\sum_{x=L}^U n(x)} \quad (6.21)$$

where k is a factor assigned to provide a maximum value to the SIE of a nonquenched standard, X is the channel number, $n(x)$ is the number of counts or pulse events in channel X , and L and U are lower and upper limits that encompass the pulse height spectrum. The lower limit L is set above zero sufficient to eliminate changes in pulse events of low magnitude produced by the 'wall effect', which could occur if fluor cocktail solvent were to penetrate the plastic wall of the scintillation counting vial. Notice the close similarity of the above equation for SIE to that used to calculate SIS (Eq. 6.6). The values of SIE are unitless, always greater than 1.0, and of magnitude that will vary according to quench (i.e., the higher the quench level in the sample, the lower will be the SIE value).

A further development based on the SIE is the transformed spectral index of the external standard (tSIE) introduced by Packard Instruments and now a product of

FIGURE 6.24 Transformed liquid scintillation pulse height spectrum of an external ^{133}Ba standard. The tSIE is calculated by the extrapolated value E times a calibration factor F to provide a quench indicating parameter in the range of zero to 1000. The highest value of tSIE = 1000 is set using an unquenched ^{14}C standard. ©1998–2018 PerkinElmer, Inc. Printed with permission.

PerkinElmer, Inc. The tSIE method of quench correction uses ^{133}Ba as the external gamma-ray source. The Compton spectrum of this external standard is measured in a MCA, such as the SIE described previously and transformed by performing a reverse back sum on the spectrum to obtain the transformed spectrum as illustrated in Fig. 6.24. From the transformed spectrum, an endpoint energy is determined by a reverse spectral transform (RST) technique using two points on the spectrum and extrapolating to the

energy axis (Kessler, 1989). The simplified mathematical expression of the reversed spectral transform is

$$\int_{\hat{E}_{\max}}^{\hat{E}} N(\hat{E}) d\hat{E} = \left(\int_{\hat{E}_{\max}}^{\hat{E}_2} N(\hat{E}) d\hat{E} - \int_{\hat{E}_{\max}}^{\hat{E}_1} N(\hat{E}) d\hat{E} \right) \frac{\hat{E} - \text{tSIE}}{\hat{E}_2 - \hat{E}_1} \quad (6.22)$$

where \hat{E} is the transformed energy and tSIE is calculated as one of the parameters of the RST function as

$$\text{tSIE} = \hat{E} - (\hat{E}_2 - \hat{E}_1) \frac{\int_{\hat{E}_{\max}}^{\hat{E}} N(\hat{E}) d\hat{E}}{\int_{\hat{E}_{\max}}^{\hat{E}_2} N(\hat{E}) d\hat{E} - \int_{\hat{E}_{\max}}^{\hat{E}_1} N(\hat{E}) d\hat{E}} \quad (6.23)$$

The final tSIE (extrapolated endpoint times a calibration factor) is calculated on the basis of the tSIE being equal to 1000 for a nonquenched ^{14}C sample, which is used for instrument calibration and normalization. Additional information on the measurement of tSIE and its applications is given by Kessler (1991a,b). The ^{133}Ba gamma-ray source for the measurement of the tSIE is positioned below the sample vial. The positioning of the external standard under the sample produces a quench measurement that compensates for variations of sample volume. The value of tSIE, therefore, can be accurately determined even for small (<1 mL) sample-fluor cocktail mixtures.

The major advantages of using the external standard quench indicating parameter tSIE rather than the QIP based on the sample spectrum (SIS) can be ascertained from Fig. 6.25, which shows quench correction curves for

FIGURE 6.25 Quench correction curves for ^3H using tSIE as the external standard quench indicating parameter with a PerkinElmer Tri-Carb 3180TR/SL liquid scintillation analyzer. Data points on the curve established with a set of ^3H quenched standards provided by PerkinElmer (square red points) and home-made laboratory prepared (blue diamond points) ^3H quenched standards in Ultima Gold LLT fluor cocktail in low diffusion polyethylene vials. From Grahek et al. (2016); reprinted with permission from Elsevier © 2016.

tritium, ^{14}C . The plots illustrate the dynamic range of the quench indicating parameter <1000 for a nonquenched cocktail mixture to less than 100 for a highly quenched sample.

The quench correction curve illustrated in Fig. 6.25 is a good example of the need to compare the performance of commercially available quenched standards with a set of quenched standards prepared in the laboratory with a specific cocktail and vial type. Commercially available quenched standards may be prepared with scintillation cocktail solvents and fluors different than the cocktails used in the laboratory. The quench correction curves produced by two different sets of quenched standards with varying cocktail and vial type often yield different quench curves as illustrated previously with Fig. 6.16. Grahek et al. (2016) demonstrated in Fig. 6.26 the fortunate equal performance of a commercially available set of quench standards and a set of standards prepared in the laboratory. Such tests are warranted if one wishes to use a commercially obtained set of quenched standards in lieu of preparing quenched standards with fluor cocktail identical to the cocktail to be used for the analysis of samples of unknown activity.

It is important to recall that tSIE, like other external standard QIPs, is radioisotope independent, and it is a function of the quality or quench level of the fluor cocktail. The second advantage of the external standard method over the sample spectrum characterization method for the determination of QIP is that the external standard method is sample count-rate independent. The external standard quench indicating parameter (QIP) does not depend on the count rate of the sample; rather it depends on the counts created by the external gamma-ray source and the resultant Compton electrons produced within the scintillation fluor cocktail. The only disadvantage of the external standard method is that each sample must be counted alone and then counted again with the external standard present. This extra counting step usually requires about 6–120 seconds additional counting time depending on the sample volume and quench level. This disadvantage is of little significance,

because sample counting with and without the presence of the external standard and the measurement of the QIP are fully automated.

Examples of quench correction curves prepared in the laboratory with radionuclide standards and scintillation fluor cocktails similar to the fluor cocktails to be used with samples of unknown activity are illustrated in Fig. 6.26. Also, we can note from Fig. 6.26 that, for a given level of quench, the counting efficiencies are higher for radionuclides that emit beta particles of higher energy. For example, the maximum detection efficiencies in the scintillation cocktails used by Ahn et al. (2013) illustrated in Fig. 6.26 are 45.3% for ^3H and 86.4% for ^{14}C . Also, from the bend and flat parts of the quench correction curve for ^{14}C , we can see that quench has less effect on the counting efficiencies of radionuclides that emit beta particles of higher energy at moderate levels of quench.

The quench indicating parameter tSIE is, like the previously described SQP(E) and ESCR external standard QIPs, a very robust and commonly employed parameter for the measurement of quench and the determination of radionuclide detection efficiencies. Numerous examples are found in the literature, and a few covering a wide range of applications are the following: the analysis of ^3H and/or ^{14}C (Gomes et al., 2017; Larionova et al., 2017; Grahek et al., 2016; Ahn et al., 2013; Fang et al., 2013; Ishimori et al., 2010; Zhilin et al., 2010; Mingote et al., 2006; Harms and Jerome, 2004), the analysis of ^{10}Be (Chmeleff et al., 2010), ^{18}F (Dziel et al., 2016), ^{55}Fe (Mikelic et al., 2007), ^{32}P , ^{33}P , ^{35}S (Altizoglou, 2004), ^{59}Fe (Kossert and Nöhle, 2014), ^{64}Cu (Wanke et al., 2010), ^{90}Sr (Maringer et al., 2017; Jäggi and Eikenberg, 2014; Lazare et al., 2009), ^{131}I (Kulkarni et al., 2011a,b), ^{151}Sm (Ramírez-Guinart et al., 2017), ^{210}Pb Laureano-Pérez et al. (2007), ^{241}Pu (Jäggi and Eikenberg, 2014).

Low-energy beta-emitters, such as tritium ($E_{\text{max}} = 18.6 \text{ keV}$), will exhibit a more significant variability in detection efficiency as a function of quench when compared to radionuclides that have higher beta-decay

FIGURE 6.26 Quench correction curves for (A) ^3H and (B) ^{14}C prepared in the laboratory with ^3H and ^{14}C standards. From Ahn et al. (2013), reprinted with permission from Elsevier © 2013.

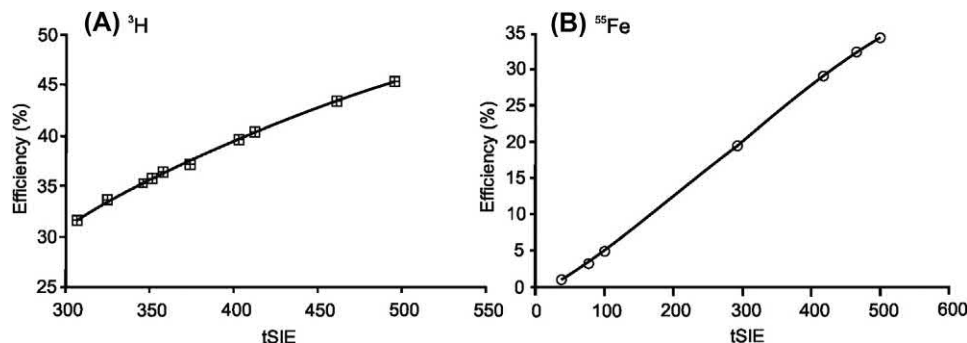

FIGURE 6.27 Quench correction curves of detection efficiency (%) versus the quench indicating parameter tSIE for (A) tritium and (B) for ^{55}Fe . (A) from [Harms and Jerome \(2004\)](#), reprinted with permission from Elsevier © 2004). (B) from [Mikelic et al. \(2007\)](#), reprinted with permission from Elsevier © 2007.

energies, such as ^{14}C ($E_{\text{max}} = 156 \text{ keV}$), ^{33}P ($E_{\text{max}} = 249 \text{ keV}$), and ^{32}P ($E_{\text{max}} = 1710 \text{ keV}$). This is illustrated clearly in [Figs. 6.19, 6.26 and 6.27](#). A maximum liquid scintillation detection efficiency for nonquenched tritium (*i.e.*, a sample containing no quenching agent) in modern liquid scintillation analyzers is $\sim 68\%$ (See [Table 6.2](#) and [Figs. 6.13 and 6.19](#)), which is achievable with an unquenched tritium standard generally used for instrument calibration. However, in practice, unquenched samples are not encountered, as the sample solution (*e.g.*, H_2O is a quenching agent as well as dissolved oxygen gas in the counting solutions). Thus, typical quench correction curves for tritium are provided by [Ahn et al. \(2013\)](#), [Grahek et al. \(2016\)](#) and [Mikelic et al. \(2007\)](#) illustrated in [Figs. 6.25 and 6.26 and 6.27A](#). The quench correction curve for ^3H illustrated in [Fig. 6.26](#) was prepared from a series of tritium quenched standards in counting vials containing the same and known activity of tritium standard and increasing amounts of nitromethane quenching agent in the range of 0–100 μL yielding an optimum detection efficiency of 45.3% for the tritiated water containing no nitromethane. If we consider a radionuclide, such as ^{55}Fe , which emits Auger electrons of energy well below the E_{max} of the tritium beta particles, we will observe yet lower detection efficiencies for samples with similar quench levels as tritium (See [Fig. 6.27A and B](#)). The radionuclide ^{55}Fe decays by electron capture (EC) to stable ^{55}Mn with the emission of 5.2 keV Auger K electrons and Mn K -series X-rays of 5.9 and 6.5 keV ([NNDC, 2011](#)). A quench correction curve for ^{55}Fe , illustrated in [Fig. 6.27B](#), reported by [Mikelic et al. \(2007\)](#), was prepared from a series of quench standards of ^{55}Fe in fluor cocktail containing increasing amounts of nitromethane quenching agent. Although quenching agents can have a very significant affect on the liquid scintillation detection efficiencies of low-energy beta-emitting nuclides (*e.g.*, ^3H) and on the detection efficiencies of radionuclides that emit Auger electrons (*e.g.*, ^{55}Fe), the quench indicating parameter tSIE as well as the previously described SQP(E) and ESCR are robust QIPs

capable of measuring accurately very low detection efficiencies ($<10\%$) (E).

6. G-number (G#)

The $G\#$ is a quench indicating parameter (QIP) first described in detail by [Grau Carles and Grau Malonda \(1992\)](#) as a patent and subsequently reported by [Grau Carles et al. \(1993a\)](#). The method was designed to provide an accurate QIP regardless of the level of quench in a sample, even when the quench level is so high that the counting efficiency of the beta-emitting radionuclide is reduced to less than 1%. The idea behind this approach of Grau Carles and Grau Malonda is based on the use of an external standard which emits considerable quantities of high-energy gamma radiation sufficient to produce appreciable numbers of Compton electrons in the sample scintillation cocktail that have energies above the Cherenkov threshold of 263 keV. The LKB Rack Beta liquid scintillation analyzers are equipped with such a gamma source, namely ^{226}Ra , and the development of this technique was therefore demonstrated with the LKB instrument. The Compton electrons produced by the ^{226}Ra external standard will generate a pulse height spectrum, which is a result of photons emitted by the sample originating from a combination of scintillation and Cherenkov events. As explained by [Grau Carles and Grau Malonda \(1992\)](#), both scintillation and Cherenkov photons are detected simultaneously within the 18-nanosecond time window of the coincidence circuitry of the liquid scintillation analyzer. However, when samples are very highly quenched in the liquid scintillation cocktail, the liquid scintillation diminishes considerably to the point that the pulse height spectrum produced by the ^{226}Ra external standard becomes the result of mostly Cherenkov photons produced by the portion of Compton electrons of energy in excess of 263 keV. In this fashion, regardless of the level of quench, a characteristic of the pulse height spectrum produced by the Cherenkov photons can be measured to provide an accurate QIP even when the

FIGURE 6.28 Compton spectra from ^{226}Ra adjusted and normalized for different quench levels. From *Grau Carles and Grau Malonda (1992)*, printed with permission.

scintillation process is quenched to the extent that beta-particle emitting radionuclides are counted at an efficiency of less than 1%.

Like all other methods of quench correction, this technique requires the preparation of a set of quenched standards of the radionuclide of interest. The quenched standards are counted in a suitable counting region defined by lower-level and upper-level discriminator settings. The count rate of each quenched standard is determined in this counting region, and the counting efficiency is calculated. The quenched standards are also exposed to the ^{226}Ra external standard gamma-ray source, and the resulting ^{226}Ra pulse height spectrum is produced in the channel or counting region between 10 and 500. Fig. 6.28 illustrates pulse height spectra produced by eight quenched standards exposed to ^{226}Ra external standard. The spectra illustrate how the pulse heights shift from higher to lower magnitudes (higher channels to lower channels) as quench increases. At very high levels of quench (standards # 4 to # 8 of Fig. 6.28), the pulse height spectra from ^{226}Ra are the consequence of mainly Cherenkov photons produced by the Compton electrons in excess of 263 keV energy.

The G-number is based on the analysis of the displacement of the final part (end-point) of the ^{226}Ra external standard pulse height spectra as a function of quench. According to *Grau Carles et al. (1993a)*, Fourier series are fitted to the pulse height spectra produced by the ^{226}Ra external standard to enable their normalization to the number of counts, y_N , of the first peak in the pulse height spectra due to Cherenkov photons created by the most energetic Compton electrons (i.e., the left-most peaks in Fig. 6.28). The spectral interval within the limits $y_N/10$ and $y_N/50$ is taken from the final part of each external standard pulse height spectrum. A linear relationship in the selected

FIGURE 6.29 Calibration or quench correction curves of counting efficiency as a function of the G-number for ^{35}S , ^{14}C , ^{45}Ca , and ^{89}Sr . From *Grau Carles and Grau Malonda (1992)*, printed with permission.

interval is obtained by raising the number of counts y to the power α or

$$y \rightarrow y^\alpha \quad 0 < \alpha < 1 \quad (6.24)$$

where α is the value that provides the best regression coefficient to the line

$$y^\alpha = ax + b \quad (6.25)$$

For the channel with a number of counts $y = y_N/100$, the G-number is given by

$$G = \frac{(y_N/100)^\alpha - b}{a} \quad (6.26)$$

Examples of typical quench correction curves obtained with quenched standards of ^{35}S , ^{14}C , ^{45}Ca and ^{89}Sr are illustrated in Fig. 6.29, where it is clearly illustrated that the G-number serves as an excellent quench indicating parameter over the widest possible range of counting efficiency from the highest detection efficiency to the lowest (<1%). This is demonstrated by the expanded quench correction curve for highly-quenched ^{45}Ca standards illustrated in Fig. 6.30 over the counting efficiency range of <1% to approximately 27%.

There is no documented rationale for the selection of the name 'G-number' for the identification of this quench indicating parameter. However, the writer can only assume that the letter 'G' calls to mind the first letter of the family names of Grau Carles and Grau Malonda, who devised this technique. Consequently, this QIP could likewise be called the 'Grau-number'. There exists a similar corollary in the previous development of the H -number by D. L. Horrocks described previously in Section V.C.2 of this chapter. In recognition of its founder, the H -number is also referred to as the Horrocks number.

D. Preparation and use of quenched standards and quench correction curves

A quench correction curve is a calibration curve of percent efficiency versus a quench indicating parameter (e.g., ESCR, $H\#$, SQP(E), and tSIE). Examples of quench correction curves are found in previous parts of this chapter. The quench correction curve is prepared from a set of quenched standards, which is a series of liquid scintillation counting vials containing a certified standard of a radionuclide in scintillation cocktail, all with the same radionuclide activity (DPM) but different levels of quench. The various levels of quench are achieved by adding small amounts (usually measured in microliters) of a quenching agent such as nitromethane, carbon tetrachloride, or other suitable chemical that will shift the sample and external standard pulse height spectrum from higher to lower magnitudes. Usually about 10 vials are prepared with radionuclide standard with each vial containing the same radionuclide activity in a scintillation cocktail, which is identical to the cocktail that will be used for the activity measurements of the same radionuclide of unknown activity. Among the 10 vials, one will contain no quenching agent and, to the remaining nine vials, an incremental amount of quenching agent is added to each vial. The vial with no quenching agent will be the least quenched among the standards, and the remaining nine vials will yield increasing levels of quench. The general procedure for the preparation of quenched standards is as follows:

1. Preparation of quenched standards

There are two methods used for obtaining a set of quenched standards. The first method is to purchase a set of sealed standards for the radionuclide of interest and scintillation cocktail type that one plans to use, and with the quenched standards, prepare a quench correction curve of percent

counting efficiency versus a suitable QIP. Quenched standards of ^3H and ^{14}C are available commercially, because of their relatively long half-lives. Some suppliers (e.g., PerkinElmer, Inc.) can provide the quenched standards according to specification including variables such as (1) radionuclide standard activity, (2) scintillation cocktail, (3) quenching agent, (4) counting vial size and type, and (5) sample volume. Also, sets of quenched standards for ^3H and ^{14}C are sold on the market without customer specifications. If a user is interested in procuring these, it is important that he or she procure the set of quenched standards with vial size, sample volume, and scintillation cocktail compatible with their experimental samples. The second method is to prepare a series of quenched standards in the laboratory and to prepare the quench correction curve from these quenched standards. This method can be the most reliable when the most accurate DPM values are required, because the user can control all aspects of the preparation of the quenched standards to most closely represent the chemistry of his or her experimental samples. A detailed description of the procedure for the preparation of quenched standards and a quench correction curve from the quenched standards is provided next. An outline of the steps is as follows:

- a. **Choose the type and size of counting vial and sample volume that will be used.** Counting vials come in various sizes (e.g., 4, 6, 8, 20 mL) and as glass or plastic. Although glass and plastic vials may perform similarly (Elliott, 1984), there can be differences depending on the cocktail used and radionuclide analyzed. Also, background counts can be lower with plastic vials. The size of the vial and cocktail and sample volume can have a significant effect on counting geometry and the quench correction curve could vary significantly according to this variable. The vial size and type, scintillation cocktail-sample volume, and cocktail composition of the quenched standards should be the same as the experimental samples (Collé, 1997a,b).
- b. **Choose the scintillation cocktail that will be used.** Commercial scintillation cocktails come in various chemical compositions with differing properties, some miscible with organic solutions and others with aqueous sample solutions (See also Chapter 7, Volume 1). Scintillation cocktails that use solvents such as toluene, xylene, pseudocumene or linear alkylbenzene may be used with samples in organic solvents while cocktails using diisopropylnaphthalene (DIN) or phenylxyl-ethane (PXE) as solvents may be mixed with aqueous samples. Most accurate results are obtained when the chemistry of the quenched standards is the same as the experimental samples. Detection efficiencies can vary between different scintillation cocktail compositions. Error can be introduced when determining the

activity (e.g., DPM) of an experimental sample mixed in a scintillation cocktail different from that from which the quenched standards were prepared. The error is particularly pronounced in the case of the LSA of low-energy radionuclides such as tritium (Collé, 1997a,b). It is best therefore to prepare quenched standards with the same scintillation cocktail to be used with the experimental samples.

- c. **Prepare a stock solution to contain the radionuclide standard of interest of known activity (DPM) in the scintillation cocktail.** The radionuclide standard should have an activity that is accurately known such as one traceable to a primary standard (e.g., NIST traceable standard) or a radionuclide standardized according to a known method of standardization. The standard used must be compatible and thoroughly miscible with the cocktail. The stock solution should be of sufficient volume to prepare more vials than standards that are needed to allow for the possibility of discarding some standard vials for reasons described subsequently. For example, if 10 quenched standards each containing 10 mL of scintillation cocktail are desired, then prepare a stock solution of more than 150 mL of scintillation cocktail containing radionuclide standard to allow the testing of 15 standards with the possibility of discarding 5 as described in step (e) below. The level of the radioactivity in the stock scintillation cocktail should be high enough to require counting the standards for only a short period of time and still achieve good or acceptable counting statistics. Activities of approximately 200,000 DPM per vial of low-energy emitting radionuclide, such as ^3H , or approximately 100,000 DPM per vial of higher-energy emitting radionuclide, such as ^{14}C , should be adequate.
- d. **Transfer the exact aliquot of radionuclide standard — scintillation cocktail stock solution into each of the vials to be used for the preparation of the quench correction curve.** The stock solution may be added by pipette or gravimetrically to approximately 15 counting vials. Gravimetric addition can be the most accurate. The volume of the radionuclide standard in scintillation cocktail should be identical to the volume of cocktail to be used when counting experimental samples of unknown radionuclide activity.
- e. **Count each of the counting vials containing standards and determine whether the count rate (CPM) of each is within acceptable counting statistics.** A counting region that encompasses the entire radionuclide pulse height spectrum can be used or other suitable counting region that would encompass a large part of the pulse-height spectrum and avoiding most background pulse events at the low-energy end of the background spectrum. The standards are of high activity and background counts can be subtracted or ignored if

insignificant. Replicate counts of each standard (e.g., count each standard from 5 to 10 times). Obtain a mean count for all of the standards. As an excess number of standards are prepared, any of the standards that deviate more than 2% from the mean count rate can be discarded. This provides us with a set of standards of equal activity in scintillation cocktail.

- f. **Select a suitable quenching agent and add increasing amounts of the quenching agent to each standard. If the experimental samples of unknown radionuclide will be counted eventually in a specific volume (e.g., cocktail + 5 mL of water sample) than a blank water sample of the same volume should be added also to the cocktail. Water is a very weak quenching agent.** In this step, the amounts of quenching agent (e.g., nitromethane) do not have to be added with precision. Only the amount of radionuclide standard in each vial, prepared in the previous step, must be exact. With respect to the quenching agent added, it is only important that each vial have increasing amounts of quenching agent so that a quench correction curve of counting efficiency versus QIP can be established over a broad range of quench levels. Nitromethane is a popular quenching agent, because it is a strong quencher and only small increments are required. For example, if the scintillation cocktail uses toluene as a solvent and there are 10 quenched standards of either ^3H or ^{14}C , then the following increments of nitromethane can be added to the vials: 0, 1, 5, 10, 18, 25, 35, 45, 55 and 65 μL to provide a broad range of quench levels. However, for a scintillation cocktail miscible with water such as Ultima Gold LLT, larger incremental amounts of nitromethane may be needed for a ^3H quench correction curve (e.g., from 0 to 100 μL , as described by Ahn et al., 2013). Notice that the first vial contains no added quenching agent. It would be the least-quenched among the standards. Radionuclide standards that emit beta particles of higher energy than ^3H ($E_{\text{max}} = 0.018 \text{ MeV}$) generally require larger increments of quenching agent to provide a quench curve that would display a significant reduction in counting efficiency against a QIP. For example, Ahn. et al. used a range of 0–200 μL of nitromethane as a quenching agent for a ^{14}C ($E_{\text{max}} = 0.15 \text{ MeV}$) quench correction curve with a cocktail containing 10 mL of Permafluor E+ and 10 mL of Carbo-Sorb E. The amount of quenching agent required will depend on the E_{max} of the beta particle spectrum of the radionuclide and the type of fluor cocktail used. Some experimental testing on the part of the user may be required to determine the most appropriate range of quenching agent to be used. For example, Fig. 6.19 shows ^{32}P ($E_{\text{max}} = 1.71 \text{ MeV}$) undergoes little change in counting efficiency over a wide range of quench level.

Quenching agents have less effect on counting efficiency as the E_{\max} of the beta-emitter increases, as illustrated in Fig. 6.19, using ^3H , ^{14}C , ^{33}P and ^{32}P as examples. Other scintillation cocktails respond differently to nitromethane. For example, cocktails containing DIN or PXE solvent may require larger increments of nitromethane quenching agent. In such cases the following increments of nitromethane for a set of 10 quenched standards may be appropriate: 0, 5, 10, 15, 28, 45, 70, 110, 150 and 230 μL for a ^3H or ^{14}C quench correction curve. Other quenching agents are CCl_4 , chloroform, acetone, and water, which are not as strong quenchers as nitromethane, also display differing degrees in their relative strength of quench. The amounts of quenching agent required will differ, because not all agents quench equally, e.g., CCl_4 is a stronger quencher than water by two orders of magnitude (Grau Carles, 2006b). Classification of quenching agents according to their quenching power is given by L'Annunziata (1987). The quenching agent used should be soluble and not react with the scintillation cocktail. A color dye can be selected as a quenching agent for a set of quenched standards when color quench is high in the experimental samples.

- g. **If in doubt concerning the amounts of quenching agents to add, predetermine this experimentally.** Whenever the amounts of quenching agent required are in doubt, it is easy to predetermine this by adding various amounts of quenching agent to scintillation cocktail in counting vials without radionuclide standard. The vials can then be counted without radionuclide only to determine the external standard quench indicating parameter (QIP) for each vial. Adjustments can be made with more or less quenching agent in order to achieve a wide range of quench levels according to the QIP.
- h. **Label the quenched standards by number or letter (e.g., 1 to 10 or A to J) and isotope, date, etc.** The quenched standards can be labeled only on the top of the counting vial cap. A round self-adhesive label may be placed on the cap or the information written on the top of the cap with a fine-tipped indelible pen.
- i. **Store the quenched standards in the dark for a day or more for stability against any possible photo- or chemiluminescence.** Photo- and chemiluminescence are possibilities that can occur when either the counting vials are open or when quenching agent is added, respectively. The samples can be counted on a daily basis to observe if there is any reduction in count rate with time as evidence of luminescence. Once stability is confirmed the quenched standards can be used to prepare a quench correction curve.

A procedure alternative to the above for the preparation of a set of quenched standards would be to dispense the desired volume of scintillation cocktail and blank sample medium to a set of counting vials. The volume would depend on the combined volume of sample and scintillation cocktail planned for the experimental counting vials (e.g., 10, 15 or even 20 mL depending on vial size and capacity). The radionuclide standard is then added to each vial in equal amounts using a very precise microliter syringe with an adapter to help assure the addition of the same amounts to each vial. A Hamilton syringe equipped with a Cheney adapter (Hamilton Company, Reno, NV 89,502, USA or CH-7402 Bonaduz, Switzerland) may be suitable. The writer finds it easier and more precise to prepare standards of equal activity by preparing a stock solution of radionuclide standard in scintillation cocktail and dispensing this solution into counting vials as described in steps c and d above.

If stored under refrigeration (5–10°C), sets of quenched standards may be stable for two to 3 years. It is best to keep records of the quench correction curves prepared from a given set of quenched standards from time to time (e.g., monthly basis) to check their stability.

2. Preparation of a quench correction curve

The quench correction curve or plot of counting efficiency versus quench indicating parameter (QIP) is determined with a set of quenched standards as described above, and this curve is stored generally in the memory of the liquid scintillation analyzer. The preparation of the quench correction curve is described as follows:

- a. Set up a counting protocol on the LSC to plot a quench correction curve of percent counting efficiency versus a quench indicating parameter. One of the QIPs that uses a sample spectrum characterization method may be used, although an external standard QIP is more often preferred for reasons described in Section V.C of this chapter. Some modern liquid scintillation analyzers store the entire pulse height spectrum of the sample counted onto the memory of the hard disk. With these instruments it is often not necessary to set the counting region defined by lower level (LL) and upper level (UL) discriminator settings. Once the pulse height spectrum of each quenched standard is stored in the instrument, the count rate in any counting region defined by LL and UL discriminator settings can be extracted. However, in older generation instrumentation, it is necessary to first define the counting region according to LL and UL discriminator settings prior to counting the set of quenched standards. The counting efficiency will vary according to counting region settings, and consequently

quench correction curves of counting efficiency versus QIP will also differ according to counting region settings.

- b. Count the quenched standards at a statistical accuracy of at least 0.5% 2s. Due to high activities of standards in each vial (100,000 to 200,000 DPM) the counting time required to reach the 0.5% 2s statistics may not exceed 5 min per quenched standard.
- c. Obtain a plot of the percent counting efficiency of the radionuclide standards versus the QIP. Modern liquid scintillation analyzers will store this data in computer memory. When experimental samples are counted, the instrument should use the QIP measured for the sample and determine the counting efficiency from the correction curve.

3. Use of a quench correction curve

The objective of the quench correction curve (also referred to as a calibration curve) is to determine the counting efficiency of experimental samples of unknown radionuclide activity. From the counting efficiency, the count rate (e.g., CPM) of the sample is converted to radionuclide activity (e.g., DPM) according to Eq. (6.7) described previously. When using a quench correction curve, it is important to keep in mind certain rules, some of which may be intuitively obvious. These are the following:

1. A quench correction curve is good for only one radionuclide, instrument and a specific scintillation cocktail, cocktail-sample volume, and even the vial type (e.g., glass or plastic).
2. The quench correction curve is dependent on counting region defined by lower-level and upper-level pulse height discriminator settings.
3. The quench correction curve is scintillation cocktail dependent (Collé, 1997a,b). It is important to be certain that the scintillation cocktail and volume of sample used for the experimental samples is the same as that used for the preparation of the quench correction curve. The quench correction curve is prepared with standards in fluor cocktail and blank sample without radionuclide. For example, if 5 mL of experimental samples of radionuclide of unknown activity are mixed with 15 mL of fluor cocktail, the quench correction curve should be prepared with 15 mL fluor cocktail containing radionuclide standard mixed with 5 mL of blank water sample in addition to the quenching agent. If a different cocktail is used for experimental samples compared to that used to prepare the quench correction curve, it is necessary to confirm that there is no significant difference between the cocktails in performance for a given radionuclide. Differences in performance of cocktails are more pronounced when analyzing for relatively low-energy beta-emitters such as ^3H and ^{14}C .

4. Quench correction curves using an external standard QIP are preferred, because these are independent of sample activity.

E. Combined chemical and color quench correction

When there are significant quantities of chemical or color quench in scintillation cocktail there can be a significant difference in the chemical or color quench correction curve obtained. This is particularly the case when there is a high degree of either chemical or color quench (at high quench levels) and for the liquid scintillation analysis of relatively weak beta-particle emitting radionuclides such as ^3H ($E_{\text{max}} = 0.0186 \text{ MeV}$), ^{63}Ni ($E_{\text{max}} = 0.066 \text{ MeV}$) and ^{14}C ($E_{\text{max}} = 0.156 \text{ MeV}$). At high values of SQP(E), which correspond to low levels of quench, Fons-Castells et al. (2017d) observed that chemical and color quench could not be differentiated, as illustrated in Fig. 6.31. However, at high levels of quench corresponding to low SQP(E) values, they found that colored substances in the sample would decrease the counting efficiency greater than samples quenched chemically, i.e., noncolored substances. Under high levels of color, it is best to decolorize the sample before adding fluor cocktail whenever possible, as described in Chapter 7, Volume 1. Fons-Castells et al. (2017d) report high correlations between % detection efficiency and SQP(E) of $R^2 = 0.996$ and 0.999 for the chemical and color quench curves.

Differences in color and chemical quench can be observed regardless of the quench indicating parameter used. The differences in the two curves is based on the two different mechanisms of quench; namely chemical quench that entails the inhibition of energy transfer from cocktail solvent to fluor molecules, and color quench that entails the absorption of light photons emitted by the scintillation cocktail (See Fig. 6.1).

FIGURE 6.31 Tritium efficiency quench curves prepared with FeCl_3 and CH_3NO_2 as color and chemical quenching agents, respectively, with an enlargement of low SQP[E] values. From Fons-Castells et al. (2017d) reprinted with permission from Elsevier © 2017.

FIGURE 6.32 Chemical and color quench correction curves based on an external standard. From Takiue *et al.* (1991a), reprinted with permission from Elsevier © 1991.

In older generation liquid scintillation analyzers, the differences between color and chemical quench correction curves may be more pronounced. For example, Takiue *et al.* (1991a) used an older model Packard 460C liquid scintillation analyzer, which utilized the older SIE (spectral index of the external standard) rather than the tSIE (transformed spectral index of the external standard) described previously in this chapter. With this older quench indicating parameter Takiue *et al.* (1991a) measured a considerable difference in color and chemical quench correction curves for ^{14}C and ^3H illustrated in Fig. 6.32. With these older generation instruments, the liquid scintillation pulse height distribution of a color-quenched sample can be very different from that of a chemical-quenched sample, even if both the samples have the same activity (see Fig. 6.33). Therefore, the pulse height distribution of the external standard can be different for either color- or chemical-quenched samples producing different QIPs and different quench correction curves. The difference can be more significant at high levels of quench as depicted on Figs. 6.31 and 6.32, and it becomes less significant as the beta-particle energy (E_{max}) of the radionuclide increases. The colors (*e.g.*, blue, red, green, yellow, etc.) can have different effects on the degree of color quenching, as the photocathodes of the photomultiplier tubes within the liquid scintillation analyzer (LSA) vary in their degree of sensitivity or response to certain wavelengths. If samples to be counted are colored and highly quenched, it is best to

FIGURE 6.33 Liquid scintillation pulse height distributions of chemical- and color-quenched ^{14}C samples. Both samples have identical activity and counting efficiencies. From Takiue *et al.* (1991a), reprinted with permission from Elsevier © 1991.

prepare two series of quenched standards, namely, one set of standards that have increasing intensities of coloring agent (color quencher) and another set of standards containing varying amounts of chemical quencher. A comparison of the two quench correction curves derived from these standards would provide evidence for any significant differences that might exist between the two types of quenching. When decolorization (*e.g.*, bleaching) of samples is not possible and samples are highly color quenched, a color-quench correction curve with radionuclide standards may be prepared with a suitable color dye as described in Chapter 7, Volume 1. Certain modern liquid scintillation analyzers are programmed to correct for color quenching (PerkinElmer, Inc.). Bukowski *et al.* (1992) found no differences between color and chemical quench correction curves for ^3H when either picric acid (yellow color quencher) or CCl_4 (chemical quencher) was used as a quenching agent and the H# was measured as the external standard quench indicating parameter (QIP). Also, Effertz *et al.* (1993) demonstrated identical quench correction curves for the measurement of ^3H when either nitromethane (chemical quencher) or yellow, red, or green (color quenching agents) were used as color quenchers and tSIE was utilized as the external standard QIP.

The best alternative when color exists in the sample is to decolorize (*e.g.*, sample bleaching or oxidation of organic samples to CO_2 and H_2O , see Chapter 7, Volume 1) before adding fluor cocktail. Decolorizing the sample eliminates the problem of color quench leaving behind only chemical quench, which is present in all samples to be analyzed. The works of Lee *et al.* (2016), Yuan *et al.* (2016), Dong *et al.* (2013), Mui *et al.* (2013), Norton *et al.* (2012), Batrakova

et al. (2010), Warrick et al. (2010), Williams and Kookana (2010), Sirelkhatim et al. (2008), and Hou et al. (2005) are excellent examples of the use of sample decolorization prior to liquid scintillation analysis of ^3H , ^{14}C , ^{63}Ni , and ^{55}Fe (all relatively weak beta-emitters), etc., thereby eliminating color quenching. If decolorization is not possible, some modern liquid scintillation analyzers are equipped with color correction programs or algorithms that will correct for the difference between chemical and color quench.

An example of a practical program for the correction of the difference between color and chemical quench correction curves, whenever these are significant, was formulated by Takiue et al. (1991a). This method entails the preparation of two sets of quenched standards of a given radionuclide. One set of standards is prepared with a color-quenching agent (e.g., bromothymol blue, methyl red, or bromocresol green) that produces minimal chemical quench, and another set of standards is prepared using a chemical-quenching agent (e.g., nitromethane or CCl_4). The sets of quenched standards are used to plot two curves consisting of a color- and chemical-quench correction curve of counting efficiency versus any external standard quench indicating parameter (e.g., ESCR, $H\#$, SQP(E), or tSIE, see Fig. 6.32). In addition, the color- and chemical-quenched standards are used to plot a second set of curves consisting of the external standard quench indicating parameter plotted against the external standard counts, referred to as double external standard relation curves (DESR curves; see Fig. 6.34). When an experimental sample, which is

FIGURE 6.34 DESR curves for chemical- and color-quenched radionuclide used for the calculation of the counting efficiency of an experimental combined chemical- and color-quenched sample, where x_0 and u_0 are the quench indicating parameter and external standard (ES) counts for the experimental combined chemical- and color-quenched sample. From Takiue et al. (1991a), reprinted with permission from Elsevier © 1991.

quenched by both chemical and color constituents, is counted, the counting efficiency of the unknown sample has the value between E_1 and E_2 , which corresponds to the external standard (ES) counts of u_0 of the DESR curves illustrated in Fig. 6.34. Hence, as demonstrated by Takiue et al. (1991a), according to the geometry depicted in Fig. 6.34, the counting efficiency (E_0) is defined as

$$E_0 = E_1 + \frac{x_0 - x_1}{x_2 - x_1} (E_2 - E_1) \quad (6.27)$$

where x_1 and x_2 are obtained from the chemical and color DESR curves, respectively (Fig. 6.34) where $x_1 = f(u_0)$ and $x_2 = g(u_0)$. The efficiency values E_1 and E_2 are obtained from the chemical and color quench correction curves, respectively (Fig. 6.32) where $E_1 = F(x_1)$ and $E_2 = G(x_2)$. Eq. (6.27) is then written as

$$E_0 = F(x_1) + \frac{x_0 - f(u_0)}{g(u_0) - f(u_0)} [G(x_2) - F(x_1)]. \quad (6.28)$$

Takiue et al. (1991a) used polynomial curve fitting with the least squares method to define the coefficients of the quench correction and DESR curves. This color correction method is easily applied with the computer application programs of most modern liquid scintillation analyzers. Nevertheless, the problem of combined color and chemical quench in samples is best averted by decolorization of samples prior to the addition of scintillation cocktail.

F. Direct DPM methods

The Direct DPM methods entail the LSA measurement of the disintegration rates of radionuclides, particularly beta-emitters, under various levels of quench without the use of quench correction curves. These methods are described subsequently.

1. Conventional integral counting method (CICM)

During the early years of liquid scintillation counting, it was discovered that an extrapolation of integral counting curves to zero discriminator bias could be used to determine the disintegration rates (DPM) of alpha-emitters (Basson and Steyn, 1954) and beta-emitters (Steyn, 1956) without interference from gamma emission. The method applied to alpha-emitters received little attention, because the LSA counting efficiency of alpha-emitters was close to 100% even in these early years of liquid scintillation development. As far as beta-emitters are concerned, this technique, known as integral counting, received some popular attention and applications in the late 1950s and during the 1960s. Further developments made this technique a practical and accurate method for the activity measurement of beta-emitting radionuclides.

The work of Goldstein (1965) demonstrated the broad range of radionuclides that may be analyzed by integral counting as well as the simplicity of the procedure involved. In the development and testing of integral counting, Goldstein (1965) used the first and only commercial LSA available at that time, which was a Packard 314 liquid scintillation spectrometer. The procedure involved three pulse height discriminators labeled AA', B, and C. The AA' discriminator was set just above the noise level to reject noise pulses. The C discriminator (upper level discriminator) was turned off or disengaged so that all of the pulses of magnitude above the B discriminator would be registered and counted. The height of the B discriminator was varied in the range of 10–30 V in 5-volt increments. The count rates for a given beta-emitting sample in scintillation cocktail were collected for each setting of the B discriminator. With the B discriminator at its lowest setting the count rate is highest. With each incremental increase in the height of the B discriminator, the count rate diminishes, because fewer and fewer pulses are detected. The resulting plot of count rate on a logarithmic scale versus the B discriminator bias (volts) setting on a linear scale would be linear with negative slope, which could be extrapolated back to zero bias volts. At this point of extrapolation, the count rate (CPM) at zero bias would be the disintegration rate (DPM) of the sample. This extrapolation method is currently referred to as the conventional integral counting method (CICM). It is an effective method for extrapolating to sample DPM for beta-emitters or beta-gamma emitters, which emit beta particles with an $E_{\max} > 200$ keV, including ^{147}Pm , ^{45}Ca , ^{99}Tc , ^{36}Cl , ^{204}Tl , ^{89}Sr , ^{90}Sr (^{90}Y), ^{91}Y , ^{32}P , ^{131}I , ^{85}Kr , $^{131\text{m}}\text{Xe}$ and ^{60}Co , among others, regardless of quench level. Corrections for quench in the sample scintillation cocktail mixtures are not necessary, because the quench level in the sample affects only the slope of the integral curve, and extrapolation of the curve to zero discriminator bias ends at the same count rate for all quench levels with expected statistical deviations ($<2\%$ error). Homma and Murakami (1977) also applied the conventional integral counting method to determine the activity of ^{226}Ra after separating the equilibrated ^{222}Rn in a liquid scintillator. The disintegration rates of ^{222}Rn and its daughters, which include both alpha- and beta-emitters were determined by this method at various quench levels.

The conventional integral counting method for sample DPM determinations generally cannot be applied to the measurement of beta-emitting radionuclides of $E_{\max} < \text{about } 200$ keV. However, Homma et al. (1994a) developed the technique into the modified integral counting method (MICM), which can be used to determine the activities of all beta-particle emitters including ^3H of very low energy ($E_{\max} = 18.6$ keV) and with higher accuracy.

2. Modified integral counting method (MICM)

The modified integral counting method (MICM) was reported by Homma and coworkers (1993a, 1993b), who modified the conventional integral counting method by extrapolating the integral counting curves, not to the zero pulse height as described above for the CICM, but to the zero detection threshold (ZDT) of the liquid scintillation spectrometer, which refers to the average energy required to produce a measurable pulse. They applied the new method to analyze the activity of alpha- and beta-emitters including ^{222}Rn and its daughters as well as the low-energy beta-emitters ^3H , ^{14}C , ^{35}S , and ^{45}Ca with 100% detection efficiency. The method is described subsequently in more detail.

The modified integral counting method as was determined by Homma et al. (1994a) is carried out by the following procedure:

- a. The first step requires the determination of the zero detection threshold (ZDT) of the particular liquid scintillation analyzer utilized for the analysis. This is carried out by measuring a standardized nonquenched ^3H sample according to the integral counting method described earlier. The observed integral count rates of the ^3H standard are plotted at several pulse heights and the curve is then extrapolated to the count rate, which is equivalent to the disintegration rate (DPM) of the ^3H standard, as illustrated in Fig. 6.35. The keV value (pulse height)

FIGURE 6.35 Determination of the zero detection threshold (ZDT) extrapolating the integral pulse height spectrum of a standardized ^3H sample to its disintegration rate, which is indicated by the arrow. From Homma et al. (1994a); reprinted with permission from Elsevier © 1994.

at this count rate represents the zero detection threshold (ZDT). The ZDT was found by Homma et al. (1994b) to vary from instrument to instrument over the range of $2.4\text{--}3.5 \pm 0.2$ keV.

- b. Once the zero detection threshold is determined for the particular instrument, the absolute disintegration rate of any low-energy beta-emitter ($E_{\max} < \text{about } 200 \text{ keV}$) including ^3H as well as high-energy beta-emitter ($E_{\max} > \text{about } 200 \text{ keV}$) is determined by extrapolating the integral pulse height spectrum of the radionuclide of interest to the previously determined zero detection threshold.

Homma et al. (1994a) demonstrated activity measurements by this MICM of ^3H and ^{14}C at various quench levels with uncertainties of $\pm 1.3\%$ and 1.4% , respectively. Examples of results obtained from the modified integral counting method applied to the activity determination of ^{35}S and ^{45}Ca are illustrated in Fig. 6.36. As noted by Homma et al. (1994a,b), it is obvious from the plots illustrated that extrapolation of the integral pulse height spectrum to only the zero pulse height leads to an intercept value that is lower than the actual DPM of the radionuclide. However, extrapolation of the integral counting curve to the zero detection threshold leads to the actual disintegration rate of the sample.

The modified integral counting method was reported also by Homma et al. (1993a,b, 1994c) for the determination of ^{222}Rn and its daughters ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po . Total α and β activity was determined with 100% counting efficiency. The MICM can be applied to the activity measurements of α - and β -emitters as single radionuclide samples or mixtures, and γ -emission does not interfere in most cases (Homma et al., 1994a). Measurements of ^{222}Rn with activity ranges of $0.2\text{--}22.9 \text{ Bq/L}$ in natural water samples obtained from private wells and springs were carried out by Murase et al. (1998) with the MICM applying 100-minute counting times, which provided activities with an overall uncertainty of 3.1% . An integral counting method was carried out together with improvements in alpha liquid scintillation spectrometry by Yoshikawa et al. (2006) to determine $^{220}\text{Rn}/^{222}\text{Rn}$ ratios. For low-activity ratios, they developed a liquid scintillation alpha spectrometry method to measure ^{220}Rn with reduced error. The modified integral counting method has a practical simplicity similar to the efficiency tracing (ET) method described in the following section of this chapter.

Hara et al. (2016) carried out extensive tests on the determination of the optimum quench level for the absolute activity measurements of beta-emitting radionuclides by the modified integral counting method (MICM) and compared the MICM to the CIEMAT/NIST method of radionuclide standardization. They measured a discrepancy of only 1% between the CIEMAT/NIST and MICM with first order

FIGURE 6.36 Extrapolation plots of the integral count rates of quenched ^{35}S and ^{45}Ca to the zero detection threshold for determination of the radionuclide disintegration rates. (1994b) with kind permission from Springer Nature © 1994.

function fitting. Nakayama et al. (2017) tested the MICM at various quench levels with ^{14}C and ^{35}S standards using different scintillators including Ultima Gold, Ecoscint, Ultima Gold XR and a toluene-based scintillator. This study demonstrated that the MICM with various quench samples conformed to assayed values.

3. Efficiency tracing (ET) with ^{14}C

Efficiency tracing (ET) with ^{14}C is another practical and simple extrapolation method applied generally to the activity measurements of β -emitting radionuclides with the exception of tritium. This method should not be confused with the CIEMAT/NIST efficiency tracing method

described in Section IX.A of this chapter, which is used for radionuclide standardization. The ET method was demonstrated by Takiue and Ishikawa (1978) to provide accurate DPM values for 14 radionuclides. A subsequent study by Ishikawa et al. (1984) showed that the technique provided accurate DPM measurements of 11 additional β and β - γ -emitting radionuclides, namely, ^{14}C , ^{32}P , ^{36}Cl , ^{46}Sc , ^{59}Fe , ^{60}Co , ^{63}Ni , ^{86}Rb , ^{90}Sr (^{90}Y), ^{131}I , ^{134}Cs , and ^{147}Pm regardless of quench level. The method was demonstrated by Fujii et al. (1986) in a study whereby the efficiency tracing DPM measurements of ^{14}C , ^{35}S , ^{32}P , ^{36}Cl , ^{45}Ca , and ^{131}I were determined for radionuclides on filter disks in LSA counting vials. The ET method is most often used to determine the activity of single and multiple β and β - γ -emitters; it can be applied also to the activity measurements of mixtures of α - and β -emitters (see Fujii and Takiue, 1988b).

The efficiency tracing (ET) with ^{14}C technique involves the following steps:

- A ^{14}C nonquenched standard is counted in six separate counting regions, such as, counting regions defined by lower-level discriminators set at 0, 2, 4, 6, 8, and 10, and upper-level discriminators set at the upper limit of the pulse height scale. For example, counting regions, such as, 0–2000, 2–2000, 4–2000, 6–2000, 8–2000 and 10–2000 keV for lower-level (LL) to upper-level (UL) pulse height discriminator settings on a linear keV equivalent scale, may serve as one example of workable counting regions. However, other similar counting regions may be used. Also, equivalent discriminator settings for liquid scintillation analyzers equipped with a logarithmic scale for pulse height analysis may be determined. See L'Annunziata (1997, unpublished work of the writer) and L'Annunziata and coworkers (Noor et al., 1996a).
- The percent counting efficiency (% E) values of the nonquenched ^{14}C standard in each of the six counting regions are calculated as $\% E = \text{CPM}/\text{DPM} \times 100$.
- A sample of unknown activity of a β -emitting radionuclide is subsequently counted in the same six regions as the nonquenched ^{14}C standard.
- The six CPM values of the sample of unknown activity are plotted against the % counting efficiency values of the nonquenched ^{14}C standard.
- The curve is then extrapolated to 100% counting efficiency, where the CPM of the unknown sample is equal to its DPM. Extrapolation may require a linear or multi-linear regression least-squares best fit of the data points and definition of the equation to the line or curve to most accurately determine the point of intersection at 100% counting efficiency. An example of eight efficiency tracing curves for the DPM determination of eight radionuclides from the work of Takiue and Ishikawa (1978) is illustrated in Fig. 6.37, and an example

FIGURE 6.37 Efficiency tracing curves of eight radionuclide samples. The dashed portion of the plots are the extrapolated segments to 100% counting efficiency. Extrapolated values indicate the counting rates at 100% counting efficiency or DPM of each nuclide. From Takiue and Ishikawa (1978), reprinted with permission from Elsevier © 1978.

of an efficiency tracing curve for the analysis of ^{35}S from the writer's work is illustrated in Fig. 6.38.

Variables such as sample scintillation cocktail volumes over the range of 1–20 mL, composition of the scintillation cocktail, amount or kind of quenching agent, or size and material of the counting vial may affect the slope of the efficiency tracing curve of the sample of unknown activity. At low quench levels the curves are often linear, as illustrated in Fig. 6.37. Linear regression analysis in these cases will define the equation to the line permitting extrapolation of the curve to 100% detection efficiency and DPM of the sample. At higher quench levels the efficiency tracing curves may not be linear, such as illustrated in Fig. 6.38. In these cases, quadratic regression may be needed to fit the data to a second-order polynomial $y = ax^2 + bx + c$, where the independent variable x is the % counting efficiency and

FIGURE 6.38 Efficiency tracing (ET) curves for the activity determinations of three samples of ^{35}S at three levels of quench. The degree of quench is measured by the sample quench indicating parameter SIS where the uppermost curve is that produced by the least-quenched of the three samples. From the work of L'Annunziata and coworkers, See Noor et al. (1996). Reprinted with permission from Elsevier © 1996.

the dependent variable y is the sample count rate (CPM). When x of the regression curve is given the value of 100%, the calculated value of y provides the extrapolated sample activity or disintegration rate (DPM). Example of radionuclide activity recoveries that have been reported by this method are given in Table 6.3. At very high levels of sample quench (e.g., $\text{SIS} < 1000$ for ^{86}Rb and $\text{SIS} < 69$ for ^{33}P) error can creep into the dpm calculation, as noted in the table. This is due to the fact that the efficiency tracing curves lose their linearity and even take on a marked concave shape complicating the mathematical extrapolation to 100% efficiency.

An additional attribute of the efficiency tracing technique is the possibility of determining the total DPM of mixtures of β -emitting radionuclides (with the exception of ^3H) and α/β -emitters as demonstrated by Fujii and Takiue (1988a,b) and L'Annunziata and coworkers [see Noor et al. (1996a)]. The activity of ^3H cannot be measured by this method, as the efficiency tracing curves for ^3H are too concave yielding inaccurate extrapolation to 100% detection efficiency. Table 6.4 illustrates the excellent recoveries

obtained for total DPM measurements of mixtures of $^{86}\text{Rb} + ^{35}\text{S} + ^{33}\text{P}$. It should be noted, however, that the technique provides the total DPM of the mixture and not the activities of the individual radionuclide components of the mixture.

This direct DPM method is very useful for the determination of activities of radionuclides of relatively short half-life for which NIST-traceable standards are not available commercially. The ET-DPM method is an automatic radionuclide activity analysis option available with some liquid scintillation analyzers (e.g., PerkinElmer, Inc. and Hitachi Aloka LSAs).

The efficiency tracing DPM technique was reviewed by Kessler (1991b). Some practical examples of the application of the efficiency tracing method can be found in the literature including the analysis of ^{222}Rn by Yasuoka et al. (2005), ^{14}C and ^{45}Ca by Dobrin et al. (2006), Takiue et al. (2004), ^{32}P by Liyanage and Yonezawa (2003), and ^{14}C by Wakabayashi et al. (1999). The method was tested by L'Annunziata (1997a) and Edler (2004) for β -emitting radionuclide samples over a wide range of quench and levels of sample activity. Kulkarni et al. (2011a,b) compared the CIEMAT/NIST standardization method to the efficiency tracing (ET) and modified integral counting methods (MICM) and found these to agree within 3.3% of the beta activity. Also, Reddy et al. (2011) have tested both the ET and MICM for activity measurements of beta-emitters, and they confirm that these methods are practical and simple yielding uncertainties down to 1% for activity measurements of beta-emitters with activities in the range of 8.33–100 Bq or higher. On the basis of previous studies, the following conclusions and recommendations are made:

- The efficiency tracing DPM (ET-DPM) technique is an accurate method for determining the total activity (DPM) of β -emitting radionuclide samples with the exception of ^3H .
- The ET-DPM method can be used to determine the total activity (DPM) of a mixture of β -emitting radionuclides.
- No quench correction curves are needed, either for chemical or color quench, when using the ET-DPM method.
- For best results samples should be counted for a duration sufficient to achieve a count rate with a % two sigma standard deviation (i.e., % 2s) of 1% or lower.
- The ET-DPM method is very useful for the determination of activities (DPM) of radionuclides of short half-life for which quenched standards are not available. When the activity of a nuclide is required within the limits established by a national bureau of standards (e.g., NIST) for what is classified as a primary standard, the CIEMAT/NIST, TDCR, or other liquid scintillation

method of radionuclide standardization is recommended. These methods are described in Section IX of this chapter and in Chapter 7 of Volume 2.

- f. The ET-DPM method may be used to determine the activity of a source radionuclide prior to initiating a tracer experiment with that nuclide. Before beginning an experiment with a radionuclide as a tracer, it is best not to accept blindly the cited activity provided by the radioisotope supplier on the label of the source container. It is best to prepare replicate samples of the radionuclide source in a suitable scintillation cocktail and use the ET-DPM method or other suitable method to confirm the activity (DPM) of the radionuclide source before beginning an experiment with that source.

Liquid scintillation analyzers, such as those manufactured by Hitachi Aloka instruments and Packard (now PerkinElmer) provide an option for the analysis of beta-emitting radionuclides by the efficiency tracing DPM method referred to as ET-DPM, which is a Direct DPM method, because no quench correction curves are required. Some examples in the scientific literature, particularly in the biological sciences, where the Direct DPM methods were used for radioassay are [Dulanska et al. \(2016\)](#), [Little et al. \(2011\)](#), [Hawkins et al., 2010](#), [Kobbe et al., 2009](#), [Borthwick et al., 2008](#), [Dianu and Podină, 2007](#), [Mordaunt et al., 2005](#), [Little and Rodríguez, 2005](#), [Breitholtz and Wollenberger, 2003](#), [Eardly et al., 2001](#), [Roberts et al., 2001](#), and [Holst et al., 2000](#)). The efficiency tracing DPM (ET-DPM) method has been demonstrated to be an excellent option when standards of the radionuclide of interest are not available for the preparation of a quench correction curve.

4. Multivariate calibration

The principles of multivariate calibration, including the multivariate methods of multiple linear regression (MLR), principal component regression (PCR), and partial least squares regression (PLSR), among others are described in detail by [Varmuza and Filzmoser \(2009\)](#), [Næs \(2002\)](#), [Martens and Næs \(1992\)](#), [Thomas and Haaland \(1990\)](#), and [Beebe and Kowalski \(1987\)](#). The practical applications of MLR are indisputable, as this statistical method is of widespread use. The authors noted that PCR and PLS is gaining acceptance in chemistry, as the laboratory computer can facilitate data collection and processing required for multivariate calibration. As a statistical mathematical tool, multivariate calibration can be applied to a chemical or physical analysis when more than one measurement is acquired for each sample. Mathematical data matrices are written according to the numbers of samples and variables implicated in an analytical result. As explained by [Beebe](#)

and [Kowalski \(1987\)](#), PLS is a factor-based modeling procedure in which factors are defined for any linear combination of the variables in the data matrices. The PLS algorithm estimates the factors in these matrices to provide a prediction of the observation on an unknown sample. Information on the mechanics of calibration and prediction using the PLS algorithm can be obtained from [Gelaldi and Kowalski \(1986\)](#) and a rigorous treatment of the methodology from [Lorber et al. \(1986\)](#).

[García et al. \(1996\)](#) applied partial least squares (PLS) as a multivariate calibration to determine (predict) ^{14}C activities in samples over the activity range of 1.48–15.16 DPM per sample-scintillation cocktail mixture. They used a Packard Tri-Carb 2000 CA/LL liquid scintillation analyzer (now PerkinElmer Tri-Carb LSA) and samples with variable quench levels using a quenching agent in the concentration range of 0%–0.6% CCl_4 . For the multivariate calibration they applied PLS regression using the PLS-Toolbox package for MATLAB devised by [Wise \(1992\)](#). The factors considered in two models constructed by [García et al. \(1996\)](#) consisted of ^{14}C content, quenching, blank, and spectral variability in one model, with blank omitted from the second model. They obtained slightly improved results omitting the blank (background) among the factors considered. Among 16 samples tested over the activity range of 1.48–15.16 DPM per sample, they obtained predicted activities with a relative error in the range of 0%–5.4% (average = 1.09% relative error). This is the first application of multivariate calibration to activity determinations for single radionuclide samples. The multivariate calibration approach to the analysis of ^{14}C is yet to be applied routinely. However, it offers the advantage of being a time-saving approach to low-level liquid scintillation counting, because background information would not be needed and, therefore, total counting time reduced.

[Sakar et al. \(2015\)](#) performed multivariate regression calibration including multiple linear regression (MLR), principal component regression (PCR) and partial least squares regression (PLSR) algorithms on ^{238}Pu , ^{239}Pu , ^{240}Pu and ^{241}Pu atom% abundances to predict the ^{242}Pu isotopic abundance. They found an excellent correlation between the predicted and standard ^{242}Pu abundances. The standard ^{242}Pu abundances were prepared from 175 Pu samples obtained from pressurized heavy water reactors analyzed during 2008–2010 as referred to as a calibration set (CS), depicted in [Fig. 6.39](#). The method was validated with a test set of 133 Pu samples collected and analyzed during 2011–13.

The multivariate calibration approach has been applied by several researchers to the simultaneous liquid scintillation analysis of mixtures of radionuclides, and these studies are discussed further on in this chapter.

VI. Analysis of X-ray, gamma-ray, atomic electron, and positron emitters

Liquid scintillation analysis (LSA) is not restricted to the activity analysis of beta- and alpha-particle emitting nuclides. LSA is also applied to the analysis of nuclides decaying by electron capture (EC) and certain gamma-ray emitters (Grau Malonda, 1999). EC is generally accompanied by the emission of inner bremsstrahlung radiation, X-rays, Auger electrons, and gamma radiation when the daughter nuclide is left in an excited energy state, as illustrated in the following general EC decay process taken from Eq. (1.223) of Chapter 1, Volume 1 and presented here again for convenience:

The electron-capture decay process depicted above, often referred to as *K* capture, is described in detail in Chapter 1, Volume 1. Nuclides emitting gamma rays may also emit internal-conversion (IC) electrons, as described in Section X.C of Chapter 1. Internal conversion occurs when the decay energy is transferred to an atomic electron, and when internal conversion occurs to a significant extent, it results in the emission of atomic electrons of energy equivalent to the nuclear decay energy less the electron binding energy. Thus, when internal conversion occurs to a significant extent, the conversion electrons as well as concurrent events between conversion electron and X-ray emissions contribute significantly to the liquid scintillation detection efficiency of radionuclides decaying by

electron capture with gamma emission. The IC electrons as well as X-ray emissions concurrent with IC electron emissions possess higher energies than Auger electrons sufficient to produce pulse heights well above the lower level discriminator setting of liquid scintillation spectrometers.

Tin-113 is an excellent example of a radionuclide that decays exclusively by electron capture with gamma emission commonly used to calibrate gamma spectrometers. The electron capture decay scheme of ^{113}Sn is illustrated in Fig. 6.40, which is from Roteta et al. (2014), and the scheme and decay data are available from Helmer (2002) and online via the National Nuclear Data Center (NNDC, 2018: <http://www.nndc.bnl.gov/nudat2/chartNuc.jsp>, accessed on January 31, 2018). The ^{113}Sn nuclide decays with a half-life of 115.09 days by exclusively electron capture to ^{113}In by mainly one of two transitions to the metastable state of $^{113\text{m}}\text{In}$ at the excited level of 646.8 keV at 2.21% intensity or to a lower excited level of 391.7 keV at 97.79% intensity, and the half-life of the metastable state of ^{113}In is reported by the NNDC to be 99.476 min, which is equivalent to 1.6579 h. Roteta et al. (2014) notes that the gamma transition labeled $\gamma 1$ of 392 keV in Fig. 6.40 at 84.97% intensity is partially converted with a total conversion coefficient $\alpha_T = 0.540$, which signifies that there are abundant internal-conversion electrons emitted with energy of the gamma transition less

FIGURE 6.40 Decay scheme of ^{113}Sn , which decays exclusively by electron capture denoted by the symbol ϵ . Data is from Helmer (2002) and the NNDC (<http://www.nndc.bnl.gov/nudat2/chartNuc.jsp>, accessed January 31, 2018). The energy levels are rounded off and given in keV. Gamma transitions with intensities higher than 0.1% are drawn with solid lines. From Roteta et al. (2014) reprinted with permission from Elsevier © 2014.

FIGURE 6.41 Three-dimensional coincidence spectrum of ^{113}Sn obtained at CIEMAT with a two-channel digital acquisition system. The spectrum shows two main regions: Region A, which contains coincidences between the low energy Auger electrons (two to four keV) and the K X-rays and Region B, which contains the coincidences between conversion electrons (364–391 keV) and K X-rays. From Roteta et al. (2014) reprinted with permission from Elsevier © 2014.

the electron binding energy equivalent to 391 keV. The gamma transition labeled γ_2 in Fig. 6.40 of 255 keV occurs with an intensity of only 2.1%, and the other transitions from the elevated states of 1030 and 647 keV are minor, and these are illustrated with broken arrows in Fig. 6.40. Roteta et al. (2014) report a total counting efficiency of 0.74 in the liquid scintillation standardization of ^{113}Sn , which would be a result mainly from Auger electron and IC electron interactions with scintillation cocktail together with a smaller fraction the K X-ray emissions, which are illustrated in the 3-dimensional coincidence spectrum of Fig. 6.41.

The electron-capture (EC) decay process often competes with positron emission, as described in Chapter 1, Volume 1. Consequently, some radionuclides that decay by electron capture, may also decay by positron emission. These nuclides are therefore grouped into this section of the chapter, as nuclides that may emit X-rays, gamma rays, atomic electrons (*i.e.*, Auger and IC electrons), and positrons. This broad potential of liquid scintillation analysis was illustrated previously in this chapter (See Fig. 6.12) where the 8 keV Auger electrons and 93 keV conversion electrons emitted from ^{67}Ga produce pulse height spectra with peaks that coincide closely to those produced by ^3H and ^{14}C (McQuarrie and Noujaim, 1983). Gallium-67, like the previously described ^{113}Sn , decays exclusively by electron capture. In addition to the emission of Auger and IC electrons, ^{67}Ga displays major gamma-ray emissions at 93, 184, 296, and 388 keV. Altogether, the atomic electrons and X-ray and gamma-ray photons interact with liquid scintillation cocktail, and detection efficiencies between 44% and 76% for ^{67}Ga are reported by Bobin et al. (2007).

FIGURE 6.42 Simulated photon interaction probability determined at the indicated energies (closed circles) for a counting vial containing 12 mL of Quicksafe A liquid scintillator. The solid line is a regression fit to the data. From Simpson and Morris (2004a), reprinted with permission from Elsevier © 2004.

Gamma-ray and X-ray photon interactions with liquid scintillation cocktail are a function of the photon energy as depicted in Fig. 6.42. Photon energies of low energy have greater probability of interaction with liquid scintillator, as the linear energy transfer (LET) of the photon is inversely proportional to its energy as illustrated in Table 1.29 of Chapter 1, Volume 1. In general, the lower the X-ray or gamma-ray energy, the higher will be the LET in the scintillation cocktail. As illustrated in Fig. 6.42, the photon interaction probabilities in liquid scintillator are high at photon energies below 100 keV. This is in agreement with the data of Zimmerman (2006a), who demonstrated very high photon interaction probabilities of >0.25 in toluene, >0.35 in Ultima Gold scintillation cocktail, and >0.5 in Hionic Fluor for photon energies of 20 keV.

Vanadium-49 is another radionuclide that decays solely by pure electron capture. It emits X-rays and Auger electrons of very low energy (<5 keV), and no gamma radiation is emitted. Rodríguez Barquero et al. (1998) and Rodríguez Barquero and Los Arcos (2000) demonstrate that liquid scintillation analysis is the preferred method, because LSA is not affected by self-absorption problems that would otherwise be prevalent with such low-energy electron emitters. They report liquid scintillation counting efficiencies between 8% and 25% for ^{49}V .

In certain cases, the counting efficiencies of radionuclides that decay by electron capture emitting X-rays and Auger electrons may be higher with the liquid scintillation technique than those attainable with the thin-walled NaI(Tl) solid scintillation crystal detector. In the case of a radionuclide, such as ^{49}V emitting only Auger electrons and X-rays of low energy, the liquid scintillation cocktail is the optimum detector, because of its intimate contact with the radionuclide optimizing detection. Also, the liquid

scintillation analyzer with its automatic sample changer and computer is more commonly encountered in laboratories than its solid scintillation counterpart. This reflects the driving force behind finding broader ranges of application of liquid scintillation counting.

The interaction of X- and gamma-ray photons with liquid scintillation cocktail (Fig. 6.42) is principally the result of the Compton effect whereby part of the energy of the X- or gamma-ray photon is imparted to orbital electrons. An ejected electron (Compton electron) imparts its energy in material in a fashion similar to that of a beta particle. The absorption of its energy by the liquid scintillation cocktail results in fluorescence with the emission of photons of visible light. In liquid scintillation cocktail, the photoelectric effect usually does not occur over 30 eV. However, the photoelectric interaction is significant and accounted for in the liquid scintillation standardization of radionuclides (particularly low-Z nuclides) decaying by electron capture and emitting low-energy X-rays (Kossert and Grau Carles, 2010, 2008; 2006; Grau Carles, 2006a,b; Grau Carles et al., 2006; Grau Malonda and Grau Carles, 2000). Bransome (1973) reports that the photoelectric effect can be evident at higher gamma-ray energies in the glass vial walls or, in the sample-scintillation cocktail mixture, if the scintillator is loaded with heavy elements.

Cherenkov photons will be produced in liquid scintillators to a significant extent if gamma-ray energies are high enough to produce Compton electrons of sufficient energy to cause the Cherenkov Effect (Grau Carles and Grau Malonda, 1992, and Grau Carles et al., 1993). Radionuclide analysis by Cherenkov counting is discussed in detail in Chapter 6 of Volume 2.

Numerous studies have been undertaken on the liquid scintillation analysis of ^{55}Fe , which decays exclusively by electron capture emitting X-rays and Auger electrons of low energy, 0.6–6.5 keV. Some examples that can be cited are Augeray et al. (2015), Bergeron and Laureano-Pérez (2014), Herranz et al. (2012), Gudelis et al. (2010), Ratel (2008), Razdolescu et al. (2008), Fischer et al. (2007), Mikelic, et al. (2007), Grau Carles and Grau Malonda (2006), Grau Malonda et al. (2006), Grahek and Mačefat (2006, 2004), Warwick and Croudace (2006), Hou et al. (2005), Grau Malonda and Grau Carles (2000), Ceccatelli and De Felice (1999), Günther (1998), Ortiz et al. (1993), Grau Malonda (1982), Cramer et al. (1971), Horrocks (1971), Miller et al. (1969), Cosolito et al. (1968), Eakins and Brown (1966), Perry and Warner (1963), and Dern and Hart (1961a,b). Electron capture decay gives rise to the emission of X-rays, Auger electrons, and internal-conversion electrons, which interact with the liquid scintillation cocktail to cause fluorescence. Researchers have reported counting efficiencies of up to 62% for ^{55}Fe (Huang et al., 2016, Augeray et al., 2015, Bergeron and Laureano-Pérez (2014), Mikelic et al., 2007, Hou et al., 2005, Ortiz

et al., 1993, Günther, 1998, and Grau Malonda and Grau Carles, 1999, 2000). A liquid scintillation quench curve with ^{55}Fe detection efficiencies in the range of 3%–35% for ^{55}Fe with tSIE as the quench indicating parameter was illustrated earlier in Fig. 6.27.

In general, the detection efficiencies of radionuclides that decay by 100% electron capture (EC) will be lower than the efficiencies of radionuclides that decay by EC and the alternative β^+ emission or radionuclides that decay via β^- emission, due to the generally higher energies of beta particles in comparison to the lower energies of Auger electrons, X-rays, and internal-conversion electrons resulting from 100% EC decay. For example, a comparison of the liquid scintillation detection efficiencies achievable with a low-energy beta-emitting radionuclide, such as ^{63}Ni (100% β^- , $E_{\text{max}} = 66.9$ keV), and a radionuclide decaying by 100% electron capture, such as ^{55}Fe , which emits very low-energy Auger electrons (0.61 keV Auger L and 5.2 keV Auger K and L electrons of 140% and 60% intensities, respectively) and K X-rays (5.9 keV K_{α} X-rays and 6.5 keV K_{β} X-rays of 24% and 3% intensities, respectively) is illustrated in Fig. 6.43. Although the liquid scintillation detection efficiencies of 100% EC nuclides may be lower than negatron or positron emitters, they are very adequate for excellent routine activity analysis (Bergeron and Laureano-Pérez (2014)van Wyngaardt et al., 2018, Yuan et al., 2018, Dziel et al., 2016, Augeray et al., 2015, Bergeron and Laureano-Pérez (2014), and Roteta et al., 2014, Herranz et al., 2012).

Another popular radionuclide, which decays exclusively by electron capture, is ^{125}I . The radionuclide is very useful as a tracer in the biological sciences (e.g., Morissette et al., 2018, Xu et al., 2018, Kobayashi et al., 2015, Mochizuki et al., 2016, 2017, Bray et al., 2014, Robinson

FIGURE 6.43 Quench correction curve for ^{63}Ni (low-energy β^- -emitter, $E_{\text{max}} = 66.9$ keV) and ^{55}Fe (decaying by 100% EC obtained emitting low-energy Auger electrons and K-X-rays) from the quench indicating parameter (SQP). From Herranz et al. (2012), reprinted with permission from Elsevier © 2012.

et al., 2014, Larsson et al., 2001, Malkov et al., 2000 and Teresa et al., 2000) and liquid scintillation is a very convenient and efficient means of analysis. The electron-capture decay results in the emission of 35.5 keV gamma radiation with 6.7% intensity and the emission of 3.7 keV conversion electrons from the K shell with 78% intensity and 30.5–35.4 keV conversion electrons from the L to O shells with 13% intensity; this is accompanied with the emission of 3.7 keV L X-ray photons with 15% intensity and 27 keV K_{α} and 31 keV K_{β} X-ray photons of 112% and 20% intensities, respectively, and 3.2 keV and 22.7 keV Auger electrons with 156% and 20% intensities, respectively (NNDC, 2018 <http://www.nndc.bnl.gov/nudat2/chartNuc.jsp>, accessed February 1, 2018, Grau Malonda et al., 2006, and Grau Malonda, 1999). Early studies reported a liquid scintillation counting efficiency of 56% for ^{125}I by standard liquid scintillation counting techniques (Rhodes, 1965), and later yet higher counting efficiencies of over 80% were reported by Jordan et al. (1974), Horrocks (1976c), Ring et al. (1980), Chandrasekaran (1981), Kits et al. (1985), and Grau Carles et al. (1994c). Subsequent studies by Grau Malonda and Grau Carles (2000) report counting efficiencies of over 88% for ^{125}I in Insta Gel Plus and Ultima Gold liquid scintillation cocktail. The liquid scintillation detection efficiency is dependent on the quench level, and an example of an ^{125}I quench correction curve taken from the work of Kim et al. (2006) is illustrated in Fig. 6.44.

FIGURE 6.44 Quench correction curve for ^{125}I based on the external standard quench indicating parameter, SQP(E). The photon emissions from ^{125}I in scintillation cocktail are due to cocktail interactions with 35 keV gamma-ray emissions in 6.7% of the transitions, internal-conversion electrons in 91% of the transitions and abundant Auger electron and Te K X-ray emissions (NNDC, 2018, <http://www.nndc.bnl.gov/nudat2/chartNuc.jsp>). From Kim et al. (2006), reprinted with permission from Radiocarbon, the University of Arizona, © 2006 Arizona Board of Regents on behalf of the University of Arizona.

As discussed in Chapter 1, either the electron capture decay process or the emission of an internal-conversion electron leaves an orbital electron vacancy. For the case of ^{125}I this vacancy may be filled by electrons from outer shells giving rise to the emission of X-rays of the Te daughter nuclide and Auger electrons. Horrocks (1976c) explained that the electron capture process in ^{125}I involves capture of a K-shell electron in 80% of the decay transitions and an L-shell in the remaining 20%. The Te L X-ray is 3.5 keV in energy (NNDC, 2018) and totally absorbed by the liquid scintillation cocktail, whereas, the Te K X-ray is emitted with 27.7 keV energy and has a high probability of escape. He concluded that the excitations in the liquid scintillation cocktail are due mainly to the absorption of Auger and internal-conversion electrons, and only a minor contribution (about 8% of the fluor excitations) is the result of X-rays produced during the decay process. Liquid scintillation remains a common method of analysis for ^{125}I (Robinson et al., 2014; Tarancón Sanz and Kossert, 2011; Grau Carles and Kossert, 2009; Kossert and Grau Carles, 2008; Ogata, 2007; Grau Malonda et al., 2006; Kossert, 2006; Van Wyngaardt and Simpson, 2006a,b; Pommé et al., 2005). An interesting approach taken by Ogata (2007) was the analysis of ^{125}I in solution within a microtube inserted inside a Bicon (BC-400) plastic scintillator with dimensions suitable to fit within a standard plastic liquid scintillation vial. No liquid scintillator solution is used, there is no fluor waste to contend with, and the sample remains unadulterated and may be reused after counting in a conventional liquid scintillation counter. Ogata (2007) reported a detection efficiency of 4%–8% for the electron-capture nuclide ^{125}I and a detection efficiency of 10%–40% for the high-energy beta-emitting nuclide ^{32}P . The detection efficiency is a function of the sample volume.

Many radionuclides can decay by either electron capture or positron emission, since positron emission can complete with EC as described in detail in Chapter 1, Volume 1. Zinc-65 is a good example of such a radionuclide used in the biological sciences as a tracer (Cresswell et al., 2017; Yamunarani et al., 2016; Huntington et al., 2008 and Wolterbeek et al., 2002). It decays for the most part by electron capture (98.6%), and only 1.4% of the ^{65}Zn nuclide transitions to stable ^{65}Cu occur via β^+ emission with a positron $E_{\text{max}} = 325$ keV (NNDC, 2018). Günther (1998) and Sandhya and Subramanian (1998) report liquid scintillation counting efficiencies up to 76%. Positron interaction with scintillation cocktail contributes only a small portion to the overall detection efficiency due to its low intensity of emission. About 50.5% of the transitions occur via electron capture (EC) to the ground state of ^{65}Cu and the remaining 48% by EC with accompanying gamma emission (Günther, 1998). Consequently, the abundant K Auger electrons (7 keV at 47% intensity) and L Auger

electrons (1 keV at 127% intensity) and low-energy (1–9 keV) X-ray photons at 40% intensity (NNDC, 2018) that accompany the EC decay process of ^{65}Zn are the emissions that generate significant liquid scintillator excitation and light emission. Liquid scintillation analysis is employed for the standardization of ^{65}Zn (Kossert, 2006; Van Wyngaardt and Simpson, 2006b; Simpson and Morris, 2004a).

Chromium-51 decays by exclusively electron capture and 10% of the excited daughter nuclei simultaneously undergo decay to the ground state with the emission of gamma radiation of 320 keV energy with insignificant emission 0.02% intensity of 319 keV conversion electrons (NNDC, 2018). X-ray and Auger-electron emission, which accompany electron-capture decay, also must be considered among the processes that generate scintillation fluor excitation. Chromium-51 decays with the emission of 5 keV X-rays in 22% of the transitions and 4.4 keV Auger electrons in 66% of the transitions (NNDC, 2018). The double radionuclide tracer ^{59}Fe – ^{51}Cr was assayed by Barosi et al. (1980) in red blood-cell kinetic studies. If the double-label is assayed by NaI(Tl) solid scintillation counting of the gamma-ray photopeaks of the two nuclides, optimum counting efficiencies of 15% and 3% are reported for ^{59}Fe and ^{51}Cr , respectively. However, if liquid scintillation counting is used, optimum counting efficiencies of 20% and 15% are reported for the ^{59}Fe and ^{51}Cr double label, respectively. The five-fold increase in the counting efficiency of ^{51}Cr is due mainly to the liquid scintillation cocktail absorption of X-ray and Auger electron energy. Work by Bradshaw et al. (2006) and Kumblad et al. (2005) provide examples of the application of ^{51}Cr as a tracer nuclide, and a 5% detection efficiency for the liquid scintillation analysis of ^{51}Cr was reported (Kumblad et al., 2005).

Positron-emitting nuclides can be assayed by liquid scintillation analysis with a high detection efficiency when positron emission is the principal mode of decay. As described in Chapter 1, Volume 1, positrons have similar interactions, ranges, and stopping powers as negatrons of similar energy; however, in addition positrons will produce annihilation radiation (0.511 keV gamma rays) when the positrons come to rest in the proximity of atomic electrons. The liquid scintillation pulse height spectra produced by positrons are similar to those of negatrons as expected (See Fig. 6.45). Roteta et al. (2006) report a liquid scintillation detection efficiency close to 100% for the positron emissions from ^{18}F . The radionuclide ^{18}F decays to the stable nuclide ^{18}O by positron emission with a positron $E_{\max} = 634$ keV in 96.7% of the transitions and by electron capture in the remaining 3.3% of the transitions (NNDC, 2018). Auger electrons from the K shell are

FIGURE 6.45 Pulse height spectrum of a ^{18}F sample measured with a Wallac 1414 Guardian liquid scintillation spectrometer with logarithmic amplifier. Background has been subtracted. From Schrader et al. (2007), reprinted with permission from Elsevier © 2007.

emitted with an energy of 0.5 keV at 3% intensity, and 0.5 keV X-rays emissions are insignificant (0.03% intensity). Positron annihilation radiation of 511 keV gamma-ray photons (See Chapter 1, Volume 1) always accompanies positron emission, and, as pointed out by Schrader et al. (2007), the liquid scintillation pulse height spectrum, illustrated in Fig. 6.45, will have some contribution from the secondary Compton electrons of the annihilation radiation. When the E_{\max} of the positrons are sufficiently above the 262 keV Cherenkov threshold in water (See Chapter 6 of Volume 2), these may be analyzed by Cherenkov counting (Table 6.5).

Wiebe et al. (1980) and McQuarrie et al. (1981) measured the Compton electron contribution to the count rate resulting from the interactions of 511 keV annihilation gamma rays with the liquid scintillation cocktail. Thus, in addition to positron-scintillation cocktail interactions, they point out that as much as 24% of the observed count rate is due to scintillation cocktail interactions with Compton electrons originating from annihilation radiation. Wiebe et al. (1980) showed that the largest amount of energy that may be deposited in a liquid scintillation cocktail is equivalent to the sum of the highest positron energy and the energy deposited by the annihilation gamma rays or

$$E_{\max} = E_{\beta^+} + 2E_{e^-} \quad (6.30a)$$

where E_{\max} is the maximum energy deposited by the positron in the scintillation cocktail, E_{β^+} is the maximum positron energy, and E_{e^-} is the energy of the Compton edge associated with 511 keV annihilation gamma radiation (341 keV). For example, in the case of ^{18}F , $E_{\max} = 635$ keV + 2(341 keV) = 1317 keV. Two times

^eCl-34m decays by isomeric transition (IT) with 44.6% intensity and β^+ emission with 55.4% intensity (NNDC, 2018).

^fThe counting efficiency is measured from ^{34m}Cl.

^gCu-64 decays via β^+ emission with 17.6% intensity, electron capture (EC) with 43.9% intensity and β^- ($E_{\text{max}} = 0.579$ MeV) emission with 38.5% intensity (NNDC, 2018).

^hFrom Wanke et al. (2010). The counting efficiency by LSA is due to both the positron and negatron emissions.

ⁱ88.9% of ⁶⁸Ga radionuclides decay via positron emission, and the remaining 11.1% via electron capture.

^jFrom Roteta et al. (2012).

the energy of the annihilation radiation Compton edge must be accounted for, because a positron annihilates with the simultaneous emission of two gamma rays of 511 keV energy.

Numerous radionuclides that decay by electron capture and/or the competing positron decay mode with the emission of gamma radiation, X-rays, and Auger and internal-conversion electrons may be measured by liquid scintillation. Among these, in order of increasing mass number, are the following: ¹⁸F (Nejjari et al., 2008; Roteta et al., 2006 and others cited previously), ²²Na (Miyasawa et al., 1991), ⁴⁹V (Rodriguez Barquero and Los Arcos, 2000 and Rodriguez Barquero et al., 1998), ⁵¹Cr (Bradshaw et al., 2006 and others cited previously), ⁵⁴Mn (Bignell et al., 2010b; Cassette et al., 2006a,b; Grau Malonda and Grau Carles, 1999), ⁵⁵Fe (Augeray et al., 2015; Bergeron and Laureano-Pérez, 2014 and others cited previously), ⁶⁴Cu (Wanke et al., 2010), ⁶⁵Zn (Cresswell et al., 2017 and others cited previously), ⁶⁷Ga (Bobin et al., 2007 and Zimmerman et al., 2006a), ⁶⁸Ga (Oropesa Verdecia et al., 2018; Roteta et al., 2006), ⁸⁵Sr (Grau Carles et al., 1994c), ⁸⁸Y (Los Arcos et al., 1991), ¹⁰⁹Cd (Wolterbeek and van der Meer, 2002; Grau Carles et al., 1994c), ¹¹¹In (Grau Carles and Kossert, 2009), ¹¹³Sn (Roteta et al. (2014), ¹²³I (Bignell et al., 2010b; Grau Carles and Kossert, 2009), ¹²⁵I (Morissette et al., 2018; Xu et al., 2018 and others cited previously), ¹³³Ba (Tinker and Smith, 1996), and ¹³⁹Ce (Van Wyngaardt and Simpson, 2006b).

VII. Common interferences in liquid scintillation counting

The counting interferences most commonly found in liquid scintillation analysis and how each can be recognized and/or corrected to obtain accurate and reproducible DPM values must be considered. Six major counting interferences exist in the scintillation counting of samples: (1) background radiation, (2) quench (color, chemical, and ionization), (3) multiple radionuclides in the same sample, (4) luminescence, (5) static, and (6) wall effect. Each of these interferences will be considered here and in other parts of this chapter with special attention given to their identification, elimination, or means of correcting for any errors that these may generate.

A. Background

Background is defined as counts arising from sources external to the sample, such as cosmic or environmental radiation, and from instrument noise and PMT crosstalk (Jonsson and Theodórsson, 2007). When determining sample count rates (CPM_s) from which sample disintegration rates (DPM_s) will be determined according to procedures described previously in Section V, it is necessary to obtain an accurate measure of the background count rate (CPM_{bkg}) whenever background counts are significant relative to the sample counts. Background count rates are

determined by counting a blank counting vial containing the scintillation cocktail plus all other chemical constituents used in the preparation of samples with the exception of the radionuclide of interest. In other words, the blank should have the same matrix (quench level) as the radioactive samples to be analyzed. For example, if the radioactive samples are measured in a sample-scintillation cocktail mixture of 50% water (1:1 water load), the background count rate should be determined in the blank sample 1:1 water-scintillation cocktail mixture. Ideally any other quenching agents that may be present in the sample should also be present in the background blank counting vial. Such a blank can be obtained by preparing a sample containing no radionuclide of interest in a fashion similar to the preparation of the experimental samples (matrix matching). Once a blank is prepared, it must be counted for a sufficient period of time to get an accurate measurement of its count rate. The time required for counting background blanks can be decided by using statistical criteria presented in Chapter 8, Volume 2, and this is discussed in the later part of this chapter concerning measurements of lower limits of detection (LLD).

Once the background count rate is determined, most modern liquid scintillation analyzers store the background pulse height spectrum in computer memory. The background counts for any given counting region of the pulse height spectrum can then be subtracted automatically from the sample count rates to provide a net count rate according to the following equation:

$$CPM_{net} = CPM_s - CPM_{bkg} \quad (6.30b)$$

If the background count rate (CPM_{bkg}) is significant compared to the sample count rate (CPM_s), it is necessary to subtract the background contribution according to the above equation. The net count rate (CPM_{net}) is then used to determine disintegration rates according to Eq. (6.7) described in Section V.B of this chapter. The majority of the background counts are found in the low end of the liquid scintillation pulse height spectrum, such as 0–5.0 keV for instruments that have pulse height spectra calibrated over the energy range of 0–2000 keV.

Methods of reducing background to optimize instrument performance are provided in Section XX of this chapter.

B. Quench

Color, chemical, and ionization quench are described in detail in Section IV of this chapter. In brief, quench affects the scintillation photon intensity and efficiency of detection of radionuclides in the liquid scintillation cocktail. The lower the radiation energy of the radionuclide, the greater is the effect of quench on the counting efficiency of the sample. Four common methods of quench correction are (1)

internal standardization, (2) sample spectrum quench correction, (3) external standard quench correction, and (4) Direct DPM methods. The mechanisms of quench and methods of quench correction are treated in detail in Section V of this chapter.

C. Radionuclide mixtures

Multiple radionuclides in samples can present an interference when the pulse height spectra of the two radionuclides overlap. In the case of beta-particle-emitting nuclides, this is due to the fact that all beta-emitting radionuclides produce a continuous spectrum of beta-particle energies from zero to the E_{max} , as illustrated in Fig. 1.45 of Chapter 1, Volume 1. If two beta-emitting radionuclides are present in the same sample (e.g., ^3H and ^{14}C of E_{max} 18.6 and 156 keV, respectively), the pulse height spectrum produced by the beta particles of one of the radionuclides (e.g., tritium) produces a broad spectrum of pulse heights created by a broad range of beta-particle energies from zero to the most energetic 18.6 keV beta particle, as illustrated in Fig. 6.46. The magnitude and shape of the spectrum will also depend upon the level of quench in the sample. The second radionuclide ^{14}C , which has a higher decay energy than tritium, emits beta particles of higher energy maximum (E_{max}), produces a pulse height spectrum overlapping that of tritium, and the spectrum of pulse heights produced by the beta particles emitted by ^{14}C extends from zero to a maximum produced by the most energetic ^{14}C beta particles of 156 keV. Fig. 6.46 is a graphic composite spectrum of a sample with both ^3H and ^{14}C . In order to quantify the separate radionuclide activities (DPM) of a mixture of two beta-emitting nuclides in a sample, the count rates and counting efficiency of each radionuclide must be determined. Several methods may be employed for

FIGURE 6.46 Overlapping liquid scintillation pulse height spectra of ^3H (beta particle $E_{max} = 18.6$ keV) and ^{14}C (beta particle $E_{max} = 156$ keV). The composite spectrum is that produced by the two radionuclides as a mixture. © 1998 PerkinElmer, Inc. Printed with permission.

the measurement of two, three, or even more beta-emitting radionuclides in a mixture by liquid scintillation analysis. These methods are described in detail in [Section VIII](#) of this chapter.

D. Luminescence

Luminescence in liquid scintillation fluor cocktails or in aqueous buffer media refers to the emission of light photons as a consequence of energy absorption and concomitant molecular excitation from origins other than nuclear radiation. Luminescence can be a practical tool in the study of biochemical reactions or an interference in liquid scintillation analysis. This section will provide a treatment of the various types of luminescence encountered in liquid scintillation analysis and recommendations on how to avoid or minimize any interference that some types of luminescence can present.

1. Bioluminescence

Bioluminescence occurs when a biochemical reaction produces photons, which is a desirable reaction when used as a tool to study certain biochemical assays. Some examples are the biochemical reactions catalyzed by avidin-alkaline phosphatase, horseradish peroxidase, β -galactosidase, luciferase, xanthine oxidase, and ATP assays via luciferin-luciferase. The liquid scintillation analyzer can be utilized to count all luminescent events when these are used to study certain biochemical reactions. Under such circumstances, the LSA counting protocol should be set to count the experimental samples in the Single Photon Counting (SPC) mode. In this counting mode, only a single PMT is used without the coincidence counting circuitry. SPC is used because all luminescent events are single photon in nature and would be eliminated by the two PMTs and the coincidence counting circuitry. Therefore, in the SPC mode the coincidence counting circuit is disabled and only one PMT is operational. In addition, because bioluminescence normally produces a higher intensity of light compared to a radioactive event, the high voltage on the PMT is automatically lowered in the SPC mode to prevent saturation of the PMT. The counting region for bioluminescent samples in the liquid scintillation analyzer is generally 0–10 keV for pulse height scales calibrated in keV energy equivalence.

2. Photoluminescence and chemiluminescence

There are primarily two types of luminescence, which can interfere in the assay of radioactive samples in scintillation cocktail. These are photoluminescence and chemiluminescence.

Photoluminescence is the result of the exposure of the sample-scintillation cocktail mixture to ultraviolet light. Photoluminescence is normally single photon in nature and decays in a matter of minutes. Therefore, letting freshly prepared samples in scintillation cocktail remain in the dark of the liquid scintillation analyzer for 10–15 min completely eliminates any photoluminescence that may occur. A precount delay time can also be used with counting protocols of certain liquid scintillation analyzers.

The second type of luminescence, chemiluminescence, is a frequent interference in the liquid scintillation assay of radioactive samples. This is the production of light within the scintillation cocktail due to a chemical reaction. Chemical reactions that cause chemiluminescence often occur when scintillation cocktail is added to the sample solution in the liquid scintillation counting vial. A chemical reaction can occur, for example, when scintillation cocktail is added to a basic sample solution (pH 8–14) or when a chemical substance, such as hydrogen peroxide, is present in the sample. The pH effects and chemical interactions with some component of the scintillation cocktail can cause molecular excitation and light emission. Some types of samples that can produce a considerable chemiluminescence are tissue or cell digests with inorganic bases (*e.g.*, NaOH, KOH, Solvable) or organic bases (*e.g.*, Soluene 350).

During the chemiluminescent reaction, single photons are produced in the scintillation cocktail and, because of their large number, they may bypass the coincidence circuit and be registered as counts together with counts produced by the radionuclides in the sample. The counting of single-photon chemiluminescence events by the coincidence (dual PMT) circuitry can be demonstrated from the equation of [Horrocks and Kolb \(1981\)](#), which is written as

$$N_C = 2\tau_R(N_1N_2) \quad (6.31)$$

where N_C is the coincidence count rate, τ_R is the coincidence resolving time (*e.g.*, 30 ns), and N_1 and N_2 are the single-event count rates from photomultiplier tubes 1 and 2, respectively. As the single-photon events from chemiluminescence increase in frequency, the probability that they produce a coincidence count rate correspondingly increases according to [Eq. \(6.31\)](#). [Horrocks and Kolb \(1981\)](#) calculated the coincidence count rate, N_C , that would be measured by a liquid scintillation analyzer with a resolving time of 30 ns for various single-photon event levels according to [Eq. \(6.31\)](#). For example, they demonstrated that, if photomultiplier tubes 1 and 2 measured the same number of single photon events to be 50,000 (*i.e.*, $N_1 = N_2$), the coincidence count rate, N_C , would be calculated to be

$$N_C = [2(30 \times 10^{-9}) / 60](N_1N_2) = 10^{-9}(N_1N_2) = 2.5 \text{ CPM} \quad (6.32)$$

They elaborate further that, if $N_1 = N_2 = 500,000$, the coincidence count rate, N_C , would calculate to be 250 CPM, and for $N_1 = N_2 = 5,000,000$, the coincidence count rate, N_C , would calculate to be 25,000 CPM. Thus, it is obvious from the above calculation that if sample count rates are low, luminescence can be a source of serious error. Luminescence count rates can be very high, depending on the chemical constituents and/or pH of the sample. In any event, luminescence should be identified, if it occurs, and it should be eliminated before counting to avoid error in the activity determinations of experimental samples.

Luminescence, which may occur in sample-scintillation cocktail mixtures, can be detected easily when counting relatively high-energy β -emitting radionuclides ($E_{\max} > 70$ keV). For example, Fig. 6.47 illustrates the pulse height spectrum of a luminescent sample, a tritium sample, and a ^{14}C sample. As illustrated in Fig. 6.47, the luminescence spectrum occurs at the very low-energy portion of the pulse height spectrum occurring generally in the 0–6 keV region for pulse height spectra on an energy equivalent scale. Luminescence in a sample can be recognized easily by one of three methods, namely, (1) spectral display, (2) counting region settings, and (3) instrumental detection and measurement. As illustrated in Fig. 6.47, a sample containing appreciable chemiluminescence produces a pulse height spectral peak in the 0–6 keV region on top of (overlapping) the main radioactivity pulse height peak. The figure illustrates the chemiluminescence pulse height spectrum overlapping with ^3H and ^{14}C pulse height spectra. When counting single-radionuclide samples, two counting regions can be used to detect luminescence. For example, when counting ^{14}C the following counting regions may be used: region A: 0–156 keV and region

B: 4.0–156 keV. If the counts in these regions are similar, then little if any luminescence would be expected. If, on the other hand, the counts in region A (0–156 keV) are much higher (25%–500%), luminescence may be predicted. In addition, many liquid scintillation analyzers are able to determine the magnitude of luminescence in a sample and calculate percent luminescence on the same page as the CPM and DPM values of each sample. The percent luminescence is calculated by the instrument according to the equation

$$\% \text{ luminescence} = \frac{\text{chance coincidence events}}{\text{true coincidence events}} \times 100 \quad (6.33)$$

When luminescence is detected or even suspected in experimental samples, it can be controlled, corrected for, or even eliminated as discussed subsequently.

3. Luminescence control, compensation, and elimination

Once luminescence is recognized as a problem with a particular set of samples, it can be controlled by using proper sample preparation procedures and even eliminated or compensated for by certain liquid scintillation counter controls. The five most common methods of reducing or correcting sample luminescence are (1) dark-adaptation of samples, (2) chemical methods, (3) temperature control, (4) counting region settings, and (5) delayed coincidence counting also referred to as random coincidence counting. A liquid scintillation analyzer equipped with three photomultiplier tubes (*e.g.*, Hidex 300 SL) that can operate in coincidence is reported to avoid sample luminescence (Haaslahti, 2010).

FIGURE 6.47 Pulse height distributions of ^3H and ^{14}C scintillation pulses and of chemiluminescence pulses, and channel settings for the analytical measurement of each activity and chemiluminescence count rate. From Takiue et al. (1985), reprinted with permission from Elsevier ©1985.

a. Dark-adaptation of samples

The most straightforward method of removing luminescence from liquid scintillation sample-cocktail mixtures is to dark-adapt the samples overnight or until the luminescence decays to the point of not contributing to erroneous sample activities (Warwick et al., 2010; Wiesenberger et al., 2010; Cheng and Wong, 2008; Ren and Mahon, 2007; Warwick and Croudace, 2006; and Groppi et al., 2005a). Photoluminescence generally decays rapidly, and dark adaptation of the samples for an hour or two should suffice for photoluminescence to disappear. The liquid scintillation analysis of samples of low activity require low background counting, and dark adaptation of samples overnight or for more than a day is a practice. Chemiluminescence has a much slower decay rate, and significant levels may persist beyond a day depending on sample temperature (Kessler, 1989). Dark adaptation of samples for 3 days in the liquid scintillation analyzer was reported by Yamada et al. (2004) to suppress chemical luminescence. Some liquid

scintillation cocktails are manufactured to be resistant to chemiluminescence (See Part b. Chemical Methods discussed subsequently and Chapter 7, Volume 1). Dark-adaptation of samples exhibiting chemiluminescence, together with other methods described subsequently, may be used to eliminate interference from this phenomenon.

b. Chemical methods

Chemical methods used to avoid or suppress chemiluminescence are reviewed by Peng (1976). Among these, neutralization of alkaline sample solutions with a nonoxidizing acid is recommended, as basic sample solutions are often the main cause of chemiluminescence. This can be accomplished by (1) adding 10 mL of acetic acid to a gallon (3.8 L) of scintillation cocktail, providing this does not alter the performance of the fluor cocktail; (2) neutralizing the basic sample solution before adding the scintillation cocktail to the sample counting vial; or (3) using a special scintillation cocktail designed to reduce or suppress luminescence such as Insta-Fluor, which contains a chemiluminescence inhibitor or Hionic-Fluor, which displays a very fast chemiluminescence decay property (See Chapter 7, Volume 1 for scintillation cocktail properties and characteristics). This normally reduces the amount of chemiluminescence. A problem associated with sample neutralization may occur when counting large macromolecules found in certain biological samples, in which acidification of samples may cause precipitation. Precipitation of sample most often includes precipitation of the radioactive material and, therefore, loss of counting efficiency and incorrect DPM values.

c. Temperature control

Acidification of sample solution, as already described, followed by heating to 40°C is often recommended to reduce chemiluminescence, or acidification may be omitted when it causes precipitation and the sample solution only heated. Heating the sample to 40°C, helps drive the chemiluminescence reaction to its endpoint. This is possible because the reaction is a chemical reaction and every 10°C increase in temperature doubles the reaction rate. Another procedure, alternative to heating, is to cool the reaction using a liquid scintillation analyzer with temperature control. Cooling slows the reaction rather than accelerating its termination. Cooling reduces counts from chemiluminescence. In addition, chemiluminescence can be eliminated altogether by counting-region setting or by delayed-coincidence counting, discussed subsequently in this section.

d. Counting-region settings

This is the recommended method for all radionuclides with the exception of tritium and some nuclides that decay

by electron capture (EC) to stable daughter nuclides with the emission of X-rays and Auger electrons. The use of “counting-region settings” to remove pulse events from luminescence is not possible in the measurement of tritium or EC nuclides emitting only X-rays and Auger electrons (*e.g.*, ^{37}Ar , ^{49}V , ^{68}Ge , and ^{131}Cs), because their liquid scintillation pulse height spectra overlap significantly with that of luminescence (See Fig. 6.47 for the case of tritium.). Auger electrons and X-rays following electron capture are of low energy, as noted in Chapter 1, Volume 1, and the liquid scintillation pulse heights from the monochromatic Auger electrons or from X-ray Compton electrons would occur in the same counting region as tritium (Takiue and Ishikawa, 1979a). Nuclides that decay by electron capture with the emission of gamma radiation from unstable daughter nuclei emit also internal-conversion electrons that produce generally pulse heights significantly higher than that of tritium. Consequently, the method of “counting-region settings”, which is described in the following paragraph, could be applicable in these cases.

The method of “counting-region settings” to remove erroneous luminescence pulse events from the sample count rate is relatively simple, but not often used. If the counting region for a mid-to high-energy β -emitting radionuclide (*e.g.*, ^{14}C and higher energy β -emitters) is set at approximately 10 keV or above, no luminescence of any kind will be observed in the sample counts and, therefore, no correction will be necessary. The only precaution when performing DPM determination is to set the same counting region for the quench correction curve and for the experimental samples. A counting region for ^{14}C to avoid error from luminescence would be, for example, 10.0–156 keV for lower level and upper level discriminator settings when using instruments that have pulse height discriminator settings calibrated to keV energy equivalence. In the case of tritium, a counting region cannot be set to avoid luminescence, because tritium emits very low energy beta particles ($E_{\text{max}} = 18.6 \text{ keV}$) producing a pulse height spectrum that greatly overlaps that of luminescence. In the case of tritium, chemiluminescence must be eliminated or measured and subtracted from the sample counts for accurate activity calculations (Takiue et al., 1984). Fig. 6.47 illustrates other discriminator settings to define three counting regions, proposed by Takiue et al. (1985), which permit the simultaneous counting of chemiluminescence, ^3H , and ^{14}C , when the DPM analysis of dual-radionuclide samples containing chemiluminescence is required. Equations for calculating the activities (DPM) of the dual-radionuclide samples and the count rates due to chemiluminescence are given by Takiue et al. (1985, 1986). Detailed information on multiple-radionuclide analysis is provided in Section VIII of this chapter.

e. Delayed coincidence counting

Most liquid scintillation analyzers are equipped with delayed coincidence counting, also referred to as random coincidence counting, as a method for the elimination of error resulting from luminescence that can be applied to the liquid scintillation analysis of all radionuclides including tritium (Varlam et al., 2009; Palomo et al., 2007). For this method to work, a delayed coincidence circuit with a 20-ns delay is added to one of the two PMTs. The sample containing the radioactivity is counted simultaneously with and without the delay coincidence circuit enabled. If the coincident circuit is used without the delay or random coincidence circuit, both the luminescence and radioactive decays will be detected. The radioactive decay events are accepted by the coincidence counting circuit, because they are isotropic multiphoton events, and luminescent single-photon events are also accepted by the coincidence counting circuit, because they occur at a high count rate in the sample and are detected within the resolving time of the counting circuit. Now, if the coincident circuit is used with a delay mode added to one of the PMTs, only the single-photon luminescence events will be detected, because of their high count rate of occurrence. Radioactive decay, which produces isotropic multiphoton events, will not be detected by the coincidence circuit due to a 20-ns delay in one of the two PMTs. Finally, the counts collected from the two readings with and without the delay circuit enabled are subtracted channel by channel of the MCA over the pulse height region equivalent to 0–6.0 keV. The resultant spectrum will be a product of the actual nuclear decay events without chemiluminescence. This special delay method is known as the luminescent detection and correction method. It can be applied to all radionuclides independent of radioisotope decay energy. Luminescence detection and correction are available with most state-of-the-art liquid scintillation analyzers (Kessler, 1989); however, caution is recommended in the application of this instrumental method of correction. The user should confirm that the luminescence subtraction is working properly for their samples. For example, Warwick and Croudace (2006) confirmed that the delayed coincidence counting option was not reliable for their particular samples, and they decided that dark-adaptation of the samples was necessary to ensure against erroneously high activities due to chemiluminescence-derived scintillations.

E. Static

Electrostatic discharge is a photon-producing interference in liquid scintillation counting. Static electricity may be generated by friction or pressure between two materials. When nonconductive materials are separated, one material develops a positive and the other a negative charge. Static consists of charged ions, positive or negative, which are

atoms electrically out of balance due to the removal or addition of electrons. The intensity of static electricity can be measured as positive or negative voltage on the surface of matter in magnitudes of tens of thousands of volts. The discharge of static electricity is a random event, but the phenomenon commonly occurs with many materials we may come into contact with when preparing samples for counting, including scintillation counting vials. Static electricity is produced easily in low-humidity rooms during the time of the year when dry heat is used to warm laboratories. A common characteristic of static electricity is its stability; it can remain on the surface of scintillation counting vials for relatively long periods of time. When the scintillation vial is placed in the counting chamber and electrostatic discharges occur, it is like an electrical lightning storm occurring in or on the surface of the scintillation vial producing random pulse events. The static charge buildup can have many causes, including shipping, handling, use of plastic gloves, and low humidity in the sample preparation area. Plastic vials tend to build up more of a static charge than glass vials.

There are primarily four methods of reducing or eliminating static from sample vials for liquid scintillation counting: (1) the use of an electrostatic controller, (2) selection of vial type, (3) antistatic wipes, and (4) humidification of the sample preparation and counting area. A brief description of each method is given.

The electrostatic controller is a circular donut-shaped device located in the elevator tube through which the counting vial must pass before it is moved into the counting chamber. In certain instruments it contains eight geometrically located electrodes, which generate a 360-degree field of electrically produced ions. When the counting vial passes through the electrostatic controller, it enters the field of electrically produced counterions, which can neutralize static electricity on the counting vial surface in a matter of 2 s. This process occurs just before the robotic positioning of the vial into the counting chamber located between the two PMTs. Contemporary state-of-the-art liquid scintillation analyzers are equipped with an electrostatic controller (e.g., Mendonça et al., 2006). Although the electrostatic controller offers no guarantee of removing all static from the counting vial surface, there may be no need to take any other steps to control static on the surface of counting vials before placing them in the LSA sample changer.

Further measures may be taken to guard against static charge collection and discharge from counting vial surfaces. One step is to select a type of counting vial that would tend to collect less static electricity. Because plastic tends to hold a static charge more than glass, the use of glass vials helps to reduce the static charge for most samples. The disadvantages of using glass vials is that they are more expensive, more difficult to dispose of, and can yield higher background count rates. The alternative to glass

vials is to use special "antistatic" plastic vials (Nakanishi et al., 2009). These vials are manufactured with a special plastic treatment that greatly reduces the amount of static on the vial surfaces compared with standard plastic vials. Yamada et al. (2004) reports that the use of Teflon counting vials with acryl resin caps with the inside wall of the caps lined with aluminum foil could suppress effectively the static electricity. Yoon et al. (2010) took the added precaution of locating the liquid scintillation analyzer 30 cm away from any other electrical devices, ventilation ducts, or air conditioner. Another technique is to wipe each vial with an "antistatic" wipe or with a moist cloth just before placing the vial into the sample changer of the liquid scintillation counter. This readily removes the static charge on the surface of the vial just before counting. The final step that may be taken to reduce static is to increase the humidity in the room where the samples are prepared as well as in the counting area.

F. Wall effect

The 'wall effect' can be classified into two types, namely, (1) the effect of certain traditional organic solvents that penetrate into the walls of plastic counting vials, and (2) a loss of detection efficiency in the liquid scintillation standardization of radionuclides due to the interaction of beta particles with the glass walls of the scintillation counting vial. These two types of 'wall effect' are encountered only in unique modes of liquid scintillation analysis and are thus treated separately as follows:

1. **Wall effect from solvent penetration into plastic counting vial.** When samples are counted in plastic vials with traditional cocktails, the organic scintillator from the cocktail can penetrate the wall of the plastic vial. Traditional cocktails are those made with solvents such as toluene, xylene, and pseudocumene. This can cause a problem when external standard quench correction methods are used, because certain plastic vials with solvent penetration can scintillate causing a distortion of the external standard pulse height spectrum. The result would be inaccurate quench indicating parameters, which would give erroneous counting efficiencies and, as a consequence, error in the DPM measurements of samples. This problem can be overcome easily by always using environmentally safer cocktails. The newer environmentally safer cocktail solvents, such as diisopropylnaphthalene and linear alkylbenzene will not penetrate into the wall of the plastic vial and cause the wall effect. As a general rule, always use glass vials when using traditional scintillation cocktails, and use either plastic or glass vials with the environmentally safer cocktails.

2. **Wall effect in the liquid scintillation standardization of radionuclides.** In the liquid scintillation standardization of radionuclides, discussed further on in this chapter, calculations may include a wall effect, that is, a reduction in detection efficiency due to nuclear decays that occur at the walls of the scintillation vial (Cassette, 2003). In the wall effect it is assumed that a 10- μm layer next to the vial wall will have only a 50% counting efficiency, as electrons interact with the glass envelope of the counting vial (Jaubert and Cassette, 2004; Johansson et al., 2003; Cassette, 2003). The influence of this wall effect is considered negligible in the standardization of high-energy beta-emitting radionuclides [e.g., ^{89}Sr ($E_{\text{max}} = 1490 \text{ keV}$) or ^{90}Y ($E_{\text{max}} = 2280 \text{ keV}$)] by the CIEMAT/NIST or TDCR methods, if the source is unquenched or only moderately quenched (Jaubert and Cassette, 2004; Cassette, 2003). For lower-energy beta-emitting radionuclides and for alpha-emitting nuclides, the wall effect must be corrected for in the standardization of radionuclides (Cassette, 2003). In the liquid scintillation standardization of ^{238}Pu an uncertainty of 0.25% on the efficiency was attributed to the wall effect (Johansson et al., 2003). A similar uncertainty to the detection efficiency of 0.2% for ^{210}Po was attributed to the wall effect (Laureano-Pérez et al., 2007). The significance of the wall effect was demonstrated by Hurtado et al. (2009) by their comparison of the theoretical beta spectrum of ^{90}Y with the spectrum that is produced by the ^{90}Y beta-particle energy deposited in a liquid scintillator (See Fig. 6.48). The comparison was made using a Monte Carlo simulation using GEANT4 code, as a tool for efficiency calculations in radionuclide standardization and stopping power calculations, etc. Fig. 6.48 illustrates how the low-energy portion of the beta spectrum is distorted by the wall effect, as the low-energy beta

FIGURE 6.48 Theoretical and wall-effect-distorted beta spectra of ^{90}Y . From Hurtado et al. (2009), Reprinted with permission Radiocarbon, the University of Arizona, © 2009 Arizona Board of Regents on behalf of the University of Arizona).

particles are absorbed in the walls of the liquid scintillation counting vial. DeVries and Griffen (2008) point out that the high LET of alpha particles in the scintillation cocktail reduce the wall effect, and assigned a liquid scintillation alpha detection efficiency of 100% in the measurement of ^{237}Np .

VIII. Multiple radionuclide analysis

There is a wide-ranging need in the scientific community to analyze multiple radionuclides as mixtures. These include dual-, triple-, and multiple radionuclide mixtures stemming from research in the chemical, biological, nuclear power, and environmental sciences, among others, as reviewed by L'Annunziata (1984b), Bukowski et al. (1992), Takiue et al. (1991b,c, 1992, 1995, 1999), Toribo et al. (1995, 1996, 1997, 1999), Fujii et al. (2000), Kashirin et al. (2000), Nayak (2001) and Reddy et al. (2009). Several methods are available for analyzing the activity of more than one β -emitting radionuclide in the same sample. Because of the broad spectrum of β -particle energies emitted by any given radionuclide anywhere between zero and E_{max} , we always observe a broad pulse height spectrum in the liquid scintillation analyzer from zero to a maximum pulse height. Therefore, all liquid scintillation pulse height spectra from different β -emitting radionuclides overlap to some degree. Because of this spectral overlap and the very broad characteristics of β -particle pulse height spectra, it was traditionally considered feasible to analyze by LSA at most three β -emitting radionuclides in the same sample provided their β -particle energy maxima differed by a factor of three or four (L'Annunziata, 1979, 1984a,b, and 1987). However, advances in LSA have revealed new regionless spectral unfolding and deconvolution methods capable of analyzing several β -emitting radionuclides in the same sample with the aid of computer processing. Even radionuclide mixtures of ^{14}C ($E_{\text{max}} = 156 \text{ keV}$) and ^{35}S ($E_{\text{max}} = 167 \text{ keV}$), which for decades were thought to be impossible to resolve by LSA, because of their similar β -particle energies, can now be identified and quantified as mixtures. A description of the techniques used to resolve and quantify mixtures of β -, and α -emitting radionuclides by LSA is provided in this section.

A. Conventional dual- and triple-radionuclide analysis

The conventional methods described in detail in this section refer, for the most part, to the analysis of two β -emitting radionuclides in a mixture. However, the same principles can apply to the analysis of three beta-emitting radionuclides as a mixture, which is included in this section.

1. Exclusion method

The exclusion method is one of the original methods applied to the analysis of a dual-radionuclide mixture by liquid scintillation analysis. It is described in detail by Okita et al. (1957), Kobayashi and Maudsley (1970) and L'Annunziata (1979). The technique is rarely used today, because of the availability of more efficient methods of dual- or triple-radionuclide analysis. Nevertheless, it is presented briefly here, as the reader will encounter occasional reference to this method in the current literature.

The dual radionuclide mixture of ^3H ($E_{\text{max}} = 18.6 \text{ keV}$) and ^{14}C ($E_{\text{max}} = 156 \text{ keV}$) will be taken as an example to describe this method, which requires a relatively large difference in β -particle energies between the two radionuclides. It is recommended generally that the E_{max} of the two radionuclides differ by a factor of 3 or 4. Two counting regions or windows are defined using lower level (LL) and upper level (UL) pulse height discriminators such that in counting region 1, also referred to as counting region A and in this case, we can refer to it as the tritium region (e.g., LL = 0.0 and UL = 18.6 keV), where both the tritium spectrum and the spillover of the carbon-14 spectrum into the tritium region are found. In this example, the pulse height analyzer is one that utilizes a multichannel analyzer with channel numbers calibrated to approximate keV energy of the ^3H and ^{14}C beta particles (See Fig. 6.49). In such a case, a nonquenched sample of ^3H will not produce calibrated pulse heights beyond 18.6 keV. In counting region 2, also referred to as region B and in this case the carbon-14 region, pulse height discriminators are set (e.g.,

FIGURE 6.49 Typical component and composite liquid scintillation analyzer pulse height spectra produced by approximately equal activities of ^3H and ^{14}C . Two counting windows (counting regions) are illustrated, namely, Window A (or Region A), which registers count rates originating from beta emissions of ^3H and ^{14}C ; whereas, Window B (or Region B) registers a count rate originating only from beta emissions of ^{14}C . © 1998 PerkinElmer, Inc. Printed with permission.

LL = 18.6 and UL = 156 keV) to allow only pulses from the carbon-14 spectrum. The name exclusion method is derived from the fact that region 2 excludes all tritium pulses. When counting a mixture of ^3H and ^{14}C , count rates (CPM) will be collected in each region, and the following equations are used to calculate the activity or disintegration rate (DPM) for ^3H and ^{14}C :

$$H = \frac{N_1 - C_{c1}}{h_1} \quad (6.34)$$

and

$$C = \frac{N_2}{c_2} \quad (6.35)$$

where H and C are the activities or DPM of ^3H and ^{14}C , respectively, in the mixed radionuclide sample, N_1 and N_2 are the net count rates (CPM), *i.e.*, background-subtracted count rates, in regions 1 and 2 of the liquid scintillation analyzer, h_1 and c_1 are the counting efficiencies of ^3H and ^{14}C in counting region 1, and c_2 is the counting efficiency of ^{14}C in counting region 2.

From these equations, it is clear that five parameters are needed to calculate the DPM for both the tritium and ^{14}C dual-labeled samples. The net CPM in regions 1 and 2 are determined automatically by the LSC. The three efficiency factors are determined using three quench correction curves, which consist of plots made from a series of tritium and ^{14}C quenched standards. The three curves are constructed by plotting % counting efficiency for tritium and ^{14}C in region 1 and ^{14}C in region 2 versus an external standard quench indicating parameter.

This method is less commonly used today for low-energy beta-emitters, such as ^3H – ^{14}C , because scintillations from beta-particle emissions from both nuclides are highly quenchable, and the counting region of the higher-energy beta-emitter (*e.g.*, ^{14}C in the above example) is restricted to include only pulse events from that nuclide. Under high levels of quench, the detection efficiency of ^{14}C drops significantly, and the pulse events can spill down excessively from region B to region A. This can yield very low detection efficiencies for the ^{14}C in Region B; although, modern liquid scintillation analyzers equipped with automatic efficiency control (AEC) or automatic quench compensation (AQP) can automatically shift counting region settings according to quench level. With respect to relatively high-energy beta-emitters, such as ^{90}Sr ($E_{\text{max}} = 546 \text{ keV}$) and ^{90}Y ($E_{\text{max}} = 2280 \text{ keV}$), which are less easily quenched, the exclusion method is more easily utilized. Eikenberg et al. (2011) report the successful application of this technique for the analysis of ^3H and ^{14}C mixtures. They report the use of either internal standards to determine the detection efficiencies of ^3H and ^{14}C or quench correction curves. Eikenberg et al. (2011) found the use of internal standards to yield more precise results. (See

Section V.A of this chapter for the use of internal standards.) Xiques Castillo et al. (2009, 2010) applied the exclusion method for the analysis of ^{90}Sr (^{90}Y) for clinical applications. They used counting regions defined by channels 5–700 for Region A and 701–1014 for Region B of a Wallac (PerkinElmer) 1029 Rackbeta liquid scintillation analyzer. The upper region (Region B) registers pulse events arising exclusively from ^{90}Y beta particle interactions with liquid scintillator, and these interactions with such a very high-energy beta-emitter are not easily quenched and any spillover of pulse events from Region B to Region A would be minimal. Another application of the exclusion method is reported by Huntington et al. (2008) for the dual-nuclide liquid scintillation analysis of ^{65}Zn and $^{69\text{m}}\text{Zn}$. A modified version of this method was applied by Feng et al. (2014a) for the analysis of ^{90}Sr and ^{90}Y . They measured the sample vial twice, without and with the addition of a small volume of ^{90}Y . The difference of both measurements was used to establish the activities of both radionuclides, correcting the quenching effect, as long as it is low. They also report that if the activity added is higher than the total initial activity the error in the measurement is lower than 3%. The inclusion method, which is described subsequently, is the most popular method, as it assures, particularly with low-energy beta-emitters, a less variable detection efficiency for both nuclides over a wide range of quench.

2. Inclusion method

In this method the counting regions are set such that there are spillup and spill down of pulse events in each region from both of the radionuclides when two beta-emitting radionuclides are analyzed as a mixture. When three beta-emitting radionuclides are analyzed, three counting regions are employed.

a. Dual-radionuclide analysis

Again, we will use ^3H and ^{14}C as an example of a typical dual mixture, keeping in mind that the procedure presented here and equations used will work for any dual mixture of β -emitting radionuclides provided the β -particle energies (E_{max} values) of the two radionuclides differ significantly. Also, in this discussion we will refer to lower-energy and higher-energy radionuclides to distinguish between nuclides that differ in their beta-decay energies. In this example, ^3H ($E_{\text{max}} = 18.6 \text{ keV}$) is the lower-energy radionuclide and ^{14}C ($E_{\text{max}} = 156 \text{ keV}$) the higher-energy radionuclide of the mixture.

For this method to work it is necessary that two counting regions (regions A and B) are established by setting the lower level and upper level pulse height discriminators to assure that there will be significant spillup of pulse events from ^3H into region B and the unavoidable

FIGURE 6.50 Typical component and composite pulse height spectra observed for two β -emitting radionuclides (e.g., ^3H and ^{14}C) in an approximately 1:1 mixture and having significantly different β -particle energy maxima. The pulse height spectra are plotted as dN/dE , i.e., the number of events or counts per energy channel versus channels of a multichannel analyzer calibrated in keV. Two counting regions are illustrated (Regions A and B also referred to as Windows A and B) for use in the inclusion method, which are set to allow spillup of the lower energy radionuclide from Region A into Region B, whereby counts from both radionuclides appear in both counting regions. © 1998 PerkinElmer, Inc. Printed with permission.

spillover of pulse events from ^{14}C into region A. An illustration of pulse height discriminator settings, which establish the counting regions for the analysis of two radionuclides by this inclusion method is given in Fig. 6.50.

Some modern liquid scintillation analyzers are available with preset dual counting regions for the activity analysis of dual mixtures such as ^3H – ^{14}C , ^3H – ^{32}P and ^3H – ^{125}I . For other radionuclide combinations, it is necessary to establish the LL and UL discriminators settings for the appropriate spillup and spillover of pulse events from the two radionuclides. The procedure used to establish these regions will be discussed later on in this section. For the case of the ^3H – ^{14}C mixtures, counting region A is normally set by discriminators LL = zero and UL = 12.0 keV, while region B is defined by the discriminator settings LL = 12.0 and UL = 156 keV, when the pulse height spectra are displayed on a linear scale in β -particle energy equivalents (e.g., Fig. 6.50). Some liquid scintillation analyzers simply make use of channel numbers, and the counting regions are defined by the channel numbers (See Fig. 6.56 further on in this section).

After the two counting regions are defined, it is necessary to prepare quench correction curves, which can be used to determine the counting efficiencies of the ^3H and ^{14}C (or lower-energy and higher-energy radionuclides) in the two counting regions. Two sets of quench standards are required, one set of ^3H and one set of ^{14}C quenched standards. If two other radionuclides need to be analyzed, a set of quenched standards of the lower-energy radionuclide and a set of quenched standards of the higher-energy radionuclide are required. The procedure for preparing a series of quenched standards was given in Section V.D of

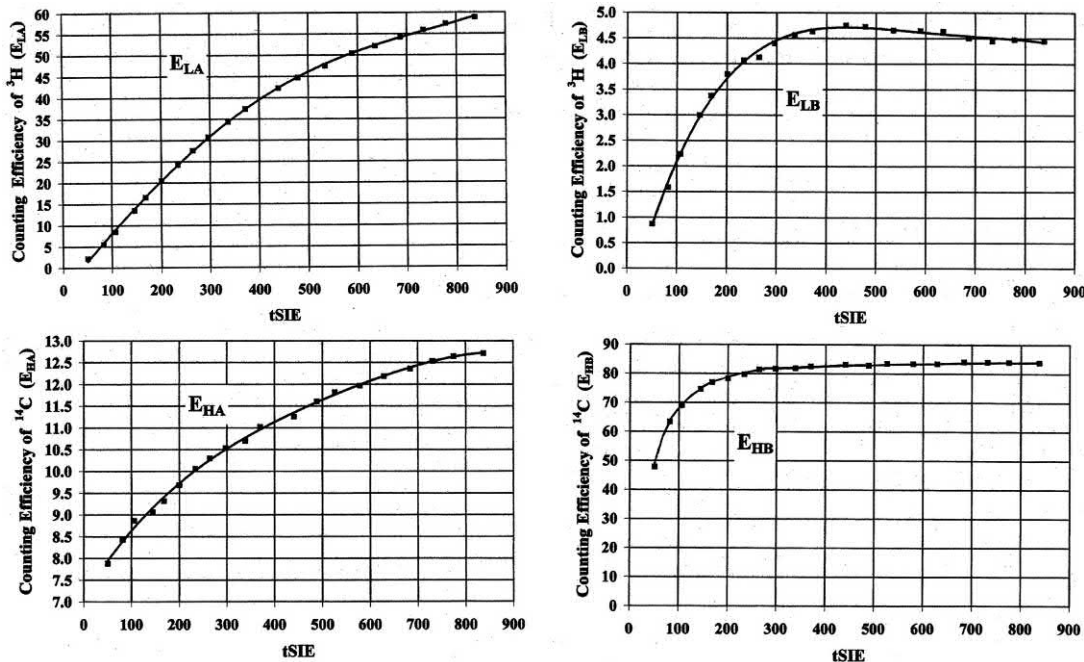

FIGURE 6.51 Quench correction curves of counting efficiency versus $t\text{SIE}/\text{AEC}$ for ^3H and ^{14}C in region A (LL–UL: 0–12.0 keV) and region B (LL–UL: 12.0–156 keV) for the dual radionuclide analysis of ^3H – ^{14}C . The notations E_{LA} , E_{LB} , E_{HA} , and E_{HB} are the counting efficiency factors defined in Eqs. (6.36) and (6.37). The quench correction curves were obtained with ^3H and ^{14}C quenched standards counted in regions A and B with a PerkinElmer 2770TR/SL liquid scintillation analyzer.

FIGURE 6.52 Illustration of automatic region tracking. Using automatic efficiency control (AEC), the liquid scintillation analyzer automatically moves the upper level discriminator of a counting region from pulse heights of higher magnitude to those of lower magnitude (right to left of the pulse height spectrum) according to the degree of quench in a sample. The pulse height spectra of five samples are illustrated, each at different levels of quench. The samples of higher quench level are those of smallest pulse number and magnitude. © 1998 PerkinElmer, Inc. Printed with permission.

FIGURE 6.53 Effect of region settings on ³³P and ³²P counting efficiencies over the range of LL-UL, 0–30 to 0–220 keV. The data points represent increasing counting region widths in increments of 10 keV. From L'Annunziata (1997b), © 1997 PerkinElmer, Inc. Printed with permission.

this chapter. Each series of quenched standards is counted in regions A and B and, as a result, four quench correction curves are created, as illustrated in Fig. 6.51.

When using quench curve correction, determination of the radionuclide activities becomes more difficult as

spillover of ¹⁴C into the tritium region (region A) increases with quench or, in other words, when the ratio of ¹⁴C to tritium increases in region A. If the number of counts from ¹⁴C into the tritium region becomes large, the correction of the tritium counts can result in a small number that is less accurate to measure. Likewise, as quench increases, the spillover of ³H pulse events into region B (¹⁴C region) diminishes and can even disappear, which makes the calculations for the ³H and ¹⁴C activities invalid. Therefore, to maintain optimal counting conditions, it is necessary to keep the amount of spillover of the ¹⁴C pulse events in the tritium region A at a fairly constant level as well as the spillup of tritium events into region B. This is accomplished using an automatic windows tracking method called AEC (automatic efficiency control) or AQC (automatic quench compensation). As the sample is counted, the liquid scintillation analyzer determines the level of quench of the experimental sample using a quench indicating parameter (e.g., *H*#, or tSIE), and the counting regions are adjusted automatically so that the spillover of the ¹⁴C into the tritium region (Region A) is kept at a fairly constant level (10%–15%), and the spillup of ³H into the ¹⁴C region (Region B) is also preserved. Fig. 6.52 illustrates that the liquid scintillation pulse height spectrum of a radionuclide diminishes as quench increases, and AEC automatically moves a discriminator setting according to the degree of quench in the sample. If dual radionuclide samples of tritium and ¹⁴C are counted using quench curves and automatic window tracking methods (e.g., AEC or AQC) are employed, the resultant quench correction curves shown in Fig. 6.51 can be used to determine the counting efficiency of each radionuclide in each counting region. As illustrated, four curves are created, one for each of the two nuclides in each of the two counting regions. The major feature to note is that the amounts of spilldown of ¹⁴C into the ³H region and the spillup of ³H into the ¹⁴C region are kept constant.

The equations used to calculate the DPM for each radionuclide are derived from the following equations, which describe the count rate in the two counting regions:

$$CPM_A = D_L E_{LA} + D_H E_{HA} \quad (6.36)$$

and

$$CPM_B = D_L E_{LB} + D_H E_{HB} \quad (6.37)$$

where CPM_A and CPM_B are the net (background-subtracted) count rates of a dual radionuclide sample in regions A and B, respectively; D_L and D_H are the disintegration rates (DPM) of the lower-energy radionuclide (e.g., ³H) and higher-energy radionuclide (e.g., ¹⁴C), respectively; E_{LA} and E_{LB} are the counting efficiencies of the lower-energy radionuclide in regions A and B, respectively; and E_{HA} and E_{HB} are the counting efficiencies of the higher-energy radionuclide in regions A and B, respectively. The four counting efficiency factors in Eqs. (6.36)

FIGURE 6.54 A composite pulse height spectrum of a ^{33}P – ^{32}P dual-radionuclide sample as displayed on the computer screen of a PerkinElmer Tri-Carb 2300 TR liquid scintillation analyzer. Counting regions A and B are set for the dual-radionuclide analysis by the conventional inclusion method. (L'Annunziata, M.F., 1996, unpublished work of the writer.)

FIGURE 6.55 The liquid scintillation beta pulse height spectra of ^{89}Sr , ^{90}Sr , and ^{90}Y . Two counting regions or windows are illustrated, namely, Window A defined by lower-level (LL) and upper-level (UL) discriminator settings set at channel 120–710, respectively, and Window B with LL and UL discriminator settings at channel 711–910, respectively. A relatively weak and broad peak of pulse events due to ^{90}Y ingrowth with ^{90}Sr parent can be seen in Window B. From Kim *et al.* (2009), reprinted with permission from Elsevier © 2009.

and (6.37) are obtained automatically by the liquid scintillation analyzer from the four quench correction curves (Fig. 6.51) stored in the computer memory of the LSA. Therefore, the preceding two equations still have two unknowns, namely, D_L and D_H , which are solved for simultaneously to obtain

$$D_L = \frac{CPM_A E_{HB} - CPM_B E_{HA}}{E_{LA} E_{HB} - E_{LB} E_{HA}} \quad (6.38)$$

and

$$D_H = \frac{CPM_B E_{LA} - CPM_A E_{LB}}{E_{LA} E_{HB} - E_{LB} E_{HA}} \quad (6.39)$$

For the activity determinations of a dual nuclide mixture, the liquid scintillation analyzer determines the net count rates of the sample in regions A and B, and the quench indicating parameter of the sample. From the value of the quench indicating parameter, the LSA automatically

FIGURE 6.56 Liquid scintillation pulse height spectra of ^3H , ^{14}C , and ^{131}I at low and high quench levels. As quench increases the pulse height spectra are reduced in intensity (fewer counts/per channel) and pulse height (shift from higher to lower channel numbers). From Bukowski et al. (1992). Reprinted with permission from Elsevier © 1992.

extracts the needed four counting efficiency factors from the quench correction curves (e.g., Fig. 6.51) and then automatically calculates the disintegration rates of the two radionuclides in the mixture according to Eqs. (6.38) and (6.39). All of the calculations are performed by the computer of the liquid scintillation analyzer.

Because the discriminator settings defining the counting regions A and B will move automatically according to the amount of quench in the sample, as measured by the QIP, it is important to note that varying the counting region settings changes the quench correction curves (efficiency vs. QIP). This is generally of little concern to the analyst, because most modern liquid scintillation analyzers save, on the hard disk of the computer, the entire pulse height spectra of the quenched radionuclide standards. Consequently, as the counting regions are changed automatically by the instrument according to quench level, so are the resultant new quench correction curves automatically determined by the instrument.

Often it is necessary to analyze radionuclide mixtures for which no preset counting regions have been established in the liquid scintillation analyzer. In such a case, it is necessary to find and select the optimum LL and UL discriminator settings to define counting regions A and B. The procedure used to obtain the proper discriminator settings is as follows, using the ^{33}P – ^{32}P dual radionuclide mixture as an example:

1. To find the appropriate LL and UL discriminator settings for the inclusion method for dual-radionuclide activity analysis, we must count firstly a known activity (DPM) of the lower-energy radionuclide (e.g., ^{33}P , $E_{\text{max}} = 249 \text{ keV}$) as a pure radioisotope sample in a wide range of counting regions starting at a LL discriminator setting of zero and progressively increasing the UL discriminator in small increments (e.g., 10 eV). Certain liquid scintillation analyzers (e.g., PerkinElmer Tri-Carb) display the pulse height discriminator settings in units of eV (0–2000 eV); others (e.g., PerkinElmer Quantulus) display the discriminator settings in channel numbers (0–1024). A net count rate (CPM) for each region setting is recorded.
2. This procedure is repeated with a known activity (DPM) of the higher-energy radioisotope (e.g., ^{32}P , $E_{\text{max}} = 1700 \text{ keV}$), which is counted in the same regions selected in the above step 1. The net count rates (CPM) of the higher energy radionuclide in the counting regions are recorded. Both samples of the low-energy radionuclide (e.g., ^{33}P , $E_{\text{max}} = 249 \text{ keV}$) and the higher-energy radionuclide (e.g., ^{32}P , $E_{\text{max}} = 1700 \text{ keV}$) used for this exercise should be at similar and low levels of quench, that is, the lowest level of quench expected for any given unknown mixture.
3. The counting efficiencies of the separate low- and high-energy radionuclides (e.g., ^{33}P and ^{32}P) standards in the various counting regions are then calculated according to the equation $\%E = (\text{CPM}/\text{DPM})(100)$.
4. The counting efficiencies of the low-energy radionuclide in the individual counting regions are plotted against the counting efficiencies of the high-energy radionuclide in the same counting regions as illustrated in Fig. 6.53.
5. The objective of this exercise is to find discriminator settings at which there will be significant overlap (spillover) of counts from both radionuclides in the two counting regions required for the inclusion method. These conditions are found in the “knee” section of the curve. Hence, a counting region is selected arbitrarily from the knee section of the curve as the counting region A for the dual radionuclide analysis. In the example using the ^{33}P and ^{32}P radionuclide standards, a counting region (LL–UL) of 0–100 keV from the knee of the curve was selected from the eighth data point counting from left to right of Fig. 6.53.
6. Having defined in this way one of the counting regions (region A), we can then proceed to select the discriminator settings for the second counting region (region B). The discriminator settings for region B are defined by selecting its LL discriminator setting to be equivalent to the upper limit of region A (e.g., 100 keV for the ^{33}P – ^{32}P double label) and selecting the UL

discriminator setting to encompass all pulses of highest magnitude arising from the higher energy radionuclide. In this example the UL discriminator setting of 1700 keV was selected, because no pulses from this double-radionuclide mixture can reach beyond 1700 keV. The second counting region (region B) for the case of the ^{33}P – ^{32}P dual radionuclide was therefore defined by the LL and UL discriminator settings of 100–1700 keV.

Fig. 6.54 illustrates the composite pulse height spectrum of a dual-isotope sample of ^{33}P – ^{32}P with an approximate 1:1 activity ratio as seen on the LSA computer screen. The discriminator settings established for regions A and B, as required for the analysis of these two isotopes in the same sample, are also seen in Fig. 6.54. Data illustrating typical recoveries obtainable by this inclusion method for the analysis of a dual nuclide combination of ^{33}P – ^{32}P is provided in Table 6.6. The inclusion method has been found to provide excellent recoveries of the ^3H – ^{14}C , ^3H – ^{45}Ca , ^{14}C – ^{36}Cl , ^{33}P – ^{32}P , ^{55}Fe – ^{59}Fe , ^{90}Sr – ^{90}Y and other double radionuclide mixtures, for a wide range of activity ratios of the two radionuclides (Hui et al., 2012, Nebelung et al., 2009, Nakanishi et al., 2009, Reddy et al., 2009, Shaffer and Langer, 2007, Rodríguez et al., 2006, Zheng and Bobich, 2004, Zheng et al., 2004, Lee et al., 2002b, Benitez-Nelson and Buesseler, 1998, L'Annunziata, 1984b, 1987, 1997b, Viteri and Kohaut, 1997, and Kessler, 1989). Reddy et al. (2009) made extensive tests of this dual nuclide analysis method for ^3H – ^{14}C combinations at low-activity levels. They obtained minimum detectable activities of 2100 DPM/L for ^3H and 1200 DPM/L for ^{14}C with

a counting time of 300 min and found the accuracy of results to be within $\pm 10\%$ for ^3H – ^{14}C activity ratios ranging from 1:1 to 1:18. Fujii and Takiue (2001) report the unique analysis of airborne ^3H and ^{14}C in activity concentrations as low as 0.01 Bq/cm³ by suspension of the radionuclides in a “foggy scintillator” created with an ultrasonic wave generator. The radionuclides could be analyzed as single or dual-radionuclide mixtures. Nebelung et al. (2009) evaluated this dual-radionuclide analysis technique with activity ratios of up to 1/50 for several combinations of nuclides and, including ^3H – ^{14}C , ^{14}C – ^{60}Co , ^{14}C – ^{90}Sr , ^{14}C – ^{99}Tc , ^{137}Sc – ^{60}Co , ^{55}Fe – ^3H , and ^{99}Tc – ^{60}Co with good accuracy. They used a PerkinElmer TriCarb 3100 TR liquid scintillation analyzer, which requires the establishment of quench correction curves using the quench indicating parameter, tSIE, with automatic efficiency control (tSIE/AEC), as described previously.

b. Dual-radionuclide analysis with daughter ingrowth

When two beta-emitting radionuclides are analyzed in two counting regions or windows, and there occurs ingrowth of a radionuclide daughter during the analysis, we have essentially the need to analyze simultaneously three radionuclides in the two counting windows. An excellent example is that of the liquid scintillation analysis of ^{89}Sr ($E_{\text{max}} = 1490$ keV) and ^{90}Sr ($E_{\text{max}} = 546$ keV) in two counting windows after the separation of ^{89}Sr and ^{90}Sr from other nuclides in the sample by chemical means, such as ion exchange. When the strontium is separated from other nuclides on an ion-exchange column, activity of the ^{90}Y

daughter of ^{90}Sr will appear immediately after the isolation of strontium, and the ^{90}Y activity will increase with time due to daughter nuclide ingrowth until the ^{90}Y activity reaches the activity of the ^{90}Sr parent nuclide, *i.e.*, secular equilibrium (L'Annunziata, 1971 and Fig. 1.144 of Chapter 1). Thus, the liquid scintillation analysis of radiostrontium, *i.e.*, ^{89}Sr and ^{90}Sr , in two counting windows must also include the measurement of the high-energy ^{90}Y ($E_{\text{max}} = 2280 \text{ keV}$) daughter activity, which will produce liquid scintillation events in the same counting windows within which the ^{89}Sr and ^{90}Sr events are counted. Thus, in this case, there is the need to analyze the activities of three beta-emitting radionuclides in two counting regions. The measured activity of the ^{90}Y will be a function of the ^{90}Sr parent nuclide activity and the time in hours since the time of isolation or separation of the strontium from other nuclides (t_0) and the time of measurement or counting (t_1). The recorded time of separation of strontium from other radionuclides and the time of counting will provide the duration in hours during which ^{90}Y ingrowth would have occurred. The calculated ingrowth of ^{90}Y allows for the mathematical correction of the contribution of ^{90}Y to the sample count rates in the two counting windows and permits the final calculated activities of ^{89}Sr and ^{90}Sr .

An excellent example of the dual counting region method with correction for daughter nuclide ingrowth, described in the previous paragraph, was reported by Kim et al. (2009) for the analysis of ^{89}Sr and ^{90}Sr in milk, which is based on the method of Eikenberg et al. (2006). The method of Eikenberg et al. (2006) utilized three counting windows to include the simultaneous analysis of an additional radionuclide, ^{85}Sr , which is used as a tracer nuclide to calculate the chemical recovery of strontium. Kim et al. (2009) isolated strontium including the ^{89}Sr and ^{90}Sr from milk using a column of ion-exchange resin that removed all other radionuclides including the ^{90}Y daughter nuclide of ^{90}Sr . The time of collection of the radiostrontium was taken as t_0 , which is the time that the ^{90}Y daughter nuclide of ^{90}Sr is removed and when ingrowth of ^{90}Y with its parent will begin. The isolated radiostrontium was counted in a liquid scintillation analyzer in two counting windows illustrated in Fig. 6.55. When counting a sample of radiostrontium, *i.e.*, ^{89}Sr and ^{90}Sr , isolated from other nuclides in the counting windows, illustrated in Fig. 6.55, Window A will yield a total count rate, which will be sum of count rates from pulse events arising from beta emissions of $^{89}\text{Sr} + ^{90}\text{Sr}$ + ingrown ^{90}Y + background events; whereas Window B will yield a summed count rate arising from beta emissions from $^{89}\text{Sr} + \text{ingrown } ^{90}\text{Y} + \text{background events}$.

Using the notation of Eikenberg et al. (2006), Kim et al. (2009) calculated the net (background-subtracted) count rates in the two counting windows A and B, which are defined as

$$N(t)^A = N(t)_{\text{Sr-89}}^A + N(0)_{\text{Sr-90}}^A + N(t)_{\text{Y-90}}^A \quad (6.40)$$

and

$$N(t)^B = N(t)_{\text{Sr-89}}^B + N(t)_{\text{Y-90}}^B \quad (6.41)$$

where in Eq. (6.40), $N(t)^A$ is the net count rate (CPS) in Window A, $N(t)_{\text{Sr-89}}^A$ is the net count rates in Window A due to ^{89}Sr at the time t of counting (^{89}Sr can undergo appreciable decay from the time of separation from the other nuclides to the time of counting; half-life of ^{89}Sr is 50.5 days), $N(0)_{\text{Sr-90}}^A$ is the count rate due to ^{90}Sr in Window A at the time of counting and the time of separation from other nuclides (^{90}Sr undergoes no observable decay; half-life of ^{90}Sr is 28.8 years), and $N(t)_{\text{Y-90}}^A$ is the count rate in Window A due to ingrowth of ^{90}Y at the time t of counting. Also in Eq. (6.41), $N(t)^B$ is the net count rate (CPS) in Window B, $N(t)_{\text{Sr-89}}^B$ is the net count rates in Window B due to ^{89}Sr at the time t of counting, and $N(t)_{\text{Y-90}}^B$ is the count rate in Window B due to ingrowth of ^{90}Y at the time t of counting. According to Eq. (6.7) described earlier in this chapter, it is obvious that the count rate (e.g., CPS) of a radionuclide is the product of the activity or disintegration rate (DPS) and detection efficiency ϵ of the nuclide, where $0 \leq \epsilon \leq 1$ for detection efficiencies in the range of 0% and 100%. Thus, Kim et al. (2009) expressed Eqs. (6.40) and (6.41) as

$$N(t)^A = A(t)_{\text{Sr-89}} \cdot \epsilon_{\text{Sr-89}}^A + A(0)_{\text{Sr-90}} \cdot \epsilon_{\text{Sr-90}}^A + A(0)_{\text{Sr-90}} \cdot f_1 \cdot \epsilon_{\text{Y-90}}^A \quad (6.42)$$

and

$$N(t)^B = A(t)_{\text{Sr-89}} \cdot \epsilon_{\text{Sr-89}}^B + A(0)_{\text{Sr-90}} \cdot f_1 \cdot \epsilon_{\text{Y-90}}^B \quad (6.43)$$

where $A(t)_{\text{Sr-89}} \cdot \epsilon_{\text{Sr-89}}^A$ is the product of the activity in disintegrations per second (DPS) of ^{89}Sr at the time t of counting and the detection efficiency of ^{89}Sr in counting Window A, $A(0)_{\text{Sr-90}} \cdot \epsilon_{\text{Sr-90}}^A$ is the product of the activity of ^{90}Sr at the time of its separation from ^{90}Y and other radionuclides and the detection efficiency of ^{90}Sr in counting window A, and $A(0)_{\text{Sr-90}} \cdot f_1 \cdot \epsilon_{\text{Y-90}}^A$ represents the contribution to the count rate in Window B arising from the ingrowth of ^{90}Y from the time t_0 of separation of the ^{90}Sr from yttrium to the time t of counting and

$$f_1 = (1 - e^{-\lambda_{\text{Y-90}} t_1}) \quad (6.44)$$

where $\lambda_{\text{Y-90}}$ is the decay constant of ^{90}Y and t_1 is the interval of time from the time of separation of ^{90}Sr from ^{90}Y , t_0 , and the time t of counting, *i.e.*, $t_1 = t - t_0$. Thus, the term $A(0)_{\text{Sr-90}} \cdot f_1$ of Eq. (6.43) represents the activity of the ^{90}Y ingrown with the isolated ^{90}Sr , and the activity of the ^{90}Y will grow according to the time interval t_1 to a maximum activity (A_{max}) equivalent to that of isolated ^{90}Sr (L'Annunziata, 1971), or

$$\begin{aligned}
 A_{Y-90} &= A_{Y-90, \max} (1 - e^{-\lambda_{Y-90} t_1}) \\
 &= A(0)_{Sr-90} (1 - e^{-\lambda_{Y-90} t_1})
 \end{aligned} \quad (6.45)$$

Eq. (6.45) is equivalent to that expressed by Eq. (1.574) of Chapter 1.

From Eqs. (6.42) and (6.43), Kim et al. (2009) arrive at the final expressions for calculating the activities of ^{90}Sr and ^{89}Sr in units of Bq/L when the strontium recovery, r_{sr} , and sample volume, V , are included, which are

$$A(0)_{Sr-90} = \frac{(N(t)^A - A(t)_{Sr-89} \cdot \varepsilon_{Sr-89}^A)}{(\varepsilon_{Sr-90}^A + f_1 \cdot \varepsilon_{Y-90}^A) \cdot r_{sr} \cdot V} \quad (6.46)$$

$$A(t)_{Sr-89} = \frac{(N(t)^B - A(0)_{Sr-90} \cdot f_1 \cdot \varepsilon_{Y-90}^B)}{\varepsilon_{Sr-89}^B \cdot r_{sr} \cdot V} \quad (6.47)$$

Quench correction curves are not needed in this case to determine the detection efficiencies of ^{90}Sr , ^{89}Sr , and ^{90}Y in the two counting windows, because all samples are prepared uniformly with the same level of quench, and minor variations of quench level have negligible effect on the detection efficiencies of these relatively high-energy beta-emitters. The determination of the detection efficiencies by the use of internal standards of ^{90}Sr , ^{89}Sr , and ^{90}Y , as carried out by Kim et al. (2009) does suffice in this case.

c. Triple-radionuclide analysis

In triple-radionuclide analysis (e.g., a mixture of $^3\text{H} + ^{14}\text{C} + ^{32}\text{P}$ or $^3\text{H} + ^{14}\text{C} + ^{131}\text{I}$), three counting regions and three sets of quench standards would be required to prepare quench correction curves for each radionuclide in each counting region. Thus, three CPM values, one for each of the three counting regions, are obtained and three

equations are solved to calculate the DPM of each of the three radionuclides. For example, Bukowski et al. (1992) describe the liquid scintillation analysis of mixtures of ^3H , ^{14}C , and ^{131}I in three counting windows, namely, Window 1 defined by channel numbers 5–300, Window 2 defined by channel numbers 300–550, and Window 3 defined by channel numbers 550–800. The channel numbers (LL and UL discriminator settings) are selected by determining the pulse height spectra of the lowest-quenched sample of each individual radionuclide with the LSA multichannel analyzer, as illustrated in Fig. 6.56. The upper limits of the pulse height spectra of the lowest-quenched samples were selected as the upper-level (UL) discriminator settings for each counting window, as illustrated in Fig. 6.56. Modern liquid scintillation analyzers equipped with automatic efficiency control (AEC) or automatic quench compensation (AQP) will automatically shift the upper-level discriminator setting to lower channel numbers according to the level of quench in the sample, as the uppermost levels of the spectra shift with quench.

When three sets of quenched standards, i.e., quenched standards for each radionuclide are counted in each of the three counting windows, separate quench correction curves of % detection efficiency versus a quench indicating parameter for each radionuclide are obtained in each counting window, as illustrated in Fig. 6.57. In the example given here the detection efficiency of ^3H in Windows 2 and 3 is zero, and the detection efficiency of ^{14}C in Window 3 is zero. This is so, because there is no spillover of ^3H into Window 2 or 3 as well as no spillover of ^{14}C into Window 3. However, other counting windows can be selected to permit some spillover of pulse events from the ^3H into Window 2 or the ^{14}C into Window 3, as the three equations

FIGURE 6.57 Quench correction curves of % detection efficiency versus the quench indicating parameter, $H\#$, for ^3H , ^{14}C , and ^{131}I in three counting windows defined by LL and UL discriminator settings at channel numbers 5–300 for Window 1, 300–550 for Window 2, and 550–800 for Window 3. The detection efficiency of ^3H is zero in Windows 2 and 3, and the detection efficiency of ^{14}C is zero in Window 3. From Bukowski et al. (2009). Reprinted with permission from Elsevier © 1992.

used to calculate the radionuclide activities can be solved with spillover.

For the analysis of experimental samples, the liquid scintillation analyzer (LSA) will determine the count rate in each counting window, the quench indicating parameter [e.g., H#, tSIE, SQP(E)] of that sample and then determine the nine detection efficiencies for the three radionuclides in each counting window. The LSA will also determine the background count rate in each counting window. With this data collected by the LSA, the following equations can be analyzed according to the notation used by Bukowski et al. (1992) to calculate the activity or disintegration rate of each of the three radionuclides in the sample:

$$\begin{aligned} W_1 &= e_{11}D_1 + e_{12}D_2 + e_{13}D_3 + B_1 \\ W_2 &= e_{21}D_1 + e_{22}D_2 + e_{23}D_3 + B_2 \\ W_3 &= e_{31}D_1 + e_{32}D_2 + e_{33}D_3 + B_3 \end{aligned} \quad (6.48)$$

Bukowski et al. (1992) used a standard Gaussian elimination matrix inversion method to solve the above three equations for D_j , which is the activity (DPM) of radionuclide j , where W_i is the count rate (CPM) in Window i , e_{ij} is the counting efficiency of radionuclide j in Window i , and B_i is the background count rate (CPM) in counting Window i . For the calculation of the activities of three radionuclides utilizing three counting windows according to Eq. (6.48), there is the need for nine counting efficiency values, one for each of the three radionuclides in each counting window (Nebelung et al. (2009). Fig. 6.57 illustrates eight of the nine quench correction curves, the missing ninth curve is that of ^{14}C in Window three; this curve would be similar to that of ^3H in Window 3, when there is no spillover of pulse events from ^{14}C into Window 3.

For another excellent example of a triple-radionuclide analysis (^3H , ^{22}Na , and ^{36}Cl) of this type and the calculations and quench curves involved, the reader should refer to Schneider and Verbrugge (1993). Nebelung et al. (2009) tested the above method of triple-radionuclide analysis with a PerkinElmer TriCarb 3100 TR liquid scintillation analyzer requiring the preparation of quench correction curves based on the quench indicating parameter tSIE/AEC. They obtained excellent recoveries from the following combination of radionuclides with activity ratios of up to 1/50: $^{55}\text{Fe}/^3\text{H}/^{14}\text{C}$, $^{55}\text{Fe}/^{14}\text{C}/^{99}\text{Tc}$, $^3\text{H}/^{14}\text{C}/^{60}\text{Co}$, $^3\text{H}/^{14}\text{C}/^{137}\text{Cs}$, $^3\text{H}/^{14}\text{C}/^{90}\text{Sr}$, and $^{14}\text{C}/^{99}\text{Tc}/^{60}\text{Co}$.

Triple-radionuclide liquid scintillation analysis is utilized for the analysis of radiostrontium, because ^{89}Sr and ^{90}Sr are encountered generally together, and with that comes the unavoidable ^{90}Y daughter nuclide of ^{90}Sr . An exception would be pure $^{90}\text{Sr} (^{90}\text{Y})$, which is used in nuclear medicine free of ^{89}Sr as a source of ^{90}Y for clinical applications. The liquid scintillation analysis of ^{89}Sr and

FIGURE 6.58 Approximate relative beta distributions of equal activities of ^{90}Sr , ^{89}Sr , and ^{90}Y and the approximate composite spectrum resulting from a mixture of equal activities of the three radionuclides. Sketched from the work of Chobola et al. (2006). See reference for more precise distributions. (Reprinted with kind permission from Springer Nature © 2006).

$^{90}\text{Sr} (^{90}\text{Y})$ utilizing three counting regions or counting windows was studied in detail by Chobola et al. (2006). They calculated the theoretical beta distributions for ^{90}Sr ($E_{\text{max}} = 546 \text{ keV}$), ^{89}Sr ($E_{\text{max}} = 1490 \text{ keV}$), and ^{90}Y ($E_{\text{max}} = 2280 \text{ keV}$) and compared these with the experimental pulse height spectra produced by the three radionuclides with a PerkinElmer TriCarb 2275 liquid scintillation analyzer. They found the composite pulse height spectrum provided by the LSA to approximate closely to the calculated beta distributions of each radionuclide. Fig. 6.58 illustrates the approximate beta distributions of equal activities of each radionuclide, and a composite spectrum, as depicted by the writer from their work. For the precise spectral distributions see Chobola et al. (2006). They selected three counting windows, as depicted in Fig. 6.58, to be defined by lower-level (LL) and upper-level (UL) discriminator settings of channel 23–200 for Window A, 201–800 for Window B, and 801–4000 for Window C. They counted the radiostrontium after passing the sample to be counted through a strontium-specific ion exchange column (SrSpec, Eichrom Technologies) that would remove all radionuclides other than strontium including the ^{90}Y daughter nuclide of ^{90}Sr .

As depicted in Fig. 6.58, Window A registers pulse events from ^{90}Sr , ^{89}Sr , and ^{90}Y , Window B registers pulse events from ^{89}Sr and ^{90}Y , and Window C registers pulse events from ^{90}Y . Chobola et al. (2006) defined three equations for the net (background-subtracted) count rates in each counting window using the matrix

$$\begin{bmatrix} I_A \\ I_B \\ I_C \end{bmatrix} = \begin{bmatrix} A \\ B \\ C \end{bmatrix} \cdot \begin{bmatrix} \eta_{AA} & \eta_{BA} & \eta_{CA} \\ \eta_{AB} & \eta_{BB} & \eta_{CB} \\ \eta_{AC} & \eta_{BC} & \eta_{CC} \end{bmatrix} \quad (6.49)$$

where I_A , I_B , and I_C are the net intensities or net count rates (CPM) obtained in counting Windows A, B, and C, and the

sample activities (DPM) of each radionuclide are $A = {}^{90}\text{Sr}$ activity, $B = {}^{89}\text{Sr}$ activity, and $C = {}^{90}\text{Y}$ activity. Within the matrix are the detection efficiencies of each radionuclide in the three counting windows or counting regions where η_{XY} denotes the counting efficiency of radionuclide X in counting region Y . Chobola et al. (2006) solved for activities A , B , and C including the constraint imposed by the ${}^{90}\text{Y}$ ingrowth. The activity C , which is the activity of ${}^{90}\text{Y}$, will depend on the activity of ${}^{90}\text{Sr}$ in the sample and the time interval in hours from the time of isolation of strontium from the ion exchange column to the time of sample counting, which would govern ${}^{90}\text{Y}$ ingrowth according to the following:

$${}^{90}\text{Y}_{\text{DPM}} = {}^{90}\text{Sr}_{\text{DPM}} [1 - e^{-\lambda t}] = A \left[1 - e^{-\frac{0.693}{64.1\text{ h}}(t-t_0)} \right] \quad (6.50)$$

The above Eq. (6.50) is identical to Eq. (6.45) discussed previously in this chapter and that expressed by Eq. (1.574) of Chapter 1, Volume 1. The various detection efficiencies of the three radionuclides required to solve the radionuclide activities, need not be determined by quench correction curves, as the radiostrontium nuclides as well as ${}^{90}\text{Y}$ are not easily quenched and the samples do not vary significantly in their chemistry or quench level. Internal standards can be used conveniently to determine the detection efficiencies, and internal standards can yield very precise detection efficiencies, if utilized properly, as described in Section V.A of this chapter.

Eikenberg et al. (2006) included a ${}^{85}\text{Sr}$ yield tracer in the three-window approach to the simultaneous liquid scintillation analysis of ${}^{89}\text{Sr}$ – ${}^{90}\text{Sr}$ (${}^{90}\text{Y}$). Like most analytical preparations for radiostrontium analysis, they separated the radiostrontium from other radionuclides (including ${}^{90}\text{Y}$) in the sample by use of cation exchange with a column of SrSpec resin (Eichrom Technologies). Ingrowth of the ${}^{90}\text{Y}$ daughter nuclide of ${}^{90}\text{Sr}$ would begin immediately after the radionuclide separation (L'Annunziata, 1971). During the radiostrontium separation process, Eikenberg et al. (2006) allowed for the isolation of the ${}^{90}\text{Y}$ from the sample for subsequent Cherenkov counting and extrapolation of the ${}^{90}\text{Y}$ curve to time t_0 , the time of separation of the ${}^{90}\text{Y}$ from the sample when it was in secular equilibrium with the ${}^{90}\text{Sr}$.

For liquid scintillation analysis, Eikenberg et al. (2006) selected a three-window counting arrangement in a PerkinElmer TriCarb 2270TR/AB liquid scintillation analyzer, which is equipped with a pulse height analyzer calibrated in keV (See Fig. 6.59). The counting regions were Window A: 0–12 keV, Window B: 12–300 keV, and Window C: 300–1200 keV. Window A would register pulse events mostly from the ${}^{85}\text{Sr}$ yield tracer. The ${}^{85}\text{Sr}$, which decays by electron capture, will produce abundant relatively low-energy Auger and conversion electron interactions with the liquid scintillation fluor cocktail, and there are in addition, X-ray and gamma photon Compton electron

FIGURE 6.59 Approximate LSC beta spectra of ${}^{85}\text{Sr}$, ${}^{90}\text{Sr}$, ${}^{89}\text{Sr}$, and ${}^{90}\text{Y}$ with the composite spectrum of the four radionuclides. Three counting windows are shown for the more precise measurement of each of the radionuclides. Sketched from the work of Eikenberg et al. (2006). See reference for more precise distributions (Reprinted with permission of Radiocarbon, University of Arizona, © 2006 Arizona Board of Regents on behalf of the University of Arizona).

interactions. Window B would register mostly ${}^{89}\text{Sr}$ and ${}^{90}\text{Sr}$ beta emissions in addition to ${}^{90}\text{Y}$ ingrowth.

Eikenberg et al. (2006) expressed the count rates (CPM) in the three counting regions as

$$\begin{aligned} N(t)_m^A &= A(t)_{85} \cdot \epsilon_{85}^A + A(t)_{89} \cdot \epsilon_{89}^A + A(0)_{90\text{Sr}} \cdot \epsilon_{90\text{Sr}}^A \\ &\quad + A(0)_{90\text{Sr}} \cdot f_1 \cdot \epsilon_{90\text{Y}}^A \\ N(t)_m^B &= A(t)_{85} \cdot \epsilon_{85}^B + A(t)_{89} \cdot \epsilon_{89}^B + A(0)_{90\text{Sr}} \cdot \epsilon_{90\text{Sr}}^B \\ &\quad + A(0)_{90\text{Sr}} \cdot f_1 \cdot \epsilon_{90\text{Y}}^B \\ N(t)_m^C &= A(t)_{89} \cdot \epsilon_{89}^C + A(0)_{90\text{Sr}} \cdot f_1 \cdot \epsilon_{90\text{Y}}^C \end{aligned} \quad (6.51)$$

where $N(t)_m^A$, $N(t)_m^B$, and $N(t)_m^C$ are the net (background-subtracted) count rates at time $t(m)$, i.e., time of measurement, in counting regions A, B, and C, respectively, $A(t)_{85}$, $A(t)_{89}$, and $A(0)_{90\text{Sr}}$ are the activities (DPM) of the added ${}^{85}\text{Sr}$ tracer at the time of measurement, the activity of ${}^{89}\text{Sr}$ at the time of measurement, and the activity of ${}^{90}\text{Sr}$ at the time of its separation from ${}^{90}\text{Y}$ on the ion-exchange SrSpec column, respectively, ϵ_{85} , ϵ_{89} , $\epsilon_{90\text{Sr}}$, and $\epsilon_{90\text{Y}}$ are the detection efficiencies of ${}^{85}\text{Sr}$, ${}^{89}\text{Sr}$, ${}^{90}\text{Sr}$, and ${}^{90}\text{Y}$ in counting windows A, B, or C, and f_1 is the ${}^{90}\text{Y}$ ingrowth term described previously (See Eq. 6.44). From the three equations describing the count rates in each counting region (Eq. 6.51), Eikenberg et al. (2006) derived the equation for calculating the activities of ${}^{85}\text{Sr}$, ${}^{89}\text{Sr}$, and ${}^{90}\text{Sr}$. They obtained highly accurate ${}^{90}\text{Sr}$ activities by collecting the ${}^{90}\text{Y}$ extracted from the original sample during

the ion-exchange separation of radiostrontium from ^{90}Y and other nuclides on the SrSpec exchange column. By Cherenkov counting of the ^{90}Y in a counting window of 0–25 keV, they could follow the ^{90}Y decay over a few half-lives and extrapolate the decay curve back to the time of separation from ^{90}Sr to determine the equal activities of ^{90}Sr and ^{90}Y , which were at secular equilibrium at the time of their separation. (See Section XVII.C and Fig. 1.144 of Chapter 1, Volume 1).

B. Three-over-two fitting and digital overlay technique (DOT)

The three-over-two method and the digital overlay techniques are described by Kouru and Rundt (1991). The three-over-two method, as noted in a previous paper by the writer (Noor et al., 1995), involves the counting of samples containing two radionuclides with three counting regions or windows. The count rate of each radionuclide is determined by solving a set of three equations for the two unknowns. By this technique, three and even more radionuclides in composite samples could be determined by using the number of counting windows greater than the number of radionuclides. This three-over-two fitting method was applied by Kim et al. (2006) to determine the activities of ^{129}I and ^{125}I , which display closely overlapping liquid scintillation pulse height spectra (See Fig. 6.60). Iodine-125 decays by electron capture with the emission of 23 keV Auger electrons (20% intensity), 30 keV conversion electrons (13% intensity), as well as 30 keV X- and 35 keV gamma radiations of the daughter nuclide. Iodine-129 undergoes beta decay with an endpoint energy (E_{max}) of 154 keV and mean beta energy of 40.9 keV, 40 keV gamma, and 30 keV X-radiation (NNDC, 2011). The beta emissions of ^{129}I (average 40 keV) are slightly higher than the Auger and conversion electron emissions of ^{125}I

producing an ^{129}I liquid scintillation pulse height spectrum with a peak at higher channel numbers illustrated in Fig. 6.60. Kim et al. (2006) were able to accurately determine the activities of both nuclides in a mixture using the three-over-two fitting method included with the EasyView software (Wallac, PerkinElmer) installed in a PerkinElmer Quantulus 1220 liquid scintillation analyzer.

The three-over-two fitting method developed into the digital overlay technique (DOT) whereby, in principle, the number of windows approaches the resolution of the multichannel analyzer of the liquid scintillation counter. This digital overlay technique uses an external standard to measure quench and a specimen overlay to obtain the DPM for single or multiple-radionuclide samples. The shape of the sample spectrum is used to resolve dual or triple radionuclide samples by fitting the spectrum of each component to the measured composite spectrum. The fitting of a reference spectrum to the sample spectrum can give a measure of the level of quench. Spectral fitting is accomplished by the instrument (e.g., Wallac RackBeta (PerkinElmer, Inc.), which maintains a spectrum library that covers a large quench region of both chemical and color quench for the radionuclides. The technique is reviewed and tested by Kouru and Rundt (1991) and described in patents by Rundt and Kouru (1989, 1992). They demonstrate this method as well as the counting region method previously described. The method is applied also in very specific models of Wallac (PerkinElmer, Inc.) liquid scintillation analyzers for quench correction and activity measurements of samples containing only one beta-emitting radionuclide. Kouru (1991), Leppänen and Kukkonen (2006), Wiegand et al. (2007), and Hueber-Becker et al. (2007) report the use of DOT for quench correction and activity analysis of ^{14}C .

C. Full spectrum DPM (FS-DPM)

Full spectrum DPM is a user-friendly method available with PerkinElmer TriCarb liquid scintillation analyzers for the measurement of many dual radionuclide combinations including ^3H – ^{14}C , ^3H – ^{32}P , ^3H – ^{35}S , ^{14}C – ^{32}P , ^{33}P – ^{32}P , ^{35}S – ^{32}P , ^3H – ^{125}I , ^{125}I – ^{131}I , ^{51}Cr – ^{14}C , ^{67}Ga – ^{68}Ga , ^{55}Fe – ^{59}Fe , ^{125}I – ^{14}C , ^{59}Fe – ^{51}Cr , and ^{89}Sr – ^{90}Sr , among others. The analysis protocol for FS-DPM is easy to set up, because no counting regions need to be defined. The full spectrum DPM method utilizes the spectral index of the sample (SIS) of the double radionuclide sample to “unfold” the separate pulse height spectra of the composite spectrum. This is possible because the SIS of the composite spectrum is a function of the individual distributions and the fractional counts of each radionuclide as well as the level of quench in the sample. The direct proportionality of SIS to the radionuclide composition in the sample was demonstrated by L’Annunziata and coworkers (see Noor et al.,

FIGURE 6.60 Pulse height spectra (counts per channel vs. channel number) of ^{125}I and ^{129}I obtained with a PerkinElmer Quantulus 1220 liquid scintillation analyzer. From Kim et al. (2006), Reprinted with permission of Radiocarbon, University of Arizona, ©2006 Arizona Board of Regents on behalf of the University of Arizona.

1995, 1996b), who determined the activity ratios of ^3H : ^{14}C and ^{35}S : ^{32}P from only the spectral index of the sample.

The key to spectrum unfolding used in the full spectrum DPM method is the SIS. At a given level of quench, each radionuclide has a defined pulse height-energy distribution and hence a unique SIS value. When two radionuclides are combined into a single sample, the resultant pulse height is the sum of the two individual distributions. The SIS of the total distribution is a function of the SIS of the individual distributions and the fractional counts of each radionuclide. If the SIS_L and the SIS_H are the spectral index values of the low- and high-energy radionuclides of a dual-radionuclide sample, then the SIS of the total distribution SIS_T can be calculated as

$$SIS_T = \frac{(SIS_L)(\sum N_{LE} + SIS_H)(\sum N_{HE})}{\sum N_{LE} + \sum N_{HE}} \quad (6.52)$$

where $\sum N_{LE}$ = accumulated counts from the low-energy radionuclide (e.g., ^3H) and $\sum N_{HE}$ = accumulated counts from the high-energy radionuclide (e.g., ^{14}C).

From Eq. (6.52) the following equations are derived, which define the count rates of the low-energy radionuclide (CPM_L) and the high-energy radionuclide (CPM_H) of a composite sample:

$$CPM_L = \frac{SIS_H - SIS_T}{SIS_H - SIS_L} (CPM_T) \quad (6.53)$$

and

$$CPM_H = \frac{SIS_T - SIS_L}{SIS_H - SIS_L} (CPM_T) \quad (6.54)$$

For a detailed treatment on the derivation of Eqs. (6.53) and (6.54), the reader may refer to Kessler (1989) and van Cauter and Roessler (1991).

To determine the count rates and disintegration rates of unknown dual-radionuclide samples, four quench correction curves must be prepared with two sets of quenched standards. Quenched standards of the low-energy radionuclide and of the high-energy radionuclide are needed. The quenched standards are counted in a regionless environment; that is, no counting region discriminator settings need to be established. The data collected by the liquid scintillation analyzer from the counting of each of the quenched standards are the quench indicating parameters (tSIE), the SIS values of the low- and high-energy radionuclide standards (SIS_L) and (SIS_H), respectively, and the percent counting efficiency of the low- and high-energy radionuclide standards. The LSA then plots automatically the four quench correction curves such as the curves illustrated in Fig. 6.61.

For the analysis of unknown activities of the radionuclide components of a dual-radionuclide sample, the liquid scintillation analyzer will first determine the total count rate (CPM_T) and the tSIE of the sample. From the one value of

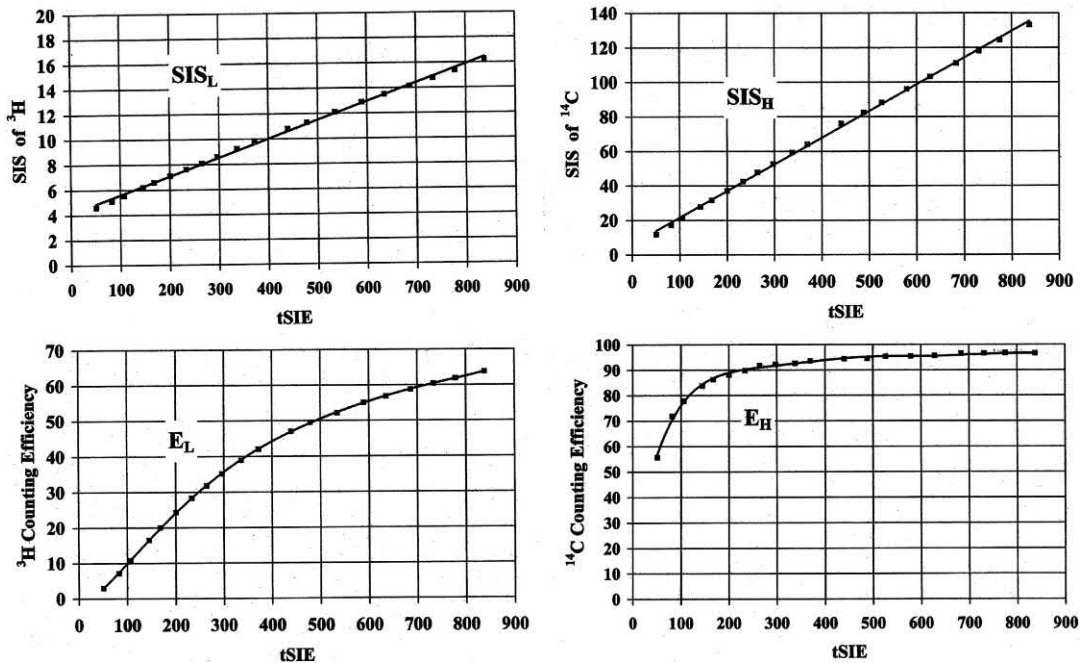

FIGURE 6.61 Quench correction curves for full spectrum DPM (FS-DPM) analysis of ^3H and ^{14}C mixtures. From the tSIE of a given sample, the liquid scintillation analyzer obtains from these curves the SIS of the lower- and higher energy radionuclides, SIS_L and SIS_H , respectively, and the percent counting efficiency of the lower- and higher-energy radionuclides, E_L and E_H , respectively. The above curves were obtained from ^3H and ^{14}C quenched standards with a PerkinElmer TriCarb 2770TR/SL liquid scintillation analyzer.

tSIE, the instrument extracts automatically the values of SIS_L and SIS_H for the composite sample using two of the quench correction curves (Fig. 6.61), which are maintained in computer memory. The LSA then calculates the count rate values of the low- and high-energy radionuclides CPM_L and CPM_H respectively, according to Eqs. (6.53) and (6.54). The instrument then automatically converts these count rates to the disintegration rates of the low- and high-energy radionuclide DPM_L and DPM_H respectively, according to the equations

$$DPM_L = CPM_L / E_L \quad (6.55)$$

and

$$DPM_H = CPM_H / E_H \quad (6.56)$$

where E_L and E_H , the counting efficiencies of the low- and high-energy radionuclides, respectively, are obtained from the respective quench correction curves illustrated in Fig. 6.61.

This DPM method provides accurate DPM values for dual radionuclides when the endpoint energies (E_{max}) of the two radionuclides differ by a factor of 3. The activity ratios can extend over the range of 1:25 and 25:1. For additional information on this technique see Kessler (1989), De Filippis (1991), van Cauter and Roessler (1991), and L'Annunziata (1997b). The method was utilized for the analysis of ^{89}Sr – ^{90}Sr mixtures by Hong et al. (2001) within 4 h after strontium separation from liquid waste. For low-level counting they report a counting efficiency of 95% for ^{89}Sr and 92% for ^{90}Sr with the full spectrum DPM method and lower limits of detection of 37 mBq/L for ^{90}Sr and 32 mBq/L for ^{89}Sr with a 60-minute counting time. An excellent illustration of the spectral unfolding power of the full spectrum DPM method is provided in Fig. 6.62 using the ^{89}Sr – ^{90}Sr combination as an example.

Altitzoglou et al. (1998) and Lee et al. (2002a,b) also report the use of the method for the analysis of ^{90}Sr with its ^{90}Y daughter. Lee et al. (2002b) compared the full spectrum DPM method and inclusion method (Section VIII.A.2) for the ^{90}Sr – ^{90}Y analysis and found equal performance for both. The full spectrum DPM method is easier to carry out for the less experienced analyst, as no counting regions need to be established. Lee et al. (2002b) tested the FS-DPM method for the analysis of ^{90}Sr in liquid waste, and the method should also be applicable to the analysis of trace activities of ^{90}Sr in samples of ^{90}Y , which are used in clinical applications where ^{90}Sr would be an undesirable contaminant. Fig. 6.63 illustrates the ^{90}Sr and ^{90}Y spectra in the FS-DPM counting mode at various times after the separation of ^{90}Sr . The figure illustrates the potential of this counting mode at any stage of ^{90}Y ingrowth, or for the analysis of traces of ^{90}Sr activity in isolated ^{90}Y .

Excellent recoveries were reported by Lee et al. (2002b) for the determination of ^{90}Sr activities. The measured

FIGURE 6.62 Unfolded spectrum of ^{90}Sr and ^{89}Sr (B) from mixture spectrum (A) by full spectrum (FS-DPM) method with a PerkinElmer TriCarb 2770 TR liquid scintillation analyzer. The pulse height spectra are plotted as counts versus pulse heights calibrated on a liquid scintillation keV scale. The unfolded spectrum of ^{89}Sr is illustrated in the rear of (B) and the unfolded ^{90}Sr spectrum in the front of (B). A very weak peak of ^{90}Y is seen together with the strong ^{90}Sr spectrum. The ^{90}Y peak was due to the ingrowth of ^{90}Y 2 hours after the separation of ^{90}Y from the sample using a SrSpec ion-exchange column. From Hong et al. (2001). Reprinted with permission from Elsevier © 2001.

FIGURE 6.63 Spectra of ^{90}Sr and ^{90}Y in FS-DPM counting mode with time after the separation of ^{90}Sr obtained with a PerkinElmer TriCarb 2770 liquid scintillation analyzer. From Lee et al. (2002b). Reprinted with permission from Elsevier © 2002.

activities in DPM were within 5% from the expected values with ingrowth of ^{90}Y measured over intervals from 0 to 15 days following the separation of ^{90}Sr . Reddy et al. (2009) made extensive tests of this FS-DPM analysis method for ^3H – ^{14}C combinations at low-activity levels.

^aActivity of ^{33}P = 72,373 DPM/mL, Activity of ^{32}P = 84,357 DPM/mL. Instrumentation: PerkinElmer TriCarb 2300 TR liquid scintillation analyzer.

^bTriplicate samples were counted for a duration of 10 minutes or until a % 2 sigma standard deviation of 1.0% was reached.

^cRatios listed are only approximate. The exact ratios can be calculated from the isotope activities (DPM/mL) and sample sizes (mL) of each isotope.

^dThe standard deviation of the mean of all triplicate measurements ranged from 0.085% to 2.97%.

From L'Annunziata (1997b), Printed with permission. © 1997 PerkinElmer, Inc.

They obtained minimum detectable activities of 2100 DPM/L for ^3H and 1200 DPM/L for ^{14}C with a counting time of 300 min and found the accuracy of results to be within $\pm 10\%$ for ^3H : ^{14}C activity ratios ranging from 1:1 to 1:18. Also, good recoveries of ^{33}P – ^{32}P combinations were obtained by the writer using the FS-DPM method, and these are illustrated in Table 6.7.

D. Recommendations for multiple radionuclide analysis

The following are a few suggestions to follow when performing DPM determinations for multiple-radionuclide samples by one of the methods previously described: (1) For the preparation of quench correction curves, prepare the sets of quenched standards in the same cocktail, vial size, and total sample volume as the samples to be analyzed. (2) Use of automatic region tracking (AEC or AQC) is recommended for dual- or triple-radionuclide analysis when using the counting-window inclusion methods of DPM analysis to maintain constant spillover of the radionuclides in the required counting regions. (3) DOT or full spectrum DPM methods require an accurate measurement of the sample pulse height spectra by the instrument pulse height analyzer following automatic subtraction of the background. When sample counts are low, long counting times will be needed to obtain well-defined sample pulse height spectra. As noted previously, Reddy et al. (2009) made extensive tests of the FS-DPM as well as the dual-window inclusion method of analysis for ^3H – ^{14}C combinations at low-activity levels. They obtained minimum detectable

activities of 2100 DPM/L for ^3H and 1200 DPM/L for ^{14}C with a counting time of 300 minutes and found the accuracy of results to be within $\pm 10\%$ for ^3H : ^{14}C activity ratios ranging from 1:1 to 1:18.

E. Complex spectral analysis

The multiple-radionuclide analysis methods previously discussed are limited to the analysis of not more than three β -emitting radionuclides in the same sample. From the beginning of liquid scintillation analysis in the 1950s up to about 1990, the regionless analysis of more than three β -emitting radionuclides in the same sample was considered to be impracticable or not feasible. The broad pulse height spectra produced by β particles made the task of deconvoluting the pulse height spectra of more than three radionuclides in the same sample appear daunting. However, with the advent of technological advances including applications of multichannel analyzers in liquid scintillation analysis and direct computer processing of LSA data, it has become possible to analyze simultaneously numerous α -, β -, and α - β -emitting radionuclides in a mixture, including nuclides decaying by electron capture emitting relatively low-energy Auger electrons and X-rays. This was evidenced by the early research reported by Takiue et al. (1990b, 1991b,c, 1992, 1995, 1999), Matsui and Takiue (1991), and Fujii et al. (1999, 2000) on the application of the most-probable-value theory to simultaneous multiple-radionuclide (as many as seven) analysis and the work of Grau Carles et al. (1993c), Grau Malonda et al. (1994a,b), and Grau Carles (1996) on the use of spectral

deconvolution and interpolation methods to multiple radionuclide (as many as six) activity analysis. These techniques can be applied also to mixtures of α - and β -emitters in one multichannel analyzer by spectral unfolding without α/β discrimination as demonstrated by Grau Carles et al. (1996). Subsequent research advances in liquid scintillation spectral deconvolution for multiple radionuclide analysis were reported by Heilgeist (2000), Kashirin et al. (2000), Verzezen and Hurtgen (2000), Malinovsky et al. (2002a,b), Nebelung (2003), Nebelung and Baraniak (2007), Nebelung et al. (2001, 2009), Ermakov et al. (2006), Altitzoglou (2008), Remetti and Sessa (2011), Dobrin et al. (2011), Remetti and Franci (2012) and Lee et al. (2017).

It was traditionally believed that ^{14}C ($E_{\max} = 156$ keV) and ^{35}S ($E_{\max} = 167$ keV) in the same sample could be neither identified nor analyzed by liquid scintillation counting, because of the very close similarities of the β -particle endpoint energies (E_{\max}) of these two radionuclides. However, work first reported by Grau Carles and Grau Malonda (1991) demonstrated the accurate analysis of these two radionuclides in a mixture using spectral dilatation-interpolation and least-squares fitting. Activity ratios of $^{14}\text{C}/^{35}\text{S}$ were analyzed with an accuracy within about 3%. Grau Carles with Rodríguez Barquero and Grau Malonda (1993a) reported further improvements to this methodology, and Malinovsky et al. (2002a) demonstrated the deconvolution of 1:8 ratios of $^{14}\text{C}/^{35}\text{S}$.

Another advancement is the application of chemometrics including multivariate calibration (MVC) to the deconvolution of α -, β -, and α - β -emitting radionuclides (without the need for α/β discrimination) in the same sample including nuclides decaying by electron capture, as reported by Toribio et al. (1995, 1996, 1997, 1999), Melado et al. (2005), and Khayatzaheh Mahani et al. (2008, 2009), Mahani et al. (2012) and Fons-Castells et al. (2017a). These techniques were successfully applied to the analysis of α - β -emitting radionuclide mixtures using plastic scintillator microspheres in an LSC (Bagán et al., 2011a). These techniques were also applied as one more step in a radionuclide separation procedure by Fons-Castells (2017b, 2017c).

These advances in the development of techniques for the analysis of several radionuclides in the same sample will be discussed here. The reader is invited to refer to the literature cited for more details on the techniques involved.

1. Most-probable-value theory

Takiue et al. (1990a,b) and Matsui and Takiue (1991) reported the application of the most-probable-value theory as a new technique applied to the simultaneous liquid scintillation analysis of four β -emitting radionuclides in the

same sample. This technique was expanded to the simultaneous analysis of six β -emitting radionuclides by Takiue et al. (1991c, 1992) and even seven β - and β - γ -emitting radionuclides (Takiue et al., 1995).

The technique requires only a contemporary liquid scintillation analyzer equipped with a multichannel analyzer, sets of quenched standards for the radionuclides to be measured, and a personal computer for data processing. The approach to this technique, as it was first devised for the analysis of samples containing mixtures of ^3H , ^{14}C , ^{32}P , and ^{45}Ca , calls for more counting regions than the number of nuclides to be measured. According to Takiue et al. (1990b) and Matsui and Takiue (1991), the method may be described using the four radionuclide composite sample consisting of ^3H , ^{14}C , ^{32}P , and ^{45}Ca , as an example. The count rates of a sample observed in each counting region are defined by the following equations:

$$\begin{aligned} n_1 &= Aa_1 + Bb_1 + Cc_1 + Dd_1 \\ &\vdots \\ n_i &= Aa_i + Bb_i + Cc_i + Dd_i \\ &\vdots \\ n_m &= Aa_m + Bb_m + Cc_m + Dd_m \end{aligned} \quad (6.57)$$

where $n_1, \dots, n_i, \dots, n_m$ are the count rates of a sample in different counting regions ($m >$ number of nuclides in the sample), A, B, C , and D are the activities of ^3H , ^{14}C , ^{32}P , and ^{45}Ca , respectively, and a_i, b_i, c_i , and d_i are the respective counting efficiencies in the i th counting region.

The counting efficiencies of a radionuclide in each counting region are determined by means of external standard quench correction curves plotted using sets of quenched standards for each radionuclide. Sets of quenched standards are not commercially available for many radionuclides. These can be prepared in the laboratory in advance by first determining the activities of separate pure β - and β - γ -emitting radionuclides using a direct DPM method, such as efficiency tracing DPM (ET-DPM) as described in Section V.F or a more precise radionuclide standardization according to the techniques described in Section IX of this chapter. Even radionuclides procured commercially should be analyzed to confirm their exact activities by a direct DPM method. Once the DPM values of the separate radionuclide standards are known, sets of quenched standards can be prepared according to the procedure described in Section V.D of this chapter.

From the series of equations listed in Eq. (6.57) and following the derivations of Takiue et al. (1990b) and Matsui and Takiue (1991), the most probable values of A, B, C , and D , that is, the activities of ^3H , ^{14}C , ^{32}P , and

^{45}Ca must be determined, and the following equation is derived to search a minimum value (S):

$$S = \sum_{i=1}^m w_i \{n_i - (Aa_i + Bb_i + Cc_i + Dd_i)\}^2 \quad (6.58)$$

where w_i is the arithmetic weight of the measurement in the i th counting region, which is calculated by $1/N_i$ where N_i is the total number of counts in the i th counting region.

The most probable value, that is, the activities of each radionuclide A, B, C , and D should satisfy the following condition:

$$\frac{\partial S}{\partial A} = \frac{\partial S}{\partial B} = \frac{\partial S}{\partial C} = \frac{\partial S}{\partial D} = 0. \quad (6.59)$$

The following normal equations are then derived:

$$\begin{aligned} A \sum w_i a_i^2 + B \sum w_i a_i b_i + C \sum w_i a_i c_i + D \sum w_i a_i d_i \\ = \sum w_i a_i n_i, \end{aligned} \quad (6.60)$$

$$\begin{aligned} A \sum w_i b_i a_i + B \sum w_i b_i^2 + C \sum w_i b_i c_i + D \sum w_i b_i d_i \\ = \sum w_i b_i n_i, \end{aligned} \quad (6.61)$$

$$\begin{aligned} A \sum w_i c_i a_i + B \sum w_i c_i b_i + C \sum w_i c_i^2 + D \sum w_i c_i d_i \\ = \sum w_i c_i n_i, \end{aligned} \quad (6.62)$$

$$\begin{aligned} A \sum w_i d_i a_i + B \sum w_i d_i b_i + C \sum w_i d_i c_i + D \sum w_i d_i^2 \\ = \sum w_i d_i n_i. \end{aligned} \quad (6.63)$$

These equations can be solved for radionuclide activities A, B, C , and D , i.e., the disintegration rate (DPM) of ^3H , ^{14}C , ^{32}P , and ^{45}Ca , respectively, using the determinant calculated by a personal computer. For example, as given by Matsui and Takiue (1991), the determinant for the calculation of the ^3H activity from the above equations is the following:

$$H = \frac{1}{K} \begin{vmatrix} \sum w_i a_i n_i & \sum w_i a_i b_i & \sum w_i a_i c_i & \sum w_i a_i d_i \\ \sum w_i b_i n_i & \sum w_i b_i^2 & \sum w_i b_i c_i & \sum w_i b_i d_i \\ \sum w_i c_i n_i & \sum w_i c_i b_i & \sum w_i c_i^2 & \sum w_i c_i d_i \\ \sum w_i d_i n_i & \sum w_i d_i b_i & \sum w_i d_i c_i & \sum w_i d_i^2 \end{vmatrix} \quad (6.64)$$

where

$$K = \begin{vmatrix} \sum w_i a_i^2 & \sum w_i a_i b_i & \sum w_i a_i c_i & \sum w_i a_i d_i \\ \sum w_i b_i a_i & \sum w_i b_i^2 & \sum w_i b_i c_i & \sum w_i b_i d_i \\ \sum w_i c_i a_i & \sum w_i c_i b_i & \sum w_i c_i^2 & \sum w_i c_i d_i \\ \sum w_i d_i a_i & \sum w_i d_i b_i & \sum w_i d_i c_i & \sum w_i d_i^2 \end{vmatrix} \quad (6.65)$$

For this case six counting regions were used in the multichannel pulse height analyzer for the measurement of the four nuclides. The discriminator settings of counting regions 1, 2, 3, and 4 are set to receive significant pulses from ^3H , ^{14}C , ^{45}Ca , and ^{32}P , respectively, with overlapping pulse height distributions. Channels 5 and 6 were set to receive pulses mostly from the medium-energy β -emitting radionuclides ^{14}C and ^{45}Ca , as the use of double channel settings for the medium-energy β -emitters produces more accurate data. The counts of the quenched standards collected in the various counting regions should exceed 10^4 to keep error at a minimum. The mean percent recovery was 2.4% for eight samples containing different proportions of ^3H , ^{14}C , ^{45}Ca , and ^{32}P at different quench levels, which represent 32 radionuclide analyses (8 samples \times 4 radionuclides). Matsui and Takiue (1991) modified the technique by using only three counting regions for the analysis of the four radionuclides in a mixture. This required counting the unknown sample at two quench levels determined by the quench indicating parameter tSIE. The sample was counted twice, that is, before and after the addition of quenching agent. Mean recoveries by this modified approach for 28 radionuclide analyses (7 samples \times 4 radionuclides) was 3.6%.

The approach described above can be applied to the simultaneous liquid scintillation analysis of six different β -emitting radionuclides in a mixture as demonstrated by Takiue et al. (1991c, 1992). They demonstrated the activity analysis of ^3H – ^{63}Ni – ^{14}C – ^{45}Ca – ^{36}Cl – ^{32}P by application of the most-probable-value theory. A PerkinElmer Tri-Carb Model 4000 was used, and the samples were counted in 12 counting regions as illustrated in Fig. 6.64. Thus, the measurement of an unknown sample requires 12 observation equations of the general type described in Eq. (6.57). The series of 12 equations are written according to the following:

$$n_i = Aa_i + Bb_i + Cc_i + Dd_i + Ee_i + Ff_i \quad (i = 1 - 12), \quad (6.66)$$

where n_i is the count rate of a sample in the i th counting region. A, B, C, D, E , and F are the activities of the six radionuclides, namely ^3H , ^{63}Ni , ^{14}C , ^{45}Ca , ^{36}Cl , and ^{32}P , and

FIGURE 6.64 Liquid scintillation pulse height distributions of six pure beta-emitters and region settings for analytical measurements. From Takiue et al. (1992), reprinted with permission from Elsevier © 1992.

a_i , b_i , c_i , d_i , e_i , and f_i are the respective radionuclide counting efficiencies in the i th channel. Because six radionuclide activities must be determined simultaneously, a six-by-six matrix is derived and written similarly to the case of a four-by-four matrix (Eq. 6.64) written for the analysis of four radionuclides. The mean recovery for 60 analyses (i.e., 10 samples \times 6 radionuclides per sample) was 3.9%.

The technique can be applied to the liquid scintillation analysis of low-level β - γ -emitting radionuclides together with β -emitters as demonstrated by Takiue et al. (1995). In this case, mixtures of the following seven radionuclides were determined by application of the most-probable-value theory: ^{51}Cr – ^3H – ^{125}I – ^{14}C – ^{45}Ca – ^{22}Na – ^{32}P . In this case, 14 counting regions were used. The lower limits of detection based on the analysis of 30 samples was calculated as 0.01 Bq/mL for higher energy radionuclides and 0.05 Bq/mL for lower energy radionuclides in the mixtures.

A further development of this technique is its application to the analysis of radionuclide combinations with similar pulse height distributions, such as ^3H – ^{125}I and ^3H – ^{51}Cr , regardless of the different decay modes of these radionuclides, that is, β emissions with ^3H and electron capture (EC) decay with ^{125}I and ^{51}Cr . Takiue et al. (1991b) demonstrated the successful application of this procedure to the analysis of combinations ^3H – ^{14}C – ^{125}I and ^3H – ^{14}C – ^{51}Cr in a wide range of activity ratios and quench levels.

Subsequent work by Takiue et al. (1999) and Fujii et al. (1999, 2000) included the combined use of liquid scintillation and NaI(Tl) spectrometers to permit the simultaneous determination of the activities of many more nuclides in only one calculation process and, at the same time, enhance the accuracy of the radionuclide activity determinations. This method is referred to as a hybrid radioassay technique, because both liquid and solid scintillation spectrometers are used for a given sample. The NaI(Tl) solid scintillation detector provides additional sensitivity, as it would be particularly sensitive to X- and gamma-ray-photon emitters and high-energy beta-emitters, which produce considerable bremsstrahlung radiation. For example, Takiue et al. (1999)

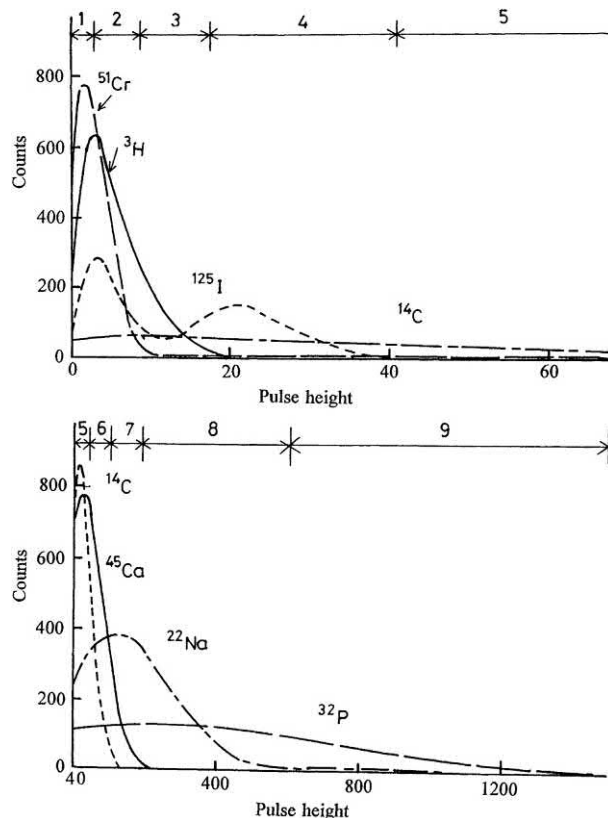

FIGURE 6.65 Liquid scintillation pulse height distributions of seven nuclides and channel settings for analysis. From Takiue et al. (1999), reprinted with permission from Elsevier © 1999.

and Fujii et al. (2000) analyzed a mixture of seven radionuclides (i.e., ^3H , ^{14}C , ^{22}Na , ^{32}P , ^{45}Ca , ^{51}Cr , and ^{125}I) using 12 counting regions defined, as illustrated in Figs. 6.65 and 6.66. The hybrid radioassay technique was applied by Fujii et al. (2000) to the analysis of the seven radionuclides in

FIGURE 6.66 NaI(Tl) scintillation pulse height distributions of ^{125}I , ^{51}Cr , ^{22}Na , and ^{32}P and channel settings for analysis. From Takiue et al. (1999), reprinted with permission from Elsevier © 1999.

waste solutions with a detection limit of approximately 0.005 Bq/mL.

The procedures outlined in this section are carried out easily with any liquid scintillation analyzer equipped with an MCA or, for the hybrid radioassay, data provided by conventional liquid and solid scintillation analyzers without any modification of the equipment and with a personal computer for data processing. If the counting protocols of the LSA allow for only three counting regions with upper- and lower-level discriminator settings, more counting regions can be established by using additional counting protocols. However, this calls for counting the samples in more than one protocol. The liquid scintillation analyzer is classified as a radionuclide spectrometer, because numerous X-ray, β -, and β - γ -emitting radionuclides can be identified and analyzed simultaneously. Beta spectrometry applications of the liquid scintillation analyzer currently play a role of increased importance in the analysis of radionuclides.

2. Spectral fitting, unfolding, and interpolation

Over the period of 1991–1996 a new technique was reported and developed by researchers at CIEMAT, Madrid, which is a powerful spectral unfolding method for the simultaneous activity analysis of numerous β -emitting radionuclides, including β -emitting nuclides of very similar energy maxima (e.g., ^{14}C and ^{35}S) and even some α/β -emitting radionuclides in the same MCA without α/β discrimination. A description of these techniques is provided here. References are cited for additional information.

The procedure involved, as described by [Grau Carles \(1993\)](#), for two types of liquid scintillation analyzers, namely, the LSA that analyzes pulse height spectra on a logarithmic scale and the LSA that uses a linear pulse height scale. As explained by [Grau Carles \(1993\)](#), the method has three key components: spectral fitting, spectrum unfolding, and spectral interpolation. These components to the analysis are described next.

a. Spectral fitting

As noted by [Grau Carles and Grau Malonda \(1991\)](#), pulse height spectra are generally defined in terms of discrete pulse heights or energy values; however, they are histograms. It is therefore necessary to have a continuous mathematical function defining the spectra. For pulse height spectra on a logarithmic scale, the spectral function is obtained by fitting Fourier series to the experimental spectra according to the following function:

$$f_F(\omega) = \begin{cases} a + b\omega + \sum_{k=1}^N c_k \sin \frac{k\pi\omega}{M} & 0 \leq \omega < \omega^* \\ 0 & \omega > \omega^* \end{cases} \quad (6.67)$$

where $\omega = 0$ and $\omega = \omega^* = M$ are the first and the last values of the spectrum and N is the number of harmonics. The coefficients a , b and c_k are:

$$\begin{aligned} a &= y_0 \\ b &= \frac{y_M - y_0}{M} \\ c_k &= \frac{2}{M} \sum_{j=0}^M y'_j \sin \frac{\pi k \omega_j}{M} \end{aligned} \quad (6.68)$$

where $y'_j = y_j - (a + b\omega_j)$

$$\omega_j = j = 1, 2, \dots, M.$$

For the case of a liquid scintillation analyzer that uses a linear pulse height scale the spectral function is obtained by fitting the Chebyshev series to the experimental spectra determined by the following:

$$f_c(\omega) = \begin{cases} \left[\sum_{k=1}^N c_k T_{k-1}(\omega) \right] - \frac{1}{2}c_1 & 0 \leq \omega < \omega^* \\ 0 & \omega > \omega^* \end{cases} \quad (6.69)$$

where $\omega = 0$ and $\omega = \omega^* = M$ are the first and the last values of the spectrum, $T_k(\omega)$ are the Chebyshev functions defined in the interval $[0, \omega^*]$ and c_k are the coefficients given by

$$c_k = \frac{2}{N} \sum_{j=1}^N f(\lambda_j) T_{k-1}(\lambda_j) \quad (6.70)$$

where the values λ_j are the zeros of the function $T_k(\omega)$.

b. Spectrum unfolding

According to descriptions by [Grau Carles \(1993\)](#) and [Grau Carles et al. \(1993b\)](#), the spectral deconvolution method is a simultaneous standardization technique, providing radionuclide activities, based on spectral shape analysis of the component nuclides in the mixture. The spectrum unfolding is based on minimizing the expression:

$$\min \left\{ \sum (y_i(X + Y) - ay_i(X) - by_i(Y))^2 \right\} \quad (6.71)$$

for a dual-radionuclide mixture, where y_i is the number of counts in channel i for the nuclide in brackets, X and Y are

the two radionuclides, and a and b are the parameters obtained from the least-squares fit. This minimum condition, as explained by [Grau Carles \(1993\)](#) and [Grau Carles et al. \(1994a\)](#), can be applied only when all spectra $y_i(X+Y)$, $y_i(X)$, and $y_i(Y)$ have the same quench value, that is, the same quench indicating parameter. Therefore, it is necessary to obtain the spectra $y_i(X)$ and $y_i(Y)$, at the same quench value of the radionuclide mixture. This is achieved by the spectral interpolation described subsequently in the next part of the analysis procedure. The activities in DPM for the two nuclides X and Y are obtained from the following:

$$A(X) = \frac{ay_i(X)}{t\epsilon(X)} \quad (6.72)$$

and

$$A(Y) = \frac{by_i(Y)}{t\epsilon(Y)} \quad (6.73)$$

where t is the counting time in minutes and $\epsilon(X)$ and $\epsilon(Y)$ are the counting efficiencies of radionuclide X and Y , respectively.

When a mixture of more than two radionuclides is analyzed, [Eq. \(6.71\)](#) is written as

$$\min \left\{ \sum_i \left(y_i \left(\sum_j X_j \right) - \sum_j a_j y_i(X_j) \right)^2 \right\} \quad (6.74)$$

where X_j are the component nuclides, a_j the coefficients that make the condition minimum, and y_i the number of counts in channel i .

c. Spectral interpolation

Spectra at different quench levels have different end points or maxima. Therefore, as noted earlier, all spectra are interpolated to the same end point and maxima to validate the application of [Eq. \(6.71\)](#) or 6.74 for spectral unfolding of dual or multiple (three or more) radionuclides, respectively. Interpolation of spectra, as explained by [Grau Carles et al. \(1993c\)](#), is carried out in the following steps: (1) a mathematical transformation is found that makes all spectra pass through common maxima, inflection, and endpoints; (2) the transformed spectra are then interpolated channel by channel; and (3) the required spectrum is found by inverse transformation.

As explained by [Grau Carles \(1993\)](#), the spectral function, such as the Chebyshev fitting described previously by [Eq. \(6.69\)](#), is a mathematical manipulation of the spectra that smoothes the spectra and eliminates all superfluous statistical fluctuations. If $f_i(\omega)$ ($i = 1, 2, 3$) are the spectral functions, these may be divided into two regions, such as

$$f_i(\omega) = \begin{cases} g_i(\omega) & 0 \leq \omega < \omega_{i\alpha} \\ h_i(\omega) & \omega_{i\alpha} \leq \omega \leq \omega_{i\beta} \end{cases} \quad (6.75)$$

where $\omega_{i\alpha}$ is the position of the maximum and $\omega_{i\beta}$ is the endpoint for spectrum i . As explained by [Grau Carles \(1993\)](#), the following mathematical transformation:

$$\omega' = a\omega \quad (6.76)$$

$$a = \frac{\omega_{1\alpha}}{\omega_{i\alpha}} \quad (6.77)$$

allows the transformation of all $g_i(\omega)$ functions, making them pass through the maximum of the spectral function $f_1(\omega)$. In the same way, the transformation

$$\omega' = b\omega + c \quad (6.78)$$

where

$$b = \frac{\omega_{1\alpha} - \omega_{1\beta}}{\omega_{i\alpha} - \omega_{i\beta}} \quad (6.79)$$

$$c = \frac{\omega_{i\alpha}\omega_{1\beta} - \omega_{1\alpha}\omega_{i\beta}}{\omega_{i\alpha} - \omega_{i\beta}} \quad (6.80)$$

takes the maximum and the endpoint of the function $f_1(\omega)$ as common points for each function $h_i(\omega)$.

When the spectral functions are transformed, a channel-by-channel interpolation provides a spectrum y_i^* . As explained by [Grau Carles \(1993\)](#), the following step determines the inverse equation, which transforms the spectrum y_i^* into the spectrum y_i :

Let $f_p^*(\omega)$ be the spectral function for y_i^* distribution and divide the function into the two regions:

$$f_p^*(\omega) = \begin{cases} g_p^*(\omega) & 0 \leq \omega < \omega_{1\alpha} \\ h_p^*(\omega) & \omega_{1\alpha} \leq \omega \leq \omega_{i\beta} \end{cases} \quad (6.81)$$

The positions of the maximum $\omega_{p\alpha}$ and the end point $\omega_{p\beta}$ of the spectrum y_i for Q_p (quench value or quench-indicating parameter) can be found by interpolation in quench correction curves of channel number versus quench indicating parameter, such as one illustrated for ^{14}C in [Fig. 6.67](#). An example of interpolated spectra of ^{14}C and ^{35}S with overlapping spectral maxima, inflection points and endpoints, is illustrated in [Fig. 6.68](#).

Then the inverse transformation

$$\omega' = a'\omega \quad (6.82)$$

where

$$a' = \frac{\omega_{p\alpha}}{\omega_{1\alpha}} \quad (6.83)$$

transforms $g_p^*(\omega)$ into $g_p(\omega)$, and

$$\omega' = b'(\omega) + c' \quad (6.84)$$

FIGURE 6.67 Fitted curves of ^{14}C local parameters versus quench: (a) end points of the spectra, (b) inflection points, and (c) position of the spectral maxima. The quench indicating parameter is SQP(E). From *Grau Carles et al. (1993a)*, reprinted with permission from Elsevier © 1993.

FIGURE 6.68 Computed ^{14}C and ^{35}S spectra for the quench value $Q = 354.7$, where Q is the SQP(E). From *Grau Carles et al. (1993a)*, reprinted with permission from Elsevier © 1993.

where

$$b' = \frac{\omega_{p\alpha} - \omega_{p\beta}}{\omega_{1\alpha} - \omega_{1\beta}} \quad (6.85)$$

$$c' = \frac{\omega_{1\alpha}\omega_{p\beta} - \omega_{p\alpha}\omega_{1\beta}}{\omega_{1\alpha} - \omega_{1\beta}} \quad (6.86)$$

transforms $h_p^*(\omega)$ into $h_p(\omega)$. The functions $g_p(\omega)$ and $h_p(\omega)$ define the spectral function $f_p(\omega)$, the spectrum y_i for the particular quench level Q_p .

The power of this method can be evidenced in the spectral deconvolution of ^{14}C ($E_{\max} = 156 \text{ keV}$) and ^{35}S ($E_{\max} = 167 \text{ keV}$), which have very close β -particle energy maxima with a ratio of the energy maxima of only 1.07. The spectral unfolding of a 2.2:1 mixture of ^{14}C and ^{35}S is illustrated in Fig. 6.69. The difference spectrum illustrated is a result of subtracting the actual ^{14}C – ^{35}S pulse height spectrum from the fitted Fourier spectral function $f_F(\omega)$. As

FIGURE 6.69 Spectrum unfolding of a sample containing ^{14}C – ^{35}S with an activity ratio of 2.2:1 and the difference spectrum. From *Grau Carles et al. (1993a)*, reprinted with permission from Elsevier © 1993.

explained by *Grau Carles (1993)*, the difference spectrum shows that the fluctuations are statistical, that is, Fourier spectral function fits the empirical data well. For the deconvoluted ^{14}C – ^{35}S sample spectrum illustrated in Fig. 6.69, *Grau Carles et al. (1993b)* determined the ^{14}C and ^{35}S activities with a 1.3% and 3.6% discrepancy, respectively, from the true DPM values. The ^{14}C – ^{35}S dual mixture was considered traditionally inseparable spectrometrically by liquid scintillation analysis. Another radionuclide pair with very similar pulse height spectral endpoints is ^3H – ^{55}Fe . *Grau Carles et al. (1993c)* again demonstrated the potential of this spectrum unfolding method with this nuclide pair. The power of the method is also demonstrated in the analysis of the traditional ^{14}C – ^3H radionuclide mixtures, as low discrepancies from the true activity values are reported by *Grau Carles et al. (1991)* at various levels of quench and high-count-rate ratios of ^{14}C – ^3H up to 100:1. *Grau Carles et al. (1993f)* demonstrated that this spectral deconvolution method will also provide good recoveries for multiple-radionuclide activity determinations in scintillation cocktails consisting of aqueous gel suspensions, such as aqueous ^{45}Ca – ^{35}S in Insta-Gel. Mean recoveries expressed as percent

discrepancy between computed and actual radionuclide DPM values for a wide range of ^{45}Ca – ^{35}S activity ratios from 10.3:1 to 1:8.1 were 2.3% and 3.1% for ^{45}Ca and ^{35}S , respectively.

In addition to dual-radionuclide mixtures, this spectral unfolding method is applicable to the activity analysis of numerous β -emitting radionuclides. When numerous radionuclides are in the mixture, the previously described Eq. (6.74) is the general expression upon which spectrum unfolding is based. The spectral unfolding and activity analysis of up to six different β -emitting radionuclides in the same mixture are reported by Grau Carles et al. (1993d,e), Grau Malonda et al. (1994a,b) and Grau Carles (1996). Among the radionuclides analyzed by this technique are mixtures of ^{89}Sr , ^{90}Sr , and ^{90}Y even before secular equilibrium was reached between the ^{90}Sr and ^{90}Y . The percent recoveries, that is, percent discrepancy or uncertainty, of the analyzed activities are amazingly low in many circumstances. An example is given in Fig. 6.70, which illustrates the spectral unfolding of a ^3H – ^{14}C – ^{125}I – ^{131}I – ^{32}P mixture and the computer output with activity analysis and percent uncertainties of the activity determinations for each radionuclide.

The spectrum unfolding technique has been tested by Grau Carles et al. (1996) with a mixture of α - and β -emitting radionuclides consisting of ^{234}Th + $^{234\text{m}}\text{Pa}$ + ^{230}Th . The activities of the α - and β -emitting radionuclides could be determined by the spectrum unfolding method without pulse shape analysis (PSA) for α/β separation. Percent discrepancies for activity determinations of the radionuclides in the mixture by spectrum unfolding were much lower than discrepancies obtained by the traditional PSA method.

The computer program MLOG is described by Grau Carles (1996) for the spectrum unfolding methods previously described. The MLOG program was applied by Grau Carles et al. (1998) to determine the separate activities of the parent-daughter nuclides, ^{125}Sb and $^{125\text{m}}\text{Te}$, and thereby determine the ^{125}Sb to $^{125\text{m}}\text{Te}$ beta branching ratio.

3. Spectral fitting and subtraction

Early work by Heilgeist (2000) applied a spectral-subtraction method to resolve mixed liquid scintillation spectra of ^{85}Sr , ^{89}Sr , and $^{90}\text{Sr}/^{90}\text{Y}$ with a PerkinElmer Quantulus 1220 liquid scintillation analyzer. Strontium-85 was included in these measurements, as it is commonly used as a tracer nuclide in the determination of chemical recoveries of strontium. The calibration of the liquid scintillation spectrometer and the evaluation of the sample spectrum required the measurement of the pulse height spectra from reference standards of the separate nuclides ^{85}Sr , ^{89}Sr , and $^{90}\text{Sr}/^{90}\text{Y}$, and isolated ^{90}Y . The reference standards are prepared at the same quench level as the experimental samples.

Pulse height spectra from the separate reference standards permit a determination of the spectral endpoints corresponding to the beta-energy maxima of each radionuclide as illustrated in Fig. 6.71. Window discriminators (pulse height discriminators) are defined, namely, E1, E2, and E3, which are set at the endpoints of the abundant low pulse height events from ^{85}Sr , and the endpoints of the pulse events from ^{90}Sr and ^{89}Sr , respectively. The ^{90}Sr endpoint (E2) was set at Channel 690, and the ^{89}Sr

FIGURE 6.71 Spectra deconvolution: ^{85}Sr , ^{89}Sr , and ^{90}Sr in model waste. The solid line is the smoothed sample spectrum, Bkg. is the background spectrum. E1, E2 (channel 690), and E3 (channel 815) are the energy limits of the component spectra. Pulse events arising exclusively from ^{90}Y beta emissions (not identified in the figure) occur beyond E3 in channels 816 to 950. From Heilgeist (2000). Reprinted with kind permission from Springer Nature © 2000.

endpoint at channel 815. Pulse events originating from ^{90}Y extend beyond channel 815 (E3) to channel 950. The ^{85}Sr , which decays by electron capture produces a large peak of low pulse heights due to Auger, conversion-electron, and X-ray Compton electron interactions with scintillation cocktail. It also produces a very weak smear of events at higher pulse heights up to discriminator E2 due to gamma-photon Compton interactions.

Background events are automatically subtracted by the liquid scintillation analyzer. A computer evaluation program adjusts the reference spectra to the positions of the measured sample composite spectrum and optimizes the positions of the window discriminators of $^{90}\text{Sr}/^{89}\text{Sr}$ at E2 and $^{89}\text{Sr}/^{90}\text{Y}$ at E3. The contribution of ^{90}Y to the composite spectrum is calculated first on the basis of its share in channels 816 to 950, which is a counting region free of any pulse events from other radionuclide emissions. Once the contribution of ^{90}Y is subtracted from the composite spectrum, the contribution from ^{89}Sr is determined from its share in the region defined by channels 691 to 815. Finally, the ^{90}Sr share is obtained after the deduction of the ^{90}Y and ^{89}Sr contributions. The contribution of ^{85}Sr due to its overlapping spectrum with ^{90}Sr was eliminated by spectral subtraction using a reference spectrum of ^{85}Sr . Quench effects are avoided by the constant composition of the scintillator solutions. Heilgeist (2000) reported recovery rates of 93.8% and a limit of detection of 0.1 Bq/kg.

Mietelski and Gaca (2002) separated numerically ^{90}Sr and ^{90}Y spectra using a fitting function with a PerkinElmer/Wallac Guardian liquid scintillation analyzer. The analysis could be performed after the separation of strontium on a column of Sr-Spec (Eichrom Industries) resin. There was no need to wait for secular equilibrium to be achieved. The overlapping spectra of ^{90}Sr and ^{90}Y are deconvoluted by the fitting function within 2% error, and the integrals of the

^{90}Sr and ^{90}Y parts of the combined spectrum would provide their count rates.

Nebelung et al. (2009) applied spectral peak functions with a PerkinElmer 1414 Liquid scintillation analyzer to deconvolute dual-, triple-, and multiple- (up to seven) radionuclide combinations for activity determinations. They used the peak fitting module of the graphic program Origin 5.0 (originally Microcal Inc., now OriginLab Corp., <https://www.originlab.com/>, accessed October 15, 2018), which contains several internal peak fit functions (Nebelung and Baraniak, 2007; Nebelung et al., 2009). Radionuclide standards of each nuclide were used to determine the spectral shape of each nuclide, which was required for the spectral fitting and analysis of multinuclide samples. The results of activity determinations of combinations of only two or three radionuclides by the curve fitting and deconvolution method yielded similar results obtained by the conventional two- and three-window counting method with a PerkinElmer TriCarb 3100 liquid scintillation analyzer. The uncertainty for activity measurements of three or more nuclides in one sample was <10%. An example of the deconvoluted spectra of a mixture of 10 Bq each of $^3\text{H}/^{14}\text{C}/^{137}\text{Cs}/^{90}\text{Sr}/^{90}\text{Y}$ is illustrated in Fig. 6.72.

A spectral deconvolution method was applied by Altizoglou (2008) to the activity analysis of radionuclides from liquid scintillation spectra of two or more radionuclides. The spectral deconvolution method is based firstly on the mathematical expression for the count rate y in each channel i of the LSA multichannel analyzer for the measured spectrum of n radionuclides or

$$y_i = \sum_n c_n \cdot S_{n,i} \quad (6.87)$$

where c_n is the unknown count rate of the radionuclide n in the sample, and $S_{n,i}$ is the content of the corresponding

FIGURE 6.72 Liquid scintillation spectrum of a mixture of five radionuclides and the spectra deconvolution measured with a PerkinElmer 1414 liquid scintillation analyzer. From Nebelung et al. (2009), reprinted with permission from Radiocarbon, University of Arizona, © 2009 Arizona Board of Regents on behalf of the University of Arizona.

channel i of a pure reference spectrum of radionuclide n . In other words, S_n is the normalized spectrum of radionuclide n , whereby, the total number of counts in the spectrum for radionuclide n would equal unity. Thus, for a complete spectrum of m number of channels, there would be m number of equations similar to Eq. (6.87).

The spectrum deconvolution described by Altitzoglou (2008) utilizes the shape of the sample spectrum on resolving its components by fitting a pure reference spectrum for each component to the measured composite spectrum. This was performed by a least-squares fitting; whereby, the unknown count rates c_n for each radionuclide n were found by minimizing the sum of the squared differences between the measured (y_i) and predicted (y'_i) rates for all channels of the spectra, or

$$\sum_i^m (y_i - y'_i)^2 = \sum_i^m \left(y_i - \sum_n c_n \cdot S_{n,i} \right)^2 \quad (6.88)$$

Altitzoglou (2008) applied an iterative fitting using the Levenberg–Marquardt algorithm, which is a nonlinear least-squares fitting. The radionuclide activities (DPM) were calculated by c_n/ϵ_n where c_n is the count rate of nuclide n and ϵ_n is its detection efficiency. Eqs. (6.87) and (6.88) are valid when the pure and composite spectra have the same quench levels. Altitzoglou (2008) applied the method to the logarithmic spectra as determined with a PerkinElmer Quantulus 1220 liquid scintillation analyzer, but the method is also applicable to the linear pulse height spectra as provided by the PerkinElmer TriCarb liquid scintillation counters. Fig. 6.73 is an example of a typical measured liquid scintillation composite spectrum of $^{90}\text{Sr}(^{90}\text{Y})$ at secular equilibrium and the component spectra

FIGURE 6.73 Typical composite spectrum of $^{90}\text{Sr}(^{90}\text{Y})$ at equilibrium as measured with a liquid scintillation analyzer, and the component spectra as calculated by the deconvolution method. The upper spectrum is the plot of the residuals of the fit. From Altitzoglou (2008), reprinted with permission from Elsevier © 2008.

as calculated by the deconvolution method. The deconvolution method was demonstrated to yield satisfactory results with low-activity samples as tested with the measurement of $^{90}\text{Sr}(^{90}\text{Y})$ in milk and soil samples. The advantages over traditional methods of multiple radionuclide analysis are no counting windows need to be set, the method is rapid and straightforward and, in the case of $^{90}\text{Sr}/^{90}\text{Y}$, it is not necessary to attain parent-daughter equilibrium for the activity analysis.

Lee et al. (2017) describe a deconvolution method that uses a spectral data base to obtain the reference pure beta spectra. This deconvolution method can be applied to spectra with the same level of quenching than the mixed total spectrum. The first step of this procedure was the fitting of the count ratio spectra. From the different methods studied, the sum of sine, Eq. (6.89), was the approach that provided the best results.

$$\begin{aligned} Y = & a1 \sin(b1E + c1) + a2 \sin(b2E + c2) \\ & + a3 \sin(b3E + c3) + a4 \sin(b4E + c4) \\ & + a5 \sin(b5E + c5) + a6 \sin(b6E + c6) \\ & + a7 \sin(b7E + c7) + a8 \sin(b8E + c8) \end{aligned} \quad (6.89)$$

Next, under the assumption that the count rate at the maximum energy (E_{max}) and 10 channels before ($E_{\text{max}-10}$) is generated by a single radionuclide and that the number of counts per specific energy is proportional to the count ratio value multiplied by the activity, the maximum energy was used to define the radionuclide and the $E_{\text{max}-10}$ to obtain the constant value that multiplies the radionuclide fitted function. Then, the spectrum obtained was subtracted from the mixed spectrum and the process was repeated until all nuclides are defined and separated from the multiple beta spectrum. This procedure was applied to the separation of a ^{32}P , ^{90}Y , and ^{106}Rh mixture obtaining relative errors lower than 2%.

A method was developed by Remetti and Sessa (2011) that is capable of deconvoluting complex liquid scintillation pulse height spectra without any preliminary knowledge of the peak shapes of the component radionuclides. They used a PerkinElmer Quantulus 1220 liquid scintillation analyzer with spectral deconvolution by Fourier series fitting with MATLAB software (The MathWorks Inc., version R2009B) according to Eqs. (6.56) and (6.57) described earlier. The calculation algorithm was structured according to the following path:

- i. **Identification of the portion of the pulse height spectrum that is due to the radionuclides of highest E_{max} , and the selection of a group of channels for interpolation.**

The radionuclide that possesses the highest energy emission will yield a pulse height spectrum where a limited portion of the upper (highest pulse heights)

part of the spectrum will be free of any overlap of pulse events from lower energy emitting nuclides. Once the channels are identified, which contain pulse events (counts) attributable only to that radionuclide, the algorithm can proceed with the next step, that of the interpolation of its contribution to the entire complex spectrum.

ii. Interpolation of the high-energy radionuclide contribution with the model “Cubic Spline”.

The model “Cubic Spline”, as described by [Remetti and Sessa \(2011\)](#), is a nonparametric interpolation model available among the functions of MATLAB. The interpolation of the high-energy radionuclide contribution to the spectrum is obtained by imposing the condition of passage of the function through the group of points of the above Step 1 and through zero in the first channel.

iii. Subtraction of the contribution by the high-energy radionuclide to the entire spectrum, and repetition of the procedure (Steps 1 and 2) for the remaining radionuclide contributions to the spectrum.

Once the shape of the spectrum, attributed to the radionuclide of highest E_{\max} , is obtained, it can be subtracted from the entire composite spectrum. This leaves behind a spectrum of the remaining radionuclides of lower E_{\max} . Then Steps 1 and 2 are repeated by subtracting singularly, *i.e.*, the pulse height spectrum of one nuclide at a time, until all of the contributing pulse height spectra of each radionuclide are unfolded from the composite spectrum.

iv. Activity calculation.

A simple integration of the unfolded pulse height spectra of each radionuclide provides the counts attributable to each radionuclide. The count rate (CPM), of course, will depend on the time needed to achieve the composite pulse height spectrum. The disintegration rate (DPM) of each radionuclide can easily be calculated with a measurement of the detection efficiency, which would be characteristic of the radionuclide emissions, quench level, and counter.

[Fig. 6.74](#) provides an example of the spectral deconvolution obtained by this technique. The discrepancies of the deconvoluted activities of the ^{90}Sr , ^{90}Y , and ^{241}Am from the expected values were reported to be within 5%. This method was implemented in a software called ABCD-Tool with some additional features as the possibility of a manual definition of the number of harmonics and the start and stop channels used for fitting ([Remetti and Franci \(2012\)](#)).

4. Modeling from spectral library

A different approach to multiple radionuclide analysis involves the establishment of a library of radionuclide spectra constituting different mixtures of radionuclides at varying

FIGURE 6.74 (Upper graph) Fourier series fitting of a composite spectrum ($^{90}\text{Sr} + ^{90}\text{Y} + ^{241}\text{Am}$). The continuous line represents the fitted function. (Lower graph) Total unfolding of the shapes of ^{90}Sr , ^{90}Y , and ^{241}Am . (From [Remetti and Sessa, 2011](#). Reprinted with kind permission from Springer Nature © 2011).

levels of quench. The spectral library, which is stored as computer data, must be prepared from radionuclide standards in various mixtures and activity ratios including also spectral distortions caused by the wall effect. [Kashirin et al. \(2000\)](#) describe this approach, which they have tested for complex mixtures of up to eight radionuclides including ^3H , ^{14}C , ^{60}Co , ^{63}Ni , $^{90}\text{Sr} + ^{90}\text{Y}$, ^{125}I , ^{137}Cs , and ^{241}Am . They applied algorithms described in patents by [Belanov et al. \(1997, 1998\)](#) to minimize deviations between real and model spectra regardless of linear or logarithmic scales used for the presentation of spectra.

Continued research along these lines reported by [Malinovsky et al. \(2002a,b\)](#), [Kashirin et al. \(2003\)](#), and [Ermakov et al. \(2006\)](#) has culminated in the establishment of a software package RadSpecDec for the deconvolution of complex pulse height spectra consisting of combinations of numerous (six or more) alpha- and beta-emitting radionuclides. As described by [Ermakov et al. \(2006\)](#) the

deconvolution algorithm is based on the modeling of spectra, which are transformed when convoluted by the superposition of individual reference spectra taken from a previously created radionuclide library of spectra. The spectra library consists of at least 10 spectra at different quench levels. The model spectrum is calculated as a sum of the individual radionuclide spectra with weight coefficients (c_j) that are adjusted during the modeling procedure with the objective that the model spectrum coincides with the sample composite spectrum to a maximum degree.

The model method was proposed by Malinovsky et al. (2002a,b) to be based on the modeling of spectra that are transformed when convoluted into a group by the superposition of individual radionuclide spectra taken from the spectral library. As described by Ermakov et al. (2006) the model spectrum is created from a linear combination of normalized spectra of various radionuclides according to the equation

$$M_i = \sum_{j=1}^J c_j M_{i,j}(T) \quad (6.90)$$

where M_i is the model spectrum, $M_{i,j}(T)$ is the library spectra of each radionuclide as a function of the quench parameter T , and c_j is the proportion or weight coefficient of each radionuclide specie. The weight coefficients, c_j , of each radionuclide are adjusted to make the model spectrum coincide with the sample spectrum to a maximum degree. Ermakov et al. (2006) describes the solution to the model as generated by a recursive minimization of a function representing the difference between a model spectrum and the real sample composite spectrum.

The modeling is carried out with groups of channels rather than the individual channels. For liquid scintillation spectrometers equipped with a logarithmic analog-to-digital converter (e.g., PerkinElmer Quantulus or Hidex Triathler), a combination of 10 channels form a group. Thus, the composite sample spectrum and the deconvoluted spectra are depicted as plots of Counts versus Group Number or Relative Activity versus Group Number, rather than the conventional Counts versus Channel Number, as illustrated in Fig. 6.75. Liquid scintillation spectrometers equipped with a linear analog-to-digital converter (e.g., PerkinElmer TriCarb) have channel numbers grouped by means of an arithmetic progression. Both logarithmic and linear pulse height spectra are resolved by the modeling technique, whereby the spectral channels become “channel groups”. The activity in disintegrations, A_j of the j th radionuclide in the composite spectrum will be a function of the total counts, N , the background-subtracted or net counts, $N - N_{bkg}$, the weight coefficient, c_j , of the j th radionuclide, and the detection efficiency, ϵ_j , of the j th radionuclide at quench level T or

FIGURE 6.75 The spectrum decoding of a mixture (^3H , ^{63}Ni , ^{35}S , ^{60}Co , $^{90}\text{Sr}/^{90}\text{Y}$, ^{137}Cs) measured with a PerkinElmer Quantulus liquid scintillation analyzer. From Malinovsky et al. (2002a,b), reprinted with permission from Radiocarbon, University of Arizona, © 2002 Arizona Board of Regents on behalf of the University of Arizona.

$$A_j = \frac{(N - N_{bkg})c_j}{T\epsilon_j} = \frac{N_j}{T\epsilon_j} \quad (6.91)$$

where $T\epsilon_j$ is the detection efficiency of the j th radionuclide at quench level T . Malinovsky et al. (2002a) and Ermakov et al. (2005) report tests on this deconvolution method with a wide variety of sample types and radionuclide combinations including low-level mixtures with good recoveries of the deconvoluted activities compared to the known radionuclide activities.

5. Spectral unfolding by region count ratios

Often the LSA of radionuclide mixtures is complicated by the need to analyze low-energy beta-emitters, such as ^3H , contaminated by much greater activities of high-energy beta impurities. Verzezen and Hurtgen (1996, 2000) describe a multiple-window spectrum unfolding technique for the analysis of low-energy ^3H in the presence of up to 10-fold higher activities of high-energy beta-emitters over a wide range of quench (e.g., $t\text{SIE} \geq 100$). The method is based on the fact that the ratio of the net count rates in two fixed counting regions for a single radionuclide is a constant at a given quench level. Consequently, any spectral shape (e.g., impurity spectrum) can be reconstructed using the established ratio and a pure reference spectrum. On the basis of this hypothesis, Verzezen and Hurtgen (2000) calculate the spectral contribution of the impurity in the low-energy part of the liquid scintillation pulse-height spectrum and correct for the impurity interference on the

measured low-energy sample spectrum. The method was demonstrated successfully over a wide range of quenching and activity ratios with mixtures of ^{99}Tc and ^{63}Ni contaminated with ^{60}Co and ^{137}Cs , respectively (Verrezen and Hurtgen, 1996), mixtures of $^{63}\text{Ni}/^3\text{H}$, $^{14}\text{C}/^3\text{H}$, $^{99}\text{Tc}/^3\text{H}$, $^{60}\text{Co}/^{99}\text{Tc}$ (Verrezen and Hurtgen, 2000), and mixtures of $^3\text{H}/^{90}\text{Sr}/^{90}\text{Y}$ (Dobrin et al., 2011).

The spectral deconvolution method described here is particularly useful for the analysis of a low-energy beta-emitting nuclide that is contaminated with a higher-energy beta-emitter. Verrezen and Hurtgen (2000) and Dobrin et al. (2011) demonstrate that the method is particularly useful in the analysis of nuclear waste streams of pressurized water reactors where activity ratios of 10^3 – 10^6 are encountered between impurities and the nuclide of interest. The overlapping character of liquid scintillation pulse height spectra can mask the presence of contaminating radionuclides low in activity relative to the nuclide of interest. The method is based on the hypothesis that the activity ratios of a beta-emitting radionuclide in two counting regions of the liquid scintillation pulse height spectrum is a constant at a constant level of quench regardless of the total activity of the radionuclide. This was demonstrated to be true by Verrezen and Hurtgen (2000) and Dobrin et al. (2011) by counting various activities of a beta-emitting radionuclide in two counting regions at identical quench levels. At a given quench level, the ratio of count rates in two counting regions due to the beta emissions of a radionuclide are a constant.

As described by Verrezen and Hurtgen (2000) the method is based on the following deconvolution algorithm

$$\text{NOI}(\text{net, low}) = \text{SMP}(\text{net, low})$$

$$- \sum_{k=1}^n K'_k(Q, \text{high}) \cdot \text{REF}_k(\text{net, low}) \quad (6.92)$$

where

$$K'_k(Q, \text{high}) = \frac{\text{SMP}(\text{net, high})}{\text{REF}_k(\text{net, high})} \quad (6.93)$$

In the above equations $\text{SMP}(\text{net}, i)$ represents the net contribution (calculated as the difference between the gross contribution $\text{SMP}(\text{gross}, i)$ and the background contribution $\text{BGD}(i)$) of a sample in a specified counting region of interest $\text{ROI}(i)$ as obtained from the spectral data. $\text{NOI}(\text{net}, i)$ and $\text{REF}_k(\text{net}, i)$ are the net contributions of the nuclide of interest and that of a reference spectrum of an impurity k to the beta spectrum in the same region of interest (i). The variable n refers to the number of radionuclide impurities in the sample. The term *low* represents a region of interest (ROI) in the low-energy range of the spectrum, whereas, the term *high* represents a ROI in the high-energy range, set behind or beyond the endpoint of the spectrum on the nuclide of interest in such a way that $\text{NOI}(\text{net, high}) = 0$, or in other terms $\text{SMP}(\text{net, high}) = \text{IMP}(\text{net, high})$. This is illustrated in Fig. 6.76 where the pulse height spectrum of ^3H , the nuclide of interest (NOI) is found only in the ROI *low*; whereby, $\text{NOI}(\text{net, high}) = 0$ and $\text{SMP}(\text{net, high}) = \text{IMP}(\text{net, high})$.

As described by Verrezen and Hurtgen (2000), Eq. (6.93) relies on the fact that the ratio of the net count rate in two fixed regions of the pulse height spectrum for a single

FIGURE 6.76 Effect of contamination of a ^3H sample with ^{99}Tc on the spectral shape as measured with a logarithmic amplifier (PerkinElmer/LKB Quantulus 1200, above) and a linear amplifier (PerkinElmer/Packard TriCarb 2200CA, below). Two regions of interest (ROI *low* and ROI *high*) are illustrated defined by a discriminator setting behind or beyond the endpoint of the nuclide of interest (^3H) pulse height spectrum. From Verrezen and Hurtgen (2000), reprinted with permission from Elsevier © 2000.

radionuclide is a constant for a given level of quenching and that any spectral shape (in this case the spectrum of the impurity, IMP) can be reconstructed using the established ratio and a pure reference spectrum if both are at the same level of quench, that is, if both possess the same quench indicating parameter, or

$$\frac{\text{IMP}(\text{net, low})}{\text{IMP}(\text{net, high})} = \frac{\text{REF}(\text{net, low})}{\text{REF}(\text{net, high})} = K(Q) \quad (6.94)$$

Verrezen and Hurtgen (2000) and Dobrin et al. (2011) used the above equations to recalculate the spectral contribution of the impurity in the low-energy region of the spectrum (ROI, *low*) thereby correcting for the impurity in the measured sample spectrum. The technique is not confined to resolving the interference caused by only one radionuclide impurity. Samples containing n impurities require $n + 2$ pulse height spectra to solve Eq. (6.92), namely, the background spectrum, the sample spectrum and n reference spectra (one for each radionuclide impurity). Thus, the analysis of the contaminated samples by this method requires the preparation of the following counting vials: a background vial, a sample vial, and one internal reference vial for each radionuclide known to be present in the sample. The final mixtures in the counting vials must possess identical chemistry to assure that they all are characterized by the same quench indicating parameter. To assure this was achieved, Dobrin et al. (2011) analyzed the nuclide of interest (NOI) ^3H contaminated with the impurity (IMP) $^{90}\text{Sr}/^{90}\text{Y}$ by preparing the following counting vials with identical chemistry: (1) a background vial containing 10 mL of distilled water and 10 mL of Ultima Gold XR cocktail; (2) a sample vial containing 1 mL of sample (aqueous), 9 mL of distilled water and 10 mL of Ultima Gold XR cocktail; and (3) reference vials, each containing 1 mL of sample, 1 mL of aqueous reference solution of the appropriate radionuclide present in the sample, 8 mL of distilled water and 10 mL of Ultima Gold XR cocktail. For the analysis of ^3H contaminated with the impurity $^{90}\text{Sr}/^{90}\text{Y}$ Dobrin et al. (2011) corrected all spectra for the contribution due to background. They subsequently reconstructed the spectrum of the impurity ($^{90}\text{Sr}/^{90}\text{Y}$) in the lower energy range using the spectral shape of the reference spectrum and the calculated ratio $K'_k(Q, \text{high})$ of Eq. (6.93). Lastly, the net spectrum of the nuclide of interest, i.e., ^3H , in the lower energy range of the spectrum (ROI *low*) was restored by subtracting the net spectrum of the impurity from the net sample spectrum. If the reference vials were prepared with known activity concentrations of the radionuclides, the detection efficiencies can be obtained for each radionuclide, and the count rates converted to disintegration rates.

6. Multivariate calibration

The application of multivariate calibration for the determination of ^{14}C activities was discussed in Section V.F.4 of this chapter. It has been applied by Toribio et al. (1995, 1996) in the liquid scintillation analysis of mixtures containing the three main α -emitting isotopes of plutonium, ^{238}Pu , ^{239}Pu , and ^{240}Pu . The multivariate methods used were principal component regression (PCR) and partial least squares regression (PLSR). As explained by Toribio et al. (1995), these methods can estimate the concentration of radionuclide of interest without the need to consider the other radionuclides present in the system that affect the experimental signal, provided the isotopes are present in both the unknown samples and the calibration set. The advantage here is that the methods are suitable for the analysis of samples with unknown interferences, thereby avoiding the need of a separation step.

For the PCR and PLSR analysis Toribio et al. (1995) used a program written in FORTRAN 77 run on a personal computer with a DOS operating system described by Tauler et al. (1991), and the programs were validated by comparison with the PLS-Toolbox package for MATLAB written by Wise (1992). The α -emissions of ^{239}Pu and ^{240}Pu have overlapping energies, and the predicted error for the PCR or PLSR separation of these two nuclides was about 35%. These two nuclides are determined together as one component or analyte, $^{240+239}\text{Pu}$, which is similar to other established procedures using surface barrier detectors. Samples containing standards and unknowns of low-level activity (3.42–174 DPM) were counted for 5 h and data analyzed by relating known plutonium activities to alpha disintegrations registered in energy channels of a PerkinElmer Tri-Carb CA/LL liquid scintillation analyzer. Relationships were sought between two matrices $\mathbf{R}(M, N)$ and $\mathbf{C}(M, K)$. Matrix $\mathbf{R}(M, N)$ contained the instrumental responses, number of counts at N measuring channels for M calibration samples, and the other matrix $\mathbf{C}(M, K)$ contained the activities of the K analytes in the M samples. The important step in the data treatment in PCR and PLSR models, emphasized by Toribio et al. (1995), is the number of factors chosen as noted previously in Section V.F.4 of this chapter. When the number is chosen correctly, the data compression step filters out noise and useless data without sacrificing significantly the desired information. One approach to the proper selection of factors is to start with a probable number of factors. The analysis is repeated using a different number of factors until the optimum number that fits the data is found. The optimum number of factors in this case was found to be four, all attributable to sample activities. No factor was attributed to background, as predictions did not improve when background was subtracted.

The values obtained for $^{240+239}\text{Pu}$ and ^{238}Pu activities for samples containing varying amounts of these radionuclides in mixtures over the range of 2.43–174 DPM had errors of about 7% and 10% for the high- and low-activity samples, respectively. Background (blank) subtraction is not required. This approach to radionuclide analysis is still at its early stages of development; however, [Toribio et al. \(1995\)](#) conclude that the multivariate calibration technique provides a detection limit one order of magnitude higher than that obtained with a surface barrier detector. However, the detection limit would be expected to drop with the use of α/β -discrimination and active shielding in LSA. With α/β -discrimination in many liquid scintillation analyzers the β -emitting isotope ^{241}Pu could also be included in the mixture, and activity measurements of mixtures containing the α - and β -emitting isotopes of plutonium in the same sample, as $^{238}\text{Pu} + ^{239+240}\text{Pu} + ^{241}\text{Pu}$, would be possible.

Organic extracting agents are often used to improve the alpha spectral resolution in the liquid scintillation analysis of alpha-emitters. However, subsequent to extraction, alpha peaks are reported to display a continuous shift along their axis with time for periods in excess of 200 h ([Toribio et al. \(1997\)](#)). To overcome error due to the instability of alpha spectral peak positions [Toribio et al. \(1997, 1999\)](#) report the application of moving curve fitting (MCF) to the multivariate calibration analysis of mixtures of the four alpha-emitting isotopes ^{242}Pu , $^{239+240}\text{Pu}$, and ^{238}Pu with <15% relative errors of predicted values and an activity quantification threshold of 15 DPM.

[Mellado et al. \(2005\)](#) applied multivariate calibration, which constitutes a set of chemometric techniques, to the activity analysis of various combinations, quench levels, and ratios of $^{90}\text{Sr}/^{90}\text{Y}$, ^{99}Tc , ^{63}Ni , ^{137}Cs , and ^{55}Fe within 15% relative error within the range covered by the calibration matrix. Chemometrics including artificial neural network (ANN) and partial least squares (PLS) as complementary tools are reported by [Khayatzaheh Mahani et al. \(2008, 2009\)](#) for the analysis of ^{226}Ra and uranium as well as thorium and uranium in aqueous samples. Relative errors of prediction for PLS and ANN in synthetic mixtures of ^{226}Ra and uranium were 18.0% and 24.8%, respectively. Also, [Mahani et al. \(2012\)](#) applied PLS for the separation of a mixture of ^{235}U and ^{238}U with prediction relative errors lower than 4%. [Fons-Castells et al. \(2017a\)](#) applied also this tool for the quantification of ^{40}K , ^{60}Co , $^{90}\text{Sr}/^{90}\text{Y}$, ^{134}Cs , ^{137}Cs , U, and ^{241}Am obtaining relative errors of prediction lower than 25%.

Now that the application of plastic scintillator microspheres to LSC are making rapid development (See [Section XVI](#) of this chapter), [Bagán et al. \(2011a\)](#) report the use of plastic scintillator microspheres together with multivariate calibration (PLS) to detect and measure the activities of α - and β -emitting radionuclides in mixtures. They quantified mixtures of ^{241}Am , ^{137}Cs , and $^{90}\text{Sr}/^{90}\text{Y}$ without the need of pulse height discrimination with errors under 10% in most

cases. Measurement time is reduced, as the counting of background blanks are not necessary. The use of plastic scintillator microspheres also obviates the need for liquid scintillation cocktail and thus reduces the disposal costs that occur with mixed radioactive waste.

The PLS tool was also applied as part of a more complex system of radionuclide separation, [Fons-Castells et al. \(2017b, 2017c\)](#) explains a quantification procedure applied to water samples that includes alpha/beta separation to obtain the indicative dose followed by a RAD disk separation to isolate ^{226}Ra , ^{228}Ra , and ^{210}Pb as well as a gamma spectrometry to determine ^{60}Co , ^{134}Cs , ^{137}Cs , and ^{241}Am . With all of this information, the PLS tool was applied to quantify the other radionuclides presents in the original sample (U, ^{40}K , $^{90}\text{Sr}/^{90}\text{Y}$, and $^{239+240}\text{Pu}$), as well as the quantification of the isotopes separated by the RAD disk, with a quantification bias below to 15%.

IX. Radionuclide standardization via LSA

Radionuclide standardization is included here as an altogether different specialty of liquid scintillation analysis (LSA), as it pertains to the purest form of measurement of the activity or disintegration rates (DPM) of radionuclides. It includes the methods used for the determination of the absolute activity of radionuclides as reference sources from which other radionuclide activities may be calibrated. The standardization of radionuclides is important in many fields, among which one of the most demanding has been radionuclide standardization for applications and research in therapeutic nuclear medicine ([Coursey et al., 1991, 1994; Zimmerman, 2006b](#)). This section will include some of the most popular liquid scintillation analytical methods applied to the standardization of radionuclides. Additional information on these techniques, among others used in radionuclide metrology, is available from Chapter 7 of Volume two entitled “Radionuclide Standardization” by Agustín Grau Malonda.

A. CIEMAT/NIST efficiency tracing

The CIEMAT/NIST method of radionuclide standardization, in its historical context, was first conceived by Agustín Grau Malonda in 1978 with the objective of developing a model/procedure applicable to any liquid scintillation analyzer, any scintillation cocktail, and any radionuclide ([Grau Malonda, 1999](#)). As the procedure could not be based solely on theoretical calculations of counting efficiency, [Grau Malonda \(1982a\)](#), in his doctoral dissertation, devised a model that combined theoretical calculations based on the radionuclide to be analyzed and experimental data provided by the liquid scintillation analyzer. Early descriptions of the method applied to the activity analysis of pure beta-particle emitting radionuclides

are provided by [Grau Malonda \(1982a\)](#), [Grau Malonda and García-Toraño \(1982a,b\)](#), [Grau Malonda et al. \(1985\)](#), and for radionuclides decaying by electron capture by [Grau Malonda \(1982b\)](#).

Agustín Grau Malonda (1938–)

The name CIEMAT/NIST currently attributed to the method is the result of a collaboration on the method that started in 1984 ([Coursey et al., 1986](#); [Grau Malonda and Coursey, 1987](#)) between the Centro de Investigaciones Energéticas Medioambientales y Tecnológicas (CIEMAT) in Madrid (the affiliation of Agustín Grau Malonda) and the National Institute of Standards and Technology (NIST), Gaithersburg, which at that time was called the National Bureau of Standards (the affiliation of Bert M. Coursey). Collaboration between the two institutions was intended to develop the method into one that could be used as a reference method for the standardization of radionuclides by any laboratory in the world with a conventional liquid scintillation analyzer. Other acronyms for the CIEMAT/NIST efficiency tracing method are found in the scientific literature including CNET or C/N efficiency tracing. The method is also referred to as $4\pi\beta$ efficiency tracing.

The principles of the method and many of the major references to this technique will be presented here. Comprehensive treatments on the procedures and calculations involved are available from books by [Grau Malonda \(1995, 1999\)](#). A paper by [García-Toraño et al. \(1991\)](#) also provides a good summary of the method. Excellent reviews on this liquid scintillation radionuclide standardization method as well as other related methods of standardization by liquid scintillation are provided by [Grau Malonda \(1999\)](#), [Günther \(2002a,b\)](#), [Zimmerman \(2006b\)](#), [Broda et al., 2007](#), [Collé, 2009](#), and [Grau Carles and Grau Malonda, 2010](#).

1. Theory and principles (^3H as the tracer)

As noted by [Grau Malonda \(1995, 1999\)](#) the original plan, conceived in 1978, was to develop a procedure for the standardization of radionuclides, which is applicable to any commercial liquid scintillation analyzer available in most laboratories, any liquid scintillation cocktail, and any radionuclide. To achieve this goal the method had to be

based on a combination of theoretical calculations related to the particular radionuclide under measurement and its emissions as well as theoretical calculations related to a primary standard tracer nuclide (e.g., ^3H) and its emissions together with experimental data from the liquid scintillation analyzer which provides information concerning the instrument, scintillation cocktail, and radionuclide (e.g., sample count rate and quench indicating parameter).

The method is centered on the theoretical computer-based calculations of the counting efficiency of the radionuclide to be analyzed and that of a reference primary standard, such as tritium, for different values of figure of merit (M) and an experimental quench correction curve obtained from a set of ^3H quench standards. The figure of merit (M) is a term used in this technique, which is defined as the β -particle energy in keV required to produce one photoelectron by the photocathode of the photomultiplier tube (PMT) or, in other words, one photoelectron that reaches the first dynode of the PMT. The relationship of radionuclide counting efficiency and figure of merit for pure β -emitters and liquid scintillation systems comprised of two photomultiplier tubes in coincidence is defined by

$$\epsilon = \int_0^{E_{\max}} N(E) \left\{ 1 - \exp \left[\frac{-E \cdot X(E)}{2 \cdot M} \right] \right\}^2 dE \quad (6.95)$$

where E_{\max} is the maximum β -particle energy, $N(E)$ is the theoretical β -particle energy distribution, $X(E)$ is the correction for ionization quenching and wall losses (wall effect), and M is the figure of merit ([Grau Malonda, 1982b](#); [Grau Malonda and García-Toraño, 1982a,b](#); [Grau Malonda and Los Arcos, 1983](#); [Grau Malonda et al., 1985](#); and [Coursey et al., 1986, 1989](#)).

The objective of the method is to obtain the counting efficiency of a nuclide under investigation (e.g., ^{14}C) from the counting efficiency of an absolute or primary standard of ^3H . Hence, the term ‘efficiency tracing’ is used in naming the technique. Because the ^3H is a primary standard, its efficiency is taken as experimental data, while that of the nuclide under measurement (e.g., ^{14}C) is obtained via a theoretical calculation and experiment. It was essential, therefore, that the calculation model for the counting efficiency, as envisaged by Grau Malonda, be so complete and accurate that the final results of the counting efficiency of the nuclide under investigation would be better than the precision limits of the experiment and instrumentation.

The term ‘figure of merit’ in this section has a totally different meaning than that used in other parts of this book, where the reader will find reference to figure of merit relating counting efficiency to background in the measurement of low activity samples. In this section, figure of merit refers exclusively to the quantitative yield of the photomultiplier dynode and its relation to counting efficiency. To avoid confusion, the term ‘free parameter’ or λ

has been adopted instead of figure of merit (M) when relating photomultiplier dynode yield and counting efficiency in this radionuclide standardization technique. Consequently Eq. (6.95) for the expression of the theoretical counting efficiency is often written as

$$\varepsilon = \int_0^{E_{\max}} N(E) \left\{ 1 - \exp \left[\frac{-EQ(E)}{2\lambda} \right] \right\}^2 dE \quad (6.96)$$

where $Q(E)$ is the ionization quenching correction factor or $X(E)$ of Eq. (6.95), and λ is the free parameter or figure of merit M of Eq. (6.95).

The calculation model relies on the decay schemes of the nuclide of interest, and for this purpose, tables of beta particle (i.e., negatron) and positron spectra were published by Grau Malonda and García-Toraño (1978 and 1981a) from which the spectral area over any given energy range may be obtained. Also, tables of calculated counting efficiencies as a function of the free parameter were published for numerous radionuclides decaying by pure negatron emission (Grau Malonda and García-Toraño, 1981b; Grau Malonda et al., 1985), electron capture decay (Grau Malonda, 1982b), positron emission (Grau Malonda and García-Toraño, 1982b), beta-gamma-ray emission (García-Toraño and Grau Malonda, 1988), and electron capture decay with gamma-ray emission (Grau Malonda and Fernández, 1985).

As the calculation of the theoretical counting efficiency must account for all beta transitions, Eq. (6.96) is modified accordingly. For example, ^{125}Sb undergoes eight beta-decay transitions to the daughter nuclide $^{125\text{m}}\text{Te}$. Consequently, to account for all beta-decay transitions, Grau Carles et al. (1998) used the following expression, according to Grau Malonda (1995, 1999), for the calculation of ^{125}Sb counting efficiency

$$\varepsilon = \sum_{i=1}^8 p_i \int_0^{(E_m)_i} N_i(E) \left\{ 1 - \exp \left[\frac{-EQ(E)}{2\lambda} \right] \right\}^2 dE \quad (6.97)$$

Where p_i , $(E_m)_i$, and $N_i(E)$ are respectively the eight beta-particle transition intensities, end-point energies (E_{\max}), and Fermi (beta-particle energy) distributions; E , $Q(E)$ and λ are as previously described. The calculated counting efficiency of ^{125}Sb as a function of the free parameter is therefore, a sum of the calculated efficiencies for each of the eight beta decay transitions.

The calculation of the theoretical counting efficiency can be yet more complex when numerous beta- and gamma transitions are part of the radionuclide decay scheme. The standardization of $^{110\text{m}}\text{Ag}$, described by García-Toraño et al. (2000), is an interesting example. It decays to ^{110}Cd by β emission (98.65%) and isomeric de-excitation by γ emission (1.35%) to ^{110}Ag . The decay scheme comprises more than 12 β branches and 50 gamma rays. García-Toraño et al. (2000) used the CIEMAT/NIST method to

standardize samples of $^{110\text{m}}\text{Ag}$, which required the calculation of the Fermi spectra of all β branches, as well as the Compton spectra produced by the γ -ray interactions with the scintillator. A total of 128 decay pathways are possible, and the researchers calculated their probabilities and counting efficiencies to obtain the overall counting efficiency. The expression used for the calculation of the theoretical counting efficiency, in this case, was that described by García-Toraño et al. (1991) for a radionuclide that undergoes β decay followed by a cascade of n γ transitions

$$\varepsilon = \int_0^{E_\beta} \int_0^{E_{\gamma 1}} \cdots \int_0^{E_{\gamma n}} N(E) S_1(E_1) \cdots S_n(E_n) \times \left\{ 1 - \exp \left[\frac{-E_\beta Q(E_\beta) - \sum_{i=1}^n E_{\gamma i} Q(E_{\gamma i})}{2\lambda} \right] \right\}^2 dE dE_1 \cdots dE_n \quad (6.98)$$

where $N(E)$ and $S_i(E)$ are the β spectrum and Compton spectrum of a given γ transition respectively, $Q(E)$ is the ionization quenching factor, λ is the free parameter or figure of merit, and E_β , $E_{\gamma 1}$, ... $E_{\gamma n}$ are the maximum energies of the β and the energies of the γ transitions, respectively. García-Toraño et al. (2000) factorized the integral expressions of Eq. (6.98) so that single integrals could be solved and the results combined to yield the complete counting efficiency.

Computer programs or codes have been developed for the rapid computation of counting efficiency as a function of the figure of merit (i.e., free parameter) as described by Grau Malonda (1995, 1999) and Grau Malonda et al. (1987). The computer program BETA (García-Toraño and Grau Malonda, 1985), BETA3 (Grau Malonda, 1999), EFFY (García-Toraño and Grau Malonda, 1981, 1985), and PTB code (Physikalisch-Technische Bundesanstalt) code, which is a modified EFFY4 code (Kossert and Schrader, 2004) have been written for computations involving pure beta (negatron or positron) emitters, and the programs EFFY2, EFFY4 (García-Toraño and Grau Malonda, 1981, 1985 and Kossert, 2003), CN2001A (Günther, 2001 and Zimmerman et al., 2002), CN2003 (software available via the Laboratoire National Henri Becquerel, http://www.nucleide.org/ICRM_LSC_WG/icrmsoftware.htm, accessed October 16, 2018) and CN2005 (Günther, 2002a, 2002b), and MICELLE2 (Kossert and Grau Carles, 2010; Altizoglou and Rožkov, A., 2016) are available for the computation of counting efficiency as a function of free parameter for complex-decay beta-emitters, and CN2004 code for a positron-emitter (Cessna et al., 2008) and for series of beta and alpha decays Cessna and Zimmerman (2010). The programs calculate the beta spectra using the

theory of radioactive beta decay, taking into account the shape factors (e.g., Grau Carles, 1995, 2005; Grau Carles and Kossert, 2006, 2007; Grau Carles et al., 2008; and Kossert et al., 2011a). An updated MICELLE2 code, reported by Kossert and Grau Carles (2010) cited further on in this chapter and the EMI2 (Grau Malonda, 1999) and EMI2X computer programs (Broda et al., 2012) were prepared to facilitate the computation of counting efficiencies of radionuclides with complex beta-decay schemes, such as those occurring in radionuclides decaying by electron capture. The total detection probability is obtained by dividing the spectrum into bands, calculating the partial detection probabilities of each of them, and summing. The average and mean energies in the spectra are also calculated. Because of the different decay processes involved, special programs have been written to compute the counting efficiency as a function of free parameter such as EFYGA for X-ray and gamma-emitters (García-Toraño and Grau Malonda, 1987), EBEGA for beta-gamma-emitters (García-Toraño et al., 1988), and VIASKL (Los Arcos et al., 1987) and VIAS1 (Grau Malonda, 1999) for K-L shell electron-capture nuclides, and EMI (Grau Carles et al., 1994b) and EMI2 (Grau Malonda et al., 1999) for electron capture-gamma and isomeric transition nuclides, and EMIS (Grau Malonda, 1999) for radionuclides decaying by electron capture, electron capture coincident with a gamma transition, and pure isomeric transition, and ADDI (Grau Malonda, 1999) computes the counting efficiency of a radionuclide decaying by electron capture and positron emission. An updated program, EMILIA (Grau Carles, 2006a) is applied to counting efficiency calculations for electron-capture and capture-gamma emitting nuclides. A paper by Los Arcos et al. (1991) provides a detailed treatment of the method applied to multigamma electron-capture radionuclides. The computer programs are available from CIEMAT, Avda. Complutense 22, 28040 Madrid, Spain. Also, the program CIENIST99 written in Visual Basic 5 reported by Günther (2000) combines the CIEMAT/NIST codes BETA, EBEGA, and EMI to accommodate multi-beta/multi-gamma transitions.

The CIEMAT/NIST procedure integrates theoretical calculations with experimental measurements. The free parameter (figure of merit) is an essential component in the theoretical calculation of the counting efficiency, while the quench indicating parameter (QIP) of a particular liquid scintillation analyzer (e.g., tSIE, SQP(E), or H#) is required for the experimental aspect of this method. However, as explained by Grau Malonda and García-Toraño (1982a,b), the figure of merit cannot be obtained directly from experiment and the quenching parameter is not theoretically computable. Therefore, the method makes use of a plot that relates the figure of merit (free parameter) with the quench-indicating parameter. Such a plot is obtained by integrating

an experimental quench correction curve of a primary standard, such as ^3H (i.e., experimental counting efficiency of ^3H vs. a QIP), with a theoretically computed curve of counting efficiency versus figure of merit. The term figure of merit may be abbreviated in the scientific literature as λ , M , or FOM.

Tritium is one of the most suitable radionuclides to use as a standard for this method when the analysis of beta-emitters is required. It is readily available as an absolute standard as tritiated water or in organic form, it has a relatively long half-life and, as noted by Coursey et al. (1998), it provides for more sensitive extrapolations to the low-energy portions of the beta-particle spectra than higher-energy standards. Radioactive standards of tritiated water disseminated by the Laboratoire Primaire des Ionizants (LPRI), France, and the National Institute of Standards and Technology (NIST), USA, were intercompared by Zimmerman and Collé (1997a) and demonstrated an apparent mean disagreement between standards of <0.4% on a relative basis. As a standard for the CIEMAT/NIST method, ^3H has the advantage that any uncertainties on the efficiency curve of this radionuclide are reduced for the efficiency calculations of the more energetic β -emitters. See Grau Malonda and García-Toraño (1982a,b) and Grau Malonda (1995, 1999) for calculations demonstrating the uncertainty propagations for tritium.

The objective is to obtain a counting efficiency quench correction curve for any radionuclide, which may decay by β -emission, β/γ with X-ray and γ -photon emissions, EC decay, and isomeric transition. The counting efficiency quench correction curve is then used to determine the absolute activity (DPM) of a radionuclide sample under investigation from its experimental quench indicating parameter.

A most concise and comprehensive explanation of the principles, upon which the CIEMAT/NIST method is based, is provided by Kulkarni et al. (2011a,b) in the following excerpt with the writer's notes in parenthesis (reprinted with permission from Elsevier © 2011):

The CIEMAT/NIST method involves the theoretical calculation of detection efficiency of a sample as a function of free parameter, the Figure of Merit (FOM). FOM cannot be measured experimentally and the quench level cannot be calculated theoretically, hence the relationship between FOM and quench indicating parameter is obtained by counting a set of ^3H quench standards. If the sample is prepared in the same scintillator, with same composition as that of the ^3H quench standards, then the relationship between FOM and quench indicating parameter, established using the ^3H nuclide, holds good for any other radioactive sample for that particular liquid scintillation counter. An advantage of using ^3H as a tracer is that the uncertainty of ^3H activity has a small effect on the uncertainty of the

measured sample activity (Grau Malonda and García-Toraño, 1982a). This is due to the fact that ^3H has (emits) low energy beta particles and (as a consequence) is affected the most due to quenching. This means a slight variation in quenching leads to a large variation in the measured efficiency and hence the FOM. In (the) case of higher energy beta-emitters, the variation of efficiency with quenching is less. Thus, a large variation in the tritium efficiency leads to a very small variation in the sample efficiency and hence less uncertainty.

2. Procedure

The procedure for obtaining the counting efficiency quench correction curve for a nuclide under investigation with ^3H as the standard is outlined next. The sequence of steps in the procedure is illustrated in Fig. 6.77, and the curves established as a result of each step are illustrated in Fig. 6.78:

- A set of ^3H quenched standards is counted in the liquid scintillation analyzer and a quench correction curve of tritium counting efficiency versus the quench-indicating parameter is plotted. See curve (A) of Fig. 6.78.
- The theoretical counting efficiency of ^3H (ϵ_T) as a function of figure of merit is computed. See curve (B) of Fig. 6.78.

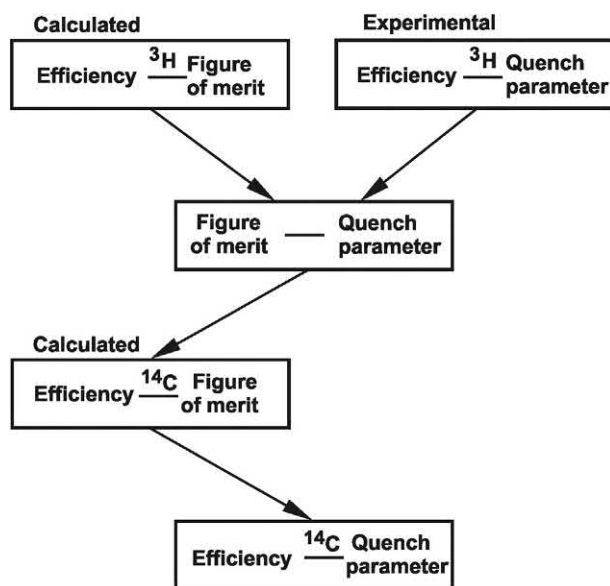

FIGURE 6.77 Outline of the CIEMAT/NIST ^3H efficiency tracing method of radionuclide standardization. The diagram illustrates the sequence of calculated and experimental relationships, which are defined to yield the quench correction curve of any radionuclide under investigation. Tritium is the standard (or tracer nuclide) in all cases, while ^{14}C , illustrated here as an example, is the radionuclide under investigation. From Grau Malonda and García-Toraño (1982a), reprinted with permission from Elsevier ©1982.

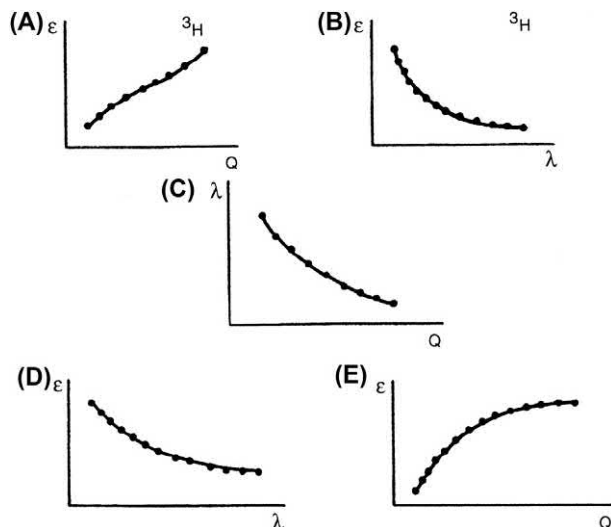

FIGURE 6.78 Calculated and experimental calibration curves obtained in the radionuclide standardization method known as the CIEMAT/NIST ^3H efficiency tracing method. The curves are described in the sequence by which they are obtained as follows: (A) experimental quench correction curve of ^3H counting efficiency (ϵ_T) versus quench indicating parameter (Q); (B) computed ^3H counting efficiency (ϵ_T) versus figure of merit or free parameter (λ); (C) "universal" curve of figure of merit (free parameter, λ) versus quench indicating parameter (Q) derived from the above two relationships; (D) computed curve of the counting efficiency of the nuclide under investigation (ϵ_{nuc} , e.g., ^{14}C) versus the figure of merit or free parameter (λ); and (E) quench correction curve of counting efficiency of the nuclide under investigation (ϵ_{nuc} , e.g., ^{14}C) versus the instrumental quench indicating parameter (Q) derived from curves (C) and (D). From Grau Malonda (1995, 1999), reprinted with permission from CIEMAT © 1995–99.

- From the preceding two relationships, a curve of the figure of merit as a function of the quench indicating parameter is obtained. Although these two relationships are determined from ^3H standards, the figure of merit as a function of quench indicating parameter is independent of any radionuclide. It is a "universal" curve, which may be applied to any radionuclide, that undergoes beta decay. The curve is suitable only for the particular liquid scintillation analyzer and scintillator used. See curve (C) of Fig. 6.78.
- The theoretical counting efficiency of the nuclide under investigation (ϵ_{nuc}) as a function of figure of merit is calculated. See curve (D) of Fig. 6.78.
- Consequently, the relationship between the counting efficiency of the nuclide under investigation (ϵ_{nuc}) and the quench indicating parameter can be obtained. This plot is obtained from the two preceding relationships, that of the universal curve of figure of merit versus the quench indicating parameter and the computed curve of ϵ_{nuc} versus figure of merit. See curve (E) of Fig. 6.78.
- The final curve obtained in step e can be used to determine the counting efficiencies of experimental samples. The experimental sample of the nuclide under

investigation is counted and the count rate (CPM) and quench indicating parameter are recorded. From the quench indicating parameter and the quench correction curve of ϵ_{nuc} versus QIP [Curve (E) of Fig. 6.78], the counting efficiency of the experimental sample ϵ_{nuc} is obtained.

- g. The activity A in units of disintegrations per minute (DPM) of the nuclide under investigation is then calculated as

$$A = \frac{\text{CPM}}{\epsilon_{\text{nuc}}} \quad (6.99)$$

The computer calculations of counting efficiency as a function of figure of merit (M) were reported by Grau Malonda et al. (1985) for 35 pure β -emitting radionuclides. These fitted data of counting efficiency as a function of figure of merit are reported as polynomial coefficients to the fifth degree according the equation

$$\ln \epsilon = A_0 + A_1 \ln M + A_2 (\ln M)^2 + \dots \quad (6.100)$$

The coefficients are listed in Table 6.8. The computer programs for calculating these coefficients and those of many other radionuclides are described in the publications cited in the previous section under Theory and Principles (^3H as the Tracer), and the entire programs are available from Grau Malonda (CIEMAT, Avda. Complutense 22, 28,040 Madrid, Spain) or Grau Malonda (1999). The figure of merit of the standard ^3H is obtained from the relationship of (ϵ_T) versus M . The good fit for these data is reported by Grau Malonda et al. (1985) according to the following fifth-degree polynomial:

$$\ln M = B_0 + B_1 (\ln \epsilon) + B_2 (\ln \epsilon)^2 + \dots, \quad (6.101)$$

where the values of B_i for ^3H are reported to be $B_0 = 3.11669$, $B_1 = -0.585619$, $B_2 = 0.137378$, $B_3 = -0.148844$, $B_4 = 0.0540364$, and $B_5 = -0.00705037$. Finally, the quench curve of ϵ_{nuc} versus a QIP for 34 of the radionuclides listed in Table 6.8 can be obtained from the experimental quench correction curve for ^3H (i.e., ϵ_T vs. QIP) and the data obtained using Eqs. (6.101) and (6.102) and the respective polynomials.

3. Specific examples

An excellent example of the CIEMAT/NIST method using ^3H as the primary standard tracer nuclide can be taken from the work of Kulkarni et al. (2011a,b) in the liquid scintillation standardization of the radionuclide ^{131}I . A chronological outline of the procedure is provided as follows:

- a. The first step taken by Kulkarni et al. (2011a,b) was to count a set of ^3H standards, quenched with nitromethane, with a Packard Tri-Carb liquid scintillation

counter (now produced by PerkinElmer). The liquid scintillation counter is equipped with two photomultipliers operating in coincidence and contains a ^{133}Ba external standard providing a quench indicating parameter, known as tSIE, described previously in this chapter. The ^3H quenched standards each contained the same known activity (0.9985 ± 0.0035 KBq/g), and same scintillation cocktail with different amounts of quenching agent. From the count rates provided by the liquid scintillation analyzer and known activity of ^3H in each counting vial, Kulkarni et al. (2011a,b) were able to plot the relationship of ^3H counting efficiency (%E) as a function of the instrumental quench indicating parameter (tSIE) illustrated by curve (A) of Fig. 6.79. The reader may want to compare this curve (A) with the same curve in the previous Fig. 6.78, which was used by Grau Malonda (1995, 1999) to describe the basic principle of the technique.

- b. Kulkarni et al. (2011a,b) then proceeded to compute the theoretical ^3H counting efficiency using the computer code CN2003 reported by Günther (2002a) and available from the Laboratoire National Henri Bequerel (http://www.nucleide.org/ICRM_LSC_WG/icrmssoftware.htm accessed October 16, 2018). The computed results provided the data for the plotting of the relationship of computed ^3H counting efficiency versus figure of merit (FOM), also abbreviated as λ or M (See curve B of Fig. 6.79 and compare that to curve B of Fig. 6.78).
- c. From curves A and B, Kulkarni et al. (2011a,b) were able to construct the universal curve of figure of merit (FOM) versus the quench indicating parameter (tSIE) as illustrated by curve C of Fig. 6.79. This may be compared to curve C of Fig. 6.78 in the example provided by Grau Malonda (1995, 1999).
- d. The subsequent relationship of the theoretical/computed ^{131}I counting efficiency as a function of figure of merit (FOM) was determined using the computer program CN2003. This is illustrated by curve D of Fig. 6.79. See also the same curve D of Fig. 6.78 provided by Grau Malonda (1996, 1999) as an example in his explanation of the method.
- e. From the relationships depicted in curves C and D of Fig. 6.79, Kulkarni et al. (2011a,b) were able to plot finally the relationship of the % counting efficiency of ^{131}I versus the instrumental quench indicating parameter (tSIE) illustrated by curve E of Fig. 6.79. This final relationship of ^{131}I counting efficiency was then used to determine the absolute activity or disintegration rate of samples of ^{131}I in terms of disintegrations per minute (DPM) from the instrumental measurements of the sample count rate in counts per minute (CPM) and the measured quench indicating parameter (tSIE). For example, if the liquid scintillation analyzer measured

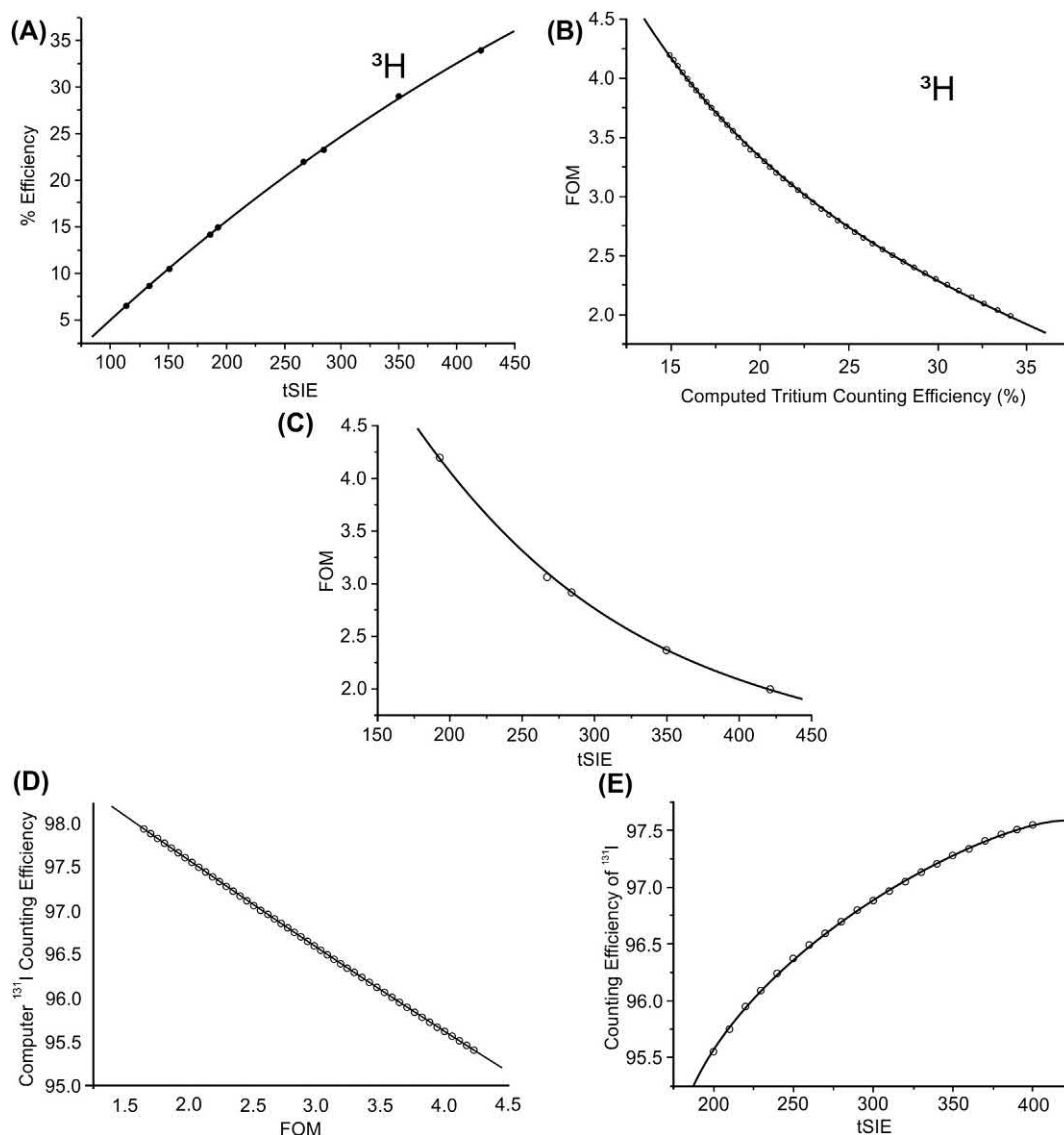

FIGURE 6.79 Set of curves/relationships established for the standardization of ^{131}I by the CIEMAT/NIST ^3H efficiency tracing technique yielding ^{131}I activity concentration measurements with a combined relative standard uncertainty of only 0.35% at a coverage factor $k = 1$. To facilitate the narrative of this example, the writer had arranged the curves to correspond to the sequence of curves of Grau Malonda illustrated in the previous Fig. 6.78. The sequence of curves are as follows: (A) Experimentally determined quench correction curve of ^3H efficiency versus quench indicating parameter (tSIE), (B) curve of figure of merit (FOM) versus theoretically computed ^3H efficiency, (C) universal curve of figure of merit versus tSIE from the previous two curves, (D) computed efficiency of ^{131}I (%) versus figure of merit, and (E) counting efficiency of ^{131}I (%) versus quench indicating parameter (tSIE) from the universal curve C and the computed curve (D) From Kulkarni et al. (2011a,b) reprinted with permission from Elsevier © 2011.

a tSIE of 325 of an unknown sample of ^{131}I , the % counting efficiency of 97.13 may be extracted from the relationship depicted in curve e of Fig. 6.79. The measured % counting efficiency (%E = 97.13%) expressed as a decimal ($E = 0.9713$) would then be used to calculate the disintegration rate (DPM) of the sample from its instrumentally measured count rate (CPM) according to the relation $\text{DPM} = \text{CPM}/E$.

The relationships established for this standardization of ^{131}I , depicted by curves A through E of Fig. 6.79, can

apply only to the specific liquid scintillation analyzer, cocktail formula, cocktail volume, and counting vials used. If another liquid scintillation analyzer (LSA) is used, even another LSA of the same make and model, the relationships described by curves A through E of Fig. 6.79, would need to be redetermined. Cassette (2016) describes a software package entitled QUENCH, which is freely available for the determination of quenching curves. The computer program provides the best fitting function to experimental data for curves with uncertainties in terms of

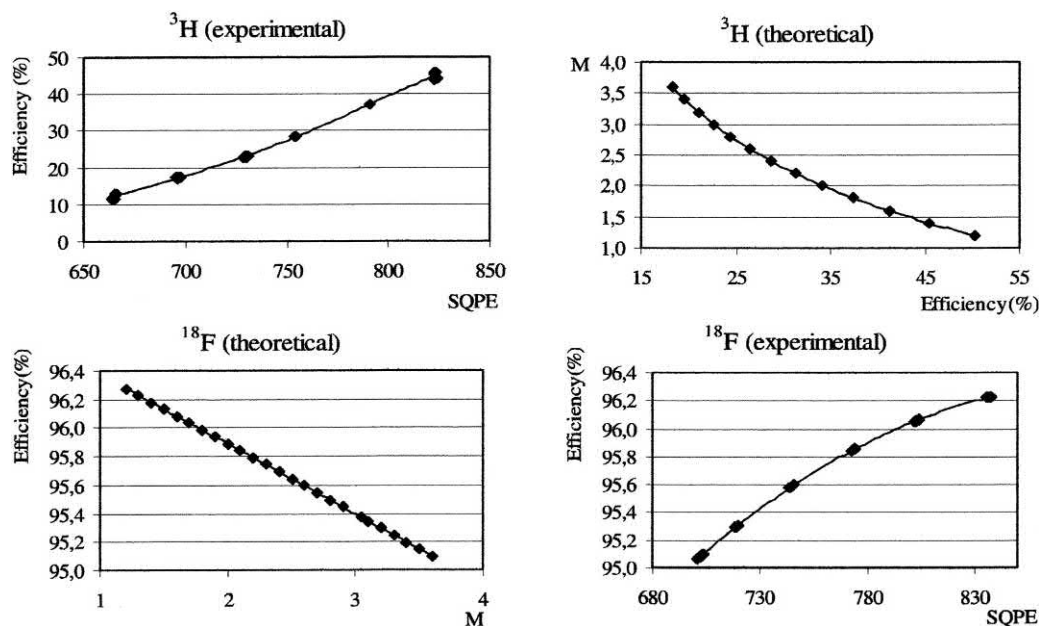

FIGURE 6.80 CIEMAT/NIST method applied to the standardization of ^{18}F . From Capogni et al. (2006), reprinted with permission © 2006 IOP Publishing Ltd.

the variables efficiency and quenching. The program provides the user with calculated detection and uncertainty with respect to a measured quench indicating parameter. The QUENCH program and user guide are available on the website of the Laboratoire National Henri Becquerel (LNHB), http://www.lnhb.fr/icrm_lsc_software/, (accessed February 9, 2018).

For the standardization of ^{131}I , Kulkarni et al. (2011a,b) were able to demonstrate that the CIEMAT/NIST method could be used to determine the ^{131}I activities with a combined relative standard uncertainty of 0.35% at a coverage factor of $k = 1$ after summing all sources of uncertainty.

Another illustrative example can be taken from the work of Capogni et al. (2006) on the standardization of [^{18}F]fluorodeoxyglucose, a radiopharmaceutical used in positron emission tomography (PET). The procedure used by Capogni et al. (2006) was the following:

- The counting efficiency of the tracer nuclide, ^3H , as a function of the quench indicating parameter, SQP(E), was determined experimentally with a PerkinElmer “Wallac 1414 WinSpectral” liquid scintillation counter using a set of tritium standards at various quench levels. The plot of % detection efficiency of the tracer nuclide versus SQP(E), i.e., ε_{T} versus SQP(E) is illustrated in Fig. 6.80 [with the heading ^3H (experimental)].
- The counting efficiency of the tracer nuclide (^3H) is calculated as a function of the free parameter (M), defined as the effective energy necessary to create one photoelectron at the photocathode. For this calculation, Capogni et al. (2006) used the CN2001 code reported

by Günther (2002a). The plot of M versus % detection efficiency of the tracer nuclide, i.e., M versus ε_{T} , is illustrated in Fig. 6.80 [with the heading ^3H (theoretical)].

- The independent nuclide relationship between the free parameter (M) and the quench indicating parameter SQP(E) was then derived from the functions previously determined in steps (1) and (2), that is, ε_{T} versus SQP(E) and M versus ε_{T} . This relationship is not illustrated as a plot in Fig. 6.80, but it would be a plot analogous to curves C of Figs. 6.78 and 6.79.
- The counting efficiency of the nuclide of interest, ε_{nuc} , (in this case ^{18}F) as a function of the free parameter (M) was calculated using the CN2001 code. The plot of % detection efficiency of the nuclide of interest (^{18}F) versus the calculated free parameter (M), i.e., ε_{nuc} versus M , is illustrated in Fig. 6.80 [with the heading ^{18}F (theoretical)].
- Finally, the counting efficiency of the nuclide of interest (^{18}F) as a function of the quench indicating parameter [SQP(E)], which is the curve illustrated in Fig. 6.80 [with the heading ^{18}F (experimental)], is obtained from the calculated counting efficiency of ε_{nuc} versus M of the previous step (d) and the derived function or relationship between the free parameter (M) and the quench indicating parameter [SQP(E)], determined in step (c).
- The count rate (CPM) of a sample of the nuclide of interest (^{18}F) and its quench indicating parameter [(SQP(E))] are measured by the liquid scintillation counter. The detection efficiency of the sample is then

obtained directly from the derived curve illustrated in Fig. 6.80, labeled ^{18}F (experimental). The activity of the nuclide of interest A_{nuc} in DPM is then calculated from the sample count rate and its detection efficiency according to the basic relationship $A_{\text{nuc}} = \text{CPM}/\epsilon_{\text{nuc}}$. In the case of ^{18}F and other short-lived nuclides, correction for decay during counting is required.

The CIEMAT/NIST efficiency tracing with ^3H as the tracer nuclide has become a very popular method for radionuclide standardization, as no special equipment is required. A common modern liquid scintillation analyzer and personal computer is all that is needed. The principal advantage of the CIEMAT/NIST efficiency tracing method is that only standards of ^3H are required, that is, no standards of the nuclide under investigation are needed. This is particularly relevant when the activities of short-lived nuclides must be determined very accurately and on-site, such as those utilized in nuclear medicine. Also, the calculated uncertainties reported in the activity analysis of a broad range of radionuclides are low. Table 6.9 lists some examples of radionuclides in order of increasing mass number reported in the literature as standardized by the CIEMAT/NIST method with the calculated standard uncertainties of the determinations expressed as a percent. The computer codes used for the calculations of the detection efficiencies against the figure of merit can be obtained from the references cited in the table. The radionuclides and references cited in Table 6.9 are not exhaustive. They serve only as examples of the broad spectrum of beta-decay radionuclides that can be standardized by this technique. See also the chapter entitled Radionuclide Standardization by Agustín Grau Malonda (Chapter 7 of Volume 2) for more additional information on radionuclides standardized by the CIEMAT/NIST method.

4. Sample, cocktail, and spectrometer stability

Liquid scintillation cocktail volume can have a significant effect on the count rate of weak β -emitters, such as ^{63}Ni ($E_{\text{max}} = 67 \text{ keV}$). A study by Zimmerman and Collé (1997b) demonstrated that a 7% variation in the liquid scintillation counting efficiency of ^{63}Ni can be observed over the scintillation cocktail volume range of 1–20 mL. However, they demonstrate that the CIEMAT/NIST method is able nevertheless to trace the observed ^{63}Ni activity to about 0.1%. To assure precise standardizations when employing the CIEMAT/NIST efficiency tracing method some researchers will centrifuge the liquid scintillation counting vial to assure that no significant amount of nuclide and cocktail remain adhered to the inner surface of the counting vial cap (Kulkarni et al., 2011a,b; Kossert et al., 2012; Kossert and Nähle, 2014; Taracón et al., 2015). Also, to reduce error and uncertainty, a common

practice is the gravimetric dispensing of accurately weighed aliquots of radionuclide solutions with a pycnometer (Kulkarni et al., 2011a,b; Van Wyngaardt et al., 2014; Altitzoglou and Rožkov, 2016; Bergeron et al., 2016) or a very sensitive analytical balance (e.g., Mettler balance) traceable to a national mass balance (Kossert et al., 2012; Kossert et al., 2017a,b).

The physical and chemical stability of samples in scintillation cocktail is a priority. Terlikowska et al. (1998) identified the cause of instability of samples which include (1) degradation of the scintillator or cocktail, (2) adsorption of the nuclide on the walls of the counting vial, (3) settlement of the aqueous phase of the nuclide source, (4) change in the physical characteristics (e.g., size) of the aqueous micelles in cocktail mixtures, and (5) evolution of quenching in the cocktail due to a chemical change in its composition (e.g., an increase of dissolved oxygen in the cocktail with time). A quench indicating parameter measured with an external radiation source may not provide any evidence of a problem in the cases of the above instabilities 2 and 4. Radionuclide samples may be counted repeatedly over a period of days to test for stability.

Bergeron et al. (2016) describe both reversible and irreversible mechanisms of cocktail instability. They provide examples, such as a settling or phase separation processes within the cocktail, which could account for a short-term reversible instability or, on the other hand, the absorption of radionuclide on the vial walls could explain the longer-term irreversible instabilities. Consequently, the stability of cocktails must be studied thoroughly for each nuclide standardized (Fitzgerald et al., 2014; Keightley et al., 2015; Bergeron et al., 2016). It is recommended also that standardizations of any particular nuclide be carried out in accord with previously tested and recommended cocktails and procedures cited in the literature.

Dark adaptation of quenched standards and samples in liquid scintillation counting vials within the stabilized temperature of the liquid scintillation analyzer is also recommended. For the standardization of radionuclides, researchers will leave sample counting vials within the counter for periods of up to 12 h to provide time for the decay of possible luminescence that can arise from laboratory room lighting (Fitzgerald et al., 2014; Altitzoglou and Rožkov, 2016; Jiang et al., 2017). Fitzgerald et al. (2014) prepared samples for counting under incandescent light rather than fluorescent lighting to reduce possible luminescence and the time needed for dark adaption.

Stable nuclide carrier is used in liquid scintillation radionuclide standardization to avoid error that might occur due to adsorption of radionuclide on the walls of counting vials. For example, the following carriers have been added to nuclide samples for this purpose: 0.25 mL of Sr carrier solution containing 4 mg Sr/g in 1 mol/L HCl in the standardization of ^{89}Sr (Coursey et al. 1998); vials previously

saturated with a carrier solution containing 100 $\mu\text{g/g}$ of NiCl_2 in 0.1 M HCl in the standardization of ^{63}Ni (Terlikowska et al., 1998); 97 μg of inactive $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ per gram of solution in the standardization of ^{59}Fe (Kossert and Nähle, 2014); carrier containing approximately 0.06 g of LuCl_3 per mL of 1 mol/L HCl in the standardization of ^{177}Lu solution (Zimmerman et al., 2001; Capogni et al., 2012; Kossert et al., 2012); 0.05 mg/g of NaI, 0.02 mg/g of $\text{Na}_2\text{S}_2\text{O}_3$ and 0.02 mg/g of LiOH in the standardization of ^{131}I (Kulkarni et al., 2011a,b); 120 mg $\text{NiCl}_2 \cdot \text{H}_2\text{O}$ per liter of 0.1M HCl in the standardization of ^{63}Ni (Kossert and Mougeout, 2015); 0.5 mg of stable samarium, europium, and terbium carriers in the standardization of ^{161}Tb (Jiang et al., 2017); and 50 μg of CoCl_2 per g of solution in the standardization of ^{60}Co (Kossert et al., 2017a,b).

Rodríguez Barquero and Los Arcos (2004) carried out a thorough long-term study that monitored the stability of samples and drift in electronic components of the spectrometer over time intervals that extended to up to 4 years. The tests were carried out with low-energy beta-emitters, namely, ^3H , ^{14}C , and ^{63}Ni where detection efficiency could be more susceptible to disturbing changes in sample and cocktail stability or spectrometer response. Their findings were that the CIEMAT/NIST method can compensate for count losses and quench parameter compensation values provided the experimental quench curve of the tracer nuclide, *i.e.*, ϵ_T versus QIP, is prepared close to the time of nuclide measurements. If this requirement is not met, significant discrepancies of up to 5.6% for ^3H , 1.5% for ^{63}Ni , and 0.35% for ^{14}C can be obtained for a 1-year time difference.

5. Cross-efficiency curves

In the preceding treatment on the theory and experimental procedure involved in the CIEMAT/NIST method, it was established that the counting efficiency as a function of the ‘figure of merit’ (M) or ‘free parameter’ (λ) is found for both the standard (tracer) nuclide (ϵ_T) and the radionuclide under investigation (ϵ_{nuc}). Under such circumstances, as noted by Grau Malonda et al. (1985), the ratio of the counting efficiencies ($\epsilon_T/\epsilon_{\text{nuc}}$) is also known as a function of M . Consequently, as the counting efficiency of the tracer nuclide (*e.g.*, ^3H) is known, the other can be computed. Tritium is considered, therefore, not only as a standard nuclide, but also a tracer nuclide, because the counting efficiency of the nuclide of interest is found against that of the reference nuclide, ^3H in this case. (Most often ^3H is used as the tracer for the standardization of beta-emitters, but we will see in the next Section that other tracer nuclides, such as ^{54}Mn , may be used for the standardization of radionuclides that decay by pure electron capture). With this in mind and in view of the curves illustrated in Figs. 6.78 and 6.79, we can see that the curves ϵ_T versus

QIP (obtained from a series of quenched standards of the tracer nuclide, *e.g.*, ^3H) and ϵ_{nuc} versus QIP (obtained from the relationships of ϵ_T vs. QIP, ϵ_T vs. M , M vs. QIP, and ϵ_{nuc} vs. M) can be integrated to provide a curve directly relating the counting efficiency of the nuclide under investigation (ϵ_{nuc}) and that of the tritium standard or tracer nuclide (ϵ_T), which is referred to as a cross-efficiency curve. Two such curves of ϵ_{nuc} versus ϵ_T are illustrated in Fig. 6.81. With this relationship, the counting efficiency of a given nuclide (ϵ_{nuc}) at a certain QIP could be determined from the counting efficiency of tracer nuclide (ϵ_T) at the same QIP.

In the example illustrated in Fig. 6.81, Kulkarni et al. (2017) determined the total activity of $^{68}\text{Ge}/^{68}\text{Ga}$ in equilibrium from their combined count rate and total efficiency, the latter of which is obtained by combining the two efficiencies from the cross-efficiency curves. They used a PerkinElmer (formerly Packard) liquid scintillation analyzer, which measures the tSIE as the quench indicating parameter (QIP) of the sample and ^3H standards. They calculated the counting efficiency of ^3H versus Figure of Merit (FOM), ^{68}Ga versus FOM, and ^{68}Ge versus FOM using the freeware program CN2003 from Günther (2002a). Germanium-68 decays by purely electron capture resulting in the emission of weak conversion and Auger electrons (See Table of Radioactive Isotopes, Appendix A in Volume 2), which accounts for its much lower liquid scintillation detection efficiencies compared to its daughter ^{68}Ga , which decays mostly via positron emission (90% probability) as well as electron capture (10% probability).

FIGURE 6.81 Cross-efficiency curves of the liquid scintillation detection efficiencies of ϵ_{nuc} versus ϵ_T obtained by the CIEMAT/NIST efficiency tracing method for the activity analysis of the parent-daughter radionuclides $^{68}\text{Ge}/^{68}\text{Ga}$. The detection efficiencies of the nuclides to be analyzed, namely, ^{68}Ge and ^{68}Ga , are plotted against the detection efficiency of the tracer nuclide ^3H . From Kulkarni et al. (2017) reprinted with permission from Elsevier © 2017.

To facilitate the application of the CIEMAT/NIST efficiency tracing method, Günther (1996) proposed the use of ‘universal’ cross-efficiency curves for the standardization of radionuclides that decay by β - or β - γ emission according to the following procedure:

- a. **Calculation of the efficiencies.** Calculating the efficiencies of radionuclides versus the corresponding tritium efficiency (i.e., cross-efficiency curve ϵ_{nuc} vs. ϵ_{T}) can be done in a national standards laboratory. The results should be parameterized as coefficients k_i of the polynomial in Eq. (6.102).

$$\epsilon_{\text{nuc}} = \sum_{i=0}^n k_i \epsilon_{\text{T}}^i \quad (6.102)$$

- b. **Verifying the results.** This step would best be done at one of the national standards laboratories, because they have a stock of standard solutions. An experimental comparison of the results with those obtained with other methods of radionuclide standardization would be necessary.
- c. **Laboratory procedure.** The user would determine the quench indicating parameter Q of the radionuclide sample automatically with each single measurement, calculating the corresponding tritium efficiency ϵ_{T} of the individual measurement using his/her own tritium quench curve (ϵ_{T} vs. Q), and calculating the efficiency ϵ_{nuc} with this tritium efficiency (ϵ_{T}) and the coefficients k_i of Eq. (6.102).

The procedure proposed by Günther (1996) is summarized in Fig. 6.82.

An example of a typical cross-efficiency curve (ϵ_{nuc} vs. ϵ_{T}) defined by polynomial coefficients k_i for the CIEMAT/NIST activity analysis of ^{161}Tb is illustrated in Fig. 6.83. With the single measurement of the instrumental quench indicating parameter (Q) of a radionuclide sample, the detection efficiency of the tritium tracer (ϵ_{T}) can be extracted from its quench correction curve (ϵ_{T} vs. Q). The value of ϵ_{T} is then used to determine the detection efficiency of the radionuclide sample ϵ_{nuc} according to Eq. (6.102) defining the best fit to the cross-efficiency curve ϵ_{nuc} versus ϵ_{T} .

Cassette and Tartès (2014) warn against considering the cross-efficiency curves as ‘universal’. They demonstrated that cross-efficiency curves, particularly in the cases of ^{63}Ni and ^{55}Fe versus ^3H , are dependent on the scintillator, on the counter used, and on the nature of the quenching phenomenon (e.g., chemical or color quenching), and thus the cross-efficiency curves cannot be considered as ‘universal’. Following the testing of cross-efficiency curves prepared

FIGURE 6.82 The procedure is illustrated in three columns from left to right, namely, Sample Preparation, Sample Measurement, and CIEMAT/NIST Theory for the preparation of the cross-efficiency curve (ϵ_{nuc} vs. ϵ_{T}). The counting efficiency of the nuclide to be measured (ϵ_{nuc}) is obtained with the quench parameter (Q) of the measurement, the tritium quench curve (ϵ_{T} vs. Q), and the tabulated coefficients of a cross-efficiency curve of the nuclide (ϵ_{nuc} vs. ϵ_{T}). The LSCAL computer program facilitated the calculation of ϵ_{nuc} from the equation for a least-squares best fit of the cross-efficiency curve. From Günther (1996), reprinted with permission from Radiocarbon. University of Arizona © 1996 Arizona Board of Regents on behalf of the University of Arizona.

FIGURE 6.83 Cross-efficiency curve (ϵ_{nuc} vs. ϵ_{T}) providing the detection efficiency of the radionuclide ^{161}Tb as a function of the detection efficiency of the ^3H tracer nuclide calculated by the computer program CN2004. The equation for the best fit of the cross-efficiency curve with polynomial coefficients k_i , illustrated above the curve, facilitates the computation of the value of ϵ_{nuc} (i.e., detection efficiency of ^{161}Tb) as a function of ϵ_{T} (detection efficiency of ^3H). From Jiang et al. (2018), in press reprinted with permission from Elsevier © 2018.

with three commercial liquid scintillation counters (Models Guardian 1414, TriCarb 3170 and Quantulus 1220), three different liquid scintillation cocktails, and chemical- and color-quenched sources, Cassette and Tartès (2014) conclude the following:

- a. The quench curves are scintillator dependent, and the degree of this dependence depends on the radionuclide.

- b. The quench curves are counter dependent. Although this is obvious for different liquid scintillation counters that provide differing quench indicating parameters (Q) such as tSIE, H#, SQP(E), etc., but it also applies to counters that have the same type of external standard, which produce the same type of quench indicating parameter. For example, the values of the tSIE for a given sample from different TriCarb counters or SQP(E) from different Quantulus counters can differ.
- c. The quench curves are dependent on the type of quenching phenomena (e.g., chemical- or color-quenching). The degree of the difference is radionuclide dependent and particularly noteworthy for ^{63}Ni and ^{55}Fe quench curves.
- d. The quench curves are dependent on the volume of the source and nature of the counting vial (i.e., clear or diffusive).

To underscore the importance of the above variables when applying the CIEMAT/NIST standardization method, [Cassette and Tartès \(2014\)](#) underscore the need for good laboratory practice, whereby the liquid scintillation counter used for the calibration of a quench correction curve be used also for the nuclide measurements and maintaining the same counting vial, scintillation cocktail, and quenching conditions between calibration and measurement.

If the liquid scintillation counter is equipped with a self-normalization procedure, the repetition of the determination of the tritium quench correction curve need not be carried out except over extended intervals of time. Best results are obtained when the quenched standards of the tracer nuclide (^3H) are counted in a time span close to that of counting the nuclide of interest as reported by [Rodríguez Barquero and Los Arcos \(2004\)](#).

Further streamlining of the CIEMAT/NIST efficiency tracing standardization method is described by [Günther \(1998, 2000, 2002b\)](#). As described previously the methodology involves the calculated theoretical efficiency curve of the nuclide under investigation (ϵ_{nuc}) versus the theoretical efficiency curve of the tracer nuclide (ϵ_{T}). The procedure, as portrayed by [Günther \(1998, 2000\)](#), is reduced to the following steps, which are also depicted in [Fig. 6.84](#):

- a. The liquid scintillation analyzer is calibrated with a set of quenched standards of a tracer nuclide (usually ^3H) by producing an instrument-measured quench curve of counting efficiency, ϵ_{T} , versus a quench indicating parameter, Q , [e.g., SQP(E) or tSIE].
- b. The count rate (CPM) and quench indicating parameter, Q , are determined for a sample of the nuclide to be measured (i.e., a sample of the nuclide of which the counting efficiency and activity are unknown). From this measured value of the quench indicating parameter of the nuclide under investigation, a fictitious tracer

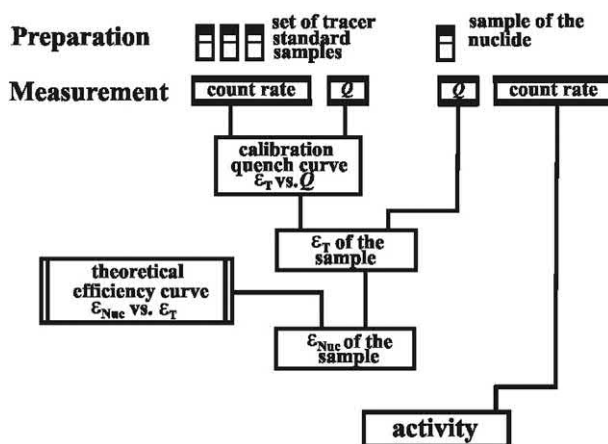

FIGURE 6.84 Principle of the CIEMAT/NIST method. Q is the quench indicating parameter measured, ϵ_{T} is efficiency of the tracer, ϵ_{Nuc} the efficiency of the nuclide to be measured. From [Günther \(1998\)](#), reprinted with permission from Elsevier © 1998.

efficiency for this individual measurement is obtained from the tracer calibration curve produced in step 1 (i.e., the value of ϵ_{T} from the calibration curve corresponding to the Q of the sample).

- c. The efficiency of the nuclide of the sample under measurement is taken from the calculated theoretical curve of efficiency of the nuclide under investigation (ϵ_{Nuc}) versus the theoretical efficiency curve of the tracer nuclide (ϵ_{T}).
- d. The activity of the nuclide is then calculated by dividing the sample count rate by its efficiency (i.e., $\text{Activity} = \text{count rate}/\epsilon_{\text{Nuc}}$).

The experimentally determined quench correction curve prepared with quenched standards of the tracer nuclide (e.g., ^3H) in step 1 can be useful for an extended period of time (several months or more) with modern liquid scintillation analyzers that are properly cared for in terms of normalization and calibration, and monitored frequently with automated instrument performance assessments (IPAs). The monitoring of instrument stability by regular automated IPAs is discussed further on in this chapter. However, the CIEMAT/NIST method depends highly on the fact that the tracer nuclide and the nuclide under investigation are measured in a cocktail that possesses the same physical and chemical characteristics. Thus, [Rodríguez Barquero and Los Arcos \(2004\)](#) demonstrate that best results are obtained when the quenched standards of the tracer nuclide are measured close in time to the measurement of the sample of the nuclide under investigation, as the physical and chemical characteristics of a sample in cocktail can change in time.

The theoretically calculated counting efficiencies of the nuclide under investigation and the tracer nuclide are carried out via computer programs (codes) already elaborated for specific nuclide decay schemes as previously described

in this chapter or available from databases containing the polynomial coefficients for the relationship of the theoretical calculated nuclide efficiency and the tracer efficiency described by the equation.

$$\varepsilon_{\text{Nuc}} = \sum_{i=0}^n k_i \varepsilon_{\text{T}}^i \quad (6.103)$$

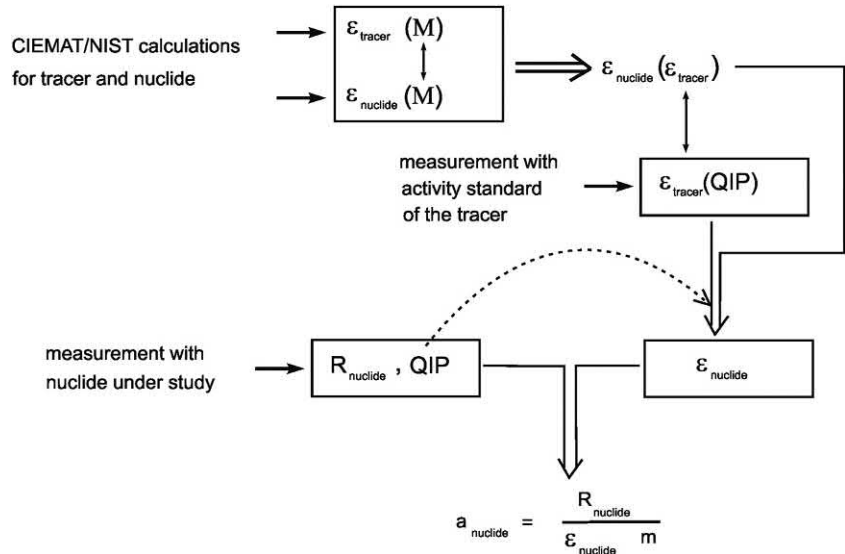

which is the general equation for the polynomial of the least-squares best fit for the relationship, as described previously (Eq. 6.102) with n number of coefficients. With the establishment of the above two curves or relationships described in Fig. 6.84 (i.e., ε_{T} vs., Q and ε_{Nuc} vs. ε_{T}), it becomes a simple matter to determine the counting efficiency of a sample (ε_{Nuc}) and thereby standardize a radionuclide sample simply from its count rate (CPM) and its quench-indicating parameter (Q).

Broda et al. (2007) provide an excellent and more detailed description of the CIEMAT/NIST method, which is illustrated in Fig. 6.85. The first step, as illustrated in the figure, is the theoretical calculations of the detection efficiency of the tracer nuclide as a function of the free parameter, M , [$\varepsilon_{\text{tracer}}(M)$, e.g., ^3H] and of the nuclide under investigation [$\varepsilon_{\text{nuclide}}(M)$] where $M = \lambda$ or FOM of Eq. (6.96). This leads to the establishment of the relationship between the two detection efficiencies, that is, the detection efficiency of the nuclide under investigation as a function of the detection efficiency of the tracer nuclide or $\varepsilon_{\text{nuclide}}(\varepsilon_{\text{tracer}})$, as illustrated in Figs. 6.81–6.84, which is also referred to as the ‘efficiency curve’. The next step, as illustrated in Fig. 6.85 of Broda et al. (2007), involves the counting of a set of quench standards of the tracer nuclide (e.g., ^3H). The quenched standards, as previously described in this chapter, are prepared with primary standard ^3H in a series of counting vials containing scintillation cocktail and

increasing amounts quenching agent (See Section V.D). The count rates (CPM) and quench indicating parameters (QIPs) of each vial are recorded. As the tracer nuclide is of a known activity (DPM), the detection efficiency of each vial is calculated (CPM/DPM), and the quench correction curve of the detection efficiency of the tracer nuclide as a function of the quench indicating parameter is obtained, i.e., $\varepsilon_{\text{tracer}}(\text{QIP})$ of Fig. 6.85. The next step is the preparation of a sample of the radionuclide under investigation for counting in liquid scintillation cocktail. The radionuclide sample in the liquid scintillation counting vial must possess the sample physical and chemical characteristics (i.e., same cocktail, cocktail volume, and chemical composition as the quench standards of the tracer nuclide). The count rate (CPM) of the sample and its’ quench indicating parameter (QIP) are measured. The value of the QIP is then used to determine the efficiency of the tracer nuclide (See curved arrow in Fig. 6.85) from the curve or function $\varepsilon_{\text{tracer}}(\text{QIP})$. With the corresponding tracer efficiency thus obtained, the corresponding nuclide efficiency ($\varepsilon_{\text{nuclide}}$) is obtained from the efficiency curve, $\varepsilon_{\text{nuclide}}(\varepsilon_{\text{tracer}})$. Finally, the efficiency of the nuclide under investigation, so determined, is used to convert its count rate (CPM), i.e., R_{nuclide} of Fig. 6.85, to the activity of the nuclide, according to the equation illustrated in Fig. 6.85, namely, $a_{\text{nuclide}} = R_{\text{nuclide}}/(\varepsilon_{\text{nuclide}} \cdot m)$, where m is the sample mass. The samples are generally added gravimetrically to the liquid scintillation cocktail. Consequently, including the sample mass m in the calculation of the sample activity will yield the sample activity concentration (e.g., DPM/g), which can be converted to units of Bq/g.

This approach has been tested by other researchers with excellent results using ^3H as the tracer nuclide. Günther (2002b) reports excellent agreement between the CIEMAT/

FIGURE 6.85 Illustration of the CIEMAT/NIST method: R denotes the measured count rate, M is the free parameter, QIP is the quench indicating parameter, ε is the counting efficiency, a_{nuclide} is the nuclide activity concentration, and m is the mass of the solution in an LSC sample. NIST and $4\pi\beta\text{-}\gamma$ standardization methods with the following deviations between the two methods expressed as a percent: ^{134}Cs (<0.3%), ^{153}Sm (<0.2%), ^{169}Er (<0.2%), ^{177}Lu (0.6%), and ^{188}Re (0.2–1.0%). It is a common practice for researchers to employ more than one liquid scintillation standardization method together with the CIEMAT/NIST method in the standardization of a radionuclide, such as the TDCR method or $4\pi\beta\text{-}\gamma$ coincidence counting technique. This further demonstrates the robustness of the methods used and reconfirms the standardization determinations.

6. ^{54}Mn as tracer nuclide

All of the previous treatments on the CIEMAT/NIST radionuclide standardization method dealt with the use of standard ^3H as the tracer nuclide. Standard tritium has proven to be the best tracer for the standardization of β - or β/γ -emitting nuclides, and it has been the standard of choice since the inception of this technique by Agustín Grau Malonda in 1978. However, for the standardization of the electron-capture decay nuclides ^{55}Fe and ^{65}Zn , Günther (1998) and Bergeron and Laureano-Pérez (2014) have demonstrated ^{54}Mn to be a more robust tracer. Iron-55 decays by pure electron capture and ^{65}Zn decays by electron capture with 98.6% intensity and the remaining 1.4% by positron emission. Günther (1998) demonstrated that the use of standard ^{54}Mn , which decays by pure electron capture, as the tracer nuclide provides radionuclide activities for ^{55}Fe with a total relative uncertainty of only 0.44% whereas the uncertainty when using tritium as the tracer was 1.67%. Likewise, the total uncertainty in the standardization of ^{65}Zn using ^{54}Mn as the tracer nuclide was only 0.44%, while the uncertainty when using ^3H as the tracer increased to 0.93%. The lower relative standard uncertainty of ^{54}Mn activity standards compared to ^3H standards attributes additional potential to ^{54}Mn as a tracer nuclide, which could even be considered as a promising tracer nuclide for the standardization of ^3H by the CIEMAT/NIST method (Kossert and Grau Carles, 2006). In addition, Kossert and Grau Carles (2010) demonstrated that the measurement of ^{55}Fe with ^{54}Mn as the tracer nuclide results in a smaller dependence of the kB factor in the model calculation of detection efficiencies. The role of the kB value in the computation of counting efficiencies is discussed further on in this chapter. Bergeron and Laureano-Pérez (2014) discovered that long-lived impurities, which can accumulate in ^{54}Mn , can yield unexpectedly high detection efficiencies. Therefore, they recommend the ^{54}Mn sources more than a few years old should be reevaluated for radionuclide impurities prior to use as a tracer.

Calculations of the detection efficiency by the CIEMAT/NIST method require comprehensive information on

the energy transferred to the scintillator, and good data on the photon absorption coefficients of X-rays emitted by electron-capture decaying nuclides is necessary. Cassette et al. (2006a,b) report new experimental data on X-ray photon absorption coefficients of liquid scintillators in the energy range of 5–12 keV, which could prove helpful in the standardization of EC nuclides, such as ^{55}Fe . The use of ^{54}Mn as a tracer nuclide for the measurement of nuclides decaying by electron capture is discussed further on in this chapter.

7. Ionization quenching and efficiency calculations (^3H or ^{54}Mn as the tracer)

The theoretical calculation of the counting efficiency of the nuclide under investigation and of the tracer nuclide (usually ^3H for β and β/γ -emitters or potentially ^{54}Mn for nuclides of low atomic number that decay by electron capture) is carried out using the basic equations Eq. (6.95) or 6.96 of Grau Malonda and coworkers (Grau Malonda, 1982b; Grau Malonda and García-Toraño, 1982a,b; Grau Malonda and Los Arcos, 1983; Grau Malonda et al., 1985), and variations of the equation depending on the decay scheme of the radionuclide under measurement (e.g., Eqs. 6.97 and 6.98). A key factor in the theoretical calculation is the computation of the ionization quench function $Q(E)$, which is included in specific subroutines of the computer codes used to calculate the theoretical detection efficiencies described previously in this chapter. The procedures used to compute the ionization quench function is described by several researchers including Grau Malonda (1999), Grau Malonda and Grau Carles (1999, 2000, 2008), Grau Carles and Grau Malonda (2001, 2006), and García and Grau Malonda (2002), Grau Carles et al. (2004), Kossert and Schrader (2004), Grau Carles et al. (2006), Zimmerman (2006), Grau Malonda et al. (2006), Grau Carles (2006a,b), Kossert and Grau Carles (2006, 2008, 2010), Broda et al. (2007, 2012), Bagán et al. (2008), Bignell et al. (2010a), Broda et al. (2012), Kossert and Nähle (2014), Kossert et al. (2011a,b, 2013, 2014, 2015, 2017a,b), van Wyngaardt et al. (2012, 2014), Tarancón et al. (2015) and Altitzoglou and Rožkov (2016).

Ionization quenching is defined and discussed in detail in Section IV of this chapter. In brief, as described by Bignell et al. (2010a), ionization quenching in scintillators is a reduction in the luminosity (photon intensity) associated with a high density of excited molecules caused by a large linear energy transfer (LET) to the scintillant. The high density of excited molecules results in a transfer of energy from one excited molecule to another resulting in superexcitation of a molecule and its ionization. Thus, this ionization, caused by the nuclear radiation as it travels through the scintillator solvent, results in a reduction in the amount of energy transferred from the charged particle to

the fluor molecules and a consequent reduction in the photon intensity emitted by the scintillation fluor. As described by [Grau Malonda \(1999\)](#), the fluorescence yield or number of photons $L(E)$ produced by an ionizing particle traveling through a liquid scintillator is a nonlinear function of the particle energy (E). The nonlinearity increases with the linear energy transfer (LET) or stopping power of the particle. Therefore, a low-energy electron or beta particle will cause higher ionization quenching than a higher-energy beta particle. Radionuclides decaying by electron capture undergo, as a consequence of the capture of an atomic electron by the nucleus, a cascade of atomic electron transitions resulting in the emission of X-rays, Auger electrons, and Coster-Kronig electrons. The Auger and Coster-Kronig electrons are of low energy (See Chapter 1, Volume 1) with relatively high LET, and the X-rays can produce Compton and photoelectrons, all of which have a high LET relative to the higher-energy beta particles emitted by most beta emitting radionuclides.

According to [Birks \(1964\)](#) the specific fluorescence or number of photons produced per particle path length of travel, dL/dx , is defined by

$$\frac{dL}{dx} = \frac{\eta_0 \frac{dE}{dx}}{1 + kB \frac{dE}{dx}} \quad (6.104)$$

where η_0 is the scintillation efficiency or number of fluorescence photons emitted per unit of absorbed energy, dE/dx is the radiation stopping power (i.e., stopping power of the scintillator for one beta particle of energy E) in units of MeV/cm or MeV cm²/g (See Chapter 1, Volume 1, [Section XIV](#) for the calculation of stopping power) and kB is the ionizing quench parameter or constant with units of cm/MeV or g/MeV cm².

In the absence of ionization quench the specific fluorescence would be defined as

$$\frac{dL}{dx} = \eta_0 \frac{dE}{dx} \quad (6.105)$$

and the term $[1 + kB(dE/dx)]^{-1}$ of [Eq. \(6.104\)](#) is the reduction in fluorescence due to ionization quenching. The formula usually used for the ionization quench function in the CIEMAT/NIST calculation of counting efficiency is the formula of [Birks \(1964\)](#).

$$Q(E) = \frac{1}{E} \int_0^{E_{\max}} \frac{dE}{1 + kB(dE/dx)} \quad (6.106)$$

According to [Grau Malonda and Grau Carles \(1999\)](#), the ionization quench function $Q(E)$ is determined by applying the Birks formula ([Eq. 6.106](#)) of which the stopping power (dE/dx) is approximated to a polynomial equation. Also, the ionization quench function is evaluated analytically whereby $Q(E)$ is expressed in terms of kB . An

empirical equation for $Q(E)$ is expressed by [Grau Malonda and Grau Carles \(1999\)](#) as a quotient of polynomial equations that are fitted for different kB values between 0.001 and 0.020 g/MeV cm². They also analyzed the influence of the tracer nuclide (i.e., ³H or ⁵⁴Mn) and demonstrated that ³H remains the recommended tracer for the analysis of nuclides that undergo beta decay, while ⁵⁴Mn provides a more robust standardization of certain nuclides that decay by electron capture and possess a low atomic number close to that of iron. Also, they note that the calculated formula for $Q(E)$ and kB values must be the same for the tracer nuclide and the radionuclide under measurement. Computer programs BETAKB and EMISKB are provided by [Grau Malonda \(1999\)](#) for the calculation of the theoretical counting efficiencies of radionuclides that undergo beta-decay or electron capture decay, respectively, with subroutines for the computation of the ionization quench function $Q(E)$ for a given Birks parameter kB (See also [Los Arcos and Ortiz, 1997](#)). [Günther \(1998\)](#) also demonstrated the improved accuracy of standardization of the electron-capture nuclides ⁵⁵Fe and ⁶⁵Zn when ⁵⁴Mn is used as the tracer. Radionuclide standardization procedures will include the determination and use of the optimum kB factor (i.e., ionization quench parameter) including reports by [Kossert and Schrader \(2004\)](#), [Broda et al. \(2012\)](#), [van Wyngaardt et al. \(2012, 2014\)](#), [Kossert and Nähle \(2014\)](#), [Altitzoglou and Rožkov \(2016\)](#), [Tarancón et al. \(2015\)](#), and [Kossert et al. \(2011a,b, 2012, 2014, 2015, 2017a,b\)](#).

8. Other factors affecting efficiency calculations

In a review of the CIEMAT/NIST and TDCR methods, [Grau Carles and Grau Malonda \(2001\)](#) presented concepts to improve the robustness of the radionuclide standardization methods. Currently, in all of the models, the counting efficiency is computed on the basis of the photoelectron output of the photomultiplier (PM) photocathode. Although the results of the model calculations agree well with the experimental results, they proposed that the correct calculated theoretical counting efficiency should be based on the final PM anode output rather than on the photocathode or any dynode outputs. As a result, modifications to the theoretical counting efficiency calculations and determinations of the optimum kB parameter were proposed ([Grau Carles and Grau Malonda, 2001](#), [García and Grau Malonda, 2002](#), and [Günther \(2002a\)](#)) and are currently implemented. In general, the Visual Basic CN2001 program has been useful for the calculation of theoretical counting efficiencies of the nuclide under measurement versus the efficiency of the ³H tracer for nuclides decaying by β , β/γ , EC, EC- γ , and for isomers and nuclides with mixed decay schemes. It is available from the Physikalisch-Technische Bundesanstalt (PTB),

Bundesallee 100, 38116 Braunschweig, Germany, and it is based on the CIEMAT programs EFFY (García Toráño and Grau Malonda, 1985), EMI (Grau Carles et al., 1994b), CEGA2 and KB (Los Arcos and Ortiz, 1997). Günther (2002a) summarized that pure beta-emitters present no problem with activities determined with uncertainties within 0.2% and 0.5%. The standardization of some nuclides decaying by isomeric transition (e.g., ^{93m}Nb) are determined with 100% efficiency). Beta/gamma-emitters are determined with as high precision as pure beta-emitters. The EC nuclides do present a problem with higher levels of uncertainty; however, better models such as those proposed by Grau Malonda and Grau Carles (2000), the EMI2 program of Grau Malonda et al. (1999), and the use of ^{54}Mn as a tracer for some EC nuclides were designed to reduce uncertainties in the standardization of electron-capture nuclides.

9. Radionuclides in decay chains

Computed detection efficiencies of radionuclides that undergo solely beta decay to stable nuclides are in the expected range between 0% and 100%, as illustrated in the efficiency curves among examples described earlier in this chapter. The liquid scintillation detection efficiencies of alpha emissions are generally very close to unity (i.e., 100%) due to the significant energy deposited by alpha particles in the scintillation cocktail. For example, in the computed detection efficiency of ^{223}Ra , Keightley et al. (2015) assigned a fixed efficiency of 0.998 ± 0.002 ($k = 1$) for the alpha emissions in the ^{223}Ra decay chain. There is approximately a 0.2% loss of alpha interactions with cocktail due to the wall effect as determined by Cassette (2001); although the wall effect has been estimated to have yet a lower significance in the detection of alpha events, as determined by Fitzgerald and Fourney (2010).

FIGURE 6.86 Radioactive decay chain from ^{227}Ac to stable ^{207}Pb . Within this chain is also the decay series of ^{223}Ra . From Kossert et al. (2015); reprinted with permission of Elsevier © 2015.

When alpha emissions are part of a decay chain including beta-decaying radionuclides in equilibrium, such as in the decay schemes of ^{223}Ra and ^{227}Ac , which proceed through a series of progeny comprising a chain of alpha- and beta-decaying radionuclides to the stable ^{207}Pb (See Fig. 6.86), alpha and beta transitions are included in the computer code computations of the CIEMAT/NIST method. The computed detection efficiencies of radionuclides, which decay through such radionuclide decay chains in equilibrium, will include a combination of the detection efficiency of each radionuclide in the decay chain. Thus, the combined or overall computed detection efficiency will exceed 100%, as illustrated in Figs. 6.86 and 6.87. The computation of these detection efficiencies will include, in addition to the unity assigned to the detection efficiency of alpha events and their branching intensities, the branching ratios and energies of beta and gamma transitions taken from nuclear decay data. The computer code used by Kossert et al. (2015) is the MICELLE2 code, which includes all beta and beta/gamma transitions in the decay chain of ^{227}Ac , and that used by Keightley et al. (2015) in the standardization of ^{223}Ra is the CN2004 code. The decay scheme of ^{223}Ra to stable ^{207}Pb , includes essentially the decay of four progeny via alpha emission, namely, ^{223}Ra

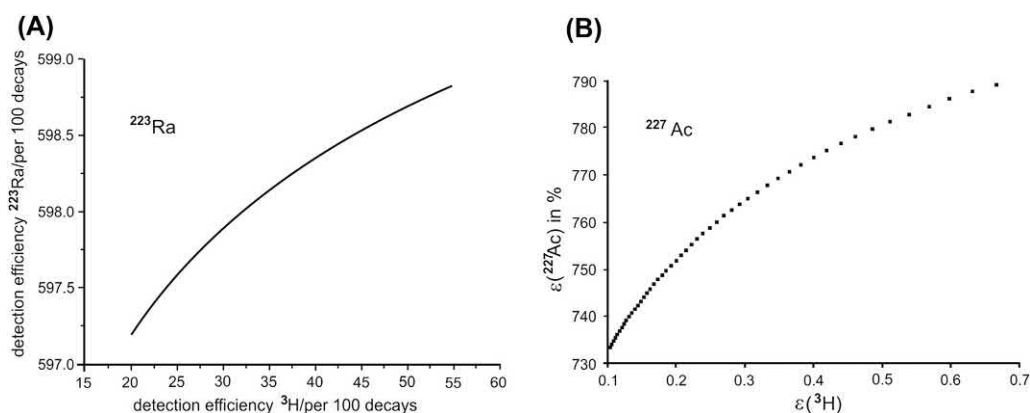

FIGURE 6.87 Cross efficiency curves (detection efficiency vs. ^3H standard tracer efficiency) obtained in the CIEMAT/NIST efficiency tracing standardization of (A) ^{223}Ra from Keightley et al. (2015) and (B) ^{227}Ac from Kossert et al. (2015). Reprinted with permission from Elsevier (c) 2015.

$\rightarrow {}^{219}\text{Rn} \rightarrow {}^{215}\text{Po} \rightarrow {}^{211}\text{Pb}$ and ${}^{211}\text{Bi} \rightarrow {}^{207}\text{Tl}$, and two progeny via beta emission, namely, ${}^{211}\text{Pb} \rightarrow {}^{211}\text{Bi}$ and ${}^{207}\text{Tl} \rightarrow {}^{207}\text{Pb}$, as illustrated in Fig. 6.86. Thus, the total computed detection efficiency, which includes the four alpha plus two beta transitions should not exceed 600%, as illustrated in Fig. 6.87A. In this case, the detection efficiency computations via the CN2004 computer code, which is an updated version of CN2001 (Keightley et al., 2015), included the four alpha and two beta emissions.

The differing alpha and beta branches in the decay chains of ${}^{223}\text{Ra}$ and ${}^{227}\text{Ac}$ serve as excellent examples of two decay chains yielding very different magnitudes of the computed detection efficiencies in the standardization of these two radionuclides. The decay scheme of ${}^{223}\text{Ra}$ is the shorter of the two schemes, as described in the previous paragraph, with essentially four alpha and two beta transitions yielding a maximum computed detection efficiency of <600% (See Fig. 6.87A). On the other hand, the decay chain of ${}^{227}\text{Ac}$ yields principally, as illustrated in Fig. 6.86, five alpha emissions, namely, ${}^{227}\text{Th} \rightarrow {}^{223}\text{Ra} \rightarrow {}^{219}\text{Rn} \rightarrow {}^{215}\text{Po} \rightarrow {}^{211}\text{Pb}$ and ${}^{211}\text{Bi} \rightarrow {}^{207}\text{Tl}$. In addition, there are principally three beta decays in the ${}^{227}\text{Ac}$ decay chain, namely, ${}^{227}\text{Ac} \rightarrow {}^{227}\text{Th}$, ${}^{211}\text{Pb} \rightarrow {}^{211}\text{Bi}$, and ${}^{207}\text{Tl} \rightarrow {}^{207}\text{Pb}$. Two other transitions have very small branches, namely, the alpha emissions of ${}^{227}\text{Ac}$ with a 1.38% intensity, and the beta transition ${}^{211}\text{Bi} \rightarrow {}^{211}\text{Po}$ of 0.276% intensity. These will contribute little to the computed detection efficiency of ${}^{227}\text{Ac}$. Thus, the computed detection efficiency of ${}^{227}\text{Ac}$ with its essentially five alpha emissions and three beta branches do not exceed 800%, as illustrated in Fig. 8.86B. In this case, the highest computed detection efficiency for ${}^{227}\text{Ac}$, which is at its lowest level of quench (highest detection efficiency of ${}^3\text{H}$ tracer) is reported by Kossert et al. (2015) to be <800% as illustrated in Fig. 6.87B.

10. Electron capture radionuclides

The higher levels of uncertainty in the standardization of electron-capture radionuclides by the CIEMAT/NIST method or low-energy beta-emitters by the TDCR method have motivated much research toward improving the efficiency calculations. (The TDCR method is discussed further on in this chapter). It is a model-based method similar to the CIEMAT/NIST method in that both methods involve theoretical calculations of the detection efficiency). With the objective of reducing the uncertainties in the activity determinations, Grau Carles et al. (2004, 2006) and Grau Carles and Grau Malonda (2006) revisited the problem of ionization quenching and photoionization-reduced energy in liquid scintillation counting of electron-capture decaying radionuclides such as ${}^{55}\text{Fe}$, ${}^{51}\text{Cr}$, and ${}^{54}\text{Mn}$. Their studies provided a more detailed simulation of the photoionization process in the atomic rearrangement

detection model for these electron-capture nuclides. Further studies were focused on Monte Carlo calculations of spectra and photon interaction probabilities in liquid scintillators (Zimmerman, 2006 and Cassette et al., 2006a,b) for X-ray and gamma-ray emitting nuclides, such as the electron-capture nuclide ${}^{54}\text{Mn}$.

Atomic electron rearrangement pathways were modeled and the MOYEN computer program developed (Grau Malonda et al., 2006) for the computation of the energy emissions in LMM Auger transitions upon which the counting efficiency calculations depend strongly. The energy of these transitions was computed for the EC nuclides ${}^{55}\text{Fe}$ and ${}^{125}\text{I}$.

A computer program, EMILIA, that includes the computation of the counting efficiency for the atomic rearrangement detection models, is reported by Grau Carles (2006a), which improved the computed counting efficiency of low-Z electron-capture nuclides under moderate quenching.

Kossert and Grau Carles (2006) utilized EMILIA code to compute the detection efficiency of the low-Z EC nuclides ${}^{54}\text{Mn}$, ${}^{55}\text{Fe}$, and ${}^{65}\text{Zn}$. They also demonstrated that ${}^{54}\text{Mn}$ could be used as a tracer nuclide for the standardization of ${}^{55}\text{Fe}$. They consider a future application would be to standardize ${}^3\text{H}$ by the CIEMAT/NIST method using ${}^{54}\text{Mn}$ as the tracer nuclide, as the uncertainty of ${}^{54}\text{Mn}$ activity standards ($\pm 0.7\%$) is lower than for ${}^3\text{H}$ standards. The standardization of ${}^3\text{H}$ using ${}^{54}\text{Mn}$ as a tracer was reported with a relative standard uncertainty of $\pm 1.01\%$ by Nähle et al. (2010). Also, Ratel (2008) underscored the potential of ${}^{54}\text{Mn}$ as a tracer nuclide instead of ${}^3\text{H}$ to increase the precision of the liquid scintillation standardization of EC nuclides, such as ${}^{55}\text{Fe}$.

The computer program, MICELLE, reported by Grau Carles (2007), extends the computation of the liquid scintillation counting efficiency to electron-capture radionuclides of atomic number $30 \leq Z \leq 54$. The program considers all subshells involved in the atomic electron rearrangements following electron capture. MICELLE also simulates samples in the gel phase, as the micelle size of gel scintillators can have an effect on the counting efficiency. The micelle program applied to the standardization of EC radionuclides ${}^{109}\text{Cd}$ and ${}^{125}\text{I}$ yielded considerable improvements in the relative standard uncertainties, particularly for ${}^{109}\text{Cd}$ ($\pm 0.5\%$) when a kB value of 0.0110 cm/MeV was used for the Birks parameter. They report a reduction in the uncertainty in the standardization of ${}^{125}\text{I}$, although there was a large dependence of the analysis on the kB value. The uncertainty in the determination of ${}^{125}\text{I}$ was improved by about 1% (Grau Malonda and Grau Carles, 2008) when models of the simultaneous interactions of electrons in liquid scintillator were included in the efficiency calculation. The simultaneous interaction of electrons produces an overlap of distributions of excited solvent

molecules and an increase in the excitation density, which required a modification of the ionization quenching factor in the calculations.

Grau Carles and Grau Malonda (2010) presented a new approach to the problem of elevated uncertainties in the standardization of low-energy beta-emitters, when the TDCR method is applied, and in the standardization of some electron-capture radionuclides, when the CIEMAT/NIST method is applied. This work considers the need to expand the TDCR and CIEMAT/NIST methods by generalizing the equations used in the model and to analyze the influence of ionization and chemical quench on the spectra and counting efficiency. They studied the influence of photomultiplier response in one, two, and three PMT systems. Particularly the effect of electronic noise discriminator level on both experimental spectra and counting efficiency are considered.

In a personal communication of the writer with Grau Malonda (2010), many of the problems with the model arise from the discrepancy between the experimental spectra and the computed one. In other words, when the total efficiency is calculated for beta-emitters, the full spectral area is computed; however, when the experimental radionuclide is counted, only the pulses with pulse heights greater than the noise discriminator level are counted. Thus, for example, the counts for the tritium spectrum turn out to be lower than the computed total spectrum. Low counts yield low efficiency, and a lower efficiency yields a higher figure of merit and consequently a higher figure of merit for the radionuclide to be standardized (e.g., ^{125}I) yielding finally a higher activity determination. Accordingly, an improvement in the accuracy of the liquid scintillation standardization of radionuclides rests with the spectral analysis.

With the objective of making improvements in the spectral analysis of electron capture radionuclides in the CIEMAT/NIST method of radionuclide standardization, Kossert and Grau Carles (2010) report an improved MICELLE2 code for the computation of the detection efficiencies of EC radionuclides to yield a more realistic treatment of photoelectron ejections and consequent atomic electron shell rearrangements yielding a more detailed atomic rearrangement model for the electron capture in the radionuclide of interest. The number of possible electron rearrangements following electron capture increase with the radionuclide atomic number. Although the K shell is the predominate shell for electron capture by the atomic nucleus (See Chapter 1, Volume 1), the MICELLE2 code accounts for probabilities for capture from outer electron shells. Kossert and Grau Carles (2010) note that fractional electron capture probabilities are generated according to the capture of an electron from the K, L_1 , L_2 , or M shell followed by probabilities for X-ray emission with a fluorescent yield (ω_K) probability or Auger-electron ejection

probability ($A_K = 1 - \omega_K$). The MICELLE2 includes specific criteria for the selection of relative probabilities for radiative (X-ray emissions) or nonradiative transitions, namely, Auger and Coster-Kronig electron emissions. As described by Kossert and Grau Carles (2010), the updated MICELLE2 program also contains subroutines that simulate the energy loss of electrons in the liquid scintillation cocktail micelles. The micelles are miniscule and generally invisible spherical volumes of aqueous phase formed within liquid scintillation cocktails that contain emulsifiers to promote the uniform mixing of organic scintillation fluor cocktails with aqueous sample. The energy from electrons or beta particles deposited within the micelles does not produce scintillation light photons and consequently this portion of the particle energy does not contribute to the detection efficiency. In the case of the standardization of ^{55}Fe , Bergamon and Laureano-Perez (2014) report there were no observable reductions in detection efficiency attributable to scintillation cocktail micelles size. Also, they found that the use of ^{54}Mn as a tracer nuclide would reduce the model dependence of the calculation of detection efficiencies provided that sources of ^{54}Mn that are more than a few years old be evaluated for the accumulation of long-lived radionuclide impurities. In a recent study on the standardization of radionuclides that decay by EC or the emission of low-energy beta particles by the TDCR efficiency calculation technique (see next section of this chapter), Nedjadi et al. (2017) computed the ionization quenching function using Birk's law while taking into consideration the energy losses in all of the micelles bisecting the electron pathway through the scintillation cocktail. The computed ionization quenching function was then used to calculate the detection efficiencies for the weak beta-emitters ^3H and ^{63}Ni and the EC decaying nuclides ^{54}Mn and ^{55}Fe . They found the effect of micelle size on the calculated detection efficiencies to be small for beta-emitters, but significant for the electron capture nuclides.

There is currently increased interest in the standardization of ^{68}Ga , which has applications in nuclear medicine as a radionuclide useful for positron emission tomography (PET) in medical clinics that do not have a cyclotron for the production of short-lived positron-emitters. Gallium-68 has a half-life of 68.33 min, and it can be milked on-site from a generator containing the ^{68}Ge parent nuclide, which decays with a half-life of 275 days. The beta decay mode of ^{68}Ga includes positron emission at 89.1% abundance and electron capture at the remaining 10.9% abundance. Roteta et al. (2012) have standardized ^{68}Ga by the CIEMAT/NIST method utilizing a Monte Carlo simulation program for the calculation of the detection efficiency. The program simulates the EC and positron decay paths and the consequent cascade of particles and photons for each path. As noted by Roteta et al. (2012), the program includes the atomic electron rearrangements in the K, L, and M shells as well as

the deposited energy via the photon interactions with scintillator. The commercial availability of $^{68}\text{Ge}/^{68}\text{Ga}$ generators for applications in clinical medicine motivated Kulkarni et al. (2017) to standardize the parent-daughter nuclides. Germanium-68 decays exclusively by electron capture while its daughter nuclide ^{68}Ga decays by EC and positron emission. Kulkarni et al. (2017) calculated the efficiencies of ^{68}Ge and ^{68}Ga versus the figure of merit (See Figs. 6.78 and 6.81 illustrated earlier in this chapter) with the freeware computer program CN2003.

11. Applications with plastic scintillation microspheres

Tarancón et al. (2015) applied an adapted version of the MICELLE2 code, which included PENELOPE code to allow for the calculation of the beta-particle energy losses due to varying degrees of particle quenching that can occur with different geometries of plastic scintillation microspheres. Their application of the CIEMAT/NIST method to the metrology of beta-emitters utilizing plastic scintillation microspheres yielded activity calculations for ^{63}Ni , ^{14}C , ^{36}Cl , and $^{90}\text{Sr}/^{90}\text{Y}$ with deviations of 8.8%, 1.9%, 1.4%, and 2.1% respectively. A very low-energy beta-emitter, such as ^{63}Ni ($E_{\text{max}} = 0.066 \text{ MeV}$) would be affected obviously by particle quenching to a greater degree than higher-energy beta-emitters.

12. Radionuclide mixtures

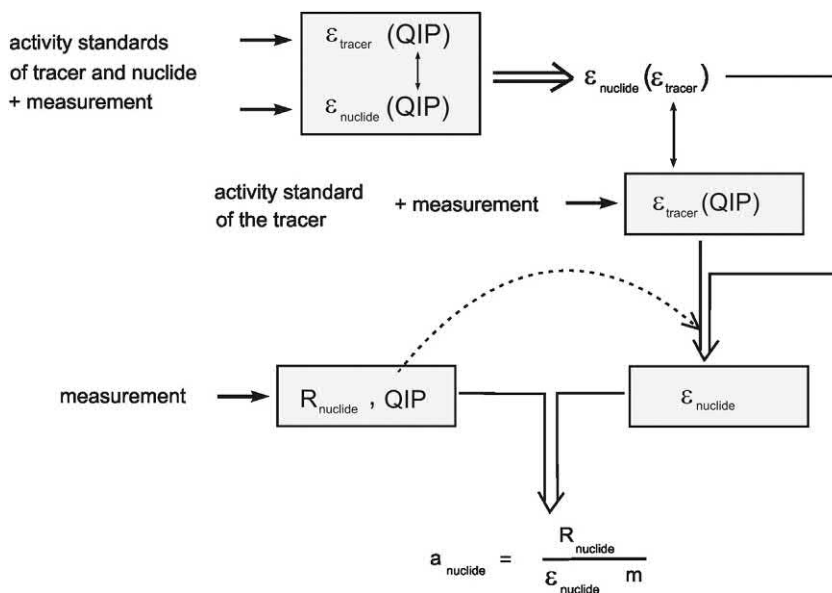

The CIEMAT/NIST method has been applied to the standardization of radionuclide mixtures. Early work by Grau Carles (1994) describes computer programs for the

deconvolution of ^{89}Sr , ^{90}Sr , and ^{90}Y mixtures with the liquid scintillation standardization of the components by the CIEMAT/NIST method. This was expanded and improved to include the standardization of more complex mixtures of several (up to five) radionuclides (Grau Carles, 1996). Günther (2002c) and Rodríguez Barquero et al. (2004) measured ^{32}P and ^{33}P activities where ^{33}P is an impurity. The relative standard uncertainties for the determination were 0.32% for ^{32}P and 1.6% for ^{33}P impurity. A triple exponential mathematical expression is described by Altsitzoglou (2004) to standardize ^{32}P in the presence of ^{33}P and ^{35}S . Van Wyngaardt and Simpson (2006a) and Van Wyngaardt et al. (2008) applied the liquid scintillation TDCR and CIEMAT/NIST standardization methods to resolved mixtures of ^{14}C and ^{63}Ni and to component mixtures of ^{32}P , ^{33}P , and ^{35}S , respectively. Mixtures of short-lived components were resolved for the CIEMAT/NIST standardization of ^{18}F (Capogni et al., 2006) and ^{64}Cu (Capogni et al., 2008).

B. Secondary standardization by the cross-efficiency method

A secondary standard measurement method that utilizes liquid scintillation counting was reported by Kossert (2006). The method is based on the CIEMAT/NIST method; however, it is distinctly different in that the efficiency curve, i.e., the counting efficiency of the nuclide under investigation as a function of the tritium counting efficiency or $\epsilon_{\text{nuclide}}(\epsilon_{\text{tracer}})$, is not calculated, but rather, it is determined experimentally. The method is illustrated in Fig. 6.88. Notice the similarity between Fig. 6.85, that of

FIGURE 6.88 Secondary standard measuring procedure. R denotes the count rate, QIP the quench indicating parameter, ϵ the counting efficiency, a_{nuclide} is the solution activity concentration of the nuclide under investigation, and m is the source mass. From Kossert (2006). Reprinted with permission from Elsevier © 2006.

the CIEMAT/NIST method, and Fig. 6.88, that of the secondary standardization method. In the secondary standardization method, there is no calculation of figure of merit (M); there is instead, the experimental determination of the quench indicating parameter (QIP).

This method of secondary standardization of Kossert (2006) is described, in a stepwise fashion, as follows:

- a. The first step, as illustrated in Fig. 6.88, involves the measurement of the counting efficiency of the nuclide under investigation, $\epsilon_{\text{nuclide}}$, as a function of a quench indicating parameter (QIP). To achieve this, a set of quench standards of the nuclide under investigation is prepared. This requires the preparation of a few vials (approx. 10 vials) each containing the scintillation cocktail and a known amount of an activity standard solution. Increasing amounts of quenching agent (e.g., nitromethane) are added to each counting vial, with the exception of the first vial, to provide counting vials with decreasing detection efficiencies (See Section V.D of this chapter). Counting of these standards in a liquid scintillation analyzer will provide the net count rates, (e.g., CPM) and values of a quench indicating parameter (QIP), such as H#, SQP(E), or tSIE, depending on the instrument used and its external standard. From the net count rates and the known activities (DPM) in each vial, the detection efficiencies of each vial are easily calculated (i.e., $\epsilon_{\text{nuclide}} = \text{CPM}/\text{DPM}$). The same procedure is carried out with a set of quenched standards prepared with ^3H , which serves as the tracer nuclide. The counting of the tritium nuclide standards will yield distinct counting efficiencies, ϵ_{tracer} , for each vial as well as varying QIP values.
- b. The two functions $\epsilon_{\text{nuclide}}(QIP)$ and $\epsilon_{\text{tracer}}(QIP)$ obtained from step (a) above are linked by the quench indicating parameter QIP to provide a working 'efficiency curve' of $\epsilon_{\text{nuclide}}(\epsilon_{\text{tracer}})$ as illustrated in Fig. 6.89 for the case of ^{125}I as an example of a nuclide under investigation. The best fit for the function $\epsilon_{\text{nuclide}}(\epsilon_{\text{tracer}})$ for the working 'efficiency curve' is obtained via a fourth-order polynomial, which provides the counting efficiency of the nuclide, $\epsilon_{\text{nuclide}}$, for a specific counting efficiency of the tritium tracer, ϵ_{tracer} , given by the equation

$$\epsilon_{\text{fit}} = \epsilon_{\text{nuclide}}(\epsilon_{\text{tracer}}) = \sum_{i=0}^4 p_i (\epsilon_{\text{tracer}})^i \quad (6.107)$$

Notice the similarity of Eq. (6.107), which uses the experimentally determined QIP as a link between the two detection efficiencies for this secondary standardization method, and Eq. (6.102), which uses the calculated figure of merit (M) as the link in the CIEMAT/NIST primary standardization method.

FIGURE 6.89 Cross-efficiency curve of $\epsilon_{\text{nuclide}}(\epsilon_{\text{tracer}})$ for ^{125}I in 15 mL of Ultima Gold cocktail plus 1 mL of water. The empty circles represent the determined efficiencies, and the 'efficiency curve' was used to calibrate another solution of ^{125}I , which was also calibrated by coincidence counting. The solid triangles represent the results of efficiencies determined with the second solution of ^{125}I . From Kossert (2006). Reprinted with permission from Elsevier © 2006.

- c. This following step need not be carried out during the same period of time as the above preparation of the 'efficiency curve'. As pointed out by Kossert (2006), this next step can be performed even years later. This next step involves the preparation of the ^3H 'calibration curve', which is the repeated measurement of the counting efficiency of the tracer nuclide, ϵ_{tracer} , expressed as a function of the quench indicating parameter (QIP). The newly measured 'calibration curve', $\epsilon_{\text{tracer}}(QIP)$ is required to account for any instability of the liquid scintillation counter in the event of any changes in time of the instrument response and measured spectra.
- d. The sample of the nuclide under investigation is now counted, and the sample count rate, R_{nuclide} , and sample quench indicating parameter (QIP) are measured and recorded. From the magnitude of the QIP , the corresponding value of the tracer counting efficiency can be obtained from the ^3H 'calibration curve' prepared in Step c. From the known tracer efficiency, the corresponding nuclide efficiency, $\epsilon_{\text{nuclide}}$, can be obtained from the 'efficiency curve' measured in Step b.
- e. With the efficiency of the nuclide under investigation, $\epsilon_{\text{nuclide}}$, obtained from the 'efficiency curve' and the nuclide count rate, R_{nuclide} , the activity concentration of the nuclide, a_{nuclide} , is calculated, as illustrated in Fig. 6.88, according to the equation $a_{\text{nuclide}} = R_{\text{nuclide}}/(\epsilon_{\text{nuclide}} \cdot m)$, where m is the mass of the sample counted.

Kossert (2006) and Cassette and Tartès (2014) have tested this secondary standardization method, and certain specifics should be considered, and these are the following:

- a. The sample scintillation cocktail composition (i.e., cocktail and sample chemistry) and the sample geometry (i.e., vial size, vial type, and sample-cocktail volume or mass) must be very similar for all measurements.
- b. The period between the measurements of the tracer nuclide, and the nuclide under investigation should be short (i.e., within a period of only a few days).
- c. The duration between the determination of the 'efficiency curve' and the measurements of the tracer nuclide and the nuclide under investigation is unlimited.
- d. The 'calibration curve' of $\varepsilon_{\text{tracer}}(QIP)$, e.g., $\varepsilon_{\text{tritium}}$ versus SCP(E) or $\varepsilon_{\text{tritium}}$ versus tSIE, is easily measured with weighed aliquots of a standard solution of tritiated water added to cocktail in a set of about 10 vials to which increasing amounts of nitromethane are added.
- e. The quench curves are counter dependent, and this holds for different counters that have similar external standards and measure the same QIP.
- f. The quench curves are dependent on the nature of the quenching, i.e., chemical or color quenching. The differences between the chemical and color quench curves depend on the radionuclide and are more significant in the measurement of ^{55}Fe and ^{63}Ni than in the measurement of ^3H .
- g. This following point is one of the key advantages of this method: The uncertainty of the tracer activity (e.g., tritium) cancels out, if the aliquots used for the determination of the 'efficiency curve' and the 'calibration curve' stem from the same standard solution.
- h. The method can be applied to the activity determinations of radionuclides with low activity concentrations (e.g., 10 Bq/g).

Kossert (2006) tested this secondary standard method against several nuclides standardized by accepted primary standardization methods. This secondary standardization method tested against ^{125}I primary standard yielded an uncertainty of the activity determination lower by only 0.03% of that of the primary standard. Likewise, the activity of ^{65}Zn was measured by this secondary standardization with an uncertainty of only 0.05% lower than that determined by primary standardization. Other nuclides tested by this secondary standardization method were ^{54}Mn , ^{57}Co , ^{67}Ga , ^{85}Sr , ^{88}Y , ^{109}Cd , and ^{111}In . In a subsequent work Kossert et al. (2006) reported the secondary standardization of ^{65}Zn by this method with an uncertainty of 0.4%.

C. Triple-to-double coincidence ratio (TDCR) efficiency calculation technique

The early works of Steyn (1956), Flynn and Glendenin (1959) and Radoszewski (1964) can be given the credit of initiating the possibility of utilizing a liquid scintillation

analyzer for the absolute measurement of beta-emitting radionuclides (personal communication of the writer with Ryszard Broda, 2004). The first triple photomultiplier liquid scintillation counting system with an electronic circuit having two different coincident outputs was reported originally by Schwerdtel (1965, 1966a,b); however, the method for the determination of the absolute activities of radionuclides was yet to be developed. An important contribution was made by Kolarov et al. (1970), who proposed a liquid scintillation detection efficiency model used in the current triple-to-double coincidence ratio (TDCR) efficiency calculation technique. Pochwalski (1978) presented the TDCR method as his thesis; he worked many years in Radoszewski's nuclear metrology laboratory in the Institute of Nuclear Research at Świerk, Poland. A triple PMT detector design and the original version of the method of radionuclide standardization now referred to as the TDCR efficiency calculation technique were published in a national report by Pochwalski and Radoszewski (1979) and in the international journals by Pochwalski et al. (1988). Thus, the TDCR efficiency calculation technique was invented in Poland. The integration of theoretical calculations of counting efficiency based on the radiation emissions of the radionuclide under investigation with the experimental data obtained from the LS, somewhat similar to the approach taken in the CIE-MAT/NIST efficiency tracing method conceived by Grau Malonda in 1978 described earlier in this chapter, was reported by Broda et al. (1988), Grau Malonda and Coursey (1988), and Grau Carles and Grau Malonda (1989). These papers formed the basis for subsequent research and development in this method, which is described subsequently.

1. Principles

The liquid scintillation analyzer (LSA), in this case, is different from the conventional and more common commercially available equipment, described previously in this chapter. The TDCR efficiency calculation technique requires an LSA equipped with three photomultiplier (3-PM) tubes and two different coincident outputs. Such equipment is available commercially (e.g., Hidex, Turku, Finland), and other 3-PM instruments are designed and manufactured by those laboratories dedicated to radionuclide standardization, such as national institutes of standards and research. Since the publication of the second Edition of the *Handbook of Radioactivity Analysis* in 2003, the national radionuclide metrology laboratories that now apply the TDCR efficiency calculation method for the metrology of radionuclides have become more widespread (Cassette, 2011). A list of several such laboratories in numerous institutions worldwide is provided in Table 6.10.

TABLE 6.10 Some national nuclear metrology laboratories reporting custom-built 3-PM liquid scintillation counting systems.

A commercially available liquid scintillation analyzer, the Hidex 300 SL (Hidex Oy, Turku, Finland) manufactured with three photomultiplier tubes, which utilizes the TDCR technique, was released in 2008 (Haaslahti, 2010). The Hidex company also produces a higher capacity (Hidex 600 SL) 3-PM liquid scintillation analyzer. The performance of the Hidex 300 SL is described by Kharitonov

et al. (2011). A schematic diagram of the workings of an instrument, referred to as the TDCR liquid scintillation counter, which is applied to the standardization (i.e., direct DPM measurement) of radionuclides, is illustrated in Fig. 6.90, and an illustration of a commercially available three-photomultiplier detector arrangement is illustrated in Fig. 6.91. The optical chamber of the LSA accommodates a

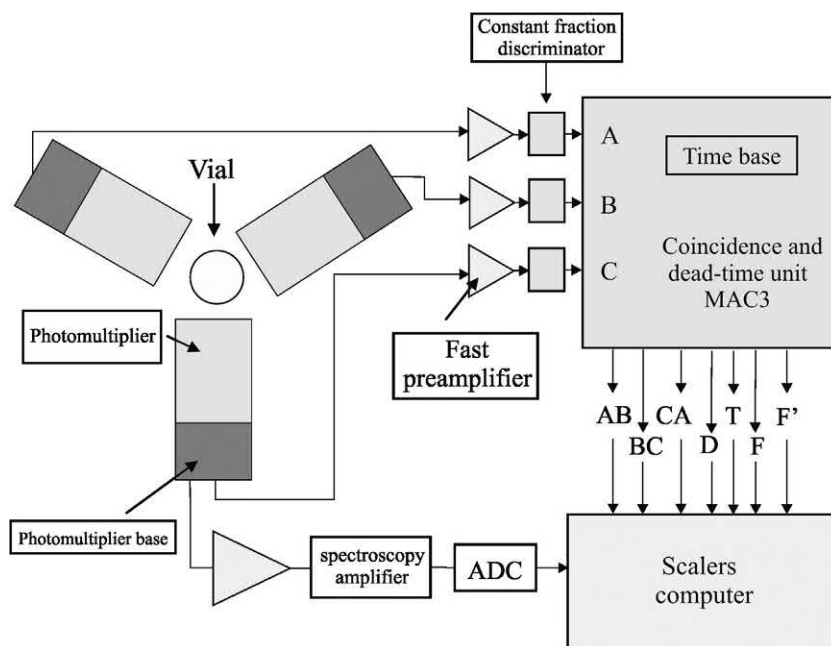

FIGURE 6.90 Diagram of the TDCR system at the Radioisotope Metrology Laboratory, CNEA, Argentina. MAC3 is the electronic coincidence module of Bouchard and Cassette (2000) for the processing of the pulses delivered by the three photomultipliers including double coincidence outputs AB, BC, and CA, the logical sum of the double coincidences D, and the triple coincidences T. standard 20-mL liquid scintillation counting vial, and facing the vial are three photomultiplier tubes at 120 degree angles to each other. With such an arrangement, dual and triple phototube coincidence outputs are possible as a requirement for the TDCR method. For example, the two coincident outputs used by Pochwalski et al. (1988) from photomultiplier tubes A, B, and C were the count rates from the triple coincidences (ABC), the three double coincidences AB, BC, and AC, and the count rate from the logic sum of the three different double coincidences (AB + BC + CA). Since this initial report of the TDCR method, many developments have been made. Advances following the development of the TDCR radionuclide standardization method are described by Simpson and Meyer (1992 and 1994b), and reviews on the theory and practice of the TDCR method are available from Broda (2003), Lee et al. (2004a,b), Broda et al. (2007), Nähle and Kossert (2011), Cassette (2011), Nähle et al. (2014), and Capogni and Antohe (2014) from which the subsequent treatment and mathematical notation utilized in TDCR are taken.

The triple-to-double coincidence ratio (TDCR) method was developed for the direct determination of the absolute activities of beta- and EC-decaying radionuclides in liquid scintillator cocktail. Like the CIEMAT/NIST method, described previously in this chapter, the TDCR technique combines experimental data with theoretical calculations of the radionuclide detection efficiency. Complete data of the radionuclide decay scheme is used to calculate the counting efficiencies based on a physical and statistical model of the beta-particle, Auger-, and Compton electron interactions with scintillation cocktail. The TDCR method utilizes a physical and statistical model of the distribution of scintillation photons and their detection probabilities in a three-photomultiplier detector system (Broda, 2003). The ionization quenching phenomena, which is the nonlinearity of the scintillator response as a function of the linear energy transfer (LET) or stopping power of the interacting electrons in fluor cocktail, discussed previously in the CIEMAT/NIST method, is also required in the TDCR technique for the theoretical calculations of counting efficiencies.

In the case of a pure β -emitting source on which are viewed simultaneously three normalized photomultiplier tubes the double-tube coincidence count rate N_d and the triple-tube coincidence count rate N_t are defined as

$$N_d = N_0 \varepsilon_d \quad (6.108)$$

and

$$N_t = N_0 \varepsilon_t \quad (6.109)$$

where N_0 is the disintegration rate of the radionuclide source and ε_d and ε_t are the true double-tube and triple-tube counting efficiencies, respectively. The detection efficiencies are determined without recourse to prior

instrumental calibration nor the use of any reference standards. Rather, the detection efficiencies are determined in an absolute manner by combining experimental measurement with theory (Simpson and Morris, 2004b). The detection efficiencies ε_d and ε_t of Eqs. (6.108) and (6.109) are unknown; however, the ratio (R) of the count rates N_t/N_d are determined or measured experimentally with the liquid scintillation counter. For a large number of disintegration rates, the ratio of the experimentally determined triple coincidence count rate to double coincidence count rate, N_t/N_d , converges toward the ratio of counting efficiencies, as described by Broda et al. (2007). Thus, using the notation of Simpson and Morris (2004b) and Lee et al. (2004a,b), the experimentally determined ratio (R) can be written as

$$R = \frac{N_t}{N_d} = \frac{N_0 \varepsilon_t}{N_0 \varepsilon_d} = \frac{\varepsilon_t}{\varepsilon_d}. \quad (6.110)$$

where N_0 is the radionuclide activity, and the product of activity and detection efficiency (*i.e.*, $N_0 \varepsilon_t$ and $N_0 \varepsilon_d$) is count rate. As in the previously described CIEMAT/NIST radionuclide standardization method of efficiency tracing (Section IX.A of this chapter), theoretical counting efficiencies are calculated and these are fitted to experimental data. The theoretical counting efficiencies ε_d and ε_t for a pure β -emitter are described, according to a ‘free parameter’ model by Grau Malonda and Coursey (1988) and Simpson and Meyer (1992a-c) as

$$\varepsilon_2 = \int_0^{E_{\max}} N(E) [1 - \exp\{-P \cdot F(E) \cdot E\}]^2 dE, \quad (6.111)$$

and

$$\varepsilon_3 = \int_0^{E_{\max}} N(E) [1 - \exp\{-P \cdot F(E) \cdot E\}]^3 dE, \quad (6.112)$$

where ε_2 and ε_3 are the double- and triple-photomultiplier tube efficiencies, respectively, $N(E)$ represents the number of β particles of energy between $E + dE$ of the β -particle spectrum calculated according to the Fermi theory of decay (Fermi spectrum), E_{\max} is the maximum β -particle energy, $F(E)$ is the relative scintillation efficiency Gibson (1968) and P is the figure of merit or free parameter, the only unknown variable of the theoretical efficiency equations. The figure of merit (free parameter) was defined previously in this chapter in Section IX.A concerning the CIEMAT/NIST efficiency tracing technique where a ‘system’ figure of merit M or λ was used, whereby $P = 1/2M$ for a double-phototube system and $P = 1/3M$ for a triple-phototube system (Simpson and Meyer, 1992b), and $M = \lambda$. The theoretical efficiencies, therefore, are a function of a single unknown parameter P . Thus, as described by Simpson and Morris (2004) and Van Wyngaardt and Simpson (2009), the efficiencies can be expressed theoretically as a function of a single floating parameter P , the so-called ‘figure-of-merit’, which is effectively a measure of the electron emission process and the consequent photon output.

Thus, a single value of P must be found iteratively to fit the experimentally measured count ratio to solve the equation

$$R = \frac{N_t}{N_d} = \frac{\varepsilon_t(P)}{\varepsilon_d(P)} \quad (6.113)$$

The theoretical counting efficiencies as a function of the figure of merit, P , are calculated and the value of P is obtained by mathematical iteration to best fit the experimentally determined triple-to-double count ratio of Eq. (6.113). As noted by Simpson and Meyer (1994b) and Simpson and Morris (2004), the figure of merit P should be single-valued for a given value of R . With the determined value of P for a given experimental sample, the activity of the radionuclide source can then be calculated using Eqs. (6.108) and (6.109) or

$$N_0 = \frac{N_d}{\varepsilon_d} = \frac{N_t}{\varepsilon_t} \quad (6.114)$$

2. Free-parameter model

The calculation of the theoretical efficiencies according to Eqs. (6.111) and (6.112) are similar to Eq. (6.96) previously described in Section IX.A. According to Grau Carles and Grau Malonda (2001), Lee et al. (2004a,b), Nähle and Kossert (2011), and Cassette (2011), the equations applicable to the theoretical counting efficiency calculations for beta-particle emitters and radionuclides that decay by electron capture (EC) in a two- or a three-photomultiplier system are the following:

$$\varepsilon_2 = \int_0^{E_{\max}} S(E) (1 - e^{-EQ(E)/2M})^2 dE \quad (6.115)$$

for two photomultipliers working in coincidence, and

$$\varepsilon_T = \int_0^{E_{\max}} S(E) (1 - e^{-EQ(E)/3M})^3 dE \quad (6.116)$$

for three photomultipliers in coincidence; whereas, the logic sum of double coincidences in a 3-PM counter is calculated as

$$\varepsilon_D = \int_0^{E_{\max}} S(E) \left[3(1 - e^{-EQ(E)/3M})^2 - 2(1 - e^{-EQ(E)/3M})^3 \right] dE \quad (6.117)$$

Thus, the triple-to-double coincidence ratio (TDCR) is expressed as

$$\begin{aligned} \frac{N_T}{N_D} &= \frac{\varepsilon_T}{\varepsilon_D} \\ &= \frac{\int_0^{E_{\max}} S(E) (1 - e^{-EQ(E)/3M})^3 dE}{\int_0^{E_{\max}} S(E) \left[3(1 - e^{-EQ(E)/3M})^2 - 2(1 - e^{-EQ(E)/3M})^3 \right] dE} \end{aligned} \quad (6.118)$$

where the variables are the same as those defined previously for Eqs. (6.95) and (6.96) in Section IX.A, namely, E_{\max} is the maximum beta-particle energy, $S(E)$ is the normalized energy spectrum transferred to the liquid scintillation cocktail, including energy from beta particles as well as Auger-, Coster-Kronig-, and conversion electrons, and photo- and Compton electrons arising from X-ray- and gamma-ray-interactions in LS cocktail [the term $S(E)$ was previously referred to as $N(E)$ Eqs. 6.95 and 6.96], $Q(E)$ is the ionization quenching correction factor, and M is the free parameter. The free parameter was expressed in Eqs. (6.95) and (6.96) as λ ; the expression for the free parameters M or λ depends on the user (*i.e.*, $M = \lambda$). The above calculations are based on a definition of the figure of merit (free parameter) as a computation of the β -particle energy in keV required to produce one photoelectron at the output of the photocathode or the photoelectron yield at the first dynode. The free parameter has units of electrons/keV.

The ionization quench function $Q(E)$ of Eq. (6.118) is determined by applying the Birks formula described previously by Eq. (6.106). The Birks formula expresses the reduction in fluorescence due to ionization quenching $[1 + kB(dE/dx)]^{-1}$ where kB is the ionization quench parameter or constant with units of cm/MeV or g/MeV cm², and dE/dx is the radiation stopping power of the scintillator with units of MeV/cm or MeV cm²/g, as discussed previously with respect to Birks definition of specific fluorescence and ionization quenching according to Eqs. (6.105) and (6.106). As described by Cassette (2011), Broda et al. (2007), and Lee et al. (2004a,b), the left term of Eq. (6.118) (N_T/N_D) is measured experimentally, and the right term ($\varepsilon_T/\varepsilon_D$) is calculated. As the beta-particle energy distribution $N(E)$ for a given radionuclide is known, and the kB ionization quench parameter is an assumed constant, the value of the free parameter must be found whereby the calculated $\varepsilon_T/\varepsilon_D = N_T/N_D$, which is the experimentally measured triple-to-double count ratio.

3. Experimental conditions and efficiency calculations

The practical aspects of the TDCR method are dealt with in detail by Broda et al. (2007). Some of the major points of the TDCR method are presented here.

Simpson and Meyer (1994b) demonstrated that any change in the counting efficiency due to any altered chemical quenching state of the sample will manifest itself in the measured triple and double counting rates, thereby producing a different value of R . They demonstrated, therefore, that the figure of merit P extracted by this method for a given sample includes affects due to chemical quenching so that the calculated sample activity N_0 is independent of chemical quench effects. Using wide ranges of CHCl_3 as a quenching agent (18–2287 mg CHCl_3 load),

they demonstrated no significant quench effect on the calculated activity of ^{14}C . Also, smaller CHCl_3 quenching agent loads (13–409 mg) had no effect on the calculated activity of ^{63}Ni , and chloroform loads of up to 60 and 270 μL produced no effect on the calculated activities of ^{99}Tc and ^3H , respectively.

The calculation of the counting efficiencies ε_d and ε_t can be carried out with computer codes, such as EFFY, written by [García-Toraño and Grau Malonda \(1985\)](#) previously described in this chapter (see also [Bergeron et al., 2016](#) and [Cassette et al., 1998](#)). [Simpson and Meyer \(1994b\)](#) and [Simpson and Van Wyngaardt \(2006\)](#) report the use of a modified EFFY2 program to operate on a personal computer, which calculates the ratio R of the triple-to-double efficiencies as a function of figure of merit. They note that in practice, [Eq. \(6.113\)](#) is solved by incrementally varying the figure of merit, P , in the computer calculation, which in effect reads the counting efficiencies corresponding to the measured ratio R from plots of efficiency curves such as those illustrated in [Fig. 6.92](#). [Simpson and Morris \(2004\)](#) and [Simpson and Van Wyngaardt \(2006\)](#) report the use of EFFY2 in the TDCR standardization of high-energy beta-emitters. [Broda et al. \(2000\)](#) describe a computer program, TDCRB-1, to calculate the radioactive concentration of a solution based on the TDCR method. Also, the DETEC SZ program is described by [Razdolescu et al. \(2002\)](#) for the TDCR calculation of the activity concentration of pure beta-emitters. Similar analysis codes, such as TDCRB-02 reported by [Broda et al. \(2002\)](#), are utilized by [Nähle et al. \(2010\)](#), [Zimmerman et al. \(2010\)](#),

[Bergeron et al. \(2012\)](#), [Gudelis et al. \(2012\)](#), and [Nedjadi et al. \(2015\)](#).

The program SPECBETA, first reported by [Cassette \(1992\)](#) and [Cassette and Vatin \(1992\)](#) is used for the calculation of the beta spectrum, *i.e.*, $N(E)$ or what is also referred to as $S(E)$, the deposited spectrum in the scintillation cocktail, a required component of the TDCR efficiency calculation. The use of SPECBETA is reported by several researchers including [Collé et al. \(2008\)](#), [Zimmerman et al. \(2008\)](#), [Fitzgerald et al. \(2010\)](#), and [Laureano-Perez et al. \(2010\)](#). [Lourenço et al. \(2015\)](#) calculated beta spectra based on the original home-made code of [Grau Malonda \(1999\)](#).

The calculation of efficiencies of EC nuclides requires data on interaction probabilities of electron-generating X-ray and γ -ray photons with scintillator, and the Monte Carlo code PENELOPE, first reported by [Baró et al. \(1995\)](#) and reviewed and refined by [Salvat and Fernandez-Varea \(2009\)](#) and [Salvat et al. \(2011\)](#), has been used for this purpose (*e.g.*, [Cassette et al., 2004](#), [Zimmerman, 2006](#); and [Razdolescu et al., 2008](#)). PENELOPE is noted by [Kossert et al. \(2014a\)](#) as the state-of-the-art simulation tool for the interaction of low-energy radiation in matter. Likewise, the simulation code GEANT4 was developed ([Agostinelli et al., 2003](#); [Allison et al., 2006](#)) and utilized to acquire X-ray and gamma-ray energy deposition spectra and interaction probabilities with scintillant for the analysis of EC and beta-gamma-emitting radionuclides (*e.g.*, [Bignell et al., 2010a,b](#), [Thiam et al., 2012](#), and [Lourenço et al., 2015](#)).

An updated MICELLE2 code, reported by [Kossert and Grau Carles \(2010\)](#) and the TDEM13 code developed by [Broda et al. \(2013\)](#), were prepared to facilitate the computation of counting efficiencies of radionuclides with complex decay schemes, such as EC nuclides that require a treatment of the ejection of photoelectrons and a detailed model of the subsequent atomic electron rearrangement processes. MICELLE2 is currently a popular code as described by [Kossert et al. \(2012, 2014b\)](#), [Jörg et al. \(2012\)](#), [Kossert and Nähle \(2014\)](#), [Fitzgerald et al. \(2014\)](#), [Bergeron et al. \(2016\)](#) and [Colle et al. \(2016\)](#). A nonradionuclide-specific computer code, TDCR-AR, is described by [Rodrigues et al. \(2008\)](#) for the analysis of data, calculation of detection efficiency, and radionuclide activity in a TDCR system. The TDCR-AR code was satisfactorily tested for the analysis of ^3H , ^{14}C , ^{55}Fe , ^{54}Mn , and ^{60}Co . Other simulation codes and programs are available from the literature, and it is common for laboratories to use programs developed ‘in-house’ for the analysis of data (*e.g.*, [Collé et al., 2008](#)). These programs may be obtained by direct contact with the authors of the published results.

Another popular code for the calculation of TDCR detection efficiencies is the TDCR07c program written in Fortran prepared by the Laboratoire National Henri Becquerel, CEA at Saclay ([Capogni and De Felice, 2014](#);

FIGURE 6.92 Results of calculations for ^{35}S of the double-coincidence efficiency ε_d (dashed line). Triple-coincidence efficiency ε_t (dash-dotted line), and the TDCR $\varepsilon_t/\varepsilon_d$ (solid line) are plotted as a function of the figure-of-merit. A value for $k_B = 0.0100 \text{ g}/(\text{cm}^2 \text{ MeV})$ was adopted in the calculation of the ionization quench function. From [Van Wyngaardt and Simpson \(2009\)](#). Capogni and Antohe, 2014; Cassette et al., 2016; da Cruz et al., 2014; Mini et al., 2014). As described by Collé et al. (2008), the program derives the detection efficiency for the logical sum of double coincidence from three individual values of triple-to-double coincidence count rate ratios, taking into account the individual quantum efficiency of each photodetector.

The computer programs, such as those described previously in this chapter, may include subroutines for the calculation of the ionization quench function $Q(E)$ for any given Birks ionizing quench parameter kB (See Eq. (6.106) of this chapter.). Cassette et al. (2000) demonstrated that the Birks kB factor is independent of the cocktail chemistry and optical design of the TDCR system, the influence of the kB factor is negligible for relatively higher-energy nuclides, such as ^{14}C ($E_{\text{max}} = 0.155$ MeV) and higher-energy beta-emitters, and the optimum value of the kB factor is independent of the high-energy nuclide. Also, for low-energy electron-capture (EC) nuclides decaying toward the fundamental level, such as ^{55}Fe , the counting efficiency is almost independent of the kB value, because the energy emission is almost monoenergetic and the nonlinearity of the scintillator (ionization quenching), in this case, has no effect on the light emission (Broda et al. (2007). However, for low-energy beta-emitting nuclides, such as ^3H , ^{63}Ni , and ^{241}Pu , the calculated counting efficiency is highly dependent on the kB value (Broda et al., 2007 and Kossert et al., 2011). The optimum kB value can be determined using different counting conditions described by Broda et al. (2007). The proper fitting of the kB ionization quench parameter in the TDCR model, as noted by Broda et al. (2002), is vital to improving the accuracy of this standardization method.

If the quantum efficiencies of the three photomultiplier tubes are different, a set of the following three equations, as described by Arenillas and Cassette (2006), Broda et al. (2007), Van Wyngaardt and Simpson, 2009), Simpson et al. (2010), and Cassette (2011), is solved for the free parameters of each phototube A, B, and C:

$$\frac{\varepsilon_T}{\varepsilon_{AB}} = \frac{\int_0^{E_{\text{max}}} S(E) (1 - e^{-EQ(E)/3M_A}) (1 - e^{-EQ(E)/3M_B}) (1 - e^{-EQ(E)/3M_C}) dE}{\int_0^{E_{\text{max}}} S(E) (1 - e^{-EQ(E)/3M_A}) (1 - e^{-EQ(E)/3M_B}) dE} \quad (6.119)$$

$$\frac{\varepsilon_T}{\varepsilon_{BC}} = \frac{\int_0^{E_{\text{max}}} S(E) (1 - e^{-EQ(E)/3M_A}) (1 - e^{-EQ(E)/3M_B}) (1 - e^{-EQ(E)/3M_C}) dE}{\int_0^{E_{\text{max}}} S(E) (1 - e^{-EQ(E)/3M_A}) (1 - e^{-EQ(E)/3M_C}) dE} \quad (6.120)$$

$$\frac{\varepsilon_T}{\varepsilon_{AC}} = \frac{\int_0^{E_{\text{max}}} S(E) (1 - e^{-EQ(E)/3M_A}) (1 - e^{-EQ(E)/3M_B}) (1 - e^{-EQ(E)/3M_C}) dE}{\int_0^{E_{\text{max}}} S(E) (1 - e^{-EQ(E)/3M_A}) (1 - e^{-EQ(E)/3M_C}) dE} \quad (6.121)$$

Eqs. (6.119) to (6.121) are solved using the multidimensional minimization Downhill Simplex algorithm

(Broda et al., 2007), and the function, which must be minimized is

$$\Delta = \left(\frac{\varepsilon_T}{\varepsilon_{AB}} - \frac{T}{AB} \right)^2 + \left(\frac{\varepsilon_T}{\varepsilon_{BC}} - \frac{T}{BC} \right)^2 + \left(\frac{\varepsilon_T}{\varepsilon_{AC}} - \frac{T}{AC} \right)^2 \quad (6.122)$$

where ε_T is the efficiency of the triple coincidence signals (T), and ε_{AB} , ε_{BC} , and ε_{AC} are the efficiencies of three double coincidence signals AB, BC, and AC, respectively. The solution gives the free-parameter variables M_A , M_B , and M_C or λ_A , λ_B , and λ_C (i.e., $M = \lambda$) for each kB value allowing the counting efficiency of each coincident event (Broda et al. (2007).

Research by Grau Carles and Grau Malonda (1989) and Broda (2003) in the application of the TDCR method to the metrology of nuclides that decay by pure electron capture (EC) demonstrate that, for a free parameter value, at lower ranges of detection efficiency there is a corresponding increase in counting efficiency as a function of the triple to double count ratio; however at higher ranges of detection efficiency there may be as many as three different values of the counting efficiency for different values of the triple to double count rate ratio (See Fig. 7.5 of Chapter 7 of Volume 2 “Radionuclide Standardization” by Agustin Grau Malonda. This different behavior in the metrology of pure EC nuclides is due to the fact that there are different efficiencies corresponding to the discontinuous decay spectra of EC nuclides (Grau Carles and Grau Malonda, 1989), such as K-shell, L-shell, γ , and conversion electron events. A solution to this uncertainty can be resolved by a three-dimensional plot of counting $\% \varepsilon$ versus TDCR versus λ (i.e., figure of merit or FM) as illustrated by Fig. 7.6 of Chapter 7 of Volume 2 “Radionuclide Standardization”. Such a plot illustrates distinct values of efficiency for each triple to double ratio. Also, the observation of three detection efficiencies for certain triple to double ratios occur only at certain levels of quench, and this irregularity can be avoided by controlling the chemical quench level.

4. The TDCR efficiency calculation technique in a nutshell

The previous sections describe in much detail the theory and practice of the TDCR efficiency calculation technique. Additional sources that document the theory, as it applies to radionuclides that undergo beta decay including pure beta-emitters, beta-gamma emitters, and electron capture nuclides, are provided by Simpson and Morris (2004), Simpson and Van Wyngaardt (2006), Van Wyngaardt and Simpson (2009). An excellent summary of the technique is

described by van Wyngaardt et al. (2012), and it is provided as follows with the writer's comments in brackets:

In this liquid scintillation counting method, a source is viewed by a three-phototube detection system and the double-coincidence count rate, N_d , and the triple-coincidence count rate, N_t , recorded simultaneously. If N_0 is the disintegration rate, then

$$N_d = N_0 \varepsilon_d \quad (6.123)$$

and

$$N_t = N_0 \varepsilon_t \quad (6.124)$$

where ε_d and ε_t are the double- and triple-coincidence detection efficiencies respectively. The efficiencies can be calculated theoretically in terms of a floating parameter, the figure of merit P , which gives an indication of the number of electrons at the first dynode of the phototube per keV deposited in the liquid scintillator (Gibson and Gale, 1968). By comparing the ratio of the experimentally measured coincidence count rates with the ratio of the corresponding theoretical efficiencies, P can be found by solving Eq. (6.125) iteratively

$$\frac{N_t}{N_d} = \frac{\varepsilon_t}{\varepsilon_d}. \quad (6.125)$$

If P is identical for each phototube/scintillation detector, the theoretical double- and triple-coincidence detection efficiencies are given by

$$\varepsilon_d = \int_0^{E_{\max}} S(E) [1 - \exp\{-PQ(E)E\}]^2 dE \quad (6.126)$$

and

$$\varepsilon_t = \int_0^{E_{\max}} S(E) [1 - \exp\{-PQ(E)E\}]^3 dE \quad (6.127)$$

respectively. The terms comprising Eqs. (6.126) and (6.127) are defined in Section 3 [See Section C, Parts 1 and 2 of this chapter] and various aspects relating to the efficiency calculations are described. Once P has been determined, the corresponding efficiencies follow directly and the source activity is given by

$$N_0 = \frac{N_d}{\varepsilon_d} = \frac{N_t}{\varepsilon_t} \quad (6.128)$$

5. Commercially available 3PM liquid scintillation analyzers

The three-photomultiplier (3-PM) liquid scintillation counters available commercially, are the Hidex 300 SL and the Hidex 600 SL with a larger sample capacity available

from Hidex Oy, Turku, Finland. The 3-PM detector structure of the Hidex 300 SL was illustrated previously in Fig. 6.91. The Hidex 300 SL super low-level liquid scintillation analyzer with three PM tubes became available commercially in 2008, and it is gaining in use internationally for the accurate measurement of radionuclides.

As noted in the previous treatment on the TDCR method, there is no need for any external standard to monitor quench to determine sample activities with a liquid scintillation analyzer equipped with three photomultiplier detectors. Jäggi and Eikenberg (2014) compared the performance of the PerkinElmer TriCarb 2200/2550, Quantulus, and Hidex 300 SL liquid scintillation analyzers for the measurement of activity concentrations of both low-energy and intermediate-energy beta-emitters, ^{241}Pu ($E_{\max} = 0.021$ MeV) and ^{90}Sr ($E_{\max} = 0.546$ MeV) demonstrating that the Hidex 300 SL is an excellent instrument for the routine analysis of pure beta-emitters. Their comparative study provided the results of ^{241}Pu activity concentrations (Bq/kg) determined by four instruments/methods, namely, (i) atom counting by inductively coupled plasma mass spectrometry (ICP-MS), (ii) the TriCarb, (iii) the Quantulus liquid scintillation analyzers that utilize two PM tubes, and (iv) the Hidex 300 SL liquid scintillation analyzer with three PM tubes. For ^{241}Pu beta activity measurements, the total alpha activity of the sample arising from ^{238}Pu , $^{239,240}\text{Pu}$, and ^{242}Pu had to be determined by α/β discrimination, which can be performed with the TriCarb 2550, Quantulus, and the Hidex 300 SL. The comparative results of the ^{241}Pu activity measurements on five different radioactive RHB slurry samples demonstrated that the relatively new Hidex 300 SL analyzer provided values of ^{241}Pu in agreement with the other standard instrumentation within expanded ($k = 1$) standard uncertainties (Jäggi and Eikenberg, 2014). The acronym RHB refers to the source of the radioactive slurry samples, which is the "Rückhaltebecken Wald" detention pond at the Paul Scherrer Institut, Switzerland. Strontium-90 activity concentration measured by both the Hidex 300 SL and TriCarb liquid scintillation analyzers were within the expanded ($k = 2$) uncertainties of an IAEA-375 reference soil sample.

Several researchers have put a metrological version (Metro version) Hidex 300 SL TDCR liquid scintillation analyzer to the test in the metrology of radionuclides by the TDCR method by comparing its performance with proven national home-made 3-PM liquid scintillation analyzers. Table 6.11 provides comparative data on radionuclide activity concentrations measured by both the Hidex 300 SL and home-made 3-PM liquid scintillation analyzers. The data illustrates how well the commercially available HIDEX 300 SL stands up to proven national 3-PM scintillation analyzers in accurate radionuclide metrology.

To confirm results obtained by one method of measuring a radionuclide activity concentration,

researchers will compare the results provided by a second or even a third method of analysis. For example, Capogni and De Felice (2014) compared their results on the determination of the activity concentrations of ⁶³Ni and ⁹⁹Tc obtained by three different counters and two different methods of analysis (TDCR and CIEMAT/NIST). Tables 6.12 and 6.13 illustrate measurements made with a national home-made portable 3-PM counter, the Metro version of the Hidex 300 SL 3-PM counter, and the TriCarb

2-PM counter in the measurement of activity concentrations (kBq/g) of ⁶³Ni and ⁹⁹Tc. To compare instrument performance Capogni and De Felice (2014) utilized the same kB factor and photomultiplier coincidence resolving times (t_c) measured in nanoseconds and dead times (t_d) measured in microseconds for each radionuclide analysis. Tables 6.12 and 6.13 illustrate the excellent performance of the Hidex 300 SL against the other TDCR counter and method used for the metrology of ⁶³Ni and ⁹⁹Tc.

6. Additional TDCR developments

a. Advances in applications

The TDCR efficiency calculation technique is a proven method for radionuclide standardization. Numerous reports on the standardization of specific radionuclides by the TDCR method have been published. Many of these reports on the metrology of radionuclides will include other methods, such as the CIEMAT/NIST technique to confirm results. Each radionuclide presents a specific challenge with respect to the efficiency calculation due to its characteristic decay scheme, and the reader may refer to the published reports for further information on the specific calculation codes and parameters utilized for each radionuclide. With this in mind, some of the published radionuclide standardizations by the TDCR efficiency calculation method with typical standard uncertainties of the determination in percent are provided in Table 6.14 in order of increasing mass number.

b. Utilization of channel photomultipliers

Channel photomultipliers are very light detectors, which contain a photocathode to convert light photons to electrons, and an electron multiplier consisting of a single narrow and hollow semi-conductive curved channel through which the photoelectrons are accelerated. Secondary electrons are produced by the collisions of the primary electrons on the walls of the channel. These

photomultipliers are described in detail in Chapter 9, Volume 1. Ivan et al. (2009) tested channel photomultiplier tubes, in lieu of the traditional photomultiplier equipped with electron multiplier dynodes, in a three-PM detector TDCR liquid scintillation analyzer. They observed significantly lower detection efficiencies; but excellent agreement in activity determinations of ^3H , ^{55}Fe , ^{63}Ni , and $^{90}\text{Sr}/^{90}\text{Y}$ when compared to the conventional counter equipped with the traditional electron dynode multiplier PM tubes. Channel photomultiplier tubes were again utilized by Ivan et al. (2010) in a new TDCR liquid scintillation counter equipped with six photomultiplier tube detectors, which was tested with several beta-emitters and, for comparative measurements, of tritiated water for validation studies. The six photomultipliers were connected in pairs and arranged in a symmetrical pattern about the liquid scintillation vial in the optical chamber of the liquid scintillation counter. The counter can be operated in two modes: as a single system with three CPMs and a double system with six CPMs, connected in pairs in summation mode. The double system with six photomultipliers resulted in a significant improvement in the detection efficiencies over the classical TDCR counter. In light of their reduced weight and size compared to the traditional dynode photomultiplier tubes, channel photomultipliers have been utilized in the construction of portable 3-PM TDCR systems as described by Kossert et al. (2014) and Nähle et al. (2014) and described in the following paragraphs.

c. Portable TDCR systems

Miniaturized TDCR systems have been developed under the framework of the project entitled “Metrology for New Generation Nuclear Power Plants” also referred to as the Metrofission Project announced by Johansson et al. (2011) and financed in part by the European Metrology Research Program (EMRP). Within the scope of this project several portable liquid scintillation analyzers equipped with three photomultiplier tubes have been designed as TDCR systems for on-site analysis of radionuclides including low-energy beta-emitters at nuclear power plants or to meet the needs for rapid and accurate radionuclide metrology at facilities where short-lived radionuclides are prepared such as at medical clinics for the diagnosis and treatment of cancer and other infirmities. The development of the portable TDCR systems are described by Cassette et al. (2013), Capogni and Antohe (2014), Capogni and De

Felice (2014), Johansson et al. (2014), Kossert et al. (2014b), Nähle et al. (2014), and Mini et al. (2014).

The miniaturization of TDCR systems have included the use of small Hamamatsu PMTs (Capogni and Antohe, 2014; Capogni and De Felice, 2014; Johansson et al., 2014) or light-weight channel photomultipliers (Kossert et al., 2014a,b,c; Nähle et al., 2014) and digital pulse processing as described in detail by Capogni and De Felice (2014) and Mini et al. (2014) consisting of a portable high-speed multichannel digitizer and digital pulse processing software that emulates the MAC3 analog board previously illustrated in Fig. 6.90. The new portable TDCR systems are tested generally against the performance of other instruments (See Table 6.11 previously described) or by comparison of results obtained with radionuclide samples of known activity concentrations as illustrated by Table 6.15. The data provided in Table 6.15 illustrates how

TABLE 6.15 The validation measurement of the new mini-TDCR system at the NPL^a. Four nuclides were used for the validation and compared against values from previous standardizations (including other methods apart from TDCR).

Radionuclide	Standardized value ^b (kBq g ⁻¹)	Uncertainty %, <i>k</i> = 1	Mini TDCR ^c	Uncertainty %, <i>k</i> = 1	Difference (%)
H-3	237.16	2.5	237.28	1.25	0.05
Ni-63	83.95	0.62	83.74	0.56	-0.25
Pu-241	79.74	0.39	78.56	2.60	-1.48

a new miniaturized TDCR system (mini-TDCR) performed by comparing the activity concentrations determined by the mini-TDCR system with the known activity concentrations of weak beta emitting nuclides determined by other TDCR systems and methods.

Another illustrative example is the work of Capogni and Antohe (2014), which involved the testing of a new portable TDCR system constructed by the ENEA-INMRI, Rome, Italy. They compared results obtained with a commercial 3-PM liquid scintillation counter, the HIDEX 300 SL “Metro version” to those obtained with the home-made instrument. The HIDEX 300 SL “Metro version” is a metrological version of the HIDEX 300 SL of tested performance at the ENEA-INMRI. Capogni and Antohe (2014) report that the 3-PM liquid scintillation systems provided the ratios of the net count rates for the triple and double coincidences, i.e., T/AB , T/BC and T/AC from which were computed the triple coincidence efficiency (ϵ_T) and the logical sum of the double coincidence (ϵ_D). They utilized the TDCR07c software, described previously, and available from the Laboratoire National Henri Becquerel (LNHB) of the CEA, France. They computed the activity concentrations (kBq/g) utilizing the triple coincidences according to

$$A_{C,T} = T/(\epsilon_T \times m) \quad (6.129)$$

and the activity concentrations from the logical sum of the double coincidences (D) were computed according to

$$A_{C,D} = D/(\epsilon_D \times m) \quad (6.130)$$

In the analysis of ^3H and ^{63}Ni they observed differences of only 0.01% between $A_{C,T}$ and $A_{C,D}$ for the two counters, i.e., the HIDEX 300 SL “Metro version” and the portable ENEA counter.

d. TDCR analysis with plastic scintillation microspheres

A development reported by Tarancón Sanz and Kossert (2011) is the application of a free-parameter model to samples containing solid plastic scintillation microspheres and radioactive aqueous solutions. Several beta-emitting radionuclide activities were measured in a TDCR system. The deviations between the determined activity concentrations and the reference values were <2.5%. However, Tarancón et al. (2015) note that the detection efficiency calculation model was highly dependent on the description of the plastic scintillation microspheres geometry, and an additional radionuclide tracing with ^{63}Ni was required to determine the exact scintillation microsphere packing. Thus, Tarancón et al. (2015) applied the CIEMAT/NIST tracing method for the measurement of pure beta-emitters, namely, ^{63}Ni , ^{14}C , ^{36}Cl , and $^{90}\text{Sr}/^{90}\text{Y}$ by utilizing an adapted MICELLE2 with the inclusion of PENELOPE code capable of measuring energy loss due to particle quenching resulting from varying geometries of heterogeneous mixtures of polystyrene microspheres and water.

D. Compton Efficiency Tracing (CET) method

Another radionuclide metrology method that involves a TDCR counter, referred to as the Compton Efficiency Tracing method, was reported by Cassette and Do (2008). This method utilizes a temporary virtual tracer source created by Compton interaction within the scintillation cocktail. A triple coincidence liquid scintillation counter measures the Compton tracer source after the Compton events are measured and selected by a gamma-ray detector such as a germanium or a cadmium telluride (CdTe) semiconductor detector. Cassette et al. (2010) note that the

CET method can offer the advantage that the tracer source, being a Compton electron source created inside the radionuclide source being measured, would have the identical chemical composition as the source under measurement. Thus, the measurement would have a reduced sensitivity to the kB factor and it would be insensitive to the chemical composition and quenching of the source. The CET method is described in Chapter 7 “Radionuclide Standardization”, Volume 2.

E. $4\pi\beta-\gamma$ coincidence counting

$4\pi\beta-\gamma$ coincidence counting is a direct method of activity determination, as it is independent of any quench indicating parameters and no reference standards are required for counting efficiency determinations. An additional advantage of this method is that the activity of a nuclide can be determined from experimental counting data only without the need for detector efficiencies.

As may be construed from the name applied to this method, it involves the coincidence detection of two types of radiations from a given radionuclide. The methods can be applied, therefore, to radionuclides that emit in coincidence more than one distinguishable type of radiation. Two types of detectors are required in coincidence to distinguish exclusively two types of radiation emissions, such as a liquid scintillation detector (or gas proportional counter) to measure a beta emission and a solid scintillation (or semiconductor detector) capable of measuring a gamma emission. Because the technique involves, in most cases, the use of a solid scintillation counter as one of the detectors, this method of radionuclide metrology is discussed in Chapter 7 “Radionuclide Standardization” of Volume 2.

X. Neutron/gamma-ray measurement and discrimination

The same year that [Herforth \(1948\)](#) under the leadership of Hartmut Kallmann, documented in her thesis the discovery that beta and gamma radiation produced scintillation in certain organic compounds, P. R. [Bell \(1948\)](#) demonstrated that fast neutrons could be detected in an anthracene scintillator by the proton recoils produced by neutron-proton collisions. Although neutrons have no charge and consequently cannot produce ionization or excitation directly in a scintillation fluor, the essentially equal mass of the neutron and protons (hydrogen atoms) in organic compounds facilitate transfer of energy from the neutron to protons via elastic scattering as described in Chapter 1, Volume 1. Because of the almost equal mass of the neutron and proton, the maximum fraction of the kinetic energy that a fast neutron can lose in a single head-on collision with a proton is calculated as 0.999 or 99.9% (See Table 1.19, Chapter 1, Volume 1). Although, partial energy transfers also occur

through less direct neutron-proton collisions, it is clear that fast neutron energy is absorbed more easily by a substance rich in protons (hydrogen atoms) compared to another substance possessing atoms of higher atomic number. The recoil protons with their acquired kinetic energy produce ionization until their energy is dissipated in the medium and they come to a full stop. A liquid scintillation cocktail, rich in protons (high H:C ratio), can be used to measure fast neutron radiation. The energy of the recoil protons dissipated in the scintillation cocktail solvent will excite the solute fluor molecules resulting in the emission of visible light similar to the effect of alpha- and beta-particle interactions discussed previously.

Another radiation type that does not carry charge but does interact in a liquid scintillation fluor cocktail is gamma radiation. Like X-radiation described previously, gamma rays will interact with liquid scintillation cocktail via principally Compton interactions with atomic electrons. The transfer of gamma-ray photon energy to atomic electrons will result in the liberation of Compton electrons. The energy of these electrons will be absorbed by the liquid scintillation solvent in the same way as beta particles described previously. Compton-electron energy absorption will result in fluor excitation and the emission of visible light of intensity proportional to the amount of energy absorbed in the scintillation cocktail.

The two mechanisms of fluor excitation via recoil proton or Compton-electron energy absorption forms the basis for the discrimination of neutron and gamma radiation, respectively, by liquid scintillation. The liquid scintillation discrimination of the two radiation types will be discussed further on in this section.

Only a brief description of the scintillation detection of neutrons and neutron/gamma-ray discrimination will be presented here. More detailed information can be obtained from references specific to the subject ([Scherzinger et al., 2017, 2016](#); [Tie et al., 2017](#); [Bourne et al., 2016](#); [Alharbi, 2015](#); [Gamage et al., 2014](#); [Liao and Yang, 2014](#); [Wang et al., 2014](#); [Enqvist et al., 2013](#); [Lawrence et al., 2013](#); [Xiaohui et al., 2013](#); [Zhang et al., 2013](#); [Nakhoshtin, 2012](#); [Enqvist and Pázsit, 2010](#); [Thomas, 2010](#); [Klein and Neumann, 2002](#)) and from Chapter 9 of Volume 1.

A. Detector characteristics and properties

The liquid scintillation cocktails used for the detection and measurement of neutrons are organic solutions generally high in hydrogen content to enhance the efficiency of trapping the neutron kinetic energy through neutron-proton collisions, which results in the production of recoil protons. Because high gamma-ray backgrounds are often present, the ability of discriminating between incident neutron and gamma radiation through pulse shape discrimination (PSD) becomes important and some liquid scintillation cocktails

are most suitable for this purpose. Also, some organic scintillation cocktails are devoid of hydrogen, such as BC-509 or EJ-313 (equivalent to NE-226) or BC-537 or EJ-315 (equivalent to NE-230), which contain deuterated benzene (C_6D_6). Such cocktails have reduced sensitivity to neutrons and can be used for the measurement of gamma radiation in the presence of neutron radiation. Examples of commercially available cocktails for the detection of neutrons and gamma radiation or for neutron/gamma-ray discrimination as well as other applications such as neutrino detection are provided in Table 6.16. These liquid scintillators are used devoid of oxygen gas. Dissolved atmospheric oxygen reduces their light output by about 30%, and eliminates any pulse shape discrimination properties that the cocktails might possess. These cocktails are purged thoroughly with nitrogen gas prior to use.

Liquid scintillation neutron detectors vary in size from small to medium-sized (4–12 cm in diameter by 4–12 cm in length) up to large volume detectors comprising several cubic meters depending on the research objectives (See Table 6.16 and Bourne et al., 2016, Scherzinger et al., 2016, Alharbi, 2015, Enqvist et al., 2013, Zhang et al.,

2013, Lavagno et al., 2010, Černý et al., 2004, Vartsky et al., 2003, and Zecher et al., 1997). The detectors are available commercially prefabricated with the liquid scintillation cocktail encapsulated in a sealed inert material (e.g., aluminum, stainless steel, indium, Teflon) of various sizes coated internally with a TiO_2 reflective paint to optimize light output and an optical window of borosilicate glass, which would be linked with the face of a photomultiplier tube. The liquid scintillation cocktail is purged with nitrogen or argon gas before the sealing of the detector to permit n/γ pulse shape discrimination. Liquid scintillation cocktail is also available in bottles or drums for laboratories that need to fabricate detectors according to specific dimensions.

The efficiency and energy resolution of the detector will be governed by its size. Energy is deposited by fast neutrons in the liquid scintillation cocktail by collisions for the most part with hydrogen atoms (n-p collisions) and to a lesser degree with the carbon atoms (See Table 1.19 in Chapter 1, Volume 1), and, as a consequence, recoil proton excitation of cocktail solvent and fluor molecules is predominant. Gamma radiation will deposit energy mainly via

TABLE 6.16 Properties and Applications of Liquid Scintillators Used for Neutron Radiation Measurements or Neutron/Gamma Radiation Discrimination among other Applications.^a

Scintillator	Properties	Applications
BC-501A ^b	Xylene ^e (>90%)	Yields excellent n/γ pulse shape discrimination (PSD) over a wide energy range up to ~ 100 MeV (D'Melloe et al. (2007) Enqvist et al. (2008) Horváth et al., 2000, and Nakao et al., 2001, Klein and Neumann, 2002, D'Melloe et al. (2007), Aspinall et al., 2007a, Enqvist et al. (2008), Liu et al., 2009, Yousefi et al., 2009, Braizinha et al., 2010, Lavagno et al., 2010, Bayat et al., 2012, Nakhostin and Walker, 2010, Nakhostin, 2012, Zhang et al., 2013, Gamage et al., 2014, Liao and Yang, 2014, Wang et al., 2014, Alharbi, 2015, Scherzinger et al., 2016, 2017 and Tie et al., 2017).
EJ-301 ^c	Aromatic fluors (<10%) ^f	
NE-213 ^d	Atomic ratio, H/C: 1.212	
	λ_{max} : 425 nm ^g	
	Light output: 78% anthracene ^h	
	Decay time: 3.2 nsec ⁱ	
	Density: 0.874 g/cm ³	
	Refractive index, n_D : 1.505	
	Flash point: 26°C	
BC-505	1,2,4-trimethylbenzene ^e (97.5%)	Exhibits high light output and transmission; Fast neutron detectors; Suitable for large volume, including anti-Compton and anti-coincidence shields; High flash point makes it safer to use and transport than xylene or toluene-based scintillators; (Cecil and Scorby, 1992, Hong et al., 2002, Klein and Brooks, 2006, Wurtz et al., 2011, Fukuda et al., 2016 and Cerutti et al., 2017).
EJ-305	Aromatic fluors (<0.5%)	
NE-224	Atomic ratio, H/C: 1.331	
	λ_{max} : 425 nm	
	Light output: 80% anthracene	
	Decay time: 2.5 nsec	
	Density: 0.977 g/cm ³	
	Refractive index, n_D : 1.505	
	Flash point: 48°C

TABLE 6.16 Properties and Applications of Liquid Scintillators Used for Neutron Radiation Measurements or Neutron/Gamma Radiation Discrimination among other Applications.^a—cont'd

Scintillator	Properties	Applications
EJ-309 NE213 with low	Solvent (proprietary): aromatic hydrocarbon (>99%)	Liquid scintillator developed as an alternative to the more commonly used for pulse shape discrimination (PSD), such as BC-501A, and EJ-301, which contain xylene solvent flash point and high degree of solvent action. EJ-309 exhibits slightly poorer PSD characteristics, but possesses more environmentally favorable chemical properties and higher flash point (Pozzi et al., 2009; Clarke et al., 2009; Enqvist et al., 2010, 2013; Zak et al., 2010; Lawrence et al., 2013; Gamage et al., 2014; Tomanin et al., 2014; Bourne et al., 2016; Lennox et al., 2017 and Bai et al., 2018).
	Organic fluors (<1%)	
	Atomic ratio, H/C: 1.25	
	λ_{max} : 424 nm	
	Light output: 75% anthracene	
	Decay time: 3.5 nsec ^h	
	Density: 0.96 g/cm ³	
	Refractive index, n_D : 1.57	
BC-509 EJ-313 NE-226	Flash point: 144°C	Essentially free of hydrogen atoms (with exception of fluor molecules) only 0.18 atom % of hydrogen atoms; Low sensitivity to fast and moderated neutrons, gamma-ray detection in a fast neutron flux; Neutron insensitivity increased with pulse shape discrimination to enhance gamma-ray detection in n/γ discrimination; Can be used to detect neutrons when it is desirable to avoid thermalizing properties of hydrogen (Cecil and Medley, 1988; Davies et al., 1994; Wolle et al., 1999; Hong et al., 2002, and Hamel et al., 2014).
	Hexafluorobenzene ^e	
	Formula: C ₆ F ₆	
	λ_{max} : 425 nm	
	Light output: 20% anthracene	
	Decay time: 3.1 nsec	
	Density: 1.61 g/cm ³	
	Refractive index, n_D : 1.38	
BC-517H EJ-321H NE-235H	Boiling point: 80°C	Mineral oil-based scintillator where long mean free paths are required and high light output important; Large volume detectors; Compatible with acrylic plastics such as Plexiglas [®] and Perspex [®] , as well as many metals and reflective coatings; Pulse shape discrimination capability. Variants of this cocktail exist including BC-717L, BC-517P and BC-517S for large tanks, plastic containers and high light output and equivalents are EJ-321L, EJ-321P, and EJ-321S (Sakai et al., 1992; Arpessella, 1996; Tayloe et al., 2006; Braizinha et al., 2010; Christensen et al., 2014).
	Flash point: 10°C	
	1,2,4-trimethylbenzene (<30%)	
	Mineral oil (>70%)	
	Aromatic fluors (<0.3%)	
	Atomic ratio, H/C: 1.89	
	λ_{max} : 425 nm	
	Light output: 52% anthracene	
	Mean free path: > 5 m ^j	
	Decay time: 2.5 nsec	
BC-519 EJ-325A NE-235C	Density: 0.86 g/cm ³	Provides excellent n/γ pulse shape discrimination for neutron energies up to 100 MeV (Horwath et al., 2000; Chen et al., 2008; Beaulieu et al., 2011; Gozani et al., 2011; Jandel et al., 2015).
	Refractive index, n_D : 1.476	
	Flash point: 81°C	
	1,2,4-trimethylbenzene (<40%)	
	Mineral oil (<60%)	
	Fluors (0.5%)	
	Density 0.86 g/cm ³	
	Atomic ratio, H/C: >NE213	
	Flash point: >62°C	
	Boiling point: > 204°C

TABLE 6.16 Properties and Applications of Liquid Scintillators Used for Neutron Radiation Measurements or Neutron/Gamma Radiation Discrimination among other Applications.^a—cont'd

Scintillator	Properties	Applications
BC-521	1,2,4-trimethylbenzene (>85%)	Utilized for neutron spectrometry with pulse shape discrimination and neutrino research; Fast neutrons leave a unique signature in Gd-loaded scintillator; They produce a prompt recoil proton pulse and, once thermalized, they are easily captured by Gd, which has an extremely high thermal neutron capture cross section. Neutron capture by Gd is signaled by the emission of three gamma rays totally ~ 8 MeV. Available at 0.25% w/w Gd (EJ-335) with mineral oil to increase hydrogen content and use in large tanks; produced at Gd content of 0%, 5% (BC-525) with mineral oil component for increased light transmission, hydrogen content, and higher flash point. Neutron capture by Gd results in a cascade of conversion electrons, X-rays, and γ -rays. BC-525 is used in neutron spectrometry and neutrino research. (Varignon et al., 2006 Banerjee et al., 2007 and Laborie et al., 2012).
EJ-331	Gadolinium (0.5%)	
NE-323	Light output: 68% anthracene	
	Atomic ratio, H/C: 1.314	
	λ_{\max} : 424 nm	
	Decay time: 3.6 nsec	
	Density: 0.89 g/cm ³	
BC-523A EJ-339 NE-321A	Refractive index, n_D : 1.50	Available at natural ¹⁰ B isotope abundance or enriched; EJ-339A contains boron loading compound enriched to 90% atom percent in ¹⁰ B and thus contains 4.6% ¹⁰ B by weight; Useful for total neutron absorption spectrometry; fast neutrons produce a prompt recoil proton pulse with initial scatterings in the cocktail; thermalized neutrons may undergo the ¹⁰ B(n, α) ⁷ Li capture; the capture pulse is in delayed coincidence with the prompt pulse; Useful in identifying neutron events; Useful for n/ γ separation by PSD. (Yen et al., 2000, Vartsky et al., 2003 , Jastaniah and Sellin, 2004 , Flaska and Pozzi, 2009 , Pinoi et al., 2014 , and Liao and Yang, 2014).
	Flash point: 44°C	
	1,2,4-trimethylbenzene (>30%)	
	Methyl borate (<60%)	
	1-methylnaphthylene (10%)	
	Light output: 65% anthracene	
	Atomic ratio, H/C: 1.74	
	Natural ratio ¹⁰ B/ ¹¹ B: 0.245	
	Enriched ratio ¹⁰ B/ ¹¹ B: 9.0	
	λ_{\max} : 424 nm	
BC-537 EJ-315 NE-230	Decay time: 3.7 nsec	Useful for n/ γ separation as sensitivity to fast neutrons is reduced by deuterium. A nondeuterated version of the scintillator (EJ-315H) is available for comparative research. (Marrone et al., 2002 , and Villano et al., 2011 , Jaworski et al., 2012 , Lawrence et al., 2013 , Xiaohui et al., 2012, 2013 , Febbraro et al., 2015 and Becchetti et al., 2016, 2017).
	Density: 0.916 g/cm ³	
	Refractive index, n_D : 1.4	
	Boiling point: 68.9°C	
	Deuterated benzene (>98%)	
	Formula: (C ₆ D ₆)	
	Aromatic fluors (<2%)	
	Light output: 61% anthracene	
	Atomic ratio, D/H: 141:1	
	Atomic ratio, D/C: 0.99	
	λ_{\max} : 425 nm	
	Blue photons (per 1 MeVee): 12,000 ^k	
	Decay time: 1.8 nsec	
	Density: 0.954 g/cm ³	
	Refractive index, n_D : 1.498	
	Short decay component: 3.5 nsec ^k	
	Boiling point: 79.1°C	
	Flash point: -11°C (12°F) ^k	
	Mean free path of fission neutrons ^k : 4.96 cm ^l

Compton interactions resulting in Compton-electron excitation of cocktail and fluor. Since both neutrons and gamma rays are generally intermixed, both radiations should be considered. The neutrons will encounter a wide range of collisions with protons including direct head-on collisions and complete transfer of energy in less-direct collisions even just a glancing with a proton resulting in various scattering interactions and only partial energy transfers to protons (See Chapter 1, Volume 1). Likewise, Compton electrons will vary in energy depending on the energy of the incident gamma radiation.

If the liquid scintillation detector is very small or the neutron or γ-ray energies very high, a considerable number of recoil protons or Compton electrons can escape from the detector. This results in an incomplete deposition of either proton-recoil or Compton-electron energy in the cocktail referred to as the 'wall effect' (Bai et al., 2018; Thomas, 2010). When the wall effect is significant, the event (n-p or γ-e) recorded by the photomultiplier tube as a pulse height would be smaller than what would be expected had the recoil proton or Compton electron deposited all its energy in the cocktail. Consequently, the 'response function', which is the pulse height registered per neutron or gamma-ray energy, would be shifted to lower pulse heights. For

example, in the analysis of γ-ray photons of energy over the range of 7–20 MeV, Navotny et al. (1997) chose NE-213 scintillation detectors large enough (e.g., 5 cm in diameter by 10 cm in length, 206 cm³ in volume) taking into account the maximum range of Compton electrons to be detected to avoid a distortion of the pulse height response by wall effects. Likewise, for the measurement of neutron radiation, Hakao et al. (2001) demonstrated that for an NE-213 liquid scintillator of 12.7 cm diameter by 12.7 cm long the proton-escape probability ranges from approximately 1% to more than 50% of the recoil protons generated for neutrons over the energy range of 25 MeV to over 300 MeV. The neutron detection efficiencies were determined by Hakao et al. (2001) by integrating the pulse height response functions at various calibrated pulse height thresholds. At a lower-limit discriminator setting or pulse height threshold of 1.15 MeV (calibrated with a ⁶⁰Co source) the neutron detection efficiencies varied from 24% to 10% over the neutron energy range of 23–132 MeV. Satoh et al. (2001) developed a Monte Carlo code, designated SCINFUL-QMD, for the calculation of neutron detection efficiencies for neutron energies up to 3 GeV in liquid scintillators such as NE-213. Other Monte Carlo and analytical models of neutron scatterings in liquid

scintillation cocktail and detector response are provided by Bai *et al.* (2017), Gohil *et al.* (2012), Patronis *et al.* (2007), Pozzi *et al.* (2007), and Enqvist and Pázsit, 2010).

It is important to note here that for heavy particles (*e.g.*, protons and α particles) the light output from the liquid scintillator is nonlinear with energy. Unlike electrons or β particles, which produce a relatively linear light output with energy over the range of 0.100–1.6 MeV (Novotny *et al.*, 1997 and Horváth *et al.*, 2000), heavy particles exhibit high values of stopping power (dE/dx) in scintillator (See Chapter 1, Volume 1) and thereby produce higher specific ionization and a saturation effect that yields less light per particle energy loss. The nonlinearity of light output per particle energy loss for protons results in recoil proton energies occurring at lower pulse heights in the pulse height spectrum. Consequently, the use of computer codes to unfold neutron and photon energy spectra require accurate measurement of the light output response as a function of energy deposited in the scintillator (Enqvist and Pázsit, 2010; Kornilov *et al.*, 2009; Klein and Neuman, 2002; Neuman *et al.*, 2002; Reginatto *et al.*, 2002; Schmidt *et al.*, 2002). Radionuclide sources with well separated γ -ray energies are used to establish the pulse height scale in terms of electron energies. Gamma-photon sources produce Compton edges in the scintillator where the Compton-electron energies can be used to convert light outputs into electron equivalent energies or MeVee (Tie *et al.*, 2017; Scherzinger *et al.*, 2016; Liao and Yang, 2014; Villano *et al.*, 2011; Hawkes *et al.*, 2010; Zak *et al.*, 2010; Guerrero *et al.*, 2008; Klein and Neumann, 2002; Nakao *et al.*, 2001; Horváth *et al.*, 2000).

The detector size will govern the number of multiple neutron scatterings. Neutron scattering can result in a broad range of energy transfers to recoil protons, from very little neutron energy when a neutron is simple glanced off a proton (near hit) up to the maximum neutron energy resulting from a head-on collision with a hydrogen atom. Recoil protons from a given neutron after multiple collisions and scatterings will produce photons, which are detected by the photomultiplier tube as they occur within the coincidence time gate of the scintillation analyzer. The sum of the photons produced by the recoil protons from the multiple scatterings of one neutron will produce a pulse height from the photomultiplier proportional to the light output. Due to the summation of photons from multiple scatterings the resultant pulse heights will be higher than what would occur at reduced scattering.

Neutrons are also scattered by carbon atoms in the scintillator; however, carbon recoils do not produce any significant light output in liquid scintillator (Klein and Neumann, 2002). The H:C atomic ratios in liquid scintillator may vary from 1.2 to 1.9 (Table 6.16). The higher the ratio or greater the atom % H in the scintillator, the higher will be the probability of n-p collisions and the production

of proton recoils. However, carbon scattering will cause neutron energy loss and consequently a reduction in pulse height response as a function of energy. As illustrated in Table 1.19 of Chapter 1, the maximum fraction of kinetic energy that may be lost by a neutron collision with ^{12}C is 28.6% resulting from a head-on n- ^{12}C collision. A neutron may lose, therefore, anywhere between zero and 28.6% of its energy in a single collision with carbon. For example, a scattered neutron that had an initial head-on collision with a ^{12}C atom may then collide with a proton, but the maximum energy of the recoil proton in this case would be 71.4% of the original neutron energy. Consequently, carbon atoms in the scintillator will reduce the pulse height response as a function of neutron energy.

At lower neutron energies, particularly where neutrons may become thermalized in the liquid scintillator, special detectors may be employed, such as BC-523, that contain natural or enriched ^{10}B in the scintillation cocktail (Table 6.16) to enhance detection efficiencies. The incident neutrons are moderated by n-p collisions in the cocktail and then undergo $^{10}\text{B}(n,\alpha)^7\text{Li}$ capture according to Eq. (1.327) of Chapter 1, Volume 1 and more specifically as follows:

The branching ratios for the two reactions are 6.3% and 93.7%, respectively. The branch described by Eq. (6.131) leaves the ^7Li at the ground state, whereas the other branch (Eq. 7.126) leaves the ^7Li at an excited state, and the α particles plus $^7\text{Li}^*$ ions create scintillation light equivalent to light produced by 65-keV electrons or beta particles. Yen *et al.* (2000) report the use of 4 cm diameter detectors of ^{10}B -enriched scintillator joined together in a circular array of 55 detectors. They report detector efficiencies of 95%, 85%, and 71% at neutron energies of 10, 100, and 1000 eV, respectively.

Gd-loaded liquid scintillators, described in Table 6.11, have excellent neutron detection properties, because of the very high thermal neutron capture cross section of Gd (See Table 1.20 of Chapter 1, Volume 1). As described by Banerjee *et al.* (2007), the mechanism of neutron detection in a Gd-loaded scintillator consists of two stages. Firstly, the fast neutron that enters the liquid scintillator will undergo multiple scatterings primarily with hydrogen atoms in a few tens of nanoseconds producing a prompt signal. After several collisions with atomic nuclei of the scintillator, the neutron slows down and is thermalized, *i.e.*, it reaches the low thermal energy stage, provided the neutron does not escape from the scintillator. The second stage consists in the capture of the thermal neutron by a Gd nucleus, because of its extremely high thermal neutron

capture cross section. Neutron capture by Gd results in the emission of three γ -rays with a total energy of ~ 8 MeV. The detection of the capture gamma rays provides a measure of the total number of neutrons emitted.

Liquid scintillators loaded with ^6Li are not available commercially; however, Fisher et al. (2011) and Bass et al. (2013) have easily prepared liquid scintillator loaded with up to 0.40% ^6Li capable of fast neutron spectrometry and thermal neutron detection with maximum background discrimination using capture-gated neutron spectroscopy. The detection method is illustrated in Fig. 6.93, which shows a fast neutron entering into a detector containing a ^6Li -doped liquid scintillation fluor cocktail. The neutron

FIGURE 6.93 An illustration of the principle of capture-gated detection. A fast neutron impinges on the ^6Li -loaded liquid scintillation detector. It rapidly gives up its energy through nuclear collisions, primarily with protons, in the moderation process. The thermalized neutron diffuses in the medium until it is captured on an atom (e.g., ^6Li) with a high capture cross section. From Fisher et al. (2011); reprinted with permission from Elsevier © 2011.

scatters from an initial collision with a proton, which on average will recoil with half of the initial neutron energy yielding scintillation light. The neutron continues to scatter off of other protons in the scintillation cocktail until it escapes from the detector or is captured by a ^6Li atom after reaching a thermal energy according to the following reaction:

As described by Fisher et al. (2011), a large fraction of the fast neutrons entering the detector will lose most of their energy through neutron-proton collisions (i.e., n-p scattering) and most of the scintillation light will originate from these n-p events. A neutron of a few MeV in energy will lose 90% of its energy through n-p scattering in the first 10 ns in the scintillator. Neutron scattering off of carbon atoms can also generate light; however, these are minor when compared to the n-p events. Capture of the thermal neutron will occur in a short time scan of <100 ns depending on the size and geometry of the detector and the concentration of the ^6Li , which has a relatively high thermal neutron capture cross section (See Table 1.20 in Chapter 1, Volume 1). The neutron capture reaction with ^6Li has a high Q value of 4.78 MeV (Qcalc, <https://www.nndc.bnl.gov/qcalc/>, accessed Feb 16, 2018). The capture reaction energy is shared between the tritium and alpha particle capture products, and due to their short range, their entire energy is absorbed in the liquid scintillator producing a high scintillation light output. An example of digitized pulse events from a photomultiplier tube resulting from the initial proton recoil from a fast neutron in the liquid scintillator followed by neutron capture by ^6Li is illustrated in Fig. 6.94.

FIGURE 6.94 Plot of the digitized PMT pulse of the detector response to a fast neutron within the ^6Li -loaded liquid scintillator. A fast neutron enters the detector and initially scatters off the protons in the scintillator. After thermalizing within the scintillator, it captures on a ^6Li , in this example approximately 1.4 μs later. From Fisher et al. (2011); reprinted with permission from Elsevier © 2011.

The method offers several advantages over the use of other neutron capture loaded scintillators, such as ^{10}B -loaded scintillators. As described by Bass et al. (2013), these advantages are the following: (i) The products of the $^6\text{Li}(n,\alpha)^3\text{H}$ reaction are charged particles and not gamma rays. Their energy is deposited completely in the liquid scintillator. (ii) The Q -value of the $^6\text{Li}(n,\alpha)^3\text{H}$ reaction (4.78 MeV) is larger than that of the $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction (2.79 MeV) yielding an energy deposit peak better separated from the noise level. (iii) The preparation and loading of scintillator with enriched $^6\text{LiCl}$ involves simple chemistry, and at a cost, which is significantly less than commercially available ^{10}B -load scintillators. A disadvantage would be the restricted availability of enriched ^6Li for some institutions.

B. Neutron/gamma-ray (n/ γ) discrimination

The detection of neutrons is complicated generally with background gamma radiation. The neutron detector can be shielded from radiation background arising from charged particles by use of shielding material between the source and detector or via magnetic field deflection. This leaves only gamma rays, which remain undeflected by magnetic fields and relatively unattenuated by absorbers.

Neutron and γ -ray interactions in a liquid scintillator may be separated by pulse shape discrimination (PSD) according to principles that are similar somewhat to alpha- and beta-particle (α/β) discrimination in liquid scintillation described further on in this chapter. The principles behind (n/ γ) discrimination rest on different degrees of excitation caused by heavy charged particles versus lighter charged particles in the liquid scintillation cocktail. Neutron interactions produce the relatively heavy recoil protons, whereas γ rays produce much lighter Compton electrons in scintillation cocktail. The heavier recoil protons produce greater specific ionization (higher LET) in cocktail than the Compton electrons and, consequently, proton interactions in cocktail fluors create higher cocktail fluor excited states that take longer for de-excitation to occur. De-excitation is manifested as fluorescence. The fluorescence is analyzed by the electric pulse it produces in the photomultiplier tube (PMT). The shape of the pulse is a function of the specific ionization of the particle (heavy particle vs. lighter particle), and the shape can be defined in two components, namely, a fast (prompt) component or rise time and a slow or delayed component also referred to as the tail. The prompt component of fluorescence has a decay time of only a few nanoseconds, while the delayed component or tail may last a few hundred nanoseconds. The differences in pulse shapes produced by neutron and γ -ray interactions in a liquid scintillator are illustrated in Fig. 6.95. A relatively heavy charged particle, such as a proton arising from neutron interactions, will produce a larger fraction of its

FIGURE 6.95 Neutron and γ -ray true pulse shapes recorded with BC501A liquid scintillator. The shape of the neutron signals shows a dependence on the energy of the recoil nuclei. The emission mechanism exhibits a prompt component, which starts within the first 5 ns and a delayed component, which occurs after a subsequent ~ 25 ns. From Guerrero et al. (2008). Reprinted with permission from Elsevier © 2008.

fluorescence in the slow component, while a much lighter charged particle, such as the Compton electron arising from γ -ray interactions, will cause fluorescence with a much smaller portion of the light in the slow component. Guerrero et al. (2008) demonstrate, with an Am–Be neutron source, that the slower neutrons exhibit a longer delayed component or tail than faster neutrons. This could be explained by the fact that protons of lower energy have a higher LET producing more high-excitation states of scintillator cocktail. The Am–Be source produces neutrons with energies up to ~ 10 MeV with an average neutron energy of 4 MeV and various gamma lines.

Two of the most common methods of exploiting the phenomena of differing pulse shapes for n/ γ discrimination with the use of analogue electronics are (i) the charge-comparison, and (ii) zero-crossing techniques (Liao and Yang, 2014; Nakhostin and Walker, 2010). The charge-comparison method involves the measurement of the integrated charge collected over two different time regions of the pulse to identify neutron and gamma events in the liquid scintillator, and the zero-crossing technique yields n/ γ discrimination by a measurement of a zero-crossing time for a suitable fraction of the pulse shape. These techniques will be described subsequently.

1. Digital charge-comparison (CC) method

The method of Heltsley et al. (1988) is commonly used. As described by Liao and Yang (2014), Wang et al. (2014),

Zecher et al. (1997), and Ranucci (1995), this PSD method entails the use of two analog-to-digital converters (ADCs), one that integrates, via a PSD algorithm, the total charge of the pulse, and the other integrates the charge from some fixed time fraction (i.e., portion) of the pulse (i.e., either the first prompt component or the longer tail component). This is illustrated in Fig. 6.96 where A_1 is the total integral charge starting from the very beginning of the pulse to an optimum endpoint where the slow tail reaches background, and A_2 is an integration of the pulse starting from a selected beginning of the tail to the same endpoint referred to as the tail integral. The ratio R of the tail integral to the total integral, as described by Eq. (6.134), is taken to discriminate between the proton and Compton electron events originating from neutron and gamma interactions, respectively in the liquid scintillator.

$$R = A_2/A_1 \quad (6.134)$$

By comparing the magnitude of the charge collected in the fraction of the pulse to the total charge collected in the pulse, one can determine which species created the pulse, proton or electron, and consequently, neutron or γ -ray.

Charge comparison n/γ discrimination techniques that compare the ‘short’ and ‘long’, or ‘total’ and ‘delayed’, or ‘total’ and ‘tail’ components of the scintillation pulse have been utilized by numerous researchers including Bourne et al. (2016), Alharbi (2015), Liao and Yang (2014), Wang et al. (2014), Zhang et al. (2013), Nakhostin (2012), Xiaohui et al. (2012, 2013), Schiffer et al. (2011), Villano et al. (2011), Pozzi et al. (2009), Enqvist et al. (2010), Hawkes et al. (2010), Lavagno et al. (2010), Clarke et al. (2009), Flaska and Pozzi (2009), Hamel et al. (2009a,b), Guerreo et al. (2008), D’Mellow et al. (2007), Černý et al. (2004) and Rochman et al. (2004). An example may be taken from the work of Lavagno et al. (2010), who utilized a

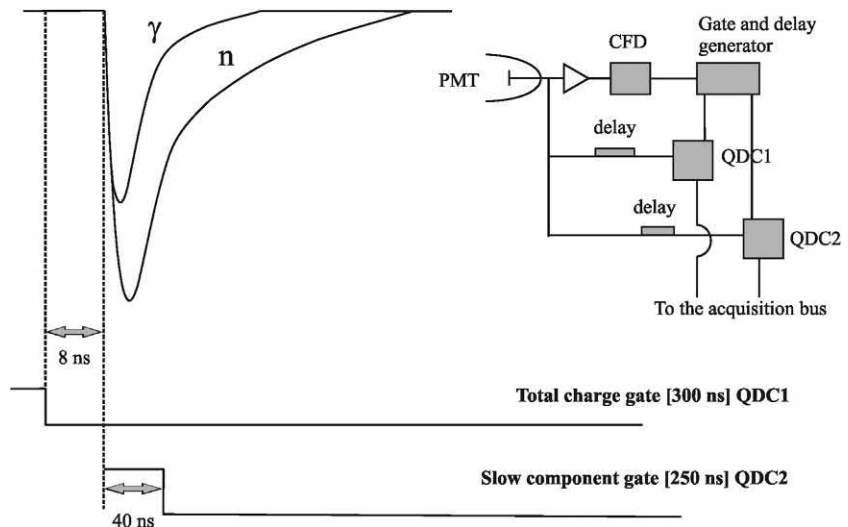

FIGURE 6.96 Pulse events produced by neutron and gamma interaction in the liquid scintillator and regions of charge integration, namely the tail integration A_2 and the total integration, A_1 . The ratio R of the two integrations is defined as A_2/A_1 . Adapted from Liao and Yang (2014), Wang et al. (2014), and Alharbi (2015).

Canberra Nuclear Instrumentation Module (NIM) 2160A Charge-to-Digital Converter (QDC) to exploit the difference in the intensity of the slow or delayed component of the light pulse (See Fig. 6.96) to the space density of the charge carriers produced by the different types of ionizing particles (i.e., protons and electrons), which yields excellent $n-\gamma$ discrimination. As described by Lavagno et al. (2010), the charge comparison method compares directly the intensity of the slow component to the total light pulse by incident ionizing radiation, i.e., the recoil protons and Compton electrons. A block diagram of the experimental setup and time relation between photomultiplier pulse and gates at the input of the QDCs are illustrated in Fig. 6.97. One QDC at the opening of the gate signal integrates the charge

FIGURE 6.97 NIM electronic block diagram and time relation between photomultiplier pulse and gates at the input of QDCs. From Lavagno et al. (2010). Reprinted with permission from Elsevier © 2010.

corresponding to the total pulse, and another QDC, triggered by the delay gate signal, collects only the charge from the slow or delayed component. The prompt component of the pulse starts after the first ~ 5 ns following excitation, and the delayed or slow component in the subsequent 20–25 ns.

The signals arising from γ -ray and neutron interactions may be distinguished by plotting the integrated intensities of the two components of the pulse against each other as illustrated in Fig. 6.98. As described by Guerrero et al. (2008), the integration of the digitized signals is carried out in two different time intervals, and the particle type of each signal is evaluated by a comparison between the two signals. Each signal arising from an electron or proton in the scintillator, as a consequence of a γ -ray or neutron interaction, respectively, is characterized by its time, amplitude, and the two integrals I_{total} and I_{delayed} . Fig. 6.98 illustrates well separated signal intensities corresponding to γ -rays and neutrons, which was reported by Guerrero et al. (2008) to be obtained from the integration of signals (See Fig. 6.96) over the 0–150 ns interval for I_{total} and from 55 to 150 ns for I_{delayed} .

As illustrated previously in Figs. 6.95 and 6.96, the amplitude of the tail section as a result of neutron interactions is higher than that produced by γ -rays. As a consequence, the ratio R for neutrons is higher than that for γ -rays (Wang et al., 2014). A histogram for γ -ray and neutron events (i.e., counts) can be constructed as a function of R , which with good discrimination, will yield two

FIGURE 6.98 Distribution of I_{total} and I_{delayed} values in a measurement of an Am/Be source. The two well separated regions correspond to γ -ray and neutron signals. From Guerrero et al. (2008); reprinted with permission from Elsevier © 2008.

separate peaks for γ -ray and neutron events, as illustrated in Fig. 6.99. A value of figure of merit (FOM) is calculated according to Eq. (6.135)

$$\text{FOM} = \frac{S}{\text{FWHM}_{\gamma} + \text{FWHM}_n} \quad (6.135)$$

where S is the separation or distance between the gamma and neutron peaks, and FWHM_{γ} and FWHM_n are the resolutions of the gamma and neutron peaks, respectively, measured by their full widths at half maximum, as illustrated in Fig. 6.99. The magnitude of the FOM serves to evaluate the degree of n/γ discrimination where optimum discrimination is obtained at highest FOMs.

The ratio of the two integrals, i.e., short integral/long integral is used as the discrimination parameter. The Charge Comparison algorithm described by Hawkes et al. (2010) can determine the optimum starting time for the pulse integration for the short integral by maximizing the FOM, which is calculated over a range of different starting times. A plot, from the work of Hawkes et al. (2010), obtained with the optimized starting time together with Gaussian fits used to measure the peak positions and widths is illustrated in Fig. 6.100.

2. Simplified digital charge-comparison (SDCC) method

The simplified digital charge-comparison (SDCC) method is a relatively new approach to n/γ discrimination, which has been tested thoroughly by Gamage et al. (2011) and Xiaohui et al. (2013). The SDCC method is based on a study by Shippen et al. (2010) demonstrating that the charge-comparison method can be optimized by squaring increments of time that fall in the region of interest of the digital pulse. As described by Xiaohui et al. (2013), the

FIGURE 6.100 FOM plot for the optimum value of the short integral starting time in the Charge Comparison Algorithm. The dotted curves show the Gaussian fits used to determine the positions and widths of the peaks. From *Hawkes et al. (2010)*. Reprinted with permission from Elsevier © 2010.

SDCC method is based on a discrimination parameter D calculated according to the following:

$$D = \log \left(\sum_{t=a}^{t=b} (x_t^2 + x_{t+0.5}^2) \right) \quad (6.136)$$

where x_t and $x_{t+0.5}$ are sample amplitudes at times t and $t + 0.5$ and a and b are the start and end times of the pulse region of interest. The optimum time interval for a pulse region of interest would depend on the detector, and *Xiaohui et al. (2013)* found the values of $a = 70$ ns and $b = 210$ ns to be optimum for their apparatus, and the D parameter is always larger for a neutron pulse than for a γ -ray event. *Xiaohui et al. (2013)* and *Gamage et al. (2011)* thoroughly tested the CC and SDCC methods as well as the pulse gradient analysis (PGA) method and found excellent n/γ discrimination among the three methods.

Irrespective of the methods utilized for n/γ discrimination, the figure of merit (FOM) or degree of n/γ separation achievable will depend on the energy thresholds applied, which is a preset threshold voltage for the recording of generated pulses arising from the proton recoil and Compton electron events in the liquid scintillator (*Binaei Bash et al., 2013; Bayat et al., 2012; Xiaohui et al., 2012; Nakhostin, 2012; Nakhostin and Walker, 2010*). The threshold energy scale of a detector system is calibrated by using the Compton edge of standard gamma-ray emitting nuclides sources such as ^{60}Co , ^{137}Cs , and ^{22}Na . For example, ^{22}Na emits a 1275 keV gamma-ray line with a 100% intensity, and it produces a Compton edge at ~ 1060 keV (*Binaei Bash et al., 2013; Bayat et al., 2012*). Energy calibration using the Compton edge enables the expression of the threshold energies in units of electron-equivalents or keVee. Thus, pulse heights that are

FIGURE 6.101 The results of n/γ discrimination for different energy thresholds (Ethr). Neutron events are illustrated on the left and gamma-ray events on the right. All events were recorded in a detector arrangement containing BC-537 liquid scintillation cocktail. From *Xiaohui et al. (2012)*; reprinted with permission from Elsevier © 2012.

generated are expressed at neutron and gamma-ray threshold energies in units of keVee, which is an electron energy equivalent unit. Highest figure of merits (FOMs) or optimum separation of neutron and gamma-rays are achieved at high threshold energies, as illustrated in *Fig. 6.101*. For example, at the threshold energies of 280 and 410 keVee some overlap of neutron and gamma-ray events were recorded by *Xiaohui et al. (2012)*, and at higher threshold energies 550 to 1000 keVee, complete separation is illustrated. Electronic noise is significant at low threshold energies resulting in diminished neutron-gamma discrimination.

As noted in the previous paragraph and illustrated in *Fig. 6.101*, low FOMs occur at low energy thresholds, that is, there is complete separation of neutron and gamma-rays are not achieved and the two peaks overlap to some degree. *Polack et al. (2015)* describe an algorithm capable of measuring the neutron and gamma photon misclassification and test as different low-energy thresholds of 40, 60, 90 and 120 keVee.

3. Pulse gradient analysis (PGA)

The digital discrimination of neutrons and γ -rays in mixed radiation fields was described by *D'Mellow et al. (2007)*. This digital discrimination method is referred to as pulse gradient analysis (PGA), which is somewhat distinct from the charge-comparison method described in the previous paragraphs. *D'Mellow et al. (2007)* note that the principle difference between the pulse produced by a neutron and that produced by a γ -ray is the neutron pulse, which exhibits a slower decay to the baseline, illustrated in

FIGURE 6.102 Plot of amplitude versus time (ns) for model pulses of a neutron and γ -ray in an organic liquid scintillator. When both pulses are attributed the same amplitude, it is clearly seen that the neutron pulse decays more slowly than the γ -ray pulse. From D'Mellow et al. (2007). Reprinted with permission from Elsevier © 2007.

Fig. 6.102. This is characterized by a gradient that is shallower on the trailing edge of the pulse. It is this feature that is exploited in the PGA method for n- γ discrimination, *i.e.*, to determine which radiation produced the pulse, neutron or γ -ray.

The PGA method developed by D'Mellow et al. (2007) does not require any measurement of the actual pulse decay rate for the n- γ discrimination. Rather, only a relative measurement of the gradient is found from two suitable samples of the digitized representation of the pulse. These digitized samples are the following: (1) the first sample is the peak magnitude of the pulse; and (2) the second sample measured 20 ns after the first sample. The optimum time for the measurement of the second sample generally occurs 15–25 ns after the peak, and it will depend on the liquid scintillator and PMT properties (D'Mellow, 2006). The second sample, which measures the pulse gradient, is strongly affected by the pulse amplitude, which requires normalizing the pulse to remove this adverse effect. For n- γ discrimination, the amplitude of the pulse is plotted against another parameter proportional to the pulse decay rate. In the PGA algorithm, the pulse decay rate is measured by the amplitude of the second sample. Thus, two distinct groups of events are measured, namely, the peak pulse amplitude and the sample amplitude corresponding to either γ -rays or neutrons. Events labeled as γ -rays had a ratio of peak amplitude to sample greater than 11.41, and those labeled as neutrons for ratios below that value. A scatter plot of γ -ray and neutron events discriminated by the PGA method is illustrated in Fig. 6.103. The optimum ratio of peak amplitude to second sample should be determined for each detection system utilized. Aspinall et al. (2007a) describe the application of algorithms to improve the digital pulse shape discrimination techniques.

FIGURE 6.103 A scatter plot with data recorded with an Am-Be source. The peak amplitude of the pulse is plotted against the amplitude of the sample for n- γ discrimination by pulse gradient analysis (PGA). From D'Mellow et al. (2007). Reprinted with permission from Elsevier © 2007.

Hawkes et al. (2010) developed miniature digitizing electronics with various n- γ discrimination algorithms, which enabled the implementation and testing of the charge-comparison and PGA methods, previously described as well as a model pulse method described by Marrone et al. (2002) and Guerrero et al. (2008). The model pulse method constructs two model pulse shapes, one for neutrons and the other for γ -rays, and the unknown pulses from a mixed neutron/gamma field are characterized according to which of the two models the pulses fit best using a χ^2 criterion. The n/ γ methods were implemented with a charge-comparison algorithm and a pulse gradient analysis (PGA) algorithm, respectively, and the model pulse method with a model pulse algorithm. The charge-comparison algorithm was found to have a small but definite figure of merit (FOM) advantage of the other two methods for the neutron fields tested; however, Hawkes et al. (2010) underscore that the FOMs of the other two methods were not much smaller and that each method has its advantages.

Gamage et al. (2011) compared four different algorithms for four different methods of n/ γ discrimination including the digital charge-comparison (CC) method, pulse gradient analysis (PGA), a neutron- γ model analysis, and the simplified digital charge collection (SDCC). He evaluated the efficiency of each of these methods in term of the FOM, which is based on the separation of the neutron and gamma events described previously by Eq. (6.135), and the SDCC method yielded the best discrimination performance for the particular experimental factors and algorithms used.

4. Zero-crossing method

The zero-crossing method of n/ γ discrimination was first worked out in detail as a result of the pioneering work of

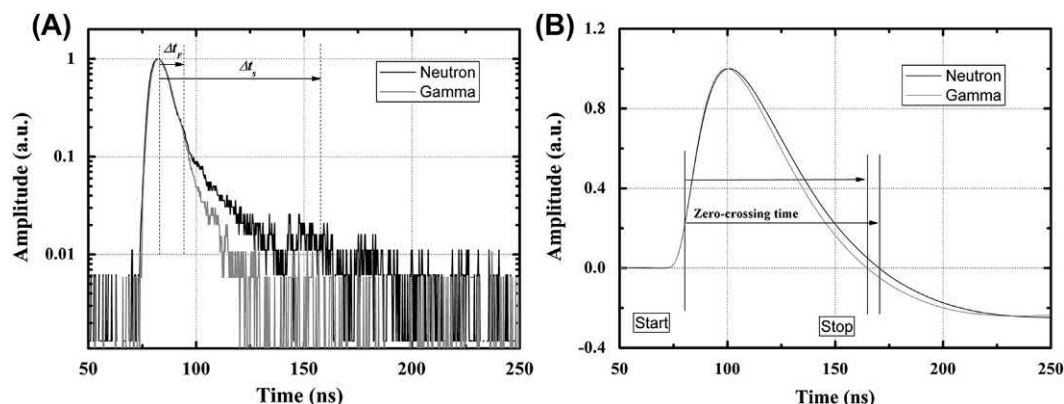

FIGURE 6.104 (A) Typical sample of PMT signals for neutrons and γ -rays. The signals approximately correspond to 500 keVee. The neutron pulse decays more slowly than the γ -ray pulse. (B) The neutron and γ -ray pulses cross the zero line at different times. From Nakhostin and Walker (2010); reprinted with permission from Elsevier © 2010.

Roush et al. (1964) at the University of Maryland. It is now one of the most common methods used for neutron-gamma discrimination in organic liquid scintillation detectors as well as stilbene and plastic scintillation detectors. Neutron-gamma discrimination is achieved by a measurement of the most suitable crossing times of shaped pulses produced by proton recoil and Compton electron events in the scintillator.

Nakhostin and Walker (2010) provide a detailed description of the method together with an algorithm for the digital implementation of the conventional zero-crossing method to achieve excellent neutron-gamma separation with liquid scintillator even at low-energy thresholds. A brief sketch of the zero-crossing method will be provided here in light of the work of Nakhostin and Walker (2010). A photomultiplier tube (PMT) is coupled to a suitable detector (e.g., a cylinder of NE213 liquid scintillator) located at a suitable distance from the neutron-gamma source. The PMT anode signals are digitized with a digital oscilloscope, which are transferred to a personal computer for pulse shaping, as illustrated in Fig. 6.104. As described by Nakhostin and Walker (2010), the pulse shaping process converts the PMT signal to a bipolar pulse, which enables the difference in the decay times of the different PMT signals to be revealed in the zero-crossing time of the shaped signals (See Fig. 6.104B). The zero-crossing time is measured by a constant fraction discriminator (CFD), which determines the start time of a signal and the delay between the start time and the time at which the shaped signal crosses the zero line. As depicted in Fig. 6.104B, pulses from recoil proton events produced by neutron interactions in the liquid scintillator arrive at the zero line after a longer time delay than pulses produced by Compton-electrons from gamma-ray interactions in the scintillator. Neutron-gamma discrimination is based on the differences in zero-crossing times of the signals.

The energy scale of the scintillator performance is expressed in units of keVee (i.e., electron energy equivalents in keV) by measuring the Compton edge produced in the scintillator with a series of gamma-ray sources, such as ^{60}Co , ^{137}Cs , and ^{22}Na . Optimum shaping time constants, which are dependent on the liquid scintillator and PMT used, are determined experimentally with the digital CFD and calculation of the figure of merits (FOMs, according to Eq. (6.135) described previously after fitting Gaussian functions to the neutron and gamma-ray events and calculation of the FWHM for the neutron and gamma-ray peaks. Examples of n/ γ discriminations reported by Nakhostin and Walker (2010) are provided in Fig. 6.105. As illustrated in the figure, the performance of this method is reflected in the good n/ γ discrimination achieved at the very low energy threshold of 50 keVee, and excellent discrimination at higher energy thresholds. The good performance of the method at very low energy thresholds is a result of the pulse shaping process that removes electronic noise, which is the common cause of poor discrimination at low energy thresholds.

5. Time-of-flight (TOF) spectrometry

Time-of-flight (TOF) spectrometry provides a discrimination between neutrons and gamma-ray photons as well as a measure of the neutron energies. A γ -ray photon travels at the speed of light, whereas neutrons travel slower. For example, a 2.0-MeV neutron travels at only $0.065c$ or 6.5% of the speed of light (See Figs. 1.71 and 1.72 of Chapter 1, Volume 1). Consequently, a γ -ray photon that produces multiple Compton scattering in a scintillation cocktail would create a pulse event in the PMT before a neutron that also undergoes multiple scattering. The n/ γ discrimination is enhanced in TOF spectrometry by separating the neutron source from the liquid scintillation detector by a suitable distance that may extend to several meters. As noted by

FIGURE 6.105 Neutron-gamma discrimination at different energy thresholds with an NE-213 liquid scintillation detector. From Nakhostin and Walker (2010); reprinted with permission from Elsevier © 2010.

Thomas (2010), time-of-flight (TOF) spectrometry requires a measurement of the time taken for the particle (*i.e.*, neutron or γ -ray) to travel a known distance (*e.g.*, the distance from the n - γ source to the detector). Thus, there is a need for two timing signals, a start signal that is triggered when the neutrons and γ -rays are created or when they pass a particular point, and an arrival signal that is triggered when the neutron and gamma rays arrive and are detected by the liquid scintillator.

Thomas (2010) outlines three ways that a start signal can be produced. These are provided below together with some examples added by the writer:

- (i) *A pulsed source, such as an accelerator with beam pulsing capabilities.* For example, a proton beam may strike a target material, producing neutrons and γ -rays, situated at a fixed and known distance from the liquid scintillation detector (See Fig. 6.106). Such an experimental arrangement is described by Rochman et al. (2004), Aspinall et al. (2007b), and Liu et al. (2009).
- (ii) *The detection of radiation (e.g., γ -ray) that accompanies the formation of a neutron.* Any suitable detector for time-correlated emissions for the start signal from a radiation source may be used. For example, a BaF_2 detector is commonly placed next to a ^{252}Cf source to signal the onset of fission by detecting one of the γ -rays that accompanies the emission of neutrons in ^{252}Cf spontaneous fission (Banerjee et al., 2007; Ronchi et al., 2009). An ionization chamber was used by Flaska and Pozzi (2007) to provide a start signal for a digitizer to determine the time zero for the measurement of neutron pulses, and a plastic scintillator next to a ^{252}Cf source was used by Venkataraman (2008). A liquid scintillator detector is placed a distance away from the source to detect both the

neutrons and γ -rays and provide a time-of-flight discrimination. For example, Ronchi et al. (2009) placed a BC-501 liquid scintillator detector 75 cm away from the source. The detected correlated fission events produce a signal in the BC-501 scintillation detector after a time-of-flight delay (t_{TOF}) with respect to the start signal from the BaF_2 detector.

(iii) *A detector used to signal neutron scattering.*

The work of Aspinall et al. (2007a,b) serves as an example of digital time-of-flight (TOF) measurements. Aspinall et al. (2007b) used an accelerator to direct a 2.924 MeV proton beam onto a thin $60 \mu\text{g}/\text{cm}^2$ LiF target,

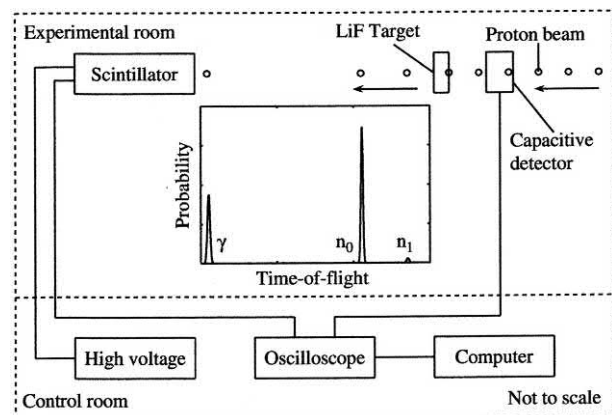

FIGURE 6.106 A schematic diagram of the experimental setup at the Neutron Irradiation Facility, National Physical Laboratory, UK. The experimental arrangement enables the digital time-of-flight discrimination of γ -ray photons and neutrons produced by a proton beam striking a LiF target according to the reaction $^7\text{Li}(p,n)^7\text{Be}$ with a flight path of 1.614 m between the target and detector. A digital time-of-flight spectrum included in the center of the diagram illustrates the peaks for the intensities of the early arriving γ -ray photons followed by the 1.225 MeV neutrons (strong peak at n_0) and 0.745 MeV neutrons (weak peak at n_1). From Aspinall et al. (2007b). Reprinted with permission from Elsevier © 2007.

which produces neutrons via the reaction ${}^7\text{Li}(p,n){}^7\text{Be}$ with neutron energies of 1.225 and 0.745 MeV corresponding to transitions to the ground and first excited states, respectively, of the product nucleus. A capacitive-type detector was placed in the proton beam line, as illustrated in Fig. 6.106, at a distance of 1.6 m from the LiF target. In this arrangement, the capacitive detector provided Aspinall et al. (2007b) with the start or proton beam pick-up signal needed to provide timing information for the TOF measurement and information on the proton pulse duration and frequency. Because the beam is monoenergetic and the target very thin, the transit time from the capacitive detector to the LiF target was constant. This provided a constant delay between the beam pick-up signal and the emission of neutrons from the LiF target. Therefore, the beam pick-up signal could be used as the start signal, as well as identify the pulse duration and period of the neutron pulses. The detector containing LS-301 organic liquid scintillator, illustrated in Fig. 6.106, was positioned 1633 mm from the LiF target. The scintillator pulses trigger the arrival or acquisition of γ -rays and neutrons, and the pulses are sent to an oscilloscope and computer to enable n - γ discrimination by pulse gradient analysis and TOF measurements. The acquisition and digital recording of scintillation pulse and corresponding beam pick-up pulse enable all detected events, *i.e.*, γ -ray photons and neutrons, to be sorted in terms of their time of arrival relative to the initial beam pick-up signal (Aspinall et al., 2007b). The discrimination of the γ -ray photons and neutrons as a function of their time-of-flight, graphically depicted in Fig. 6.106, illustrate the early arrival of the γ -rays followed by two well discriminated peaks for neutrons, with a strong peak for neutrons n_0 of 1.225 MeV and a weak peak for neutrons n_1 of 0.745 MeV.

Time-of-flight (TOF) spectrometry is the standard method for testing data obtained from the various n/γ discrimination methods (Lennox et al., 2007). Thus, any improvements or developments into the n/γ pulse shape discrimination (PSD) methods previously described (*i.e.*, the charge-comparison (CC) method, simplified digital charge-comparison (SDCC) method, pulse gradient

analysis (PGA) and zero-crossing method) can be tested by TOF spectrometry. For example, Aspinall et al. (2007b) used the TOF spectrometric analysis described above (See Fig. 6.106) to verify the digital discrimination of gamma-ray photons and neutrons by pulse gradient analysis (PGA). The PGA method will provide an n/γ ratio as described previously, and the TOF spectrometry will provide the relative proportions of each event type (*i.e.*, neutrons of certain energies and total gamma-ray photons). The n_{total}/γ from TOF spectrometry can be used to confirm n/γ ratios determined by one of the PSD methods. For example, Table 6.17 provides data from Aspinall et al. (2007b) where the TOF data taken from the time-of-flight spectrum illustrated in Fig. 6.106 confirms the separate PGA discrimination method. The n_{total}/γ from the TOF spectrometry agrees well with the n/γ ratio obtained by PGA analysis. The TOF spectrometry permits the determination of the proportions of each component in the radiation field, *i.e.*, neutrons of various energies and gamma-ray photons. Whereas a pulse shape discrimination (PSD) method, such as PGA will provide only the total proportions of neutrons and gamma-ray photons as illustrated in Table 6.17.

Sunil et al. (2013) utilized time-of-flight to measure neutron energy while implementing the zero-crossing method (described in Section 4 above) to discriminate and separate neutrons from gamma photons. They measured the neutron energy distributions at various angles with respect to a beam of 145 MeV ${}^{19}\text{F}$ projectiles incident on a thick Al target. The neutron energy distributions were measured with five EJ-301 liquid scintillation detectors situated at a distance of 1.5 m and at 0° , 30 degree, 60 degree, 90 degree and 120 degree angles with respect to the projectile beam.

As underscored by Lennox et al. (2017), time-of-flight experimentation is used as the gold standard for testing data for neutron/gamma pulse shape discrimination (PSD), and as a result, there will be future increasing reliance in time-of-flight data for the algorithm development in PSD. They present a methodology for identifying data sets with minimal contamination of mislabeled neutron and gamma pulses in time-of-flight measurements.

TABLE 6.17 The neutron and γ -ray ratios for the TOF and PGA discrimination methods.

Method	n_0	n_1	n_{total}	γ rays	Scatter	n_{total}/γ
TOF	0.43	0.017	0.45	0.28	0.27	1.61
Error	± 0.01	± 0.003	± 0.01	± 0.01	± 0.01	± 0.07
PGA	—	—	0.59	0.41	—	1.44
Error	—	—	± 0.02	± 0.01	—	± 0.06

6. General research into n/γ discrimination

Different approaches to the discrimination of $n-\gamma$ events in an organic scintillator include methods based on the application of artificial neural networks (ANN), which were reported by Liu et al. (2009), Ronchi et al. (2009) and Akkoyun (2013). The methods were verified with mixed neutron/gamma field data assessed by time-of-flight measurements.

Studies by Nakhostin (2012, 2015) demonstrate the performance of recursive algorithms for digital processing of neutron-gamma discrimination in liquid scintillation detectors with normal and low light outputs by the charge-comparison and zero-crossing methods, which remain the most common techniques currently used. Bayat et al. (2012) demonstrate the use of Ultima Gold LLT liquid scintillation as an alternative to the NE-213 and its Bicorn equivalent BC-501A scintillator. Zare et al. (2013) carried out Monte Carlo simulations on light transport and experimentation on the timing response of an NE-213 scintillation detector coupled to two PMTs to improve n/γ discrimination. Monte Carlo simulations and experimentation by Binaei Bash et al. (2013) and Ghal-Eh (2011) demonstrate how lightguides and light transport to PMTs can have a significant effect on n/γ discrimination. The use of a Multi-Pixel Photon Counter (MPPC) with detectors based on stilbene and EJ299-33 plastic scintillators reported by Grodzicka-Kobylka et al. (2018) demonstrated excellent capability of MPPC arrays for n/γ discrimination by the zero-crossing method comparable to classical PMTs.

Deuterated benzene- and deuterated xylene-based scintillators have been demonstrated by Becchetti et al. (2017, 2016) and Febbraro et al. (2015) to be useful in neutron energy measurements without time-of-flight.

XI. Double beta ($\beta\beta$) decay detection and measurement

The discovery, principles, and current research on double beta decay are reviewed in Chapter 1, Volume 1. Only a brief treatment of the liquid scintillation techniques employed in the search for neutrinoless double beta decay will be given here.

The first observation of double beta decay was made by Steven R. Elliott, Alan A. Hahn, and Michael K. Moe at the University of California, Irvine in 1987. They measured double beta decay in a sample of ^{82}Se enriched from its natural abundance of 8.7% to an isotope abundance of 97% to provide more source material for the double beta decay as well as reduce contamination from other sources (Elliott et al., 1986, 1987; Moe, 1986; Moe and Rosen, 1989). The decay scheme is written as follows:

where the parent nucleus decays to a daughter nucleus of the same mass number A , but with an increase in atomic

number Z by two. In general terms, the double beta decay process is expressed in terms of the nuclear atomic and mass numbers as

$$(Z, A) \rightarrow (Z + 2, A) + 2e^{-} + 2\bar{\nu} \quad (6.138)$$

Thus, in accord with the beta decay scheme, within the nucleus of the parent nuclide, two neutrons decay to two protons with the simultaneous emission of two beta particles and two antineutrinos. This type of beta decay is abbreviated as $2\nu\beta\beta$ to signify the simultaneous emission of two neutrinos and two beta particles.

Double beta decay is a rare event manifested by very long half-lives from 10^{18} to 10^{24} years. Because of the rarity of the event, the measurement of double beta decay is extremely difficult requiring highly enriched radionuclide sources and sophisticated coincidence counting instrumentation, which may include very large liquid scintillation detectors as well as other detector types, with the capability of extreme suppression or vetoing of background radiation (Obara, 2017; Gando, 2016; Fukuda et al., 2016; Segui, 2016; Signorelli and Dussoni, 2016; Biller, 2015; Descamps, 2015; Hans et al., 2015; Inoue, 2013; Lefevre, 2013; McGrath et al., 2010; Elliott et al., 2006; Gómez et al., 2007; Campbell et al., 2008; Caccianiga and Giammarchi and Fiorini, 2001). The National Nuclear Data Center of the Brookhaven National Laboratory (BNL-99822-2013-CP, <http://www.nndc.bnl.gov/bbdecay/list2013.html>, accessed February 22, 2018) lists 11 nuclides that are known to undergo $2\nu\beta\beta$ double beta decay (i.e., the emission of two beta particles and two neutrinos); these are listed in Table 6.18. In order of increasing atomic number. An additional nuclide, ^{130}Ba , listed at the bottom of Table 6.18 has been registered to decay by $2\nu\text{ECEC}$, which is double Electron Capture with the emission of two neutrinos. The long half-lives of these nuclides ranging from 10^{18} to 10^{24} years underscores the rarity of the double beta decay events, and the need to utilize huge and dedicated detectors for their measurement.

As discussed in Chapter 1, Volume 1, beta decay is not confined to negatron emission. There also exist positron and electron capture (EC) decay processes, which are other forms of beta decay. Research is underway with very large detectors including liquid scintillation detectors for the measurement of $\beta^{+}\beta^{+}$, $\beta^{+}\text{EC}$, and ECEC decay processes (Belli et al., 2016; Kang et al., 2013; Rukhadze et al., 2012; Andreotti et al., 2011; Kolhinen et al., 2010; Barabash et al., 2007, 2008). The nuclide ^{130}Ba , listed in Table 6.18, is the single nucleus that has been confirmed to decay by $2\nu\text{ECEC}$.

There is much research underway in numerous laboratories around the world directed toward the search for the detection of neutrinoless double beta decay ($0\nu\beta\beta$) utilizing liquid scintillation detectors and other detection methods, and only a few of the experiments on this work involving liquid scintillation are cited here, among the citations listed in the previous paragraph (Obara, 2017; Bialek et al., 2016; Fukuda et al., 2016; Gando, 2016; Segui, 2016; Barabash,

2015; Maneschg, 2015; Nakamura, 2012; Barabash, 2011; Cremonesi, 2010; Klapdor-Kleingrothaus et al., 2004; Fiorini, 2001; Caccianiga and Giammarchi, 2000).

Beyond the standard model there exists the possibility that the neutrino could be its own antiparticle referred to as a Majorana neutrino. According to this theory, if the electron neutrino possesses a rest mass (now estimated to have a mass upper limit of $< \sim 2.3 \text{ eV}/c^2$) and is its own antiparticle, a neutrino emitted in one beta decay could be reabsorbed in the second beta decay resulting in a double beta decay in which no neutrinos are emitted. *i.e.*, a neutrinoless double beta decay often abbreviated as $0\nu\beta\beta$ (See Chapter 1, Volume 1). Patrigan (2016, 2017) reports the upper limit to the rest mass of the electron neutrino to be $m_{\nu_e} < \sim 2.3 \text{ eV}/c^2$ at a 95% confidence level (CL). Future research is aimed at increasing the sensitivity of the mass measurements to \sim the range of $\sim 0.01\text{--}0.1 \text{ eV}$ (Barabash, 2015). Neutrinoless double beta decay ($0\nu\beta\beta$) decay has yet to be demonstrated (Barabash, 2015). However, there is now great confidence that $0\nu\beta\beta$ will be demonstrated, and a renewed effort is underway worldwide toward this objective as a result of work for over a decade that has demonstrated neutrino oscillations, that is, neutrinos can “oscillate” from one flavor into another (*i.e.*, electron-, muon-, and tau-neutrinos) as they travel through space and matter. Oscillation is the changing of neutrino

flavors back and forth from one to another, and this could occur only if the neutrino possessed mass. Experimental research on neutrino oscillation is reviewed by Messier (2006), and the Nobel Prize in Physics (2015) was awarded jointly to Takaaki Kajita of the University of Tokyo, Kashiwa, Japan and Arthur B. McDonald of Queen’s University, Kingston, Canada for, in the words of the Nobel Committee “the discovery of neutrino oscillations, which show that neutrinos have mass”. As a result of the success toward the demonstration of neutrino oscillations, current research in the search for neutrinoless double beta decay is moving forward with great effort, as it would reaffirm the mass of the neutrino, as only a particle with a definite mass can oscillate from one form into another.

A reported observation of $0\nu\beta\beta$ in ^{76}Ge was made by Klapdor-Kleingrothaus et al. (2004) and confirmed (Klapdor-Kleingrothaus, 2006; Klapdor-Kleingrothaus and Krivosheina, 2006) after data collection over a period of 13 years with high-purity p-type germanium detectors enriched in ^{76}Ge to 86%–88%. Such a detection arrangement is optimum in terms of yielding maximum detection efficiency for a given detection method, because the source (^{76}Ge) is the detector. *i.e.*, source = detector. However, Agostini et al. (2016) reports that a previous claim for evidence of a $0\nu\beta\beta$ decay signal is strongly disfavored, and the field of research is open again.

Several approaches to the application of liquid scintillation detection and measurement of neutrinoless double-beta decay ($0\nu\beta\beta$) are underway or in the planning stage. Barabash (2015) provides a review of the present status and prospects for the future for the various double beta decay experiments now planned and underway. The following paragraphs will describe the major projects now underway that involve liquid scintillation detectors.

A. KamLAND-Zen project

The KamLAND-Zen project is aimed at the detection and measurement of neutrinoless double beta decay, which involves the incorporation of the nuclide source into a liquid scintillation detector. Nuclides that undergo double beta decay and are easily loaded into liquid scintillators can be measured by liquid scintillation to observe the neutrinoless double beta decay. A large underground liquid scintillation detector, which is aimed at the detection and measurement of neutrinoless double beta decay in ^{136}Xe is the KamLAND-Zen detector, which is located at the Kamioka Observatory, an underground neutrino detection facility near Toyama, Japan. The acronym KamLAND-Zen signifies KamLAND Zero Neutrino double beta decay experiment. The KamLAND detector was originally designed to detect and measure antineutrinos, which are emitted with abundance from the surrounding commercial nuclear reactors. Thus, the name KamLAND represented Kamioka Liquid Scintillator Antineutrino Detector. The detector was key to providing evidence for neutrino oscillations with solar neutrinos that would diminish the population of electron neutrinos originating from the nuclear reactors. This gave evidence for neutrino mass, as only neutrinos with mass can oscillate from one flavor to another. The KamLAND detector was converted to KamLAND-Zen with the purpose of measuring neutrinoless double beta decay in ^{136}Xe .

Double beta decay of ^{136}Xe could occur by either of the following two processes:

or

The $Q_{\beta\beta}$ value for the ^{136}Xe is 2.479 MeV. In the case of $2\nu\beta\beta$, the 2.479 MeV decay energy would be shared among four particles, namely, the two beta particles and the two antineutrinos. However, in the case of $0\nu\beta\beta$, the 2.479 MeV decay energy would be shared only among the two beta particles. Thus, the $2\nu\beta\beta$ double beta (i.e., two electron) spectrum, for the ^{136}Xe decay would encompass a broad spectrum of energies, as illustrated in Fig. 6.107, because the two beta particles must share the decay energy

FIGURE 6.107 Double beta decay two-electron spectra for the case of xenon-136. The broad spectrum on the left is that of the double beta energies for the $2\nu\beta\beta$ decay; and the line spectrum on the right is that of $0\nu\beta\beta$ decay. The vertical scale is in arbitrary units and the proportion between the neutrinoless line and the $^{136}\text{Xe} \rightarrow ^{136}\text{Ba} + 2e^- + 2\bar{\nu}$ spectrum is arbitrary as well. The $Q_{\beta\beta}$ value is 2.479 MeV. From Caccianiga and Giammarchi (2000). Reprinted with permission from Elsevier © 2000.

with the two antineutrinos. Whereas, $0\nu\beta\beta$ double beta (i.e., two electron) spectrum would be a line spectrum centered at the decay energy of 2.479 MeV, as illustrated in Fig. 6.107, as the two beta particles are emitted simultaneously and share the entire decay energy. In the search for two neutrino double beta decay ($2\nu\beta\beta$), two beta particles would be detected simultaneously, and the sum of their energies would always be less than the decay energy. However, evidence for neutrinoless double beta decay ($0\nu\beta\beta$) would be provided by the simultaneous detection of two beta particles with combined energies equal to the decay energy. The advantage of using liquid scintillation for the detection of double beta decay of ^{136}Xe is that the xenon gas can be dissolved directly into the liquid scintillator permitting the detection of the two beta-particle kinetic energies.

The original KamLAND detector, which was converted to the KamLAND-Zen detector, is illustrated in Figs. 6.107 and 6.108. The KamLAND-Zen is located at 1000 km underground from the top of Mt. Ikenoyama, Gifu Prefecture, Japan. A detailed description of the detector is provided by Asakura et al. (2016), and a brief overview is provided here. The inner balloon of the detector is 3.1 m in diameter made of 25- μm thick transparent nylon containing 300 kg of ^{136}Xe in liquid scintillation cocktail. In the second phase of the project for the measurement of $0\nu\beta\beta$ decay in ^{136}Xe , the inner balloon will contain 800 kg ^{136}Xe achieved by loading enriched xenon (90.93% ^{136}Xe and 8.89% ^{134}Xe) into liquid scintillator having a combined weight of 13 tons. The liquid scintillator cocktail (Xe-LS) within the inner balloon consists of 2.7 g/L of the fluor PPO

FIGURE 6.108 Schematic diagram of KamLAND-Zen detector. The 300 kg ^{136}Xe in the Xe-loaded liquid scintillator in the inner balloon noted in the figure is currently 383 kg ^{136}Xe , and in the next phase of the experiment, it will be increased to ~ 800 kg ^{136}Xe (Obara, 2017). For a perspective of the detector dimensions, a figure of a person is illustrated standing in the Clean Room in the upper deck of the detector on the right. From Asakura et al. (2016); reprinted with permission from Elsevier © 2016.

(2,5-diphenyloxazole) and 2.48% enriched xenon gas dissolved in a solvent consisting of 82% decane and 18% pseudocumene. The 13 tons of Xe-loaded liquid scintillator (Xe-LS) in the inner balloon comprises the detection medium for $2\nu\beta\beta$ and $0\nu\beta\beta$ decay of ^{136}Xe . The inner balloon is suspended in 1000 tons of liquid scintillator (KamLAND LS) within an outer balloon measuring 13 m in diameter consisting of 135- μm thick nylon and ethyl vinyl alcohol copolymer. This outer scintillator (KamLAND LS) serves as an active shield for external gamma-radiation as well as a detector for internal radiation from the inner scintillator (Xe-LS) and inner balloon (Asakura et al., 2016). The transparent outer balloon is suspended in 1400 tons of buffer oil contained in a 18 m diameter stainless steel tank. In the inner surface of the stainless-steel tank 1879 photomultiplier tubes (PMTs) are mounted facing the liquid scintillator (See Figs. 6.108 and 6.109). The stainless-steel tank is finally surrounded with 3200 tons of a water Cherenkov outer detector that serves as a cosmic-ray muon veto detector as well as serving to further shield the liquid scintillation detector from external radioactivity.

Due to the rarity of $0\nu\beta\beta$ relative to $2\nu\beta\beta$ decay, the main requirements are a high concentration of source material (i.e., ^{136}Xe) within a suitable detector) and the reduction of interfering background radiation to a maximum. Detection of both $2\nu\beta\beta$ and $0\nu\beta\beta$ from the initial 112-day and 115-day second phase of KamLAND-Zen measurements are reported by Inoue (2013) and Gando (2016). Efforts are focused toward methods for the reduction of background. Fig. 6.110 illustrates the spectrum acquired by the KamLAND-Zen detector from $2\nu\beta\beta$ and $0\nu\beta\beta$ together with spectra from background radiation sources. The spectra from $2\nu\beta\beta$ ends just under the ^{136}Xe

FIGURE 6.109 Cross-sectional illustration of the KamLAND-Zen detector. ^{136}Xe is dissolved into liquid scintillator filled in the mini-balloon. The mini-balloon is suspended from the top. Many of the numerous (1879) photomultiplier tubes (PMTs) can be seen mounted on the interior wall of the spherical stainless-steel tank facing the inner mini-balloon containing the Xe-loaded liquid scintillator. For a perspective of the detector dimensions, a person is illustrated at the upper deck to the right. From Nakamura (2012); reprinted with permission from Elsevier © 2012.

FIGURE 6.110 Observed energy spectrum from 38.6 kg yr of ^{136}Xe exposure from the KamLAND-Zen detector. Best fit spectrum for $2\nu\beta\beta$ and backgrounds are shown together with 90% confidence level (C.L.) upper limit for $0\nu\beta\beta$. Arrows pointing to the spectra of the $2\nu\beta\beta$ and the $0\nu\beta\beta$ decay were added by the writer. The $2\nu\beta\beta$ spectrum extends from zero to just under the ^{136}Xe decay energy of 2.479 MeV and the $0\nu\beta\beta$ spectrum is a monoenergetic peak (Gaussian) peak at the Q -value (2.479 MeV). From Inoue, 2013; reprinted with permission from Elsevier © 2013.

decay energy (Q -value = 2.479 MeV); whereas that of $0\nu\beta\beta$ peaks at the Q -value. The resolution of the monoenergetic peak for the $0\nu\beta\beta$ decay is limited by the resolution of the liquid scintillation detector. The interferences from background are apparent from the observed energy spectrum for ^{136}Xe decay illustrated in Fig. 6.110. Asakura

et al. (2016) describes in detail the main sources of background, namely, (i) radioactive impurities from and external to the inner balloon, (ii) impurities within the Xe-loaded liquid scintillation fluor cocktail (Xe-LS), and (iii) spallation products generated by cosmic-ray muons. The results illustrated in Fig. 6.110 for the $0\nu\beta\beta$ are limited by the background peaks from $^{110\text{m}}\text{Ag}$ and ^{214}Bi , a daughter nuclide of ^{238}U . Distillation of the liquid scintillator is planned to remove the $^{110\text{m}}\text{Ag}$. The inner balloon was fabricated 100 km from the Fukushima reactor site a few months after the accident, and replacing this inner balloon should reduce radionuclide contamination due to fallout. Obara (2017) recommends replacing the inner balloon material with polyethylene–naphthalate, which has scintillation ability, and it would reduce background from ^{214}Bi from the inner balloon material surface by 99.7%. Gando (2016) notes that obviously it is not possible to eliminate the $2\nu\beta\beta$ events in the $0\nu\beta\beta$ signal energy region; however, the energy resolution can be improved from 4.0% to $< 2.0\%$ at the Q -value of the ^{136}Xe double beta decay by introducing high quantum efficiency PMTs, light collecting mirrors surrounding the PMTs, and brighter liquid scintillator.

B. SNO+ project

Another detector, which is under development for the liquid scintillation detection and measurement of neutrinoless double beta decay ($0\nu\beta\beta$) is the SNO+ Project. SNO+ entails the conversion of the Sudbury Neutrino Observatory (SNO) in Canada into a liquid scintillation detector (named SNO+) for double beta decay detection and measurement with ^{130}Te (Bialek et al., 2016; Segui, 2016; Biller, 2015; Descamps, 2015; Kamdin, 2015; Hans et al., 2015). In the previous edition of this book published in 2012, the writer had described the plans for the SNO+ project to measure $0\nu\beta\beta$ in ^{150}Nd ; however, the SNO+ project reevaluated and altered the project in 2012 to measure $0\nu\beta\beta$ in ^{130}Te in lieu of ^{150}Nd for the following advantages, as described by Segui (2016) and Biller et al. (2015): (i) Te has a high 34% natural abundance of ^{130}Te . Tellurium-130 has the highest natural abundance of any double beta-decay isotope (Hans et al., 2015). (ii) The internal U/Th backgrounds can be actively suppressed via Bi-Po α tagging. (iii) The external gamma radiation can be adequately attenuated in the outer regions of the detector volume. (iv) Tellurium-130 has a much lower rate (factor of ~ 100) of $2\nu\beta\beta$ backgrounds relative to ^{150}Nd . (v) Tellurium has no inherent atomic absorption in the optical range. (vi) Natural tellurium is relatively inexpensive.

Double beta decay of Tellurium-130 has a Q -value of 2.527 MeV (QCalc, <https://www.nndc.bnl.gov/qcalc/qcalc.jsp>, accessed February 27, 2018). The SNO+

Project will measure the $2\nu\beta\beta$ and $0\nu\beta\beta$ decay spectra, which would occur by the following:

or

The SNO+ detector is a large-scale liquid scintillation detector located 2070 m underground (6800 m.w.e) at the Sudbury Neutrino Observatory (SNO) Laboratory in Sudbury, Canada. A cross-sectional illustration of the SNO+ detector is illustrated in Fig. 6.111. The SNO+ detector is the original SNO detector previously used exclusively for the detection and measurement of neutrinos by charged current (CC) and neutral current (NC) reactions with deuterium as well as electron scattering (ES) reactions. The 12 m diameter inner acrylic vessel of the SNO detector was filled with D_2O surrounded by ultrapure H_2O shielding for the previous work on neutrino measurements. The D_2O is replaced with 780 tons of Te-loaded liquid scintillator to create the SNO+ detector for the detection and measurement of neutrinoless double beta in ^{130}Te . The scintillator cocktail consists of 2 g/L of 2,5 diphenyloxazole (PPO) dissolved in linear alkylbenzene (LAB). For the first phase of the experiment, the scintillator will contain 0.3% natural tellurium (34% natural abundance of ^{130}Te) providing ~ 790 kg of ^{130}Te source material

FIGURE 6.111 Cut-away view of the SNO+ detector. The inner 12 m diameter acrylic sphere contains the active volume of Te-loaded liquid scintillation fluor cocktail. A 54% optical coverage is provided by ~ 9500 photomultiplier tubes (PMTs) placed along the inner walls of a 17 m diameter geodesic structure with interior and exterior shielding by pure water. The PMTs are illustrated as bright dots within the triangular panes of the outer structure. For a perspective of the detector dimensions, a person is illustrated walking toward the upper deck in the cave to the right. From Kamdin (2015); reprinted with permission from Elsevier © 2015. For the color version of this figure, the reader is referred to the online version of this book.

providing a high yield of $\sim 10,000$ photons/MeV. Higher Te-loading of the scintillator is possible in future upgrades of the detector (Descamps, 2015). It is foreseen that tellurium loading of up to 0.5% in the liquid scintillation will be possible in a future phase of the project, which would provide 1.3 tons of ^{130}Te source material for $0\nu\beta\beta$ decay detection and measurement. The acrylic vessel containing Te-loaded liquid scintillator is surrounded with 1700 tons of ultrapure water, and an additional 5300 tons are included in the space outside of the detector. The water will provide shielding from background radiation (Segui (2016)).

Biller (2015) provides calculated estimated average spectra from $2\nu\beta\beta$ and $0\nu\beta\beta$ decay for ^{130}Te as well as the spectra for background radiations with the SNO+ detector. The estimated average spectra with two-full years of data collection are illustrated in Fig. 6.112. Only the tail-end of the ^{130}Te $2\nu\beta\beta$ spectrum is illustrated, as this is the region of importance in observing the monoenergetic peak for the $0\nu\beta\beta$ at the Q -value of 2.527 MeV. Estimated background radiation spectra are illustrated, which would be due to electron scattering (ES) of ^8B solar neutrinos, ^{208}Tl , $^{212}\text{Bi} + ^{212}\text{Po}$, $^{214}\text{Bi} + ^{214}\text{Po}$, and external radiation sources. Higher Te-loading of liquid scintillator has been demonstrated, and future phases of the experiment with loading ~ 10 times higher would increase sensitivity. An increase in Te-loading of scintillator of up to 5% has been demonstrated (Segui, 2016), which would provide a total of 13 tons of ^{130}Te source material for future phases of the SNO+ project.

FIGURE 6.112 Expected average spectra of contribution backgrounds for two live years of data compared to a signal corresponding to a 200 meV Majorana neutrino mass, assuming a light level of 200 p.e./MeV (photo-electrons/MeV) and a value for the matrix element of 4. Background radiation spectra are color coded. Arrows added by the writer point to the tail end of the $2\nu\beta\beta$ spectrum and the peak of the monoenergetic $0\nu\beta\beta$ spectrum centering at the Q -value of 2.527 MeV. Color coding of the background radiation spectra is visible in the electronic version of the book. From Biller (2015); reprinted with permission from Elsevier © 2015.

C. EXO-200 project

An alternative approach to the detection of neutrinoless double beta decay in ^{136}Xe is to convert the source into the detector (*i.e.*, source = detector). In other words, rather than add the ^{136}Xe to a liquid scintillation cocktail, the alternative would be to take advantage of the fact that liquid xenon itself undergoes excitation with the emission of scintillation light photons at 175 nm wavelength in the vacuum ultraviolet (VUV) region (See Section XVII of this chapter). Thus, liquid xenon enriched in ^{136}Xe would serve both as the source of the decay emissions and the detector. This technique is currently taken by the Enriched Xenon Observatory (EXO). The first phase of EXO is EXO-200, which utilizes a detector containing 200 kg of liquid xenon enriched in ^{136}Xe to 80%. Construction of the detector was carried out at the SLAC National Accelerator Laboratory of Stanford University, Menlo Park, CA, USA, and it is installed at the Waste Isolation Power Plant (WIPP) near Carlsbad, NM, USA.

The EXO-200 detector consists of a cylindrical chamber that contains the 200 kg of enriched liquid xenon and serves as both a scintillation detector and time projection chamber (TPC) illustrated in Fig. 6.113. The detector is surrounded by a cylindrical wall of VUV Teflon reflectors and two walls of avalanche photodiodes (APDs) for the detection and gain multiplication of the VUV scintillation photons. The conception of a time projection chamber (TPC) originated from the work of David R. Nygren (Nygren, 1974) while working at the Lawrence Berkeley

FIGURE 6.113 Drawing of the EXO-200. The thin copper chamber contains ~ 175 kg of liquid Xenon enriched to 80.6% in the isotope ^{136}Xe . From Pocar (2013); reprinted with permission from Elsevier © 2013.

Laboratory of the University of California (L'Annunziata, 2016). The TPC can provide the three-dimensional coordinates of energy deposition in the liquid xenon. The dimensions of the TPC are 40 cm in diameter and 44 cm in length. A complete description of the design, construction and function of the TPC is provided by Auger et al. (2012) and Pocar (2013). As described by Auger et al. (2012), the ionization channel of the TPC includes the cathode and field cage, which defines a region of uniform electric field with two wire planes or grids (U and V) and large avalanche area photodiodes (APDs) that provide a three-dimensional readout of ionization and scintillation in the liquid Xenon. Each end of the TPC cylinder contains two wire grids. The two wire planes or grids consist of a charge collection U wire plane and a shielding V wire plane is located in front of the U wires is biased to provide full electron transparency. The V wires also provide readout in addition to the U wires and the two wire planes are oriented at 60 degrees to each other, which provides a two-dimensional localization of the ionization cloud (See Fig. 6.114). An array of ~ 250 avalanche photodiodes are in close proximity (6 mm) from the wire grids. The third longitudinal coordinate of an energy deposition is obtained from the time interval between the scintillation signal collected in the APDs and the collection of charge at the wire grids. A set of field-shaping rings lined with VUV Teflon reflector tiles, grades the field and limits the drift region to two cylinders, each of 18.3 cm radius and 19.2 cm length (Pocar, 2013).

When a double beta decay event occurs in the ^{136}Xe , the beta particles will interact with the liquid xenon. The liquid

xenon will emit scintillation photons that are detected by the APDs. The simultaneous emission of two beta particles will produce ionization in the liquid Xenon and the electron cloud produced with drift toward the U and V wire grids, as illustrated in Fig. 6.114 for a $0\nu\beta\beta$ event. The wire grids will register the two coordinates of the event, and the third coordinate will be registered from the liquid scintillation photon emission collected by the APDs.

Auger et al. (2012) and Pocar (2013) provide detailed descriptions of the EXO-200, a combined liquid Xenon TPC and scintillation detector. The detector is located underground at a depth of ~ 1600 m.w.e. in a salt deposit at the Waste Isolation Pilot Plant, near Carlsbad, New Mexico. A low-background cryostat surrounds the detector with 2400 L of high-purity HFE7000 fluid, which provides radiation shielding as well as heat transfer. Additional shielding is provided by 5 cm of low-background copper serving as the cryostat housing encased with further shielding provided by 25 cm of high-purity low-background lead. A clean room housing the detector is surrounded with 50 mm thick plastic scintillation panels, which detect muons traversing the lead shielding with 95.9% efficiency.

In the planning stage of the EXO Collaboration is a larger experiment named nEXO, which would entail a 5-ton detector of liquid Xenon enriched in ^{136}Xe including the possibility of tagging of the ^{136}Ba daughter nuclides, which would provide a complete elimination of background (Dolinski, 2012). Detailed descriptions of the EXO-200 detector and the future prospects of the EXO Collaboration for the detection and measurement of neutrinoless double beta decay in ^{136}Xe are provided in papers by Pocar (2015, 2013), Auger et al. (2012), Dolinski (2012), Neilson et al. (2009), Leonard et al. (2008) and Ueshima et al. (2008).

D. ZICOS project

ZICOS is a new project, which is currently in its initial stages of research and planning (Fukuda, 2016; Fukuda et al., 2016). The acronym ZICOS is used for the Zirconium Complex in Organic Scintillator neutrinoless double beta decay experiment, which would research the detection and measurement of $0\nu\beta\beta$ of ^{96}Zr . The ZICOS project has developed a liquid scintillation cocktail that will consist of zirconium organometallic complex in liquid scintillator containing PPO and POPOP as primary and secondary fluors dissolved in anisole solvent. The light yield of the cocktail is comparable to BC505 scintillator with a decay time of 20 ns. The scintillation cocktail has a capacity to contain a Zr concentration of 70 g/L. The isotope ^{96}Zr has a natural abundance of 2.8%; however, it is commercially available enriched to 58.5%, which would yield 128 kg of ^{96}Zr source material in the scintillation detector currently planned.

FIGURE 6.114 Geometry of the readout wire planes showing a simulation of an electron cloud drift from a $0\nu\beta\beta$ event in the liquid Xenon. The electron cloud is colored blue and illustrated with a drift trajectory toward the U and V wire grids. The anode (U) and induction (V) wires, illustrated as colinear, are in reality oriented 60 degrees from each other. From Auger et al. (2012). For the color version of the figure, the reader is referred to the online version of this book.

The ZICOS detector would have a 1.5 m radius or a total volume of 14.1 m³. The detector would be located within an outer cylindrical tank 5.4 m in diameter and 5 m in height. The tank would be filled with pure water to veto the penetrating muons by the measurement of Cherenkov photons and attenuate the external gamma-ray and neutron radiation. The Q value for the double-beta decay of ⁹⁶Zr is 3.356 MeV, which is high, and it is expected that the backgrounds from ²⁰⁸Tl would be reduced to one-tenth of the magnitude of the KamLAND-Zen project with the measurement of Cherenkov photons.

XII. Detection and measurement of neutrinos

In a letter addressed to the participants of a Regional Meeting on Radioactivity at Tübingen, Germany, on 4 December 1930, Wolfgang Pauli postulated the existence of an elusive neutral particle of near zero rest mass, which would accompany beta decay. The particle remained elusive and unproven as to its existence for over 25 years. Nevertheless, during that time, the particle remained an essential component in our understanding of beta decay. In 1934, Enrico Fermi coined this particle as the ‘neutrino’ from the Italian language meaning “little neutral one” in his elaboration of the beta-decay theory (See [L’Annunziata, 2016](#) for a detailed historical account.)

A. Reines and Cowan reaction

The neutrino remained elusive until 1956, when its existence was demonstrated finally by Nobel Laureate Frederick Reines and Clyde Cowan, Jr ([Reines and Cowan, Jr, 1953, 1956, 1957](#)). They confirmed the existence of the neutrino using liquid scintillation detectors to demonstrate inverse beta decay where an antineutrino interacts with a proton to yield a neutron and positron, *i.e.*,

Reines and Cowan constructed a liquid scintillation detector next to a 700 MW nuclear reactor at the Savannah River Plant in Aiken, SC, USA, to detect the abundant antineutrinos emitted by the beta decay of fission products. Their detector was composed of a target chamber consisting of 200 L of water containing 40 kg of dissolved CdCl₂ sandwiched between two tanks of 1400 L of liquid scintillator schematically illustrated in [Fig. 6.115](#). Each end of the scintillator tanks was viewed by 55 photomultiplier tubes (not illustrated). The water provided target protons for the antineutrinos. As illustrated in [Fig. 6.115](#), the interaction of an antineutrino with a water proton would create a neutron (n) and a positron (β⁺). The positron would be annihilated when coming to rest and in contact with an electron, and the resulting annihilation radiation

FIGURE 6.115 Detection scheme used by Reines and Cowan for the antineutrino signature signal. An antineutrino is illustrated entering the tank of aqueous CdCl₂ solution and striking a target proton. The proton converts to a neutron and positron. The positron annihilates on an electron with the emission of two 0.511 MeV gamma rays in opposite directions detected by the liquid scintillator in tanks above and below the water target tank. The neutron produced by the antineutrino interaction slows down in the water and is captured by a cadmium nucleus, and the resulting gamma rays are detected by the liquid scintillator in the adjacent tanks approximately 10 μs after the positron annihilation. *From Reines (1995), Nobel Lecture with permission from The Nobel Foundation ©1995.*

(two 0.51 MeV gamma-ray photons emitted in opposite directions) would be detected in coincidence by the two liquid scintillation detectors above and below the water tank ([Fig. 6.115](#)). The neutron produced by the antineutrino interaction would slow down quickly (~10 μsec) in the water and be captured by a cadmium nucleus in the water target chamber. The characteristic multiple gamma rays following the neutron capture would be detected in coincidence by the two liquid scintillation detectors. The antineutrino signature therefore consisted of a delayed coincidence between the prompt scintillation pulses produced by the β⁺ annihilation and the scintillation pulses produced microseconds later by the neutron capture in cadmium. With the unique signature for the antineutrino provided by the detector design devised by Reines and Cowan, the high neutron flux produced by the Savannah River reactor (1.2 × 10¹³/cm² sec), and reduced cosmic ray backgrounds from massive shielding 11 m from the reactor and 12 m underground were essential to the success of their experiment. Nevertheless, a detector running time of 100 days over a period of about 1 year was required to provide sufficient conclusive signals from the antineutrino signature.

A more complete account of Pauli’s hypothesis of the existence of the neutrino and the work of Reines and Cowan, which culminated in the discovery of the neutrino

is provided in a previous book by the writer (L'Annunziata, 2016).

B. Liquid scintillation schemes for neutrino detection and measurement

The detection scheme of Reines and Cowen described above is one among others used today for the liquid scintillation detection and measurement of neutrinos. Neutrinos will interact with matter in various ways including electron scattering (ES), charged current (CC) interactions, and neutral current (NC) interactions. These mechanisms of interaction are described in detail in Chapter 1, Volume 1. Among the schemes available for neutrino detection and measurement by liquid scintillation are the following:

1. Neutrino-electron scattering

The neutrino-electron elastic scattering reaction, $\nu e^- \rightarrow \nu e^-$, is detected in a large mass (>100 tons) of liquid scintillator. Solar neutrinos can be detected via this elastic scattering reaction, such as in the Borexino and SNO+ Collaborations for the measurement of solar neutrinos described subsequently.

The scattered electron can receive any kinetic energy from the neutrino less than or equal to the kinetic energy of the neutrino (Kraus, 2006). A wide spectrum of pulse heights from the different scattering reactions will be produced in the liquid scintillator, but for monoenergetic neutrinos characteristic of certain nuclear reactions inside the sun, a liquid scintillation spectral 'Compton-like' edge can serve as a signature for a ν line energy (Agostini et al., 2017; Bellini, 2016; Davini, 2012; Avanzini, 2011; Alimonti et al., 2002). For example, the solar neutrinos that are a result of the ${}^7\text{Be}$ electron capture reaction in the sun produce a mono-energetic ν line at 0.862 MeV. As described by Agostini et al. (2017), Bellini (2016) Avanzini (2011) in reviews on the Borexino neutrino detector and illustrated in Fig. 6.116, the ${}^7\text{Be}-\nu$ line at 0.862 MeV produces a profile of the recoil electrons in the liquid scintillator with a spectral 'Compton-like edge' at 0.665 MeV. This serves as a spectroscopic signature for the solar ${}^7\text{Be}$ neutrinos. Agostini et al. (2017) explain that the scattering of monoenergetic neutrinos with energy E_ν off electrons leads to recoil electrons with a Compton-like continuous energy spectrum with maximum scattered electron energy defined by

$$T_e^{\max} = 2E_\nu^2 / (m_e + 2E_\nu) \quad (6.144)$$

where T_e^{\max} is the maximum electron recoil energy, E_ν is the neutrino energy, and m_e is the electron mass equivalent to 0.511 MeV. For the monoenergetic 0.862 MeV solar neutrinos from ${}^7\text{Be}$ decay, Eq. 6.144 yields the maximum electron recoil energy of $T_e^{\max} = 0.665$ MeV,

FIGURE 6.116 A Monte Carlo based fit over the energy region 270–1600 keV for the Borexino detector; the event energies are estimated using the number of photons detected by the PMT array. Rate values in the legend are integrated over all energies and are quoted in units of counts/(day · 100 ton). The arrow pointing to the ${}^7\text{Be}$ neutrino electron scatter Compton-like edge at 0.665 MeV was added by the writer. Color coding of radiation sources are visible in the electronic version of the book. From Bellini (2016) and Davini (2012); reprinted with permission from Elsevier © 2016.

as illustrated in Fig. 6.116, and detailed reviews are provided by Agostini et al. (2017), Bellini (2016), Calaprice (2015), Miramonti (2015), Davini (2012), and Avanzini (2011).

Liquid scintillation detectors designed for the measurement of neutrinos are very large to provide adequate media for background veto as well as massive amounts of liquid scintillator measuring in the hundreds or thousands of tons. A schematic of the Borexino detector is illustrated in Fig. 6.117, which illustrates the immensity of the neutrino detector. The Borexino detector is constructed in the Laboratorio Nazionale del Gran Sasso, Italy, and the

FIGURE 6.117 Schematic view of the Borexino detector. An abstract figure of a person is drawn by the writer on the right side to provide a perspective of the relative size of the detector. From Agostini et al. (2017); reprinted with permission from Elsevier © 2017.

name Borexino is derived from the Italian for BOREX experiment (BORon solar neutrino Experiment). The detector, as described by [Agostini et al. \(2017\)](#), is based on the principle of graded shielding, with the inner liquid scintillator core at the center of a set of concentric shells of decreasing radio-purity from inside to outside (see [Fig. 6.117](#)). The liquid scintillator detector consists of 278 tons of pseudocumene solvent doped with 1.5 g/L of PPO (2,5-diphenyloxazole) fluor. The liquid scintillator is confined within a thin spherical nylon vessel of 8.5 m diameter surrounded by 2200 photomultiplier tubes (PMTs), defining the so-called Inner Detector (ID). All but 371 PMTs are equipped with aluminum light concentrators designed to increase the light collection efficiency. The detector core is shielded from external radiation by 890 tons of buffer liquid, a solution of pseudocumene and 3–5 g/L of the light quencher dimethylphthalate. The buffer is divided into two volumes by a second nylon vessel with a 11.5 m diameter, preventing inward radon diffusion. A 13.7 m diameter Stainless Steel Sphere encloses the central part of the detector and serves as a support for the PMTs directed toward the scintillator as well as the outer muon PMTs directed toward the outer water detector and shield. An external domed water tank of 18 m diameter and 16.9 m height, filled with ultra-high purity water, serves as a passive shield against neutrons and gamma rays as well as an active muon veto. The Cherenkov light radiated by muons passing through the water is measured by 208 external PMTs defining the so called Outer Detector. The detector is shielded by 3300 tons of radiopure liquids.

2. Reines-Cowan inverse beta decay reaction

The Reines-Cowan reaction described previously is commonly used for the detection and measurement of anti-neutrinos, where fission product beta-decay is abundant

emitting electron anti-neutrinos ($\bar{\nu}_e$). The anti-neutrinos are detected by inverse beta decay

with a threshold energy $Q = 1.80$ MeV ([Agostini et al., 2017](#); [Kraus, 2006](#); [Alimonti et al., 2002](#)). The positron (e^+) that is emitted will possess a kinetic energy equal to the neutrino energy (E_ν) – Q , which is deposited in the liquid scintillator. In addition, the positron almost immediately undergoes annihilation in contact with an electron of the scintillation cocktail (e^+e^- annihilation energy = 1.02 MeV). The positron signal created in the liquid scintillator will be the sum of its kinetic energy + 1.02 MeV annihilation energy ([Kraus, 2006](#); [Alimonti et al., 2002](#)). Neutrino spectroscopy is therefore possible, as the energy deposited (E_{dep}) and the pulse height produced (PH) in the liquid scintillator by the positron is proportional to the anti-neutrino energy or

$$\begin{aligned} \text{PH} \propto E_{\text{dep}} &= E_\nu - 1.80 \text{ MeV} + 1.02 \text{ MeV} \\ &= E_\nu - 0.78 \text{ MeV} \end{aligned} \quad (6.146)$$

An example of the potential of antineutrino energy spectroscopy based on inverse beta decay is provided by [Agostini et al. \(2017\)](#) from data obtained from the Borexino detector provided in [Table 6.19](#). The antineutrino energies presented in the table were correlated with gamma-ray bursts (GRBs) the most energetic events in the universe, which release energy equivalent to 10^{54} erg (~ 1 solar mass), under the assumption of isotropic emission of energy ([Agostini et al. \(2017\)](#)). The GRBs are detected with a frequency of ~ 1 event per day from the entire sky.

Even at the anti-neutrino threshold energy where $E_\nu = Q = 1.80$ MeV, the inverse decay reaction produces a liquid scintillation pulse signal at 1.02 MeV, which corresponds to the annihilation radiation. [Agostini et al. \(2017\)](#) and [Alimonti et al. \(2002\)](#) point out that the $\bar{\nu}_e$ tag is made

TABLE 6.19 Borexino confidence level 90% upper limits for fluence of electron antineutrinos from gamma-ray bursts^a.

possible by a delayed coincidence signal produced by a 2.2 MeV γ -ray emitted by the capture of the neutron by a proton. The delayed coincidence pulse occurs ~ 200 μ sec after the emission of a neutron from the inverse beta decay, which is the delay caused by the moderation of the neutron to thermal energies and its capture by a proton of the liquid scintillator. The delayed coincidence of ~ 200 μ s of the positron annihilation signal and the 2.2 MeV gamma-ray signal produced by a neutron capture on a proton serves at the $\bar{\nu}_e$ tag. Only a small number (1%) of the neutron captures occur on ^{12}C producing 4.95 MeV gamma rays. The unique $\bar{\nu}_e$ tag reduces background by a factor of ~ 100 (Alimonti et al., 2002).

Collaborations have been undertaken to measure reactor neutrino oscillation by locating large Gd-loaded liquid scintillation detectors near and far (~ 1 km) from the nuclear reactor. Among these collaborations are (i) the Double Chooz experiment (Haser, 2016) located at the Chooz nuclear power plant in France, (ii) Daya Bay Reactor Neutrino Experiment in Shenzhen, China (Beriguete et al., 2014 and Ding et al., 2008), and (iii) the RENO Collaboration (Reactor Experiment for Neutron Oscillation) in the Republic of Korea (Park et al., 2013). Research has been undertaken to improve the quality, purity and performance of Gd-loaded scintillators for large neutrino detectors (Beriguete et al., 2014 and Yeh et al., 2010). Gadolinium has a very high thermal neutron capture cross section (See Table 1.20 of Chapter 1, Volume 1). The delayed signal due to neutron capture in Gd is shorter (~ 30 μ sec) than that produced in conventional liquid scintillator (~ 200 μ sec), and it is identified with the emission of an ~ 8 MeV gamma ray. The strong gamma-radiation provides a unique signature, for the incident anti-neutrino and thus improved background reduction.

The measurement of the anti-neutrino production by reactors can be used to reveal the fissile composition of reactor fuel thereby providing continuous, nonintrusive, and unattended measurements important to nuclear safeguards (Dai et al. (2011).

3. Inverse beta decay (charged current interactions) yielding negatrons and unstable nuclei

In contrast to the detection of anti-neutrinos discussed in the previous Reines-Cowan reaction, neutrinos can be detected by charged current interactions (inverse beta decay) producing negatrons according to the interaction

where the neutrino interacts with a neutron of a nucleus in the liquid scintillator yielding a proton and a negatron. If the product nucleus is unstable, the energy deposited

in the scintillator by the nuclear decay can provide a tag for the neutrino interaction. Several nuclei may be used for neutrino interactions, which would yield an unstable nucleus and suitable tag for the neutrino inverse beta decay. Raghaven (1976) was first to indicate that inverse beta decay on ^{115}In , which has a natural abundance of 95.72%, would make for an efficient solar neutrino detector. Indium-loaded liquid scintillators with up to 15 wt% Indium have been developed for solar neutrino detection (Chang et al., 2011; Motta et al., 2005; Raghaven, 2001; Suzuki et al., 1990; Payne and Booth, 1990). The inverse beta decay reaction of a neutrino with ^{115}In is written as

where the ^{115}Sn product nucleus is unstable indicated by an asterisk superscript. This reaction has a low threshold energy of 128 keV, which provides the measurement of the incident neutrino energy, which is defined by the equation

$$E_{\nu_e} = E_{e^-} + Q_d \quad (6.150)$$

where E_{ν_e} is the incident neutrino energy, and E_{e^-} is the beta particle or negatron energy deposited in the liquid scintillator and Q_d is the capture threshold (Pallavicini, 2015; Grieb et al., 2011). In the case of the inverse beta interaction of neutrinos with ^{115}In , the interaction has a low threshold energy of 128 keV (Suzuki et al., 1990), and the negatron energy deposited in the liquid scintillator E_{e^-} would be a function of the neutrino energy according to the equation

$$E_{\nu_e} = E_{e^-} + 128 \text{ keV} \quad (6.151)$$

The low threshold (128 keV) of the indium interaction provides a high sensitivity of this scintillator to neutrinos from the solar proton-proton fusion reaction (≤ 430 keV) and to solar neutrinos produced by electron capture (EC) in ^7Be (860 keV) as pointed out by Payne and Booth (1990). The ^{115}Sn daughter nucleus decays with a very short half-life (3.2 μ sec) by isomeric transition emitting three gamma rays at 101, 116, and 498 keV, which provide a unique signature for the incident neutrino.

On the basis of the above inverse beta interaction of neutrinos with ^{115}In , a large neutrino detector utilizing Indium-loaded liquid scintillator is under development under the scope of the LENS Collaboration. LENS is an acronym referring the experiment named Low Energy Neutrino Spectroscopy, which was initiated at the Virginia Polytechnic and State University (Virginia Tech), Blacksburg, VA, USA, in 2005 where major breakthroughs in detector design, Indium-loaded liquid scintillator development and background rejection were made. Ragu S. Raghaven, who first proposed the utilization of ^{115}In in the detection of solar neutrinos by inverse beta decay in 1976 is on the team of researchers at Virginia Tech. Readers may

review papers by [Pallavicini \(2015\)](#) and [Grieb et al. \(2011\)](#) for more information on the development of the LENS detector, which would contain at full capacity up to 125 tons of Indium-loaded liquid scintillator.

Other examples of interactions in liquid scintillator that have potential for the detection and measurement of solar neutrinos by inverse beta decay are the following:

and

The excited states of ${}^{160}\text{Tb}^*$ and ${}^{176}\text{Lu}^*$ de-excite with very short lifetimes of 75 and 50 nsec, respectively, emitting gamma rays of 63.7 and 72 keV, respectively. [Gratta and Wang \(1999\)](#) point out that the low threshold for these reactions of 240 and 300 keV are well below the maximum solar proton-proton fusion neutrino energy. Also, the very fast (nsec) correlation time between beta-particle energy (e^-) deposition in the scintillator and γ -ray emission by the daughter nuclides provides a powerful signature for the solar neutrino event and background reduction. [Lightfoot et al. \(2004\)](#) report the development of 10 wt% Gd-loaded liquid scintillator for solar neutrino detection as well as neutron measurements. Gadolinium-load scintillator has been produced for some large-scale neutrino detectors such as the RENO neutrino detector ([Park et al., 2013](#)) and the Daya Bay reactor neutrino detector ([Beriguete et al., 2014](#)). These two detectors measure antineutrinos via the Reines-Cowan inverse beta-decay interaction described above according to $\bar{\nu}_e + p^+ \rightarrow n + e^+$ (Eq. 6.145).

4. Neutrino charged current interactions with ${}^{13}\text{C}$

The charged current interaction of solar neutrinos with ${}^{13}\text{C}$ nuclei naturally occurring in liquid scintillator can be used to detect the high-energy solar neutrinos derived from the ${}^8\text{B}$ reaction in the sun, which yields neutrino energies ≤ 15 MeV ([Ianni et al., 2005](#)). The ${}^{13}\text{C}$ isotope occurs naturally with an abundance of 1.1%. When very large neutrino detectors are involved, which utilize hundreds or even thousands of tons of liquid scintillator, the mass of ${}^{13}\text{C}$ in the scintillator will measure in tons. The LENA (Low Energy Neutrino Astronomy) detector for solar neutrino detection and measurement is a next-generation neutrino detector under development as part of an international collaboration. The detector is to be installed at the Center of Underground Physics in the Pyhäsalmi (CUPP) in central Finland. The detector would consist of 50,000 tons of liquid scintillator containing PPO and bis-MSB as primary and secondary fluors dissolved in linear alkylbenzene solvent contained in a tank measuring

100 m in height and 32 m in diameter with 32,000 photomultiplier tubes. The detector design and function is described by [Wurm et al. \(2015\)](#) and [Lachenmaier et al. \(2010\)](#).

The charged current interaction of a neutrino with a ${}^{13}\text{C}$ nucleus of the liquid scintillator detector with the transition of the unstable ${}^{13}\text{N}$ product nucleus to the ground state is the following:

The reaction threshold is $Q = 2.22$ MeV, and the kinetic energy of the electron or negatron (T_e) can be expressed as $T_e = E_\nu - Q$ neglecting the small recoil energy of the ${}^{13}\text{N}$ nucleus, which is of the order of a few keV ([Möllenberg et al., 2014](#); [Ianni et al., 2005](#)). The pulse height produced by the negatrons can thus provide spectrometry of solar neutrinos derived from the ${}^8\text{B}$ reaction in the sun, which are of energy in excess of the 2.22 MeV threshold energy. [Ianni et al. \(2005\)](#) point out the advantage of this mode of detection is that the process of ${}^{13}\text{N}$ decay to its ground state by positron emission according to

can be used to monitor the solar neutrino interactions with the ${}^{13}\text{C}$ nuclei, as the visible energy released in the ${}^{13}\text{N}$ decay is the sum of the positron kinetic energy and the energy released in the e^+e^- annihilation.

C. Collaborations for LS neutrino detection and measurement

There are several international collaborations underway with the objective of measuring the solar neutrino flux and neutrino properties as well as the measurement of neutrinos from other sources by means of large liquid scintillation detectors. The advantage of liquid scintillation is the possibility of preparing hundreds and even tens of thousands of tons of scintillator. Such liquid scintillators provide tons of target material for the elusive neutrino, and the target nuclides can be loaded into the liquid scintillators either enriched or at natural isotope abundance. The geometry of the liquid scintillator detector is easily designed. Even with such large detectors, years of scintillator signal collection and extreme measures of background reduction are often required. Numerous international collaborations are underway in the implementation and development of massive neutrino detectors, and some were described in the previous paragraphs. Reviews describing various detectors, their design and objectives are provided by [Agostini et al. \(2017\)](#), [Ianni \(2017\)](#), [Lu \(2017\)](#), [Segui \(2016\)](#), [Calaprice \(2015\)](#), [Jaffe \(2015\)](#), [Pallavicini \(2015\)](#), [Smirnov et al. \(2015\)](#), [Wurm et al. \(2015\)](#), [Oberauer \(2012\)](#), [Wang \(2012\)](#), [Cabrera \(2010\)](#), and [Alimonti et al. \(2009\)](#).

XIII. Microplate liquid scintillation counting

Many applications use radioactivity as a method of screening numerous compounds or reactions in an effort to find a new therapeutic agent, drug candidate, or to assess a molecular biology function. In these types of applications, many thousands of samples may be counted each week. Because of the numerous samples involved, large amounts of scintillation vials and cocktail are required for traditional liquid scintillation analysis, which add cost to the sample analysis. A large number of samples also creates a large amount of radioactive waste. Consequently, microplate scintillation counting instruments have been developed to reduce waste, increase sample throughput via the simultaneous analysis of several samples with multiple detectors, provide automation capabilities, and reduce the cost of consumable materials and waste disposal.

The microplate scintillation counter uses a microplate sample format, which was developed to provide for the analysis of large numbers of samples. A microplate is a small container with many sample wells. It is about the size of a postal card measuring approximately $12.7 \times 8.6 \times 1.9$ cm (L \times W \times H). Typical microplates can have numerous wells for holding samples, and the following are examples: (i) 24-well plates (6 \times four wells), 96-well plates (12 \times eight wells), and 384-well plates (24 \times 16 wells). The typical sample capacities for these plates are the following:

- (i) The 24-well microplate holds up to 375 and 1500 μ L of sample plus scintillation cocktail per well for shallow- and deep-well plates, respectively.
- (ii) The 96-well microplate holds 75 and 350 μ L of sample per well for shallow- and deep-well plates, respectively.
- (iii) The 384-well microplate holds up to 80 μ L of sample per well.

It is clear that only relatively small samples can be analyzed in these microplates, but the footprint is small, compact, and easy to automate. As a result of the small sample size and small amount of scintillation cocktail required, the activity analysis of many samples, often encountered in biological research, can be carried out without producing a large amount of radioactive waste. The second major feature of the microplate scintillation counter is the ability to count up to 12 samples simultaneously (*i.e.*, up to 12 detectors) on one microplate.

Only a brief description of the microplate scintillation analyzer is provided here. Additional information on this instrumentation is available in Chapter 9 of Volume 1. The microplate scintillation counter can be of single- or multiple-detector design (up to 12 detectors). Some commercial microplate scintillation counters are the TopCount

and MicroBeta counters from PerkinElmer, Inc., Waltham, MA, USA, and the Sense Beta available from HIDEX, Turku, Finland.

A. Detector design and background reduction

The microplate scintillation and luminescence instrument can be of single- or multiple-detector design with up to 12 detectors all packed in close proximity in a very small area. The microplate instrument can count samples directly in microplate wells using one of two mechanisms: single or dual photomultiplier tube (PMT) detectors. In the single PMT detector arrangement, illustrated in Fig. 6.118, the PMT detectors are placed directly above the sample wells; whereas, in the dual PMT arrangement there are two photomultipliers one above and one below each sample well. With the single PMT arrangement, a white reflective and opaque microplate is utilized whereby light photons produced by the radioactivity in the liquid scintillator is reflected back toward the phototube, and a unique method of background reduction, namely, time-resolved liquid scintillation counting (TR-LSC) is utilized. Microplate counters with two PMTs per sample must utilize microplates with clear bottoms to enable the transmission of photons to the second PMT, and coincidence counting is implemented to reduce background noise in addition to TR-LSC. A unique advantage of the dual photomultiplier microplate scintillation analyzers is the option to disable one of the PMTs to permit the utilization of opaque reflective microplates.

The single-PMT time-resolved liquid scintillation counting (TR-LSC) technique uses pulse counting to distinguish between true scintillation pulse events and background noise. This obviates the need for a second PMT per sample and reduces lead shielding requirements. Single-PMT counting with TR-LSC uses scintillators with relatively long decay periods. A scintillator with a long decay constant emits photons, after β -particle excitation,

FIGURE 6.118 Single PMT detector design in microplate scintillation counting. A cross section of a microplate segment is illustrated showing three white opaque sample wells and three photomultiplier tubes (PMTs) aligned above each sample well whereby up to 12 PMTs analyze simultaneously as many as 12 samples. © 1998 Perkin Elmer, Inc. Printed with permission.

FIGURE 6.119 Time-resolved liquid scintillation counting (TR-LSC) employed in PerkinElmer microplate scintillation and luminescence counters. © 1998 Perkin Elmer, Inc. Printed with permission.

over a longer period of time. Each scintillation pulse produces a photon packet followed by a series of pulses as illustrated in Fig. 6.119, whereas, PMT noise creates single pulse events. In TR-LSC the characteristics of a pulse are determined over a period of time (*e.g.*, 200 ns) after the initial photon packet is detected. If it is followed by one or more additional pulses within the resolving time period of 200 ns, the pulse is accepted as a true scintillation event. If no additional pulses are detected within the resolving time period, the initial pulse is rejected as background noise. The resolving time circuit to initiate pulse decay discrimination is triggered when a pulse height exceeds the single photon event (SPE) threshold. The number of pulses above the SPE threshold is counted during the resolving time period. Multiple pulses detected in the resolving time are accepted as a valid event, which is further analyzed in the pulse height analyzer of the LSA. If multiple pulses are not detected in the resolving time interval, the triggering pulse is rejected as background noise.

B. Applications

A microplate scintillation counter has numerous applications, and with these are distinct sample preparation methods that are used for radioactivity analysis. All of

these applications are intended for small sample volume and high sample throughput analysis. An excellent guide to the use of microplate counters, such as the TopCount and MicroBeta, is provided by Kahl et al. (2012). References to specific applications with microplate counters are included below.

When liquid scintillation counting is required with the microplate analyzer, scintillation cocktail, and sample are added to each well of the microplate. This method is used for counting organic or aqueous samples directly in the microplate wells. An example of this can be taken from enzyme activity studies in which the sample is extracted or filtered directly into the liquid scintillation cocktail and counted. Many examples of analysis of radionuclides, such as ^3H , ^{14}C , ^{32}P , ^{35}S , and ^{125}I , in the biosciences can be found in the literature. Among these, a few will be cited here that relate to specific microplate liquid scintillation counters, namely, (i) the TopCount (PerkinElmer, Inc., Waltham, MA, USA) liquid scintillation and luminescence counter (Christiansen, 2018; Hosogi et al., 2018; Kojima et al., 2018; Lozac'h et al., 2018; McCabe et al., 2012; Rauly-Lestienne et al., 2011; He et al., 2011), (ii) the MicroBeta (PerkinElmer, Inc., Waltham, MA, USA) liquid scintillation and luminescence counter (Cunha de Oliveira et al., 2018; Kumar et al., 2018; Ingwersen et al., 2018; McCarthy et al., 2018; Shu et al., 2018; Varaschin et al., 2018), and (iii) the Hidex Chameleon V or Sense Beta (HIDEX, Turku, Finland) liquid scintillation and luminescence counter (Abe et al., 2016; Melkes et al., 2016; Boag et al., 2015; Brun et al., 2014; Ferraz et al., 2014; Matta et al., 2011, 2008; López et al., 2010).

In addition to liquid scintillation analysis, microplate scintillation analyzers are used for the measurement of beta-emitting radionuclides by means of solid scintillation. Solid scintillation counting in microplates involves depositing a sample into the well of a special plastic microplate (*e.g.*, LumaPlate, Scintiplate, Cytostar-T), which contains a solid scintillator at the bottom of the well. The material is dried and then counted in a microplate scintillation counter. The application of scintillating microplates is discussed in more detail in Chapter 9 of this volume.

C. Advantages and disadvantages

The microplate scintillation and luminescence counter has the basic advantage of high sample throughput with up to 12 samples, which can be analyzed simultaneously for radioactivity or luminescence. Hands-off fully automated analysis of thousands of samples is possible, particularly in the simplest case of a microplate analyzer with 32 microplates stacked for counting, each microplate containing 96 samples wells, which provides for 3072 unattended sample analyses. Microplates containing 384 sample wells each with 80 μL capacity can be stacked up to 40 microplates at

one time, which provides for over 15,000 samples with unattended analysis. The cost reduction in microplate counting compared with conventional liquid scintillation counting due to the reduced cocktail consumption and consequent reduction in radioactive waste expense and counting vial cost is a definite advantage. Microplates offer also a format that is easy to handle, leaving less chance for error caused by placing samples out of order, as sample wells cannot be mixed up or intermixed. Once samples are prepared on a microplate, they are kept in place on the microplate as a fingerprint. Microplates are easily portable and stored without occupying much space.

A disadvantage of the microplate scintillation analyzer is the small volumes of sample that can be accommodated in the sample wells. A 20-mL liquid scintillation vial can accept approximately 10 mL of aqueous sample mixed with 10 mL of suitable liquid scintillation cocktail. However, the largest sample well of a 24-well microplate has a capacity of only 1.5 mL (1500 μ L), of which approximately 0.75 mL at most can be aqueous sample and 0.75 mL suitable cocktail. That is a 13-fold difference in sample size between the two methods of analysis. Therefore, for relatively low sample activities in microplate scintillation counting longer counting times are required.

XIV. PERALS, LS alpha-spectrometry with LAAPDs, and MNPs

Photon-Electron Rejecting Alpha Liquid Scintillation (PERALS) spectrometry was developed to provide an instrument that could measure α -particle radiation with good resolution, high counting efficiency, and low background.

A. PERALS spectrometry

The interaction of alpha particles with liquid scintillation cocktail was described earlier in Section II.B of this chapter. Of particular interest is that alpha particles are generally detected at a very high counting efficiency of about 100% even with high degrees of quench in the scintillation cocktail. However, alpha particles produce only about one-tenth the light intensity (*i.e.* scintillation light output) as beta particles or gamma radiation per unit of radiation energy. A 5-MeV alpha particle will produce a pulse height spectral peak at approximately 500 keV when liquid scintillation pulse heights are calibrated on a scale equivalent to particle energy in keV. Such pulse height energy scales are calibrated with beta particles or electrons, as electrons yield a linear light output per particle energy dissipated in the liquid scintillator. This posed a problem in the liquid scintillation analysis of α -emitters when found in the presence of β -emitters, because their pulse height spectra would overlap even though the energy of the α -particle radiation was 10 times that of the β -particle

radiation. For example, the overlapping liquid scintillation pulse height spectra of the α -emitter ^{210}Po ($E = 5.30$ MeV) and the β -emitter ^{90}Sr ($E_{\text{max}} = 546$ keV) are illustrated earlier in Fig. 6.2 in Section II.B of this chapter. Therefore, since the early 1970s research has gone into the development of liquid scintillation spectrometers that could reject the pulses produced by β particles and Compton electrons from γ radiation and provide an instrument that could measure α -particle radiation with good resolution, high counting efficiency, and low background. This led to the development of Photon Electron Rejecting Alpha Liquid Scintillation (PERALS) spectrometry. The history of the work that led to the development of PERALS spectrometry, is described by McDowell and McDowell (1991). A description of the instrumentation, its performance, and applications will be provided here.

The development of PERALS spectrometry had to solve two problems of α -particle liquid scintillation spectrometry: (1) the poor energy resolutions obtained with α -emitters in quenching aqueous-accepting scintillation cocktails in conventional liquid scintillation analyzers and (2) the interference caused by overlapping spectra from β - and γ -emitters in the same sample. The problem of resolution of α pulse height spectra was solved by modifying the following elements of the liquid scintillation system as described by McDowell and McDowell (1993): (1) the α -emitters of interest had to be placed into a nonquenching, organophilic complex in a completely organic and highly efficient scintillator; (2) the detector assembly had to be modified with an efficient reflector arrangement and light-coupling optics to transmit the maximum amount of scintillation light to the photocathode of the PMT, and (3) a diffuse reflector had to be used in the detector assembly so that the scintillation light from an α event occurring anywhere in the sample would appear the same to the PMT, because of the nonuniform response of PMTs.

The basic design of the high-resolution α liquid scintillation spectrometer, known as the PERALS spectrometer, is illustrated in Fig. 6.120. The α -emitters are firstly placed into an organic “extractive scintillator” often via a solvent extraction process that enables the radionuclides to pass from the aqueous sample phase into the organic scintillator phase. A culture tube measuring 10 \times 75 mm containing 1 mL of the radionuclide sample in the extractive scintillator is placed in the detecting chamber of the PERALS spectrometer (Fig. 6.120). The instrument contains only one photomultiplier tube. Dual photomultiplier tubes are not needed, in contrast to conventional liquid scintillation analyzers, because the thermal electron noise in the phototubes is always well below the pulse heights produced by α -particles (McKlveen, and McDowell, 1984). Light-coupling silicone oil and a white reflecting surface made of barium sulfate and binder are important to meet the light transfer requirements from the sample tube to the

FIGURE 6.120 Cross section of a PERALS spectrometer detector. From McDowell and McDowell (1993), Reprinted with permission from Radiocarbon, University of Arizona, © 1993 Arizona Board of Regents on behalf of the University of Arizona).

photocathode for optimum resolutions of α -particle pulse height spectra.

To provide for clean α -particle pulse height spectra without the interference from β -particle smear, the PERALS spectrometer discriminates the α -particle from β -particle events in the liquid scintillator. The instrument makes use of pulse shape discrimination (PSD), which can take advantage of the longer decay time of light produced by α -particle interactions in scintillation fluid and reject the faster decaying light produced by β -particle or γ -ray interactions. Fig. 6.121 illustrates the light pulse shapes of alpha and beta events in a liquid scintillator. Depending on the scintillator used, the decay times of α -particle interactions can be 30–40 ns longer than β -particle interactions. As explained by Cadieux (1990), each input pulse to the system generates an amplified voltage pulse for pulse height analysis and a pulse shape signal with a voltage proportional to the time length of the incoming pulse. A discriminator generates a gating signal for only the alpha particles after analyzing the pulse shape voltages. The proper discriminator gating signal is set by use of a microcurie γ -ray source outside of the PERALS sample chamber, which generates Compton electrons that simulate β -particle interactions inside the scintillation fluid cocktail, whereby the discriminator can be adjusted to reject pulse events from the Compton electrons. Following pulse shape discrimination, a multichannel analyzer collects and analyzes pulse height spectra from the α -particle interactions.

Technical support, application notes, and procedures in the use of the PERALS spectrometer and extractive scintillators and solvents are available from ORDELA, Inc, Oak Ridge, TN, USA. The company name ORDELA is derived

from Oak Ridge DEtector Laboratory (<http://www.amale.com/ORDELA/perals/Default.htm>, accessed March 9, 2018).

B. Extractive scintillators and solvents for Alpha LS spectrometry

The extractive scintillator or solvent contains an organic extractant (extractive molecule) capable of forming selective complexes with certain alpha-emitters to facilitate their removal from aqueous solutions and transfer into the organic scintillator phase. The organic extractants chosen must be pure, exhibit a minimum of quenching, and be high in the extractive power for the target element(s) as described by McDowell and McDowell (1993) and McDowell (1996). Popular extractive scintillators consist of a combination of scintillator (e.g., PPBO), solvent (e.g., toluene), and an extractant. The extractant is available commercially and may consist of one of the following: di(2-ethyl-hexyl)-phosphoric acid (HDEHP), 1-nonyldecylamine sulfate, tri-*n*-octylamine sulfate (TNOA), tri-octyl-phosphine oxide (TOPO), or similar compound that will serve as a ligand for the extraction of the alpha-emitter from aqueous solution. The extractants are available commercially in pure form or in toluene solution, which provides users the option to select the fluid to add for the preparation of a liquid scintillation cocktail.

Some commercial extractive scintillators used for PERALS spectrometry are produced by ETRAC Laboratories, Inc., Oak Ridge, TN, USA, among which are ALPHAEX (actinide extracting scintillator), THOREX (thorium extracting scintillator), URAEX (uranium extracting scintillator), POLEX (polonium extracting scintillator), RADAEX (radium extracting scintillator), and RADONS (radon extracting scintillator). Extractive

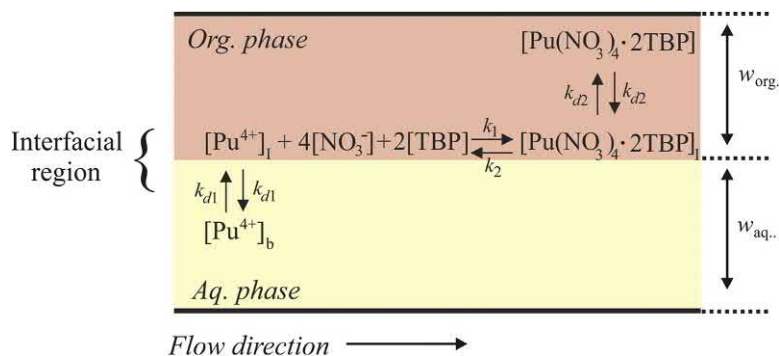

FIGURE 6.122 The extraction model of two-phase flow in the microchannel. The Pu(IV) in the aqueous phase diffuses to the interfacial region. The reaction of Pu(IV) with TBP proceeds at the interface between the two phases and the Pu(IV)-TBP complex is formed. This complex is extracted into the organic phase and diffuses into the organic phase. From Yamamoto et al. (2015); reprinted with permission from John Wiley and Sons © 2015.

scintillators generally contain an organic extractant, such as di(2-ethyl-hexyl)-phosphoric acid (HDEHP), 1-nonyldecylamine sulfate, tri-*n*-octylamine sulfate (TNOA), or tri-octyl-phosphine oxide (TOPO).

The extractants serve as complexing agents or ligands that can remove certain radionuclides from aqueous solution (aqueous phase) into an organic phase prior to liquid scintillation alpha spectrometry of the radionuclide. Yamamoto et al. (2015) developed a glass chip microchannel for the measurement of the rates of extraction of alpha-emitting radionuclides from aqueous solution, which provides an excellent means of studying the mechanisms and efficiency of radionuclide extraction. Fig. 6.122 illustrates the method utilized by Yamamoto et al. (2015) to measure the rates of extraction of Pu^{4+} from 3M HNO_3 solution into an organic phase of 30% tri-*n*-butylphosphate (TBP) extractant in *n*-dodecane solvent. The method involves feeding solutions of the organic extractant phase and aqueous Pu^{4+} acid phase simultaneously through a channel of a microchip device measuring 40 μm in width and up to 200 mm length. The two solutions were made to pass through the channel simultaneously at a rate of 5–20 $\mu\text{L}/\text{min}$. The two phases do not mix and travel simultaneously through the channel of 40 μm width, whereby the width of each channel (i.e., the organic extractant phase, w_{org}) and the aqueous Pu^{4+} phase (w_{aq} , See Fig. 6.122) is 20 μm . Upon exiting the channel, each phase is analyzed for Pu^{4+} by PERALS spectrometry, and the extraction rate and optimum contact time between the two phases can be calculated. The technique is useful in the measurement of Pu^{4+} extraction rates and could be applied to other alpha-emitters and organic extractants.

C. Extractive magnetic nanoparticles (MNPs) for Alpha LS spectrometry

O'Hara et al. (2011) demonstrated the potential of magnetic nanoparticles for the extraction of alpha-emitting radionuclides, namely Po, Ra, U, and Am, from chemically unmodified and pH-2 human urine samples. This work

demonstrated the use of novel sorbent materials, specifically magnetic nanoparticles: Fe_3O_4 and a composite manganese iron oxide (Mn-Fe-O), which would adhere to alpha-emitting radionuclides to permit the extraction of the radionuclides from urine by collecting the magnetic field induced nanoparticles with a magnet followed by a high-throughput alpha counting of the radionuclides. The method demonstrated a rapid screening method for alpha-emitters in human urine by alpha spectrometry. A subsequent study by O'Hara et al. (2016) demonstrated the ability of the nanoscale amphoteric metal oxides with magnetic attributes, namely commercially available magnetite (Fe_3O_4) and Mn-doped magnetite to extract quantitatively the alpha-emitting radionuclides from aqueous solution over a wide range of pH, as illustrated in Fig. 6.123. This demonstrated the potential of using magnetic nanoparticles for the extraction of alpha-emitting radionuclides from natural waters for their subsequent radionuclide analysis.

The above research led to the development by O'Hara and Addleman (2017) of a new approach to the analysis of the extraction and liquid scintillation analysis of alpha-emitting radionuclides in natural waters. The method involves the utilization of magnetic nanoparticles (MNPs) for the extraction of alpha-emitting radionuclides from aqueous solution, followed by the collection of the MNPs and liquid scintillation analysis. The supermagnetic Fe_3O_4 particles utilized were 27 ± 8 nm in size providing a surface area of 42 m^2/g and a specific magnetization of 81 emu/g . The objective of developing a method for extraction for alpha-emitting radionuclides with magnetic nanoparticles is the finding of a fast method with minimal labor and a reduction in the use of toxic and corrosive reagents. O'Hara and Addleman (2017) demonstrate the efficient extraction of ^{241}Am and ^{210}Po in natural waters with the MNPs with improved minimal detectable activities. They demonstrate that the MNP suspensions can be added directly to liquid scintillation cocktail for LS analysis or dissolved in acid forming a faint colored ferric chloride solution, which is then added to the liquid scintillation cocktail.

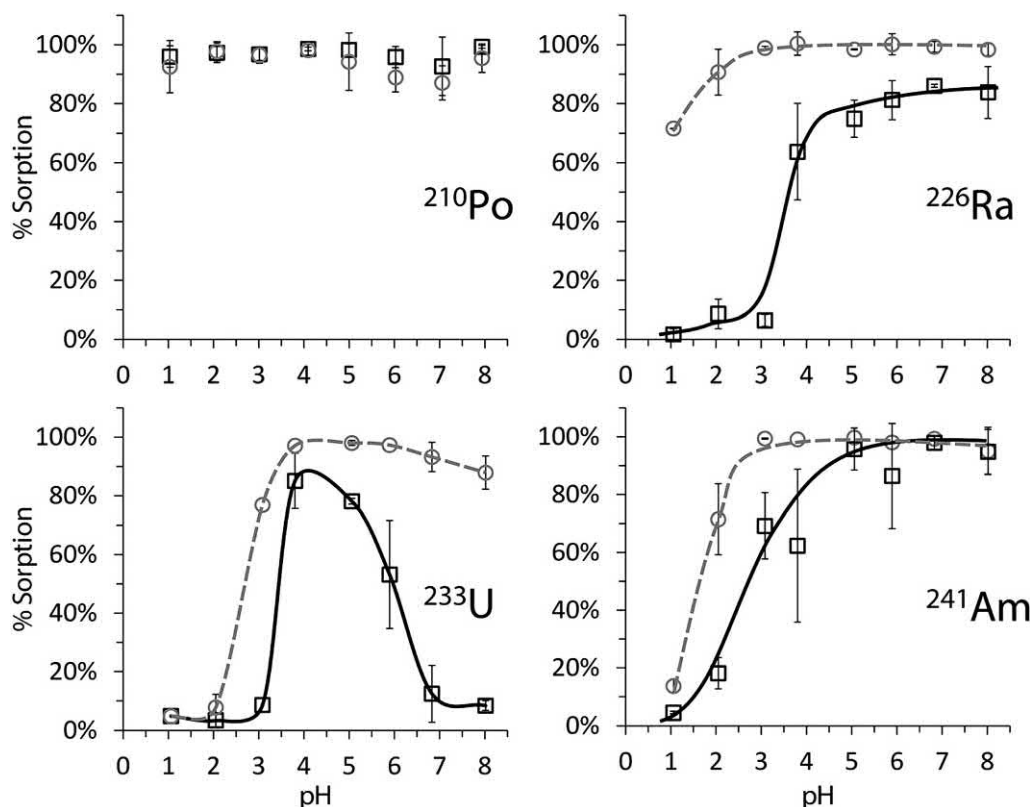

FIGURE 6.123 Sorption of α -emitting radionuclides onto Fe_3O_4 (\square) and Mn-doped Fe_3O_4 (O) NPs from Hanford ground water that was pH adjusted between ~ 1 and the natural pH of ~ 8 . Contact time was 4 h. From O'Hara et al. (2016); reprinted with permission from The Royal Society of Chemistry © 2016.

The procedure for extracting ^{241}Am and ^{210}Po from aqueous solutions is outlined in Table 6.20 and illustrated in Fig. 6.124.

The methodology developed is groundbreaking, and the writer foresees the possibility that this methodology can be extended to PERALS spectrometry by the following sequence: (1) alpha-emitting radionuclides are extracted from natural waters by MNPs; (2) the MNPs are then dissolved in acid; (3) the alpha-emitting radionuclides are extracted from the aqueous dissolved MNP-acid solution by organic extractive scintillators; and (4) the organic extractive scintillator is then analyzed by PERALS spectrometry.

D. Applications of PERALS spectrometry

Applications of extractive scintillators to PERALS alpha spectrometry of Pu isotopes are reviewed by Vajda and Kim (2010) and in Chapter 4, Volume 1 on Alpha Spectrometry. PERALS spectrometry has proven to be a valuable tool in the measurement of ^{226}Ra and ^{222}Rn in drinking water with detection limits of 0.006 Bq/L of ^{226}Ra using only 6 mL of sample (Aupiais et al., 1998) and 0.68 Bq/L of ^{222}Rn with the extraction of 1 L of water (Hamanaka

et al., 1998). A fast sample preparation method for PERALS analysis of radium in water samples is reported by Aupiais (2005) yielding detection limits of 0.04 Bq/L of ^{226}Ra for 5 mL of sample and 240,000 s counting times. An example of the α -particle discrimination achievable by PERALS with low-activity water samples is provided by Fig. 6.125 illustrating the pulse height spectra of ^{226}Ra , ^{222}Rn , and ^{218}Po with α -particle emissions at 4.78, 5.49, and 6.00 MeV respectively. PERALS spectrometry has demonstrated to be a practical method for the analysis of the actinides with high resolution and at low levels of activity. For example, the following studies can be cited: the analysis of ^{232}U – ^{234}U – ^{238}U at resolutions of 266, 233, and 200 keV FWHM reported by Dacheux et al. (2000), limits of detection as low as 1 mBq/L with extraction of uranium, thorium, plutonium, americium, and curium in aqueous solutions of up to 250 mL (Dacheux and Aupiais, 1997, 1998). Aupiais (2004a,b) provides alpha spectra deconvolution methods for PERALS analysis of actinide elements in water including the rapid PERALS analysis of uranium activities in water with detection limits of 0.2 $\mu\text{g/kg}$ or 0.003 Bq/kg with a counting time of 240,000 s. Measurements of ^{237}Np by PERALS spectrometry at levels as low as 23.7 and 9.5 pg/L after counting times of 3 and

TABLE 6.20 An outline of the MNP-based analyte collection and analysis method for liquid scintillation analysis of alpha-emitting radionuclides, presented as a supplement to Fig. 6.124. As outlined in the table and illustrated in Fig. 6.124, the LS analysis may be performed by counting the MNP as a suspension or dissolved in solution.

10 days, respectively, were demonstrated by Aupiais et al. (1999). Selective extraction of ^{210}Po for PERALS spectrometry by Véronneau et al. (2000) and Aleissa et al. (2006) yielded detection limits below 1 mBq/L for 200 mL of solution and 1000 min counting times, and 0.5 L

samples and 180 min counting times, respectively. Because of the relatively high spectral resolutions achieved by PERALS spectrometry, the normal Gaussian shape of alpha peaks sometimes display a high-energy tail in addition to the pure Gaussian function. Aupiais and Dacheux (2000) demonstrated that this asymmetry is due to internal conversion. They conclude that for the accurate PERALS analysis of some radionuclides, such as isotopes of actinide elements, it is necessary to account for L- and M-shell internal conversion contributions in the activity

FIGURE 6.124 MNP-based analyte collection and analysis method flow diagram. See Table 6.20 for a description of the steps. From O'Hara and Addleman (2017); reprinted with permission from The Royal Society of Chemistry © 2017.

FIGURE 6.125 Radium spectrum of La Bourboulis-Choussy thermal water (3000 ± 200 mBq activity and 88,650 s counting time). From Aupiais et al. (1998); reprinted with permission © 1998 American Chemical Society.

measurements. In the spectral deconvolution of actinide elements, [Aupiais \(2004a\)](#) demonstrated the need to account for contributions due to internal conversion.

The PERALS spectrometer can be considered one of the most sensitive liquid scintillation α -spectrometric methods available. As reported by [McDowell and McDowell \(1993\)](#) the PERALS spectrometer rejects 99.99% of ambient and sample β and γ counts from the α spectrum providing ambient radiation backgrounds of 0.001 CPM or less. An alpha pulse height energy resolution of 4.2% FWHM is achievable, which is limited by the quality of contemporary PMTs. The lower limits of detection are estimated at 0.17 mBq (0.01 DPM). The α counting efficiency is 99.7%, as a small 0.3% is lost through α -particle collisions with the sample tube. The use of PERALS instruments in mobile laboratories to diagnose radionuclide contamination for radiological or nuclear events was proposed by [Castagnet et al. \(2007\)](#). A PERALS spectrometer was successfully linked with high purity germanium and bismuth germanate gamma-ray photon detectors by [Cadieux et al. \(2015\)](#) to provide an alpha-gamma coincidence spectrometer for the rapid measurement of actinides in the presence of high beta-gamma fields.

The major disadvantage of PERALS spectrometry is that it is specific for the spectrometric analysis of α -emitters only, that is, this instrument or method cannot be applied to determine α and β activities simultaneously as reviewed by [Pates et al. \(1996a\)](#). Other conventional liquid scintillation analyzers equipped with automatic sample changers are available commercially that provide α/β separation by pulse decay analysis or pulse shape analysis and spectrometric analysis of both α - and β -emitters in the same sample, albeit at a lower α -particle energy resolution than obtained by PERALS spectrometry. However, much improved alpha spectral energy resolutions are possible with conventional LSAs when certain detergent-free and moisture-free extraction cocktails and short optical path

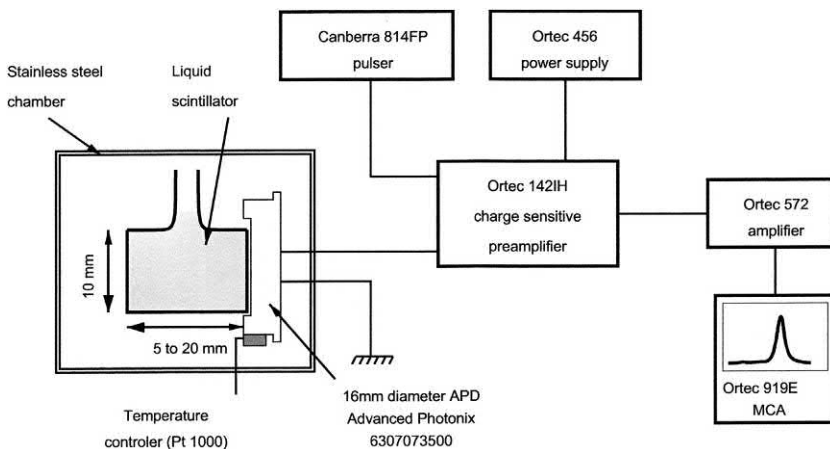

(small vials) are used ([Aupiais et al., 2003](#)). The simultaneous liquid scintillation measurement of α - and β -emitters in the same sample by conventional liquid scintillation analysis is described in the following [Section XV](#) of the chapter.

E. LS alpha-spectrometry with LAAPDs

An improvement in liquid scintillation alpha-spectrometry with energy resolutions of 5% for ^{232}Th (200 keV FWHM) and 3.9% for ^{216}Po (260 keV FWHM) was reported by [Reboli et al. \(2005\)](#) by the use of a silicon Large Area Avalanche Photodiode (LAAPD) in lieu of the standard photomultiplier tube.

[Reboli et al. \(2005\)](#) demonstrate that the LAAPD can be used for alpha liquid scintillation spectrometry and yield better energy resolutions than photomultiplier tubes. The improved energy resolution obtained with the photodiode is reported due to the uniformity of the large spectral response of the APD. The experimental arrangement used by [Reboli et al. \(2005\)](#) for the measurement of the liquid scintillation alpha spectra with the LAAPD is illustrated in [Fig. 6.126](#). Actinides are counted in scintillation cocktails containing fluors in diisopropylnaphthalene isomers (DIN) solvent containing HDEHP (di-(2-ethylhexyl)phosphoric acid) actinide extractant contained within a 10 mm diameter cylindrical fused silica cuvette (see [Fig. 6.126](#)). The cuvette containing 400 μL of sample in liquid scintillator is optically coupled to a windowless avalanche photodiode (APD) with silicone fluid or immersion oil. The cuvette is wrapped with Teflon tape with the exception of the face coupled to the APD, which is etched externally to provide uniformity of light collection on the photosensitive surface of the APD. Optimum resolutions of alpha spectra are obtained by cooling of the sample and APD down to a constant temperature, as low as -40°C , and a small cuvette length of 5 mm.

FIGURE 6.126 Experimental arrangement for the determination of liquid scintillation alpha spectra with an avalanche photodiode (APD). From [Reboli et al. \(2005\)](#); reprinted with permission from Elsevier © 2005.

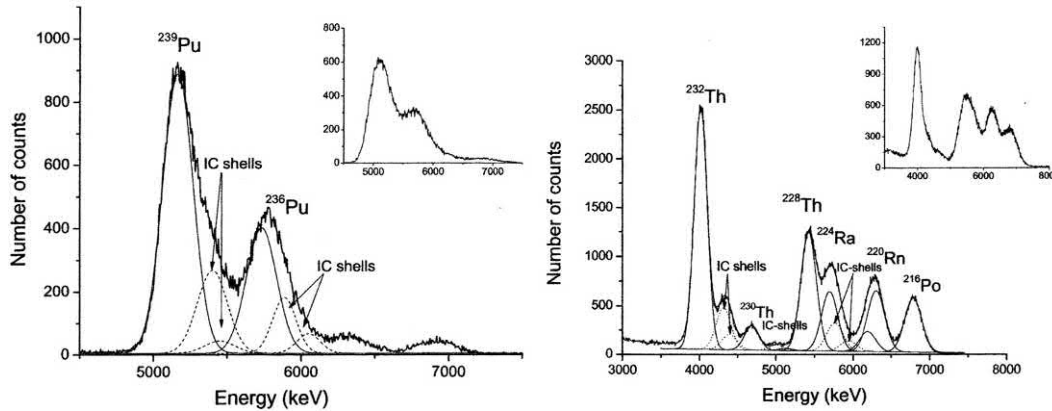

FIGURE 6.127 (Left) Pulse height spectra of ^{239}Pu and ^{236}Pu at -40°C obtained with the liquid scintillation-APD detector. The resolution is equal to ~ 240 keV for the two isotopes. The ^{236}Pu and ^{239}Pu activities are 4 and 8 Bq, respectively, and the counting time is 17 h. The plot in the upper right shows the ^{239}Pu and ^{236}Pu spectrum measured with the PERALS spectrometer. (Right) Pulse height spectra of ^{232}Th and daughters at -40°C obtained with the liquid scintillation-APD. The resolution is equal to 200 keV for ^{232}Th and 262 keV for ^{216}Po . The ^{232}Th activity is 2 Bq, and the counting time is 6 h. The straight lines represent the main α -particle spectra, and the dashed lines represent the pile-up of the main α -particle + IC shell peaks. The plot in the upper right shows the ^{232}Th and daughters spectrum measured with the PERALS spectrometer. From [Reboli et al. \(2005\)](#); reprinted with permission from Elsevier © 2005.

Typical liquid scintillation alpha spectra with the APD detector compared to spectra obtained by PERALS spectrometry are illustrated in [Fig. 6.127](#). Improvement in energy resolution over PERALS is clearly discernible from the spectra. As described by [Reboli et al. \(2005\)](#), the liquid scintillation-APD spectra show a fine structure. The alpha-decay of the plutonium isotopes (^{239}Pu and ^{236}Pu) and the thorium isotopes (^{232}Th , ^{230}Th , and ^{228}Th) do not lead to the ground state and undergo further deexcitation via internal conversion (IC) mainly on L and M shells. The liquid scintillation-APD spectra of [Fig. 6.127](#) offer sufficient energy resolution to illustrate the spectral displacement of the energy peaks of the α -transitions toward higher energy values.

The precise differences in energy resolution between spectra produced by the liquid scintillation-APD and PERALS spectrometers are provided in [Table 6.21](#). The

improvement in energy resolution of the liquid scintillation-APD detector is reported by [Reboli et al. \(2005\)](#) to be due to higher quantum efficiency and more uniform active area than that provided by photomultiplier tubes to this date. The silicon photodiodes have a larger spectral response than PMTs, which facilitates the matching of the fluorescence spectra of scintillators with the APD spectral response.

XV. Simultaneous α/β analysis

As described in Sections II.B and XIV of this chapter, α and β pulse height spectra often overlap. The pulse height spectra of the α - and β -emitters $^{210}\text{Po} + ^{90}\text{Sr}(^{90}\text{Y})$, respectively, illustrated in [Fig. 6.2](#), are a good example of this spectral overlap. In spite of the energies of α and β

particles differ in one order of magnitude, the energy finally detected by the PMTs is quite similar since α particles have a lower rate of scintillation solvent excitation. This is well illustrated in Fig. 6.128 from Bhade et al. (2017) in which the relation between particle energy and the energy of the peak detected (i.e., the average energy of the spectrum in a Quantulus 1220 detector) for alpha- and beta-emitting radionuclides is shown.

Since α and β discrimination on the basis of the pulse height is not possible, many contemporary liquid scintillation analyzers are equipped with the circuitry capable of analyzing α - and β -emitting radionuclides in the same sample.

A. Detectors

Discrimination between α and β decay events is done by the instruments through pulse decay analysis (PDA) or pulse shape analysis (PSA), first reported by Buchtela et al. (1974) and Thorngate et al. (1974), to differentiate alpha from beta decay events. In pulse decay analysis, a pulse decay time discriminator often referred to as the pulse decay discriminator (PDD), monitors the length of time for the decay of a pulse event originating from photon emission due to fluor cocktail excitation. As described in Section XIV and illustrated in Fig. 6.121, fluor excitation events originating from α -particle interactions have 35–40 ns longer decay lifetimes than events originating from β -particle interactions. This is due to the longer deexcitation and light emission processes in scintillation fluors after α -particle interactions, which exhibit higher linear energy transfer (LET). In PDA, the differences in the lengths of pulse decay events resulting from α - and β -particle interactions can be measured by the charge differences

collected at the photomultiplier output at the tail portion of the pulse events. (See also Sections X.B.1 and X.B.2 on the similarity with pulse shape discrimination used to discriminate n/γ interactions with liquid scintillators.) The fluorescence decay resulting from an α -particle interaction, displays a longer tail (Fig. 6.121), and consequently produces a higher charge at the PMT output for the tail portion of the pulse event when compared to a fluorescence decay pulse event produced by a β -particle. The actual difference in decay lifetimes between the α and β events depends on the chemical composition of scintillation fluor cocktail used and particle energies (Pujol and Sanchez-Cabeza, 1997; Pates et al., 1998; Rodriguez Barquero and Grau Carles, 1998).

Instruments that use pulse shape analysis (PSA) to discriminate between α and β events also take advantage of the greater length of the α -produced pulse compared to the β -produced pulse. In PSA, the ratio of the area of the tail of a pulse, beginning at 50 nsec after pulse initiation, is compared to the total pulse area (McDowell, 1966 and Rodriguez Barquero and Grau Carles, 1998), which provides a method of assigning a pulse to a β event (short pulse) or α event (long pulse). This is also referred to as pulse shape discrimination (PSD).

Application of such strategies in commercial liquid scintillation analyzers is combined with data treatment in order to provide the final user with useful data that could lead after optimization of parameters and calibration to the result of alpha and beta decay events in a sample. In Hidex liquid scintillation analyzers (e.g., 300 SL, 600 SL and Triathler) each pulse is classified according to its energy and the pulse length index (PLI). The pulse length index is obtained after the analysis of the pulse after 40 ns of the rise time. As a result, a 2D/3D spectrum is obtained (Eikenberg et al., 2014 and Fig. 6.129). In this case, two parameters can be used for discrimination: PLI-discriminator and energy channels. Therefore, the count rate for alphas is the area above the PLI-discriminator (4 in Fig. 6.129) and the

FIGURE 6.129 Pulse length index (PLI) values (y-axis) illustrated for pure alpha (^{226}Ra) and beta ($^{228}\text{Ra} + ^{228}\text{Ac}$) emitters in a two-dimensional illustration with the channel number on the x-axis. From Eikenberg et al. (2014), reprinted with permission from Elsevier © 2014.

lower and upper energy channels (1000 and 18,269 in Fig. 6.129). The count rate for betas is the area below the PLI-discriminator (4 in Fig. 6.129) and the lower and upper energy channels (1 and 1000 in Fig. 6.129).

In PerkinElmer detectors (e.g., Quantulus and TriCarb series), two spectra are generated. All of the pulse events originating from scintillation photon emissions with a decay time longer than the PDD setting are sent to the α -MCA and those events which have a shorter lifetime are sent to the β -MCA. It is necessary, therefore, to find the optimum PDD setting to get the best separation of α - and β -radionuclide activities into separate MCAs.

B. Establishing the optimum PDD setting

The optimum pulse decay discriminator setting is found by counting a pure α -emitter source and a pure β -emitter source in the liquid scintillation analyzer in the same fluor cocktail, sample composition, sample volume, and type of vial used as the experimental samples to be measured. The optimum PDD setting is affected by sample quench level, the specific quenching agents (chemical and color) in the sample, and the E_{\max} of the β -emitter (Pates et al., 1998; DeVol et al., 2007). The β -particle energy is an influencing factor, because the PMT pulse event has a specific length for a given β -particle energy, and the pulse length increases with increasing event energy. Also, as noted by Pates et al. (1998) the delayed component (tail) of pulse events is a function of the amount of π -electron singlet and triplet excitation states in the scintillation solvent produced by the ionizing radiation. Alpha-particles (or heavy charged particles with high LET) will produce more triplet-state excitation than the lighter beta particles. The triplet states take longer to undergo deexcitation fluorescence. However, the solvents as well as quenching agents present in the sample can affect the delayed component of deexcitation. Some components in cocktails can inhibit deexcitation and prolong triplet-state excitation, while other chemicals in the cocktail (e.g., O_2 , CCl_4 , $CHCl_3$, etc) are electron scavengers, and able therefore, to interact with higher energy states and reduce the delayed component. Moreover, the presence of quenching agents causes a reduction of the number of photons produced and therefore the pulse shape is modified which could affect the final classification of the particle.

When gross α and gross β determinations are needed and the radionuclides in the experimental samples may not be known, one uses an α and β standard of similar energy to that of the α and β radionuclides in the samples (Passo and Cook, 1994) and similar quenching agents to those one might expect in the sample. Different methods for establishing the optimum PSD has been described.

1. Equivalent α and β spillover criteria

This method is the most commonly used and is based on searching the PSD setting in which the spillover of alphas into the beta counting region is equivalent to the spillover of betas into the alpha counting region (Bhade et al., 2010; Zapata et al., 2012; Palomo et al., 2011; Çakal et al., 2015). This PSD setting value usually coincides with the PSD setting with minimum mean spillover. The following calibration steps are required:

1. The pure β -emitter standard dissolved in a suitable liquid scintillation cocktail is placed into the LSA for counting. The chemical composition of this standard should be the same as those of the unknown experimental samples. During this calibration procedure the instrument automatically counts the pure β -emitter standard at various pulse decay discriminator settings and stores the results obtained. In Hidex detectors, pulses are classified according to the its pulse length index and energy in a 3D spectrum, whereas in PerkinElmer detectors, all pulses of duration longer than the PDD setting are sent to the α -multichannel analyzer (α -MCA) and pulses of shorter duration to the β -multichannel analyzer (β -MCA).
2. The pure α -emitter standard dissolved in a suitable cocktail of the same chemistry as the previously described β -emitter (Step 1) is placed into the LSA for counting. Its chemical composition should also be the same as the unknown experimental samples. As in Step 1, the instrument automatically counts the pure α -emitter standard at various pulse decay discriminator settings and stores the results obtained following the same set-up described in Step 1.
3. In PerkinElmer detectors, the percent spillover of the β events into the α -MCA and the percent spillover of the α events into the β -MCA are calculated. A curve of the percent spillover versus the PDD setting as illustrated in Fig. 6.130 is then plotted. In Hidex detectors, the percent spillover of β events into the α -integration region (above PLI) and the percent spillover of the α events into the β -integration region (below PLI) are calculated for one or several α - and β -integration regions (Fig. 6.131).
4. The pulse decay discriminator setting at which the two spillover curves cross is selected as the optimum PDD setting for simultaneous α/β analysis in the same sample (e.g., PDD = 62 of Fig. 6.130 and PLI = 14 of Fig. 6.131). The two spillover curves plotted in this fashion are referred to as crossover plots. At the crossover PDD setting there is minimum spillover of α events into the β -MCA and β events into the α -MCA,

FIGURE 6.130 PSA optimization. From Todorović et al. (2012), reprinted with permission from Elsevier © 2012.

when the activities of both α and β events must be determined. However, if only the α -emitter activity is of interest in a sample containing both α - and β -emitters, a higher PDD setting can be selected, well above the crossover setting (e.g., PDD > 90 of Fig. 6.130), where the spillover of β events into the α -MCA approaches zero. Alternatively, if only the β -emitter activity is of interest in a sample containing both α - and β -emitters, a lower PDD setting can be selected, well below the crossover setting (e.g., PDD < 40 of Fig. 6.130), where the spillover of α events into the β -MCA is lowest.

2. Inflection point criteria

As described before, the general method for determining the optimum PSA is based on the cross-over plots obtained using an α -emitter and a β -emitter. In the case that a pure α -emitter and a β -emitter is not available, or they are very

different from the radionuclides in the real sample, this method cannot be applied without risk of having high errors. For this situation, Feng et al. (2014b) propose a general method to determine the optimum PDD parameter based on the measurement of a sample containing an alpha- and a beta-emitter and determining the PDD parameter value where there is the inflection point of the count rate in the alpha α -MCA. In this point, it is estimated that beta and alpha misclassification are equivalent and compensated. The following calibration steps are required:

1. A solution containing a mixture of an alpha- and a beta-emitter is dissolved in a suitable liquid scintillation cocktail and is placed into the LSA for counting. The chemical composition of this standard should be the same as those of the unknown experimental samples. During this calibration procedure, the instrument automatically counts the sample at various PDD settings and stores the results obtained.
2. A curve of the count rate in the region of interest of the α -MCA versus the PDD setting, as illustrated in Fig. 6.132, is plotted.
3. The data is fitted to the function $y = ax^3 + bx^2 + cx + d$.
4. The inflection point of y (obtained when the second derivative is equal to 0; $x = -b/(3a)$) is the optimum pulse decay discriminator setting (e.g., PDD = 110–130 of Fig. 6.132). At the optimum PDD setting α events spillover is compensated with β events spillover.

3. Plateau criteria

One of the problems usually referred when using the equilibrium spillover criteria is that calibration

FIGURE 6.132 The effect of ROI on the count rates of Np=Pa at various PSAs. From Feng et al. (2014b), reprinted with permission from Elsevier © 2014.

radionuclides do not have the same detection efficiency and/or spillover than the radionuclides on the samples. That usually happens when α and β particles come from ^{226}Ra and daughters. Bhade et al. (2018) propose a method for the analysis radium/radon based on a selection of the optimum PDD parameter as that in which the variability between the detection efficiencies of signals on the α -MCA and on the β -MCA is minimum. In this point, it is estimated that beta and alpha misclassifications are equivalent and compensated. The following calibration steps are required:

1. A ^{226}Ra standard dissolved in a suitable liquid scintillation cocktail is placed into the LSA for counting. The chemical composition of this standard should be the same as that of the unknown experimental samples. During this calibration procedure the instrument automatically counts the ^{226}Ra standard at various pulse decay discriminator settings and stores the results obtained.
2. Region of interest (ROI) is fixed excluding ^{214}Po to avoid errors caused by cancellation of events by the Quantulus guard detector. In the ROI defined the α/β ratio should be 1.5 in a homogeneous liquid scintillator (three alphas ^{226}Ra , ^{222}Rn and ^{218}Po and two betas ^{214}Pb and ^{214}Bi) and one in a homogeneous liquid scintillator (two alphas ^{222}Rn and ^{218}Po and two betas ^{214}Pb and ^{214}Bi).
3. Alpha efficiency and beta efficiency are calculated taking into account all the events into the α -MCA and β -MCA regions of interest respectively. A curve of the efficiencies versus the PDD setting, as illustrated in Fig. 6.133A, is plotted.
4. The optimum pulse decay discriminator setting corresponds to that in which the alpha and beta efficiencies present a plateau (e.g., PDD = 85 of Fig. 6.133A). At the optimum PDD setting α events spillover is compensated with β events spillover and therefore α and β

efficiencies can be used. Moreover, it is checked that in this region the α/β ratio has the expected value (Fig. 6.133B).

All of the procedures described above make use of standards without quenching agent added. However, De Vol et al. (2007) and Fons-Castells et al. (2017d) provide a thorough study on the effects of chemical and color quench and radionuclides used to calibrate instrumentation for α/β discrimination. Among these findings, it is important to note that the quenching agent will have a direct effect on total spillover which can change from less than 5% in less quenched samples (i.e., SPQ(E) values between 800 and 850) to 15% or more in highly quenched samples (i.e., SPQ(E) values between 500 and 550) (See Fig. 6.134).

Moreover, both studies show that the effect is dependent of the type of quenching agent. In other words, a liquid scintillation analyzer may determine that two samples in two distinct counting vials have the same level of quench [i.e., same quench indication parameter, tSIE or SPQ(E)]; however, if different chemical agents are producing the quench, the spillover can be different between the two samples. Fig. 6.135 illustrates how the α -MCA and β -MCA spectra obtained at equivalent SPQ(E) and with the same PDD parameter for chemical and color quenching are very different leading to a different classification. This behavior is also seen in the analysis of a natural uranium sample. In this case, the β/α ratio for color and chemical quenched samples present a very different behavior due to the different misclassification of alpha particles from ^{234}U and ^{238}U (Fig. 6.136). It is important therefore that the matrix of the experimental samples be constant and that the liquid scintillation analyzer be programmed for minimum spillover under the same conditions as the experimental samples.

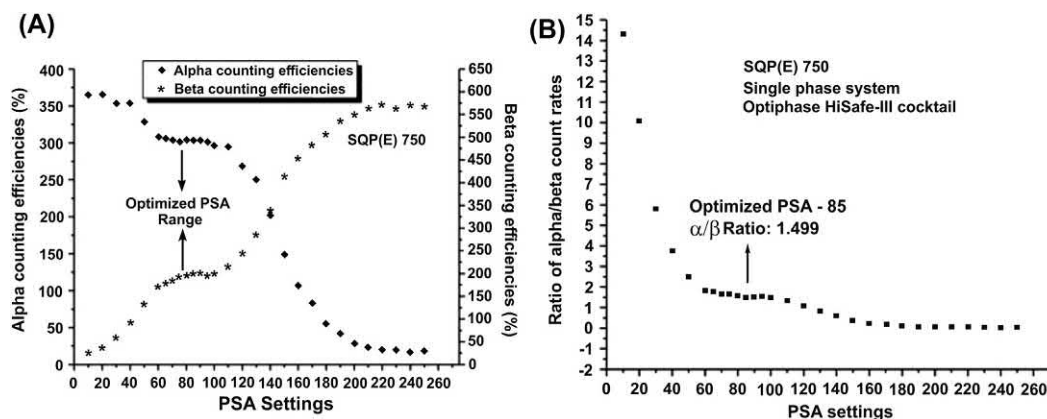

FIGURE 6.133 (A) Variation in alpha and beta counting efficiencies when mixed α/β ^{226}Ra standard was counted on different PSA settings. FIGURE 6.136 Ratio between β and α counts as a function of SQP[E] for color and chemical quench in ^{nat}U standards. From Fons-Castells *et al.* (2017d), reprinted with permission from Springer Nature © 2017.

DeVol et al. (2007) also point out that pure alpha-emitters may yield different spillovers than nuclides that emit alpha with gamma cascade events, such as ^{241}Am . Nuclides with gamma cascade events are more likely to be classified by the pulse shape discriminator as alpha events, because of the pulse duration. Gamma cascade events are common with alpha-emitters.

Another important aspect that should be taken into account is the energy of the beta- and alpha-emitters used in the optimum PDD setting. Salonen (2006a) was first to report that alpha spillover is a function also of the energy of the alpha particle. The alpha spillover of lower-energy alpha particles is greater than the spillover of high-energy alpha particles when samples are measured at a constant PDD setting (*i.e.*, constant pulse shape analysis) (See Fig. 6.137). Several combinations of pairs of radionuclides are described in the bibliography for establishing the optimum PDD setting: $^{40}\text{K}/^{236}\text{U}$ (Fons-Castells et al., 2017a); $^{90}\text{Sr}/^{236}\text{U}$ (Zapata et al., 2012); $^{90}\text{Sr}/^{241}\text{Am}$ (Rusconi et al., 2004; Bhade et al., 2010; Çakal et al., 2015; Todorovic et al., 2012; Lin et al., 2012); $^{40}\text{K}/^{241}\text{Am}$ (Palomo et al., 2011); $^{36}\text{Cl}/^{241}\text{Am}$ (Salonen, 2010); and $^{99}\text{Mo}/^{242}\text{Pu}$ (Hou, 2017). In summary, the sample matrix should be as close as possible in chemical and physical properties to the alpha and beta standards used to determine the optimum PDD setting for minimum spillover.

C. α/β spillover corrections and activity calculations

Once the optimum PDD setting is determined, the detection efficiency of the α particles in the α -MCA and that of the β particles in the β -MCA must be measured. This may be best determined by use of internal standardization as described in Section V.A of this chapter. The α -MCA and β -MCA will provide net (background-subtracted) count rates (CPM) for α and β particles, respectively. The net count rates must be corrected for spillover or misclassification and the net count rates converted to α and β activities

(disintegration rates). The calculations required for the determination of α and β count rates corrected for spillover are derived by Bhade et al. (2010). The following equations described by Bakir and Bem (1995) provide the sample gross α and β activity concentrations in units of Bq/L taking into account sample volume (V) and concentration factor (C), for samples concentrated prior to counting:

$$A_{\alpha} = \frac{I_{\beta}E_{\beta} - I_{\alpha}S_{\beta/\alpha}}{(E_{\alpha}E_{\beta} - S_{\alpha/\beta}S_{\beta/\alpha})VC60} \quad (6.156)$$

$$A_{\beta} = \frac{I_{\alpha}E_{\alpha} - I_{\beta}S_{\alpha/\beta}}{(E_{\alpha}E_{\beta} - S_{\alpha/\beta}S_{\beta/\alpha})VC60} \quad (6.157)$$

where A_{α} and A_{β} are the gross α particle and gross β particle activities, respectively, in units of Bq/L, I_{α} and I_{β} are the net (background subtracted) count rates in the α and β multichannel analyzers, respectively, $S_{\alpha/\beta}$ and $S_{\beta/\alpha}$ are the percent spillover of α events into the β MCA and β events into the α MCA, respectively, E_{α} and E_{β} are the detection efficiencies for α particles in the α MCA and β particles in the β MCA, respectively, V is the volume of analyzed sample in liters, C is the concentration factor or the degree of concentration of the sample prior to analysis, and 60 is a conversion factor to change count rate from CPM to CPS.

The backgrounds, count rates, and detection efficiencies in the α MCA and β MCA will depend on the pulse height discriminator settings used in the α and β channels, respectively, and instrumental background-reducing count mode used (*e.g.*, LLCM or NCM) as described in Section XX.C. The optimum PDD setting must be determined at the same pulse height discriminator and background-reducing count mode settings as those used for the experimental sample analysis.

D. Optimizing α/β discrimination in PDA

As described previously, there are several parameters that play a crucial role in α/β discrimination in pulse decay analysis. The following are some guidelines to follow, which can enhance α/β separation performance:

1. Control the chemistry of the sample. The cocktail-sample mixture must be homogeneous and constant for standards and samples. The chemistry of the sample, including the scintillation cocktail and kinds and amounts of quenching agents present, should be the same as those of the α and β standards used to plot the crossover curves for determination of the optimum PDD setting. The sample must be completely solubilized in the liquid scintillation cocktail. Acids are often necessary to keep α -emitter salts in solution in the cocktail. Organic samples and filters are often processed through ashing followed by acid dissolution of salt

FIGURE 6.137 Alpha and beta misclassification percentages as a function of the PSA value for different alpha- and beta-emitters (● ^{137}Cs , ■ ^{40}K , ▲ ^{90}Y , □ ^{236}U , and ○ ^{241}Am). From Zapata-García et al. (2012), reprinted with permission from Elsevier © 2012.

TABLE 6.22 Acid Loading Performance of α/β Compatible Liquid Scintillation Cocktails^a.

Cocktail (10 mL)	H ₂ O (mL)	1 M HCl (mL)	2 M HCl (mL)	1 M HNO ₃ (mL)	2 M HNO ₃ (mL)	% Misclassification (minimal sample loads)
Ultima Gold	3.50	0.25	0.10	0.70	0.30	0.6
Ultima Gold XR	10.0	2.00	0.90	3.00	1.75	2.2

residues (Yang and Guo, 1995). Table 6.22 provides some guidelines on the acid loading capacity (mL acid/10 mL cocktail) at room temperature (20–22°C) of certain cocktails. The minimum α/β misclassification (at crossover point from spillover curves) for small sample sizes (≤ 0.5 mL acid) is also provided. Water-soluble paper for smear tests is a sample type that might be used to avoid excessive acids in cocktail (Takiue et al., 1989a), although glass fiber filter, cotton-tipped or polyurethane foam are also demonstrated as a good swipe material for α/β contamination assays (Dai et al., 2012).

2. Minimize the sample quench. The sample volume (e.g., aqueous solution) will dilute the scintillation fluor cocktail and also introduce quenching agents. Moreover, as not all chemical components have the same quenching effect, the optimization of the conditions, such as acid concentration or pH, can lower the quenching effects.
3. Minimum α/β spillover is obtained generally at lowest levels of quench.
4. Use organic acceptor cocktails rather than cocktails that have surfactants or emulsifiers. Table 6.22 lists liquid scintillation cocktails that provide excellent α/β

discrimination performance. They all use diisopropyl-naphthalene (DIN) as a solvent with the exception of Insta-Gel XF, which has pseudocumene as a solvent. Pseudocumene and the linear alkylbenzenes (LAB) are “fast” solvents, which are less efficient for α/β separation (See Figs. 6.138 and 6.139). Naphthalene is added to Insta-Gel XF in a proportion of 20% w/v to improve α/β separation by acting as an intermediate in the energy transfer process between solvent and fluor increasing the production of π -electron triplet excitation states produced by α -particle interactions (Passo and Cook, 1994). Naphthalene is not required with the Ultima Gold Cocktails, as the DIN solvent serves the same purpose (Thomson, 1991). The DIN solvent-based cocktails, particularly Ultima Gold AB, have been demonstrated to provide excellent α/β separations, while increasing surfactant concentration degrades the cocktail performance for α/β analysis (Pates et al., 1993, 1996b).

5. Use organic extractive scintillators that are selective for the α -emitters of interest. The use of organic (water immiscible) extractive scintillators was described in Section XIV of this chapter. This is recommended when only the α -activity is desired, as after extraction

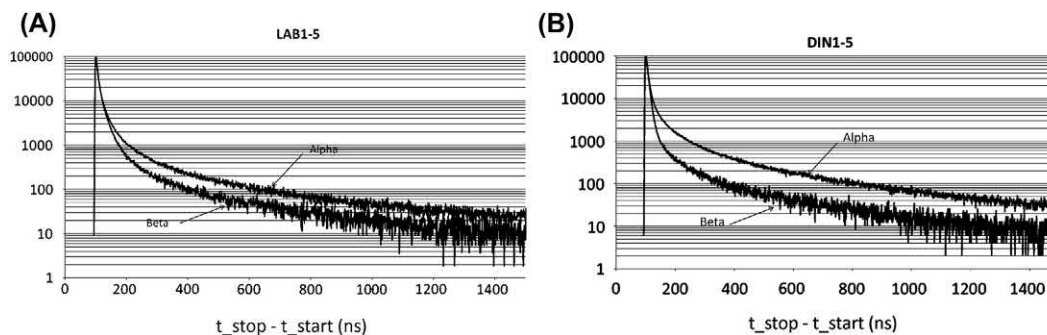

FIGURE 6.138 Raw time histograms of the α and β measurements performed on (A) LAB-based and (B) DIN-based scintillators using the set-up for particle irradiation. of the dissolved aqueous sample with the selective organic scintillator, the α -emitters transfer from the aqueous phase to the organic scintillator leaving most of the β -emitters behind in the aqueous phase. Organic extractive scintillators are useful when only α -emitters are of interest, when there is an overwhelming β -emitter activity with α -emitters of interest, and to improve the energy resolution of α pulse height spectra. The work of [Yang et al. \(1992, 1994\)](#) and [Aupiais et al. \(2003\)](#) are recommended as additional resources on this topic.

6. Use specific extractive resins to concentrate the radionuclides of interest. For example, actinide extractive resin, available from Eichrom Technologies, Inc., Darien IL, USA, or Triskem International, Bruz, France, is used to extract elements of high atomic number (e.g., Th, U, Pu, Am, Cm, etc.) from aqueous solutions ([Horwitz et al., 1997](#); [Eikenberg et al., 1999](#)). 3M Empore RadDisc, Mapplewood, MN, USA, is used to separate radium isotopes (i.e., ^{228}Ra and ^{226}Ra) from lead isotopes (^{210}Pb) in water samples ([Eikenberg et al., 2014](#); [Fons-Castells et al., 2017b](#)). Strong basic anion exchange resin (AG1X4) from Bio-Rad Laboratories, Hercules, CA, USA, was used to separate alpha-emitting radionuclides from $^{99\text{m}}\text{Tc}$ eluate to check its purity ([Hou, 2017](#)). In all cases, the extraction of the radionuclides of interest together with α/β pulse shape discrimination provide improved limits of detection ([Horwitz et al., 1997](#); [Eikenberg et al., 1999](#)).
7. Purging the dissolved oxygen from the cocktail with argon gas will improve α/β separation by reducing quench. This is not commonly performed except in research to obtain unquenched samples, as the additional step is time consuming and the gain in α/β separation is relatively small.
8. Time-resolved pulse decay analysis (TR-PDA) significantly improves α/β separation or, in other words, reduces misclassification of α as β and β as α ([Passo,](#)

[1996](#)). TR-PDA, available with PerkinElmer liquid scintillation analyzers, is PDA combined with time-resolved background discrimination (TR-LSC), which is described briefly in Section XX.C.5.d of this chapter. This effect, as described by [Passo \(1996\)](#), is due to enhanced α rejection from the β -MCA and associated lowering of the β spillover into the α -MCA due to a change in the shape of the α misclassification curve.

E. Quenching effects in α/β discrimination

As noted previously in [Section C](#), the α/β discrimination is improved by minimizing quench in the sample, which is accomplished by reducing the sample volume as the amount of water and acids among other substances in the sample can cause quench. In this scenario, the best α/β separation performance is obtained by keeping, for the experimental samples, the same quench level (sample chemistry), sample volume, and vial type as for the α - and β standards used to determine the optimum PDD setting. However, if it is not possible to maintain a constant quenching level on the samples, quenching should be taken into account in the activity determinations. A general strategy used for such purpose is to measure the alpha and beta standards at different PDD settings and for a wide range of quench levels. Therefore, activity quantification is done using the optimum PDD setting at the quench level of the sample, taking into account the corresponding alpha and beta detection efficiencies and spillover ([Yang, 1996](#)), [Çakal et al. \(2015\)](#), [Palomo et al., 2010](#), [Bhade et al. \(2010\)](#). In spite of quenching minimization, the following are important effects of quench on α/β separation and guidelines to follow in controlling the effects of quench or even taking advantage of these affects, when they occur:

1. Alpha misclassification increases with quench. Once the optimum PDD setting is determined for a given sample quench level as described in [Section B](#) above, any

FIGURE 6.140 Percent misclassification curves of alpha and beta events as a function of quench level (tSIE) measured at a constant PDD setting determined at tSIE 620. © 1998 PerkinElmer, Inc. Printed with permission.

increase in quench level causes an increase in the misclassification of α events into the β -MCA. This can be seen from the alpha into beta curve of Fig. 6.140, which was prepared by measuring firstly the optimum PDD setting for a given value of quench (e.g., tSIE = 620 in this example) and then measuring the percent spillover at various quench levels after adding incremental amounts of quenching agent. The degree of change in misclassification is a function of the type of quenching agent present in the sample (Fig. 6.134, Section XV). Some quenching agents are strong electron scavengers (e.g., O_2 , $CHCl_3$, CCl_4), and these are able to interact more easily with π -electron triplet states reducing the delayed component of fluorescence deexcitation (Pates et al., 1998). Therefore, it is important that the chemistry of the α and β standards used to determine the optimum PDD setting and the quenching agents used to model the variation of the optimum PDD setting with the quenching parameter be identical to the chemistry of samples under investigation. Quenching agents used are HNO_3 (Palomo et al., 2010), nitromethane (Bhade et al., 2010), colored compounds, mixture of components usually present in samples (e.g., SIMS solution composed of metallic ions such as Na (18.3 g L^{-1}), Fe (6.0 g L^{-1}), Al (5.7 g L^{-1}), Ni (2.9 g L^{-1}) and Nd (1.5 g L^{-1}) in 1M HNO_3 in Feng et al. (2017) and dry residue mass (Stojkovic et al., 2017; Çakal et al., 2015).

- Counting efficiency of α -emitters is expected to remain at 100% (Aburai et al., 1981; Takiue et al., 1989a; Parus et al., 1993); however, loss of α events into the β -MCA occurs with increased quench whereby not all α events are detected. Caution should be taken in assuming 100% detection efficiency, and the detection efficiency should be determined in all cases. Reduced counting efficiencies can also occur with instruments that count afterpulses to discriminate against background as described in Section XX.C.

- Beta misclassification decreases with an increase in quench as illustrated in Fig. 6.140. However, the percent misclassification and counting efficiency are a function of the E_{\max} of the β -particle emitter (Pates et al., 1998). Therefore, to assure accurate measurement of misclassification and optimum PDD setting, it is best to plot a crossover curve using the same β -emitter or one of similar E_{\max} as that of the β -emitter expected in the samples to be analyzed.

F. Practical applications of α/β discrimination and analysis

PERALS spectrometry was discussed in the previous Section XIV of this chapter as a method that yields the highest resolution of alpha spectra energy lines by liquid scintillation. However, conventional liquid scintillation analyzers with α/β discrimination and the use of appropriate nonaqueous and nondetergent scintillation cocktails can yield very good and practical energy resolutions. There are numerous applications of the alpha spectrometric analysis of radionuclides, or combined analysis of alpha- and beta-emitting radionuclides with conventional liquid scintillation analyzers equipped with α/β discrimination. Some of these applications will be cited in the following paragraphs.

Aupiais et al. (2003) demonstrated that the energy resolution of a conventional liquid scintillation analyzer (*i.e.*, a PerkinElmer Tri Carb 2770) equipped with α/β discrimination could be enhanced by 200% by using specific non-water miscible cocktails and a short optical path. Under such conditions an energy resolution of about 200 keV for the 4.2 MeV energy line of ^{238}U could be obtained with either the Tri Carb or the PERALS spectrometers. Also, under such conditions the sensitivity of the Tri Carb liquid scintillation analyzer was 40% lower than that of the PERALS spectrometer, because of the higher α/β discrimination of PERALS and its shorter optical path. Figs. 6.141 and 6.142 illustrate the improvement in alpha

FIGURE 6.141 Uranium isotopes spectra: (left) Ultima Gold AB cocktail in standard PerkinElmer vial ($V = 20$ mL, $\phi = 26$ mm, resolution of E_α of ^{238}U at 4.2 MeV = 509 keV) spectrometer Tri-Carb; (right) Alphaex cocktail in standard culture tube ($V = 1$ mL, $\phi = 10$ mm, resolution of E_α of ^{238}U at 4.2 MeV = 260 keV), spectrometer PERALS. spectral energy resolution obtained with the PerkinElmer Tri Carb LSA compared to the PERALS spectrometer when detergent-free Ultima Gold AB cocktail or Alphaex cocktail (an actinide extracting scintillator specific for alpha measurement) is used. When the sample light path in the Tri Carb LSA is reduced further by employing a 1 mL sample vial ($\phi = 16$ mm), the energy resolution is improved significantly close to that obtained with the PERALS spectrometer. In conclusion, the energy resolution on liquid scintillation alpha spectrometry can be

improved by using a lower or shorter optical path and no-water miscible cocktails, such as the toluene-naphthalene based cocktails (e.g., Alphaex) or detergent-free diisopropylnaphthalene (DIN-based) cocktails (e.g., detergent-free Ultima Gold AB). The preparation of the detergent-free Ultima Gold AB cocktail is described by Aupiais et al. (2003) and the Alphaex cocktail is available from ETRAC, Knoxville, TN, USA. Both cocktails contain HDEHP as a nuclide extractant and primary and secondary fluors.

As noted previously, the % spillover of alpha pulse events into the β MCA and beta pulse events into the α MCA will be a function of quench level. In addition, as the quench level of a sample increases, the alpha pulse height spectra will shift from higher to lower pulse heights (i.e., higher to lower channel numbers) and the resolutions of the spectral energy lines will deteriorate with peak broadening (i.e., increase in FWHM). Such an effect is observed in Fig. 6.143, which illustrates the liquid scintillation alpha spectra of ^{226}Ra and its daughter nuclides in equilibrium at various levels of quench (i.e., tSIE = 462, 374, 283, and 218) where the least quenched sample has the highest tSIE. For the alpha spectrometric analysis of ^{226}Ra and isotopes of uranium, Stamoulis et al. (2010) established a spectral deconvolution technique, which involved the correlation of the peak's centroids, corresponding to different radionuclides, to the characteristic energies at different degrees of quenching. Values of the centroids of the peaks and the corresponding FWHMs were used as initial parameters for fitting the spectra with overlapping Gaussians using the Origin analysis program. The derived values of peaks' centroids and FWHMs for each radionuclide were correlated to the quench indicating parameter tSIE.

FIGURE 6.143 Alpha spectra of ^{226}Ra and its daughters in equilibrium. These spectra correspond to four degrees of quenching with the tSIE index value varying from 218 (highest quench level) to 482 (lowest quench level). From Stamoulis et al. (2010). Reprinted with permission from Elsevier © 2010.

Among the applications of α/β discrimination is the determination of gross alpha and gross beta activities of samples such as drinking water, as governmental regulatory agencies often place limits and regularly monitor ground-water supplies and drinking water. Some example of gross alpha and gross beta activity determinations of water supplies are the works of Bakir and Bem (1995), Warrick and Croudace (2002), Kleinschmidt (2004), Happel et al. (2004), Wong et al. (2005), Wisser et al. (2006), Staffová et al. (2006), Salonen (2006b), Ruberu et al. (2008), Bhade et al. (2010), Forte (2011), Palomo et al. (2011), Lin et al. (2012), Todorovic et al. (2012), Çakal et al. (2015). Gross alpha and gross beta activity measurements have also been applied to the rapid analysis of aerosol filters for environmental monitoring (Sas et al., 2010), urine analysis for terrorism preparedness in the possible event of population exposure (Piraner and Jones, 2009), the assessment of gross alpha- and beta-emitters in nuclear fuel processes (Lara-Robustillo and Rodríguez et al., 2006) and the analysis of gross alpha- and beta-emitters in nasal swabs (Dai et al., 2012).

Other common applications of α/β separation (*i.e.*, discrimination) liquid scintillation spectrometry are the analysis of ^{222}Rn in drinking water (Galán López et al., 2004; Pates and Mullinger, 2007; Salonen, 2010), the spectrometric analysis of isotopes of the ^{238}U and ^{232}Th day series (Bem et al., 2004; Bianchi et al., 2005; Kim et al., 2008, 2017bib_Kim_et_al_2008; Stamoulis et al., 2010; Eikenberg et al., 2014; Stojković et al., 2016; Ozden et al., 2017bib_Kim_et_al_2017; Fons-Castells et al., 2017b), the alpha-emitting nuclides $^{234,238}\text{U}$, $^{238-240}\text{Pu}$, ^{241}Am , ^{244}Cm , and the beta-emitting nuclides $^{90}\text{Sr}/^{90}\text{Y}$ and ^{241}Pu (Versilov et al., 2002; Eikenberg et al., 2002), isotopes of Np in nuclear waste (Diodati and Sartori, 2007), analysis of ^{241}Am and ^{243}Am (El Mrabet et al., 2004; Alamelu et al., 2006), analysis of ^{237}Np , $^{238-240}\text{Pu}$, and ^{241}Am (Feng and He, 2009), the simultaneous determination of ^{226}Ra , ^{233}U , and ^{237}Np (Nebelung and Baraniak, 2007) and the analysis of alpha-emitter impurities (plutonium and americium) in $^{99\text{m}}\text{Tc}$ eluate from $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator (Hou, 2017).

An interesting approach to α/β discrimination was applied by Groppi et al. (2005b) to the alpha spectrometry of $^{211}\text{At}/^{211\text{g}}\text{Po}$ nuclides, which are prepared by α -cyclotron irradiation of ^{209}Bi target material according to the reaction $^{209}\text{Bi}(\alpha, 2n)^{211}\text{At}$. The ^{211}At product nuclide decays ($t_{1/2} = 7.21\text{ h}$) by alpha emission to ^{207}Bi daughter with the main alpha at 5.87 MeV 41.8% and by EC (58.2%) to the very short-lived ^{211}Po daughter ($t_{1/2} = 0.516\text{ msec}$). The ^{211}Po daughter also decays by alpha emission with the main alpha at 7.45 MeV. The $^{211}\text{At}/^{211\text{g}}\text{Po}$ parent-daughter nuclides at secular equilibrium are used in radiotherapy. The high LET and short range of the alpha particles from

FIGURE 6.144 Liquid scintillation spectrum of $^{211}\text{At}/^{211\text{g}}\text{Po}$ in extracted organic phase measured with the Triathler (Hidex, Turku, Finland) liquid scintillation counter with pulse shape discrimination as a function of channel number and time duration of pulses. The counts in appropriate windows are used to obtain the decay curves of the two nuclides in secular equilibrium. From Groppi et al. (2005b). Reprinted with permission from Elsevier © 2005.

both nuclide attributes to these nuclides the power to eradicate tumor cells in the treatment of cancer. At secular equilibrium both nuclides decay at the half-life of the parent, *i.e.*, 7.21 h. Thus, the alpha-emissions remain in the patient long enough to irradiate the cancer cells, and do not remain for any excessive period of time. Alpha/beta discrimination of the $^{211}\text{At}/^{211}\text{Po}$ assigns the alpha emissions to the αMCA and pulse events from Auger and conversion electrons to the βMCA . The alpha spectra produced by the $^{211}\text{At}/^{211}\text{Po}$ in a Triathler liquid scintillation analyzer (Hidex, Turku, Finland) with α/β pulse shape discrimination is illustrated in Fig. 6.144. The alpha spectra of the two nuclides decay at the same half-life, and the spectra were used to measure quantitatively the activities of the alpha-emitters.

Another approach based on alpha/beta discrimination is the simultaneous analysis of several specific alpha- (^{241}Am , ^{226}Ra , and $^{\text{nat}}\text{U}$) and beta-emitters (^{40}K , ^{60}Co , $^{90}\text{Sr}/^{90}\text{Y}$, and ^{137}Cs) in water samples using partial least squares (PLS) multivariate analysis of the $\alpha\text{-MCA}$ and $\beta\text{-MCA}$ spectra (Fons-Castells et al., 2017a). Water samples analyzed were treated following the usual procedure for gross α and gross β : dryness evaporation of 100 mL of sample, redissolution in 10 mL of HCl solution at pH = 1.5, and analysis of an aliquot of 8 mL with 12 mL of Ultima Gold AB in 20 mL PE vials in a Quantus Detector. PSA discrimination value was set at 100 based on previous calibration done with ^{40}K and ^{236}U . PLS calibration matrix was built using 54 spectra obtained from the analysis of a standard of the six radionuclides, at

three activity levels by triplicate in the same way as the samples. ROI for β -MCA and α -MCA were 454–915 and 75–895. Selectivity ratio spectra obtained when applying the PLS model show that predictor channels for ^{241}Am , $^{90}\text{Sr}/^{90}\text{Y}$, ^{241}Am , $^{90}\text{Sr}/^{90}\text{Y}$ (Fig. 6.145A) do not overlap and good quantification is expected, whereas for ^{40}K , ^{60}Co , and ^{137}Cs there is an overlap that may cause higher interference (Fig. 6.145B).

The PLS model was applied successfully to synthetic samples containing mixtures of radionuclides with deviation lower than 12% for all the isotopes except ^{137}Cs which has higher level of deviation (from 20% to 100%) and with limits of detection lower than 1 Bq/kg for the betas and 0.3 Bq/g for the alphas. It was also seen that the model could be adapted to the sample measured by adding or removing those radionuclides that are expected or not in the sample. In this case the model was adapted for the analysis of two samples from IAEA intercomparisons with relative bias lower than 20% for most of the radionuclides (Tables 6.23 and Table 6.24).

XVI. Plastic scintillators in LSC

Plastic scintillators (PS) are a solid solution of fluorescent solutes in a polymeric aromatic solvent (Bagán et al., 2010). PS behavior as a detector for the analysis of radionuclides in a liquid scintillation counter is very similar to liquid scintillation cocktails, and it was researched by Tarancón et al. (2002a,b, 2003, 2004, 2017). PS composition is equivalent to the basic composition of liquid scintillation cocktails, being PS only differentiated by its solid state. PS may include, as solvent lineal polymers such as polystyrene or polyvinyltoluene, or three-dimensional polymers, by adding a crosslinker as divinylbenzene. In addition to the typical primary and secondary fluorescent solutes as PPO, POPOP, and others. PS may also include secondary solvents like naphthalene or DIN. Plastic scintillators based on lineal polymers are insoluble in aqueous solutions, whereas PS based on three-dimensional polymers are insoluble in aggressive and organic media (Bagán et al., 2014a).

The format of plastic scintillators for radionuclide determination is formulated to favor the proximity between the emitters and detector. Thus, the shape of PS for this application are microspheres (PSm) with a diameter between 10 and 300 μm, pellets measured in mm (Furuta et al., 2017; Furuta, E., Ito, T., 2018), and foils (PSf) with a width between 50 and 100 μm (Merín et al., 2017) (see Fig. 6.146). Among these, the format most used with liquid scintillation spectrometers are PSm.

Plastic scintillator microspheres (PSm) provide several advantages, such as: (i) There are no mixed-waste disposal costs. (ii) Samples can be easily recovered and PSm can be reused innumerable times, if washed properly. (iii) Phase separation is avoided, whereby phase separation causes samples to be unstable during the counting process. This capability opens the possibility of counting samples with very high salt matrices, even those with salt concentrations difficult or impossible to mix suitably with liquid fluor

**FIGURE 6.146** Images of PSm (Secondary electron microscope image) and PSfoils. From Tarancón et al. (2017). Reprinted with permission from Springer Nature © 2017.

FIGURE 6.147 Scintillation mechanism when using Plastic Scintillator microspheres. From Tarancón *et al.* (2017). Reprinted with permission from Springer Nature © 2017.

cocktails. (iv) PSm can be implemented in selective determinations (PSresins) and even used in continuous measurements as consequence of the PSm solid state. (v) A conventional liquid scintillation counter can be used.

Concerning liquid scintillation cocktails, the use of PSm also exhibit some drawbacks, namely, (i) sample preparation needs an additional step of mixture homogenization, (ii) it causes a decrease in detection efficiency for low energy beta-emitters (e.g., ^3H), (iii) the detection process is interfered by two additional quenching phenomena: particle quenching and optical quenching, and (iv) to the current date, the number of suppliers are limited and cost is higher than liquid scintillation cocktails.

In plastic scintillation, sample preparation for radionuclide measurement follows a similar procedure as liquid scintillation. First, the appropriate amount of PSm is added to the counting vial, afterward the sample solution is added, and finally the vial content is homogenized by using a shaking procedure as a Vortex. It is important to pay attention to the relationship between the amount of PSm and the volume of sample in order to avoid an excess of scintillator, which would not be in contact with the sample, or supernatant sample solution, which would not be in

contact with the scintillator. The convenient relationship for any kind of PSm diameter is 1.5g of scintillator 0.625 mL of solution. Counting vials are measured in a liquid scintillation counter exactly in the same way as liquid scintillation samples.

The reusability of the PSm after washing in citric acid was demonstrated by (Tarancón *et al.* (2003)).

The generation of a signal as a consequence of the interaction of the emitted beta or alpha particle with the scintillation media is equivalent in plastic and liquid scintillation. When a beta or alpha particle reaches the plastic microspheres, energy is absorbed by the polymeric aromatic compounds proportional to the particle energy deposited, as discussed in Chapter 9, Volume 1. The polymeric aromatic compounds at various excited energy states then transfer this energy to the fluor solutes in the plastic microspheres, which finally emit the photons (See Fig. 6.147). The only differences arise at the beginning and at the end of the process when two additional interferences may happen: particle quenching and optical quenching.

Particle quenching is the loss ~~lost~~ of energy of the beta or alpha particles due to the interaction with the medium during particle trajectory from the point where

FIGURE 6.148 Scheme of particle (A) and optical (B) quenching processes using plastic scintillator microspheres. From Tarancón *et al.* (2017). Reprinted with permission from Springer Nature © 2017.

FIGURE 6.149 Pulse height spectra from ^3H , ^{14}C , and $^{90}\text{Sr}/^{90}\text{Y}$ and background spectra produced with plastic scintillator beads with a conventional PerkinElmer Quantulus counter in 7 mL counting vials. From Tarancón et al. (2004). Reprinted with permission from Elsevier © 2004.

disintegration happens until reaching the surface of the PSm (Santiago et al., 2011). An increase in PSm diameter will result into a longer particle trajectory to PSm, which will lead to a lower detection efficiency (Fig. 6.148). On the extreme opposite, optical quenching is the loss of photons produced due to the successive changes on the refraction index when photons travel from their emission until leaving the counting vial. The larger the diameter of the PSm, the lower the number of changes in the solution:PSm, therefore the higher is the detection efficiency observed.

These two quenching mechanisms result into opposite outcomes on the detection efficiency. A convenient compromise is achieved when PSm have a diameter in the range of 10–300 μm .

The pulse height spectra produced by beta-emitters in the PSm in a liquid scintillation counter show similarities to those produced by liquid scintillation, as illustrated in Fig. 6.149. Full spectrum detection efficiencies for ^3H , ^{14}C , and $^{90}\text{Sr}/^{90}\text{Y}$ with PSm and aqueous radionuclide solution in 7 mL polyethylene counting vials were reported by Tarancón et al. (2004) to be $0.13\% \pm 0.04$, $17.79\% \pm 0.54$, and $90.02\% \pm 0.02$, respectively, and full spectrum

backgrounds were 1.09 ± 0.04 , 0.47 ± 0.04 , and 1.43 ± 0.07 cpm. The low background count rates are very favorable for this counting method, and optimized counting windows produced remarkably yet much higher figures of merit (E^2/B), where E is the % detection efficiency and B the background count rate. Thus, routine low-level counting (i.e., low activity samples) were demonstrated with relative errors $< 5\%$ for medium and high-energy beta-emitters. The low detection efficiency for ^3H is understandable, as the low-energy beta particles ($E_{\text{max}} = 18.6$ keV) undergo particle quenching when they travel through the aqueous solution until they reach the plastic microsphere to produce a scintillation pulse event.

Reduction of the PSm diameter produces an increase in the detection efficiency, which becomes relatively more important if the radionuclide considered has lower energy values (see Table 6.25). For ^3H a reduction from 145 to 17 μm increases the detection efficiency from 0.81% to 4.51%.

Alpha-particles can also be detected by using PSm with high detection efficiencies. Also, in this case, the values obtained depend on the PSm diameter (see Table 6.26). The alpha-particle spectral distribution as a function of PSm diameter is shown in Fig. 6.150.

Smaller sized plastic scintillator beads (< 100 nm), also referred to as nanosuspensions, were tested by Weekley et al. (2004) for the analysis of ^{14}C also to reduce costs of organic liquid scintillation cocktails and cost of mixed organic radioactive waste disposal. They reported a ^{14}C counting efficiency of 45.1%. Zhu and Jay (2007) synthesized fluor-containing nanoparticles (nanosuspensions) from styrene-in-water microemulsions to determine ^{14}C activities in various sample matrices by aqueous LSA. The average diameter of the nanoparticles was ~ 30 nm. Several α - and β -particle emitting nuclides were tested and the relative counting efficiencies are listed in Table 6.27. The low detection efficiencies of the low-energy β -emitters (e.g., ^3H and ^{63}Ni) are considered by Zhu et al. (2006) and Zhu and Jay (2007) to be offset by the positive environmental effects and reduced costs of mixed (organic) waste disposal.

FIGURE 6.150 Spectral distribution of ^{241}Am analyzed by using PSm of different diameters. From Tarancón et al. (2017). Reprinted with permission from Springer Nature © 2017.

An infinitesimally small PSm would get the beta- or alpha-emitters embedded within the plastic scintillator closer to the conditions of liquid scintillation measurements. This scenario is almost achieved when the counting solution is evaporated to dryness onto the PSm, resulting in detection efficiencies close to 100% (Bagán et al., 2014b).

Furuta et al. (2009) demonstrated that plastic scintillator of cylindrical shape (capable of fitting in a conventional liquid scintillation counting vial) are a powerful tool for the identification of beta-emitting radionuclides. This is discussed further on in Section XVIII of this chapter.

When PSm are used, detection efficiency calibrations for color and chemical quenching follow the same procedures as in liquid scintillation measurements. A series of standards with increasing quenching effect are measured together with a quenching parameter (e.g., SQP(E)).

For calibrating particle quenching, classical quenching parameters, based on the sample spectrum or on the Compton spectrum generated by a gamma external source, cannot be used since the spectra do not shift as consequence of this quenching effect. However, these parameters can be easily substituted for another quenching parameter such as sample solution density.

Optical quenching, as well as ionization quenching, does not need calibration, because it is constant for all counting samples prepared in the same experimental conditions.

The possibility of applying plastic scintillator microspheres for the standardization of beta-emitting radionuclides using the free-parameter model in lieu of organic liquid scintillation fluor cocktails was demonstrated by Tarancón Sanz and Kossert (2011) and Tarancón et al. (2015). The free-parameter model applied to efficiency tracing and TDCR techniques of radionuclide standardization are discussed in detail in Section IX of this chapter.

TABLE 6.27 Quantification of various α and β -emitting radionuclides by liquid scintillation counting using fluor-containing nanoparticles. Relative counting efficiency is defined as CPM from the nanosuspensions/CPM from conventional organic LSC.

Isotope	Mode of decay (E_{max}) (MeV)	Relative counting efficiency (%)
^3H	β^- (0.018)	3.2
^{63}Ni	β^- (0.066)	8.19
^{14}C	β^- (0.156)	45.3
$^{90}\text{Sr}/^{90}\text{Y}^{\text{a}}$	β^- (0.546/2.28)	82.5
^{204}Th	β^- (0.763)	71.3
^{32}P	β^- (1.71)	100
^{241}Am	α (5.49)	96.2
^{239}Pu	α (5.15)	100

^a ^{90}Sr samples contain progeny isotope ^{90}Y , which is likely why this sample exhibited greater counting efficiency than ^{204}Tl . From Zhu and Jay (2007). Reprinted with permission from IOP Publishing Ltd. © 2007.

Employing the free-parameter model with the TDCR technique and efficiency tracing with ^{63}Ni , Tarancón Sanz and Kossert (2011) demonstrated the standardization of several beta-emitters with deviations from known reference activities between 0.1% and 2.5%.

The potential of polystyrene PSm as a detector for α/β pulse shape discrimination in conventional liquid scintillation counters was investigated by Bagán et al. (2010). Again, the study was implemented in light of the advantage of avoiding the use of organic liquid scintillation cocktails and the disposal costs of mixed waste. In a comparison of the performance of the PSm to the conventional use of organic fluor cocktails in α/β discrimination, Bagán et al. (2010) demonstrated that the detection efficiency and pulse heights produced by the beta-emitters with plastic scintillator microspheres were lower achieving improved beta discrimination. On the other hand, the analysis of alpha-emitters with the PSm resulted into a poorer alpha discrimination. The α/β discrimination capability of the plastic scintillator is apparently related to the particle energy loss during travel to the plastic microspheres. Bagán et al. (2010) postulate that this energy loss would reduce the excitation of the polystyrene and consequently reduce the number of triplet excitation states key to the pulse shape discrimination of alpha particles from beta particles. The addition of a secondary solvent as naphthalene or diisopropylnaphthalene translate into a delay on the pulse, especially those proceeding of the alpha-emitters, significantly improving the alpha–beta discrimination capability (see Fig. 6.151).

A new approach to the α/β discrimination taken by Bagán et al. (2014b), which would avoid the energy loss by both alpha and beta particles, is to evaporate the samples to dryness onto the scintillator microspheres.

Yeman et al. (2017) describes the current state-of-the-art of plastic scintillators based on polyvinyltoluene and

their capability to neutron signal discrimination in a gamma radiation background.

Another advantage that PSm can offer is the analysis of aqueous samples containing high salt matrices, which can be difficult to mix with conventional liquid scintillation fluor cocktails. Using ^{14}C as a test nuclide in samples coming from studies of oil reservoirs and Detec (UPS-89) polystyrene plastic scintillation beads between 180 and 250 μm diameter provided by Detec (<http://detecsciences.com/>), Gatineau, QB, Canada or Detec-Europe, F-56,000 Vannes, France, Bagán et al. (2009) demonstrated that samples high in salt content (up to 2.8 M NaClO_4) could be analyzed efficiently, and the plastic microspheres can be reused after a simple citric acid wash. The high salt concentrations however, added a new dimension to the detection efficiency calculations, as the increase in sample density with salt concentration would diminish slightly the detection efficiency due to particle quenching. Thus, two quench parameters should be considered, the classical SQP(E) for color quenching correction and the density for particle quenching, as illustrated in Fig. 6.152.

The slight decrease in detection efficiency of the ^{14}C with increased sample density is expected, as the relatively weak beta particles must travel from the solution to the PSm before excitation of plastic and fluor molecules. As two detection efficiency factors are involved, the overall detection efficiency of the radionuclide (E_{unk}) is calculated as

$$E_{\text{unk}} = E_C \times E_S \times E_0 \quad (6.158)$$

where E_C is the relative efficiency caused by color quenching, i.e., the efficiency of the color-quenched sample divided by the efficiency of the standard without quenching agent E_0 , and E_S is the relative efficiency caused by the particle quenching (salt concentration), i.e., the efficiency of the salt-quenched standard

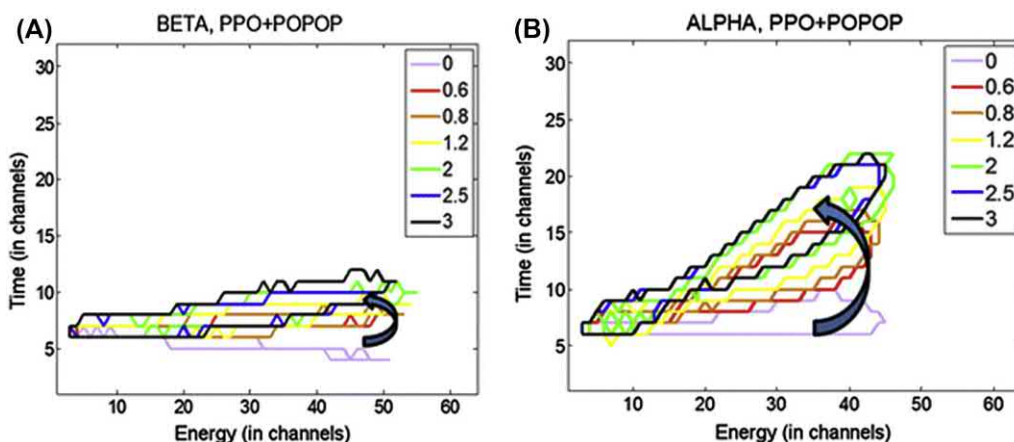

FIGURE 6.151 Energy versus pulse time distribution for a beta-emitter ($^{90}\text{Sr}/^{90}\text{Y}$) (A) and an alpha-emitter ^{241}Am (B) as a function of the naphthalene concentration measured in a Triathler detector. divided by the efficiency of the standard without quenching agent, E_0 .

Relative errors on the quantification of ^{14}C activity in aqueous samples from the radiotracer studies following this procedure were always under 5%.

Another interesting application of PSm is related to ^{222}Rn . Mitev *et al.*, (2016) and Pelay *et al.*, (2017), studied the absorption behavior of ^{222}Rn in plastic scintillators in comparison to the behavior observed for other polymeric material as polycarbonates. The experimental setup includes the exposition of the PSm produced at the University of Barcelona to a ^{222}Rn atmosphere and their subsequent inclusion in a 20 mL glass vial followed by its measurement in a commercial counter. The results showed that the diffusion length in PSm was around 120 μm whereas the partition coefficients in air were 4.95 ± 0.54 in air and 37.2 ± 1.9 in water. These values are lower than the concentration capabilities exhibited by Makrofol materials (N 112 and DE 26) but the PSm enables the capability of direct detection and does not require any other manipulation. Detection efficiency of the PSm with ^{222}Rn absorbed is 314% (a maximum of 500% is expected due to ^{222}Rn and its progeny) and the resolution of the spectrum distribution depends on PSm diameter and packaging in the measurement vial.

Continuous monitoring of activity in a fluid has been one important goal since the beginning of liquid scintillation techniques. The use of scintillating cocktails mixed with the aqueous samples has been a permanent option with variable success depending on the degree of homogenization of the mixture and always affected by the continuous consumption of reagents and waste production. The use of solid scintillators has appeared historically as an alternative mainly for ^3H determination in liquid effluents. Singh and Kadwani (1974) and Noakes *et al.* (1998) developed a

continuous monitoring detector for ^3H in air and in aqueous samples with the same common component: a cell filled with plastic scintillator powder. Variations from this approach have continued over the years all taking advantage of the stability of using plastic scintillators as detectors. Bae *et al.* (2017) describes a specific mobile tritium monitoring detector for a continuous inflow system designed for water samples based on electrolysis and a plastic scintillator detection system. Tarancón *et al.* (2012) describes a continuous monitoring instrument for beta and alpha-particles quantification in aqueous samples.

Plastic scintillators are solid and this turns into a great advantage for the incorporation to these detector strategies to improve the selectivity of the determinations. Spectra distribution of beta and alpha emissions and the limited resolution and quenching effects on scintillation techniques make a previous separation step obligatory before any specific determination can be made. Plastic scintillating resins (PSr) unify these steps of separation and preparation to the measurement by coating the PSm by an extractive material (see Fig. 6.153).

In practical terms, PS resins are packaged in solid phase extraction cartridges and inserted in the separation experimental set-up as is customary with the commonly used extraction chromatography resins. The only difference is that once the radionuclide of interest is isolated, no further steps of elution are necessary and nor additional preparation for measurement is required due to the fact that PSr cartridges can be disconnected, included directly into a 20 mL vial and introduced into the liquid scintillation counter. No additional scintillator is required, because the PSm core is already included. The main advantages of PSr are the reduction of time and manpower required for sample processing as well as the reduction of reagents and waste. Nevertheless, this technique also has its drawbacks such as

FIGURE 6.153 Scheme and secondary electron microscope images of PSm and PSr produced at the University of Barcelona. From *García et al. (2018)*.

the still in progress development of PSr (since only a few are already commercially available) and the potential higher cost specially related to the nonscintillating resins.

There are two main approaches to incorporate the selective extractant onto the plastic scintillator: impregnation or covalent binding. In the first case, extractant is added by deposition, in the second it is bond to the polymer. The first approach is the most widely used, but its stability depends on the solubility of the extractant in the sample solution. The second approach does not have this problem, but often the incorporation of the extractive molecule results in a critical reduction of the scintillation capability. *Duval et al. (2016 a,b)* describes an extractive scintillating polymer sensor for Uranium determination in ground water. *Bliznyuk et al. (2018)* describes a more recent approach based on hybrid organic–inorganic beads with the Superlig 620 (SL) material with high affinity to radiostrontium. The application includes SL particles used as core and halloysite clay nanotubes (HNT) modified with a polyvinyltoluene (PVT). The developed SL–HNT–PVT hybrid extractive scintillating material allows real-time detection of low-level concentrations of radiostrontium in water. *Bagán et al. (2011b)* applied impregnated PSr with a 1M solution of 4,4'(5')-di-*t*-butylcyclohexano-18-crown-6 (DtBuCH18C6), to act as an extractant for Sr, in a similar fashion as Sr-specific resins, to extract strontium from solution. The ^{90}Sr is retained by the extractant-impregnated PSr, and the ^{90}Y remains with the rinse solution. The PSr were counted directly in the liquid scintillation analyzer. Drinking water, sea water, and river waters were tested, and a minimum detectable activity of 0.46 Bq/L for a 10 mL sample is reported with sample errors <4% *Bagán et al. (2011b)*.

Sáez-Muñoz et al. (2018) used the same Sr–PSr to establish an emergency procedure to $^{89}\text{Sr}/^{90}\text{Sr}$ determinations in milk. For their study, several types of milks were analyzed including cow, sheep and goat, skimmed, semi-skimmed, and in powder form. Total $^{89}\text{Sr}+^{90}\text{Sr}$ activity was quantified with relative bias lower than 7% in all cases. The entire analysis, including pretreatment lasted only 5h. *Bagan et al. (2012)* undertook further studies on radiotracer determinations in oil reservoirs by using a specific PSr for S^{14}CN^- , which was the active ^{14}C molecule in the radiotracer. The extractant in this case was Aliquat 336. Quantification was achieved with bias lower than 5% and the detection limit for 100 mL of sample was 0.08 Bq L $^{-1}$.

Barrera et al. (2016) describes a PSr for ^{99}Tc determinations in water and urine using also Aliquat 336. In all samples the quantification bias was lower than 8% and the detection limit for 10 mL of sample was 0.36 Bq L $^{-1}$. Some other PSr are related to the determination of ^{210}Pb and ^{126}Sn (*Lluch et al. 2016*).

A potential evolution of the use of PSr can be its incorporation to the protocols followed by the automated separation systems that are being commercially available in the recent years.

XVII. Scintillation in noble liquids

Liquid noble gases, such as helium, neon, argon, and xenon, have properties of high scintillation yield as a medium for the detection of ionizing radiation and nuclear recoil energy. In particular, liquid xenon is considered most suitable for γ -ray detection, because of its high atomic

number and short decay constants of the scintillation light ($\tau_1 = 4.3$ ns, $\tau_2 = 22$ ns for short and long components, respectively), which comes close to that of plastic scintillators (Hitachi et al., 1983; Tanaka et al., 2001; Aprile and Doke, 2010). The efficiency of liquid xenon as a scintillator is reported by Aprile et al. (1990) to be similar to that of NaI(Tl) solid scintillation detector, but with a shorter scintillation decay time. Both liquid argon (LAr) and liquid xenon (LXe) are widely studied as efficient liquid scintillation detectors for (i) alpha particles and internal conversion electrons (Aprile et al., 1990, 2005; Miyajima et al., 1992; Tanaka et al., 2001; Ni et al., 2005; Kastens et al., 2009), (ii) α/γ and n/γ pulse height discrimination (Benetti et al., 1993; Peiffer et al., 2008), and (iii) γ radiation and neutron spectrometry from the scintillation efficiency of electron and nuclear recoil events (Arneodo et al., 2000; Akimov et al., 2002; and Aprile et al., 2005). Liquid rare gas detectors are currently being studied for their utility in various fields including (i) nuclear medicine as imaging detectors including positron emission tomography (Gomez-Cadenas et al., 2016; Gallego Manzano et al., 2015; Retière, 2010; Amaudruz et al., 2009; Grignon et al., 2007; Doke et al., 2006; Gallin-Martel et al., 2006, 2009, 2012), (ii) tomography imaging telescopes (Time Projection Chambers) for research in medium-energy gamma-ray astrophysics (Tomás et al., 2018; Zou et al., 2016; Aprile and Doke, 2010; Cennini et al., 1999, and Aprile et al., 1990), (iii) galactic Dark Matter Search consisting of weakly interacting massive particles (Akerib et al., 2016; Alfonsi et al., 2016; Sorensen et al., 2009; Aprile et al., 2006b; Neves et al., 2005, 2007, and Akimov et al., 2002), (iv) relativistic heavy ion detection (Tanaka et al., 2001), (v) the search for the rare muon decay, *i.e.* $\mu^+ \rightarrow e^+ + \gamma$ (Ogawa et al., 2017; Ieki, 2016; Adam et al., 2010; Uchiyama, 2010; Iwamoto, 2010; Sawada, 2010; and Nishimura and Natori, 2011), and (vi) the EXO-200 (Enriched Xenon Observatory for $0\nu\beta\beta$, *i.e.*, neutrinoless double beta decay) which utilizes a detector containing 200 kg of liquid xenon in the search for neutrinoless double beta decay (Pocar, 2015, 2013; Auger et al., 2012; Dolinski, 2012; Arisaka et al., 2009; Neilson et al., 2009; Leonard et al., 2008; Ueshima et al., 2008). Applications of liquid xenon are numerous in light of the advantageous detector characteristics of high atomic number, scintillation efficiency, and short fluorescence decay times.

The mechanisms of scintillation in liquid argon and liquid xenon are similar and have been investigated thoroughly (Kubota et al., 1978a,b, 1979; Doke, 1981; Doke et al., 1990). As described by Cennini et al. (1999), Mei et al. (2008) and Aprile and Doke (2010), scintillation light in liquid argon (LAr) is produced by ionizing radiation

either by direct ionization of an Ar atom followed by excimer formation and de-excitation according to

or via ionization, recombination, excimer formation, and de-excitation as

De-excitation from the Ar_2^* to the dissociated ground state 2Ar gives rise to fluorescence displaying fast and slow decay components of about 5 ns and 1 μ s, respectively, with relative yields of 23% and 77% at an emission of approximately 128 nm wavelength. The light emission is abundant with approximately one photon emitted per 25 eV of energy dissipated in LAr by ionizing radiation or 40,000 photons per MeV. In the case of liquid xenon (LXe) excitation, light emission is at 175 nm and the lifetimes of the singlet and triplet states of the excited dimer Xe_2^* are 4 and 22 ns, which makes liquid xenon the fastest of the noble liquid scintillators (Hitachi et al., 1983; Aprile et al., 2005).

The wavelength of light emission is in the vacuum ultraviolet (VUV) region. Consequently, glass-faced photomultipliers are used with wavelength shifters. Metal-channel photomultipliers are fabricated by Hamamatsu Photonics to efficiently detect the fast scintillation light from LXe. These PMTs are designed to operate within the LXe to efficiently detect the 175 nm Xe light photons (Giboni et al., 2005). Other photomultipliers with MgF_2 or CaF_2 windows have been used. The addition of liquid xenon in small concentrations (≤ 100 ppm) into LAr serves as a wavelength shifter from 128 to 173 nm permitting photomultipliers with quartz windows (Cennini et al., 1999). The scintillation mechanism for liquid xenon is similar to that described above for LAr with an average of one photon emitted per 14.7 eV of energy dissipated by ionizing α particles (Tanaka et al., 2001). Avalanche photodiodes (APDs) and silicon photomultipliers are researched as alternatives to the photomultiplier tube for liquid rare gas scintillation detectors (Solovov et al. (2000; Aprile et al., 2006a; and Shagin et al., 2009).

Arneodo et al. (2000) demonstrated the excellent linear response of scintillation fluorescence versus energy deposited in liquid xenon using several γ -ray sources. Typical energy distribution in liquid Xe with ^{57}Co and ^{137}Cs γ -ray sources placed outside the LXe scintillation detector measuring 5.0 and 4.6 cm for the top and bottom diameters and 4.0 cm in height are illustrated in Fig. 6.154. The width of each energy distribution is dominated by a light collection efficiency that varies from 5% to 12% depending on the point of interaction of the γ -ray within

FIGURE 6.154 Liquid xenon scintillation light spectrum of ^{57}Co and ^{137}Cs . From Arneodo et al. (2000). Printed with permission from Elsevier © 2000.

the LXe detector volume. The overall detector efficiency was estimated by Arneodo et al. (2000) to be approximately 1.5% for the 175 nm UV photons from the LXe scintillation taking into account the average light collection efficiency of 8%, PMT quantum efficiency of 19%, and photo-extraction potential of LXe of 15 eV.

Calibration of LiXe detectors can be performed from the decay of xenon metastable states, illustrated in Fig. 6.155, produced by fast neutron activation. All of the short-lived metastable states decay within a few days leaving no longtime activity in the detector after the neutron activation, as demonstrated by Ni et al. (2007). The characterization of the response of noble liquid scintillation detectors at low energies can be performed with $^{83\text{m}}\text{Kr}$ as a calibration source (Kastens et al., 2009). The $^{83\text{m}}\text{Kr}$ decays via isomeric transition with emission of 9.4 and 32.1 keV

FIGURE 6.155 Background subtracted spectra from activated xenon 12 h after a 5-day neutron activation. The energy resolutions for the 164 and 236 keV peaks are 7.0% and 5.1%, respectively. From Ni et al. (2007). Printed with permission from Elsevier © 2007.

FIGURE 6.156 Activities of energy peaks due to 9.4 and 32.1 keV conversion electrons after doping $^{83\text{m}}\text{Kr}$ into the liquid xenon detector. The 9.4 and 32.1 keV peaks have a resolution of 23% and 14%, respectively. From Kastens et al. (2009). Reprinted with permission © 2009 The American Physical Society.

conversion electrons and with a half-life of 1.83 h. The spectral energy peaks, illustrated in Fig. 6.156, at 9.4 and 32.1 keV are reported to have a 23% and 14% resolution respectively. Such a source with short half-life leaves no long-lived residue in the detector.

XVIII. Radionuclide identification

It is possible to use a liquid scintillation analyzer to identify automatically an unknown pure β -emitting radionuclide sample; once it is identified, the LSA can automatically determine the activity (DPM) of that same sample.

One of the obstacles encountered in identifying β -emitting radionuclides by LSA is that the pulse height spectrum of all β -emitters are broad over the range from 0 keV to the end point energy corresponding to the E_{max} of the β emissions. Also, the pulse height spectrum of a given β -emitter changes in pulse height distribution and endpoint energy according to the level of quench in a sample. Consequently, the pulse height distribution of a higher-energy β -emitter under a high degree of quench could resemble that of a lower-energy β -emitter under a low degree of quench.

By means of a double-ratio technique Takiue et al. (1989b) developed a method for identifying unknown β -emitters. The technique is based on combining the information provided by two quench indicating parameters, tSIE and SIS, which were described previously in this chapter. The tSIE is produced by the external standard, and it provides information defining the level of quench in the sample-scintillation fluor cocktail mixture. The SIS is a sample-spectrum quench indicating parameter, which depends not only on the degree of quench in the sample but also the β -particle energy spectrum. The two quench-indicating parameters together, therefore, provide information that reflects the pulse height distribution and shape of a particular pulse height spectrum at any given quench level. The combined information provided by the two

quench indicating parameters is used to identify pure β - or β/γ -emitting radionuclides.

The technique developed by Takiue *et al.*, (1989) requires the preparation of a series of quenched “standards” of all of the pure radionuclides that may need to be identified as unknown samples. The word “standards” is enclosed in quotation marks, because the activity need not be known in the series of quenched standards. The activities of the quenched standards should be high enough to determine accurately the SIS of each of the standards, and they are used only once to prepare a double-ratio curve for a particular radionuclide.

Once the series of quenched standards has been prepared for each radionuclide of interest, the SIS and tSIE of each quenched standard are determined and plotted as illustrated in Fig. 6.157. The family of curves, illustrated in the figure, becomes separated from the lowest curve for ^3H to the uppermost curve for ^{32}P according to the maximum energy (E_{max}) and average beta-particle energy (E_{av}) of each radionuclide, because the SIS plotted along the ordinate reflects both E_{max} and E_{av} . The curves, therefore, provide a definition of the magnitudes of the pulse height

spectral distributions as a function of quench, which are radionuclide specific.

To apply this technique, an unknown sample is monitored for its SIS and tSIE value and then compared with the double-ratio curves, such as those illustrated in Fig. 6.157, that were prepared in advance. From the tSIE and SIS of an unknown sample, the radionuclide can be identified using the double-ratio curves provided the deviation $\Delta S/S$ of the experimental plotted point of the unknown sample is less than ± 0.02 , or

$$\frac{\Delta S}{S} = \frac{(\log Y_1 - \log Y_0)}{S} < \pm 0.02 \quad (6.161)$$

where ΔS is the difference in ordinate ($\log Y_1 - \log Y_0$) between the plotted point Y_1 and the corresponding value Y_0 on the double-ratio curve, and S is the logarithm of the SIS value ($\log Y_0$) on the curve. Takiue *et al.* (1989b) demonstrated that the activities of the unknown samples can also be determined automatically, if the double-ratio curves are linked by computer program to the quench correction curve of the appropriate radionuclide. In essence, therefore, an unknown pure β -emitter in scintillation fluor cocktail could be placed in an LSA for both automatic identification and activity analysis.

The above procedure was demonstrated to work for several radionuclides with the exception of ^{14}C and ^{35}S . The close similarities of the β -particle energy spectra of ^{14}C ($E_{\text{max}} = 156 \text{ keV}$) and ^{35}S ($E_{\text{max}} = 167 \text{ keV}$) produce overlapping double-ratio curves, which prevents the identification of these two radionuclides in unknown samples. However, Natake *et al.* (1996) showed that pulse height analysis could be used to identify ^{14}C and ^{35}S in unknown samples. The slight difference in the pulse height distributions could be distinguished using the sample channels ratio (SCR), which is the ratio of two counts in two measurement channels. The optimum channel settings were selected to obtain as great a difference between the two radionuclides as possible for a given quench level. The SCR for a series of quenched “standards” of ^{14}C and ^{35}S are then plotted against the H number in what is referred to as a double quench parameter curve (DQP) curve. The H number is an external standard quench indicating parameter (QIP) described previously in this chapter. Other external standard QIPs, such as tSIE or SQP(E), can also be used in this technique. To apply the technique, the SCR and the H number are determined for the unknown sample and the two QIP values are plotted on the previously prepared DQP curve. The radionuclide is then identified when the plot of that point lies in the neighborhood of either the ^{14}C or ^{35}S DQP curve.

In another approach to identify unknown pure β -emitters Dodson (1996) developed the technique of characterizing the pulse height spectrum according to the following

FIGURE 6.157 Double ratio curves for identifying an unknown radionuclide. Each curve is constructed from the SIS and SIE of a series of quenched “standards” of each nuclide. From Takiue *et al.* (1989b). Printed with permission from Elsevier © 1989.

three properties: E_{\max} , the isotope center number I and the spectral resolution (FWHM or F). The isotope center number I is defined as

$$I = \frac{\sum (N_i E_i)}{\sum (N_i)} \quad (6.162)$$

where E_i is the energy of the N_i electron. For quenched sets of radionuclide standards, both I and F are found to be linearly dependent on E_{\max} . The slopes and intercepts of the linear equations defining I and F as a function of E_{\max} over a range of quench levels are tabulated for each radionuclide. The measurement of I , E_{\max} , and FWHM of an unknown nuclide's sample spectrum coupled with a relevant algorithm permit the identification of the unknown nuclide within the parameters of the defined reference set.

Alpha-particle emitters were identified by Kaihola (2000) of Wallac Instruments (now PerkinElmer, Inc.) who demonstrated that the external standard quench indicating parameter SQP(E) could be used to correlate the alpha-particle sample pulse height distribution with its emission energy as a function of quench level. Two known energy calibration lines as a function of quench are required to verify the emission energy and identify the radionuclide in liquid scintillation alpha spectroscopy.

Another approach to the identification of pure beta-emitting radionuclides with a conventional liquid scintillation counter was taken by Furuta et al. (2009). They measured the pulse height spectra of six pure beta-emitting radionuclides using plastic scintillator (Saint-Gobain BC-400) that is placed into glass counting vials. Three different instruments were used including Beckman Coulter LS-6000S, LS-6500 and PerkinElmer Tri-Carb 3270TR/SL liquid scintillation analyzers. The radionuclides were dried onto separate plastic scintillator sheets, which were inserted into plastic scintillator cylinders or containers. The plastic

scintillator containers were then placed inside a conventional glass LSC vial. After calibrating the x-axis of the pulse height spectra to read 0.5 keV per channel, the channel of the spectrum end-point for ^3H , ^{14}C , ^{35}S , ^{45}Ca , and ^{33}P yielded the theoretical maximum beta energy (E_{\max}) of each radionuclide, as illustrated in Fig. 6.158. The absolute nuclide decay energy is not measured with the plastic scintillator; however, the plastic scintillator permitted the identification of the nuclides by the end-points and shapes of the spectra. The end-point of the pulse height spectrum of the high-energy ^{32}P ($E_{\max} = 1710 \text{ keV}$) is not illustrated in Fig. 6.158. Furuta et al. (2009) demonstrated that the end-point of this spectrum was reported to reach up to 1612 keV, because the plastic scintillator was not thick enough to absorb all of the beta-particle energy in this case.

A new approach developed to identify and quantify radionuclides in contaminated drinking waters and pipeline deposits was performed by Warwick and Croudace (2013). They measured nine different beta-emitter radionuclides (^3H , ^{14}C , ^{35}S , ^{63}Ni , ^{147}Pm , ^{99}Tc , ^{36}Cl , ^{129}I , and ^{131}I) in four different liquid scintillation cocktails (Gold Star, Ultima Gold AB, Ultima Gold XR, and Hisafe 3) using three different Quantulus LS counters. From these measurements they obtained the SQPE parameter as a measurement of the quenching of the sample and the SQPI(95) parameter as a mixed measurement of the quenching and the energy of the radionuclide. The relation of both parameters correlates with the maximum energy of the radionuclide, as illustrated in Fig. 6.14 illustrated previously in this chapter and Fig. 6.159, without influence of the quenching, the instrument or the cocktail used, demonstrating its application for radionuclide identification.

Also, another relationship between SQPI(95) and SQPI(50) was tested in front of the SQPI(95) parameter, as presented in Fig. 6.14. In this case, the factor is influenced

by the quenching. However, radionuclide populations are clearly defined and therefore could be used for identification. In addition, the presence of alpha-emitters could be confirmed but no specific radionuclide identification is possible. This second relation permits the identification of the different radionuclides present but with some limitations, as the discrimination between ^{131}I and ^{192}Ir , that could be solved as a second step with the use of the previous SQPE SQPI relation.

XIX. AIR luminescence counting

An innovative approach to α -particle counting is the use of a liquid scintillation counter to detect luminescence events caused by the α -particle excitation of N_2 in air. The technique was devised by Takiue and Ishikawa (1979b). As explained by these investigators, the alpha particle passing through air dissipates its energy, forming excited nitrogen molecules N_2^* , excited nitrogen molecular ions N_2^{+*} , and excited nitrogen atomic ions N^{+*} as follows with relative energy consumptions as given in parenthesis:

where W_α is the α -particle energy dissipated in air, e^- is an electron, and N is the nitrogen atom. The emission spectra

are derived from entirely N_2^* and N_2^{+*} bands. Emission wavelengths of the air luminescence are found in the region of 220–520 nm, which is within the range of sensitivity of photomultiplier tubes used in conventional liquid scintillation analyzers. Sand *et al.* (2014) demonstrate with a calibrated ^{239}Pu source that alpha particles generate 19 ± 3 photons/MeV of alpha-particle energy released in air at normal pressure (22°C and 43% relative humidity), and this relation is linear over the energy range of 0.3–5.1 MeV.

The oxygen in air (21%) does not contribute to the air luminescence, but rather acts as a quencher by forming a complex with N_2^* , leading to a radiationless deactivation of excited molecular nitrogen. Argon, with a natural concentration in air of only 1%, undergoes luminescence. However, its photon emissions make little contribution to the overall nitrogen luminescence because of the low concentration of argon in air compared to that of nitrogen (78%).

The sample preparation and counting procedure recommended by Takiue and Ishikawa (1979a) is simple and relatively inexpensive. Approximately 0.1 g of a solution of α -particle emitting nuclide is deposited onto a 0.84 mg/cm^2 thick Tetoran film, dried with an infra-red lamp, and inserted into an empty liquid scintillation glass counting vial so that the film and sample remain suspended in the air around the center of the vial.

The sample may be counted as such without further preparation, or the air in the vial may be purged with pure nitrogen as a gas scintillator.

When the nuclides are counted in air, counting efficiencies of 72% and 74% for ^{210}Po and ^{241}Am , respectively, are obtained, and purging with pure nitrogen leads to

an increase of 10%–15% in counting efficiency. The method offers several advantages: (1) there is no concern about quenching except for that of oxygen, which remains constant from sample to sample; (2) there is no need to be concerned about the preparation and handling of costly scintillators, as air is the only medium of detection; (3) the technique offers excellent reproducibility from sample to sample because of the absence of variable quenching agents; (4) the spectral emissions of nitrogen overlap well with the spectral response of photomultiplier tubes used in liquid scintillation analyzers, obviating the need for wavelength shifters; and (5) normal air containing 78% nitrogen may be used as the detection medium.

The main disadvantages of the air luminescence method are (1) reduced counting efficiency, as liquid scintillation with fluor cocktail provides 100% counting efficiency for α -emitters even under high levels of quench; (2) there is no α -radionuclide spectroscopy capabilities, since the pulse height spectrum is a peak produced by the air luminescence photons; (3) the limitation of the sample size to about 0.1 mL of radioactive solution that is deposited and dried on the transparent film; and (4) there is no possibility of analyzing β -emitters in the sample, that is, simultaneous α/β discrimination and analysis is not feasible.

These original findings of Takiue and Ishikawa were expanded by Takiue (1980) for the routine analysis of α -emitters on smear (swipe) paper in air without scintillation cocktail. The technique involves swiping a 100 cm² contaminated area with a smear paper (25 mm diameter, 30 mg/cm²) at a pressure of about 0.2 kg/cm². The contaminated smear sample, thus obtained, is placed directly in an empty glass scintillation counting vial with the contaminated side of the paper facing upward and measured without adding a liquid scintillation cocktail, as illustrated in Fig. 6.160.

FIGURE 6.160 Measurement geometry for a smear sample in air (contaminated side of paper is facing upward) and detector photomultiplier tubes of a liquid scintillation spectrometer. From Takiue (1980). Printed with permission from Wolters Kluwer Health/Lippincott, Williams & Wilkins © 1980 Health Physics Society.

The α -particle counting efficiency is reduced because of the 2π counting geometry with the smear sample at the bottom of the counting vial. Takiue (1980) observed variation in smear removal efficiencies from different contaminated surfaces. The counting efficiencies of ^{210}Po or ^{241}Am as smear samples on paper varied between 10% and 20% from sample to sample. The following advantages of the air luminescence method for monitoring α -emitter radioactive contamination can be cited: (1) sample preparation for α -contamination surface monitoring is simple and inexpensive, because no scintillation cocktail is required or cocktail waste produced; and (2) low backgrounds are achieved (~ 9 CPM with the instrumentation used by Takiue), providing a detection limit of $1 \times 10^{-7} \mu\text{Ci}/\text{cm}^2$ for loose contamination. Disadvantages of the air luminescence method are (1) much lower and more variable counting efficiencies (10%–20%) are obtained in air luminescence analysis of smear samples, compared to a constant 100% counting efficiency obtained by liquid scintillation analysis, and (2) β -emitters cannot be analyzed by air luminescence, that is, simultaneous α/β discrimination and analysis with air luminescence is not possible.

Caution must be taken to assure that there are no significant activities of β particles with energies in excess of 180 keV, which is the threshold energy for the production of Cherenkov radiation by β particles (electrons) in glass. For samples containing high-energy β -emitters, Takiue (1980) demonstrates that a double-region counting technique could be used to discriminate between pulses produced by Cherenkov photons and air luminescence.

Further studies by Homma et al. (1987) demonstrated the possibilities of measuring ^{222}Rn and its daughter nuclides in air in the gaseous phase by air luminescence counting. A counting efficiency of 42% was achieved. The endpoint of the air luminescence spectrum produced by ^{222}Rn is about 18 keV, hence a preset counting region normally used for ^3H liquid scintillation analysis, could be used for the air luminescence analysis.

In the liquid scintillation analysis of ^{222}Rn , Murase et al. (1989a) demonstrated that air luminescence produced by ^{222}Rn and its daughters in the gaseous phase above the liquid scintillator can give rise to significant air luminescence counts. Therefore, to avoid error caused by air luminescence in the LSA of ^{222}Rn , currently approved methods require filling the liquid scintillation vial to a total volume of 20 mL with sample and fluor cocktail. For example, the procedure used by the U.S. EPA (EPA/EERF-Manual-78-1) for the analysis of radon in water (see Passo and Cook, 1994) calls for the injection of 10 mL of freshly sampled water into 10 mL of an organic accepting liquid scintillation cocktail (e.g., Opti-Fluor O). The ^{222}Rn partitions into the organic fluor phase, and insignificant gaseous space remains in the standard 20-mL liquid scintillation counting vial for any significant air luminescence

interference. To avoid any interference from luminescence by ^{222}Rn alpha particles in the air above the liquid scintillation cocktail, Murase et al. (1999) selected a lower-level discriminator setting of 25 keV. Thus, all pulse events that may originate from air luminescence would be rejected, as these are found in the 0–18 keV region only.

Murase et al. (1989b) demonstrated the air luminescence analysis of ^{210}Po , ^{238}U , and ^{241}Am . The technique involves spotting small amounts (0.1 mL) of aqueous solutions of the α -emitters on the bottom of glass liquid scintillation vials and evaporating the samples to dryness with an infrared lamp. The counting efficiencies obtained were between 33.3 and $33.7 \pm 0.23\%$. The air luminescence pulse height spectra correspond to the region of 0–18 keV for pulse heights calibrated on an energy scale. Therefore, a counting region preset for the analysis of ^3H by LSA can be used for the air luminescence counting. Following air luminescence counting, the samples can be recovered from the vials for other studies. The counting efficiencies for the air luminescence determinations are easily determined by subsequent liquid scintillation analysis of samples. These can be carried out at random or for as many vials as desired. Liquid scintillation analysis after air luminescence was carried out by Murase et al. (1989b) after dissolving the radionuclide residue by wetting the bottom of the vial with 0.5 mL H_2O followed with liquid scintillation cocktail. The liquid scintillation analysis of α -emitters is 100%. Therefore, simply the activities (DPM) of samples obtained by liquid scintillation analysis can be used to calculate the air luminescence counting efficiency, as the count rate by LSA is also the disintegration rate. A disadvantage of the air luminescence analysis is the very small sample size of 0.1 mL that can be analyzed. Larger samples might leave too thick a residue at the bottom of the scintillation vial after drying, which would produce samples with significant self-absorption.

Air luminescence counting was used by Homma et al. (1996) to standardize ^{222}Rn samples that are applied to calibrate detectors utilized for the determination of ^{222}Rn in air. The standardization of ^{222}Rn as described by Homma et al. (1996) involves collecting a sample of ^{222}Rn from approximately 20 mL of sample of a 0.1 M HCl solution of 20 kBq $^{226}\text{RaCl}_2$ with a syringe and then transferring the ^{222}Rn gas to a standard liquid scintillation counting vial, which was filled with air and closed with a silicon rubber stopper. The ^{222}Rn in the vial is allowed to sit for 3.5 h before measurement to allow the daughters ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po to reach transient equilibrium with the ^{222}Rn . This sample is referred to as the ^{222}Rn “standard”. The ^{226}Ra solution from which the ^{222}Rn is taken does not have to be a standardized solution, because the ^{222}Rn determination is not based on secular equilibrium between ^{226}Ra and ^{222}Rn . It is not even necessary to know how much ^{222}Rn from the ^{226}Ra solution was actually removed. It is necessary only to standardize the ^{222}Rn that is

transferred into the rubber stopper-sealed scintillation counting vial. Standardization of the gaseous ^{222}Rn is done by air luminescence counting. The air luminescence counting efficiency of the ^{222}Rn was determined by using the counting efficiency of a standardized ^{210}Po source. The ^{210}Po counting efficiency (E) was determined by calculating $E = \alpha/A$, where α is the air luminescence count rate of a ^{210}Po source and A is the α -particle emission rate of the ^{210}Po source expressed in α particles per second in a solid angle of 2π steradians. Homma et al. (1996) underscore the importance of measuring the air luminescence counting efficiency of ^{222}Rn , as instrument models may vary in optical properties, PMT properties, and circuit properties. Morita-Murase et al. (2001, 2003) have pursued further the application of air luminescence counting to the measurement of ^{222}Rn . They standardized a ^{222}Rn sample collected with a syringe from the air space above a $^{226}\text{RaCl}_2$ solution. The ^{222}Rn was injected into a small quartz tube (7 mm in diameter by 40 mm in length) sealed at both ends with silicon rubber stoppers. After 3.5 h, transient equilibrium of ^{222}Rn with its daughters ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po is reached. The activity of the ^{222}Rn was then determined via analysis of the daughter ^{214}Pb γ -rays with a Ge semiconductor well detector. The small quartz tube with known ^{222}Rn activity was placed into a standard empty liquid scintillation vial, and the vial agitated until the quartz tube was broken liberating the ^{222}Rn into the air of the vial. The ^{222}Rn was counted with a liquid scintillation analyzer to provide the air luminescence counting efficiency of ^{222}Rn for the particular liquid scintillation analyzer used. An air luminescence counting efficiency of $42.6 \pm 0.2\%$ for ^{222}Rn was reported. Morita-Murase et al. (2003) report that the low-level count mode (LLCM) of the PerkinElmer TriCarb 3170 TR/SL should not be used for air luminescence counting, because the LLCM rejects pulse events that are not produced in liquid scintillator. Instead, the normal count mode (NCM) may be used with the PerkinElmer TriCarb instruments.

XX. Liquid scintillation counter performance

This chapter so far has dealt with the basic principles and procedures of liquid scintillation analysis. The remainder of the chapter will review the methods used to optimize the performance of the LSA. This is particularly important when sensitivity is key to our measurements. In addition, we need methods that can be used to assess the performance of the LSA, commercial or custom made, to insure the reliable and reproducible data from the instrumentation.

A. Instrument normalization and calibration

The first item to be addressed is that of assessing performance and calibration of the LSC to be sure that the activity

data (DPMs) are accurate and reproducible. The first area to review is the calibration methods that are used for LSCs. One method is to use a flame sealed standard in scintillation cocktail, usually a ^{14}C source as the calibration normalization source for the LSC. This sealed standard should be a calibrated standard such as a one traceable to a primary standard from a national institute of standards so that its DPM is accurately known and it produces light pulses similar to those found in real samples. [Jaubert et al. \(2006\)](#) report that flame-sealed purely organic liquid scintillation sources can be used as reference sources for periods of more than 10 years, provided the sources are stored at ambient temperature in reduced light.

The calibration procedure of liquid scintillation analyzers varies according to the manufacturer of commercial instrumentation. One method of calibration (*e.g.*, PerkinElmer Tri-Carb LSAs) involves loading an unquenched ^{14}C standard source into the counting chamber, the high voltage for each of the PMTs is set automatically to obtain the optimum ^{14}C efficiency, and the ^{14}C endpoint energy of the standard is fixed at 156 keV with the minimum background. Such a calibration should be performed at least weekly as long as the instrument is being used. Another method of calibration (PerkinElmer Quantulus LSAs) uses a GaAsP LED placed very close to the PMTs that flashes 60 times per minute and emits a constant light flux. The output from each PMT is analyzed automatically and with the use of a feedback circuit, the high-voltage is modified in order to correct deviations of output from the PMTs. In this way, changes in light detection and electronic parts of the PMT are corrected and stability is guaranteed ([McCormac, 1992](#)). This normalization is done automatically every time a sample is measured.

B. Assessing LSA performance

Assessing the performance of the LSA when a new counter is bought or built or on a routine basis is important to have assurance that the instrument is operating within acceptable parameters and to have a standing record over time of the instrument performance. On one hand, when a new counter is introduced in the laboratory, several tests should be performed before starting with routine analysis with two objectives: to assure the correct operation of the instrument and to define the parametric limits for correct and known operation of the counter. These limits will be used later to check the performance of the instrument during routine analysis. On the other hand, to maintain good laboratory practice and satisfy regulatory agencies, it is often necessary to have records of the instrument performance on a routine basis, such as daily, weekly, or monthly, to provide proof that deviations in instrument performance do not have any effect on the analytical results.

1. New commercial counters

When a new commercial counter is introduced in the laboratory, several measurements should be performed to confirm that the counter is working correctly and following the producer specifications. It is also useful to define the conditions in which future measurements are going to be performed since, in agreement with good practices in analysis, it is necessary to measure under known conditions. Basic assessment is done through measurements suggested by the LSA producer. These measurements are focused to reproduce technical specifications of the counter regarding background, counting efficiency for ^3H and ^{14}C standards and figure of merit for ^3H and ^{14}C in predefined counting windows. Some producers also include recommendations regarding counting efficiency for alpha-emitters or quenching assessment through the quenching indicator of a nonquenched sample.

Since each commercial LSA present their own configuration options, an evaluation of the performance of each option is usually needed. This is more relevant in the case of new models of LSA in which the data or experiences reported in the bibliography by other users is scarce. [Wanke et al. \(2012\)](#) evaluated how different parameters of the metrological version of a new HIDEX 300 SL detector affect the activity determination of several radionuclides through the TDCR method. Results of activity were compared to the data obtained with a well-known and evaluated detector. Parameters evaluated include threshold setting, coincidence time, and linearity. Threshold evaluation ([Fig. 6.161](#)) permits an adjustment of the detection to the maximum sensitivity without excessive noise. In the work performed, measurements at a value of 45 resulted in excessive noise counts, and therefore the threshold setting was adjusted to 50. The coincidence time parameter permits the determination of the time interval in which pulses from

FIGURE 6.161 Single count rates in the PMTs over the threshold setting in the measurement of ^{63}Ni From [Wanke et al. \(2012\)](#), reprinted with permission from Elsevier © 2012.

FIGURE 6.162 Deviations in the measurement of ^{63}Ni and ^{99}Tc over the coincidence time setting. The threshold was 50. From [Wanke et al. \(2012\)](#), reprinted with permission from Elsevier © 2012.

each PMT are considered to come from the same disintegration and can be counted as a true signal. A coincident time that is too short can lead to the loss of some scintillations of few photons; whereas a coincident time that is too long can lead to the counting of noise signals. [Fig. 6.162](#) shows that for ^{63}Ni and ^{99}Tc source, a coincidence time of 30 ns was the optimum option. Another feature evaluated by [Wanke et al. \(2012\)](#) was the linearity of the counter. Stability of the counter at high count rates is usually not needed in environmental analysis, but in fields like metrology in which high count rates are measured, an evaluation of the linearity should be performed to define the limits in which highly precise measurements are obtained. The linearity of the HIDEX 300 SL for the analysis of a ^{241}Am standard solution with Ultima Goldtm AB was demonstrated to be good for counts rates below 100,000 cpm; however, deviation regarding the expected count rate starts to be significant at 1,000,000 cpm ([Fig. 6.163](#)). Lost of linearity is usually attributed to the dead-time configuration of the counter and how the live-time is calculated.

Final evaluation of this LSA (HIDEX 300 SL) was done by a bilateral comparison performed by two different laboratories (PTB and ENEA) by [Kossert et al. \(2014c\)](#). In this comparison, six LSA instruments were used to determine the activity of LS sources containing ^{90}Sr : four LSAs from the PTB (one noncommercial and three commercial instruments including the new HIDEX 300 SL being one of them); two from ENEA (both commercial including another new HIDEX 300 SL being one of them). The scheme of the comparison is shown in [Table 6.28](#). Results obtained ([Fig. 6.164](#)) show that activities were in good agreement, since the uncertainty bars are overlapped and the slightly higher values for both HIDEX 300 SL (0.25% for PTB and 0.32% for ENEA) can be attributed to loss of linearity at the high count rates of the samples (2500–3000 cps).

FIGURE 6.163 Linearity measurements—Deviations of the measured count rates from the expected ones in the measurement of ^{241}Am . The bars indicate only statistical uncertainties. From [Wanke et al. \(2012\)](#), reprinted with permission from Elsevier © 2012.

One key parameter of an LSA that should also be tested is the quenching indicator. [Minne et al. \(2008\)](#) evaluated the stability of the SQP(E) parameter in a Quantulus LSA using a ^{152}Eu gamma source with samples of beta-emitters of different energy with the same quenching level and high activity level (around 1000 Bq). They observed that for $^{90}\text{Sr}/^{90}\text{Y}$ samples, the quenching indicator changed with the counting time of the external standard. Moreover, for the same level of quenching, samples containing $^{90}\text{Sr}/^{90}\text{Y}$ or ^{85}Sr presented different quenching indicators (788(9) and 749(0.5)). This behavior was related to the energy of the radionuclides measured. When the spectrum obtained in the measurement of the beta-emitter was at higher energies than the spectrum from the Compton electrons generated by the gamma source, the quenching parameter was defined by the position of the spectrum of the radionuclide. In order to prevent deviations from the calculation of the quenching indicator, [Minne et al. \(2008\)](#) recommend the use of a constant and high (10' or 15') counting time for the external standard.

Another strategy also used to assess the performance of a new counter is to measure the same samples with the new counter and an old counter used in routine analysis. With this aim, [Jäggi et al. \(2014\)](#) performed the analysis of ^{241}Pu and ^{90}Sr in several complex samples (waste and soils) in their new commercial detector (Hidex 300 SL) and compared the results with those obtained with their routine counters (PerkinElmer Tricarb 2550, Tricarb 2200 and Quantulus) and other techniques (ICP-MS). Analysis included quenching correction (using TDCR and tSIE) of the counting efficiency since samples presented color. In the case of ^{241}Pu , the results from the analysis of a soil (IAEA-375) and a radioactive slurry sample showed that performance of the new counter was comparable to the routine ones. On the contrary, the analysis of ^{90}Sr in soils yielded a little discrepancy between the detectors. In this case, the authors recommended that some of the features of

TABLE 6.28 Proposed comparison scheme.

No.	Action	Date
1	PTB prepares two sets of LS sources of the radionuclide ⁸⁹ Sr	Week 0
2	The sources will be measured at PTB using established measurement equipment for primary standardization (LS with TDCR and CIEMAT/NIST efficiency tracing)	Week 1
3	The sources will be measured in the Hidex TDCR counter at PTB. At least one measurement will be carried out with defined instrument settings according to an agreed protocol	Week 1
4	One set of sources will be shipped to ENEA	Week 2
5	The sources will be measured in the Hidex TDCR counter at ENEA. At least one measurement will be carried out with defined instrument settings according to an agreed protocol	Week 3
6	ENEA sends sources back to PTB	Week 4
7	Test measurements at PTB of both sets of sources to confirm that sources are stable	Week 5
8	ENEA submits results to PTB	Week 6
9	ENEA also submits file(s) with measured raw data to PTB which then analyzes data of both laboratories with the same software	Week 6
10	Joint report on the comparison including recommendations for other users	After week 10

the instrument should be checked before it will be used in routine analysis.

2. New custom-made counters

Some specific applications, such as activity measurements by means of the TDCR method with counters with three PMT in metrology, ultra low-level measurements in underground laboratories or on-line continuous analysis, require the use of an LSA with special features. These special characteristics are not implemented in commercial LSAs, and as consequence, custom-made LSAs are built for these applications. Some of these custom-made LSAs take advantage of new instrumental developments, like digital electronics, which facilitate its implementation. In these cases, an optimization process through simulations to

know the ideal configuration of the LSA usually precedes the assessment of the correct working of the counter.

One example of the use of simulations in the optimization of the LSA performance, prior to the LSA development, is the Ultra-Low Background Liquid Scintillation Counter (ULB LSC) developed by the Pacific Northwest National Laboratory. Bernacki et al. (2015) reported the evaluation of the optical features of the detection chamber though Monte Carlo simulation using TracePro software. Simulation was done considering a 20 mL vial of ground glass filled with liquid with a refraction index of 1.56 and wavelength emission at 420 nm. Several chamber designs were evaluated (Fig. 6.165) including the classical chamber (vial facing PMT), spherical chambers of different radii and chambers with collinear and noncollinear light collection

FIGURE 6.165 (A) LSC model with a spherical reflective collection chamber added. The chamber has a radius of 50.8 mm and the assembly is centered on the LSC cocktail column. (B) LSC U-shaped design that can accommodate lead shielding between the PMTs and LSC vial to reduce the effects of NORM background originating in either PMT. (C) Linear hollow cavity reflective light guide for the LSC system with reduced rectangular cross section and protruding vial cap, both top and side views. Rectangular-to-circular light guide sections on both ends mate the light guide to 50.8 mm (45 mm clear aperture) PMT face plates. From [Bernacki et al. \(2015\)](#), reprinted with permission from OSA publishing © 2015.

paths. Chambers were evaluated in terms of photon collection efficiency, irradiance map of the PMTs and time-of-flight plot. Results obtained showed that a U-shaped chamber provided the better collection efficiencies whereas TOF response, in spite of the distance between PMT, was acceptable (i.e., lower than 1.5 ns).

For the design of the shielding of the LSA to reduce background, [Erchinger et al. \(2015\)](#) used Monte Carlo simulation with GEANT 4. In a preliminary evaluation of the approach, the gamma-ray flux associated with U/Th/K in the underground laboratory was simulated and measured with a NaI detector. Agreement between simulated and experimental data ([Fig. 6.166](#)) showed the validity of the simulation. The final simulation accounted for various measurement parameters including a detection chamber with U-shape geometry and materials of the LSA included:

copper, lead of two activities, two PMTs (with its bases), plastic scintillator veto panels, and borate polyethylene teal ([Fig. 6.167](#)). They explored the background originated by external gamma sources, lead shield, radioactivity in the IFHC copper, radioactivity in the reflective coating, radioactivity in the PMTs, background from the vial, cross-talk, and neutron background. Total background was estimated to be of 14(1.2) cpd, being copper shielding (47%), lead shielding (25%), and external gamma rays (14%) the main sources of background.

Regarding the performance assessment of custom-made counters, there are several examples based on counters with three PMTs devoted to activity measurements by the TDCR method. The TDCR method is a primary standardization method of beta-emitting radionuclides (or decaying through more complex decay schemes) and most of the national

metrology institutes, and some other laboratories, have developed their own TDCR detector. As a consequence, each TDCR is unique, and a specific performance assessment has to be performed for each one. The differences between detectors lie on the type of PMT used (e.g., classical PMT, channel-PMT, miniature-PMT), reflective material of the counting chamber, electronics (analogical or digital), intended use (portable or non-portable) and applicable for measurements in combination or not with other means of measurement (e.g., $4\pi(\text{LS})-\gamma$). In spite of the differences, performance assessment is usually based on the same principles, namely, compare the activity determined with the new TDCR with the certified activity of standards measured and/or with the activity determined using a reference detector (TDCR or LSA) from the same institute or from a reference institute. In the case of performance assessment of the electronics, a comparison is usually done regarding the MAC3 unit, the electronics developed at the LNHB (Bouchard et al, 2000). Finally, the instrument performance assessment usually includes an evaluation of parameters such as threshold, dead-time, coincidence resolving time, and linearity. Table 6.29 summarizes the strategies used for the different metrology institutes.

3. Routine instrument performance assessment

A routine Instrument Performance Assessment (IPA) is carried out generally with a set of standards that are traceable to a primary standard from a national institute of

standards. These standards can be the same as those used for calibrating the instrument.

The IPA is normally carried out on a regular basis and the results stored and printed in a tabular and/or graphic form with a time and date stamp. Eight parameters should be assessed using a set of three unquenched standards (e.g., purged with argon in a flame-sealed counting vial), namely, (i) a tritium standard, (ii) a ^{14}C standard, and (iii) a background standard, i.e. a standard consisting only of scintillation cocktail. The three standards can measure the following instrument performance: (1) tritium efficiency, (2) tritium background, (3) tritium figure of merit, (4) tritium chi-square, (5) ^{14}C efficiency, (6) ^{14}C background, (7) ^{14}C figure of merit, and (8) ^{14}C chi-square. The tritium and ^{14}C efficiencies are determined by the LSA using two sealed standards counted in predefined counting regions. This requires approximately 1 min for each sample, as these samples are generally of sufficiently high activity that only short count times are needed. This test should be performed daily. The backgrounds are determined using a sealed background standard with two preset counting regions for tritium and ^{14}C . This requires approximately 60 min because an accurate CPM value of the background needs to be obtained to assure reproducibility. Background assessment should be performed at least weekly. The ^3H figure of merit and ^{14}C figure of merit performance values are determined using the E^2/B calculation, which is the percent counting efficiency squared divided by the background count rate in CPM. This is an excellent indicator of any change in performance for the LSC. It can be calculated using the ^3H and ^{14}C standards, and it should be performed daily. The final performance parameters are the ^3H chi-square and ^{14}C chi-square. This is a monitor of short-term stability in the LSA and involves counting the ^3H and ^{14}C sealed radionuclide standards 20 times for 0.5 min each. The chi-square tests are used to confirm that the count rate measurements vary within the normal and expected deviations; that is, the count rates are neither too consistent nor too variable to be true. The chi-square tests should be performed weekly. By monitoring and recording these eight parameters, Good Laboratory Practices (GLP) can be satisfied.

The instrument performance assessment (IPA) can be either performed manually by the LSC users with the data placed into a spreadsheet or automatically by an LSC that has automatic IPA and instrument calibration. Fig. 6.168 shows a plot of the data obtained with an automatic IPA program on a PerkinElmer Tri-Carb LSA. This type of graph can be displayed, stored in computer memory, and printed for each of the eight IPA parameters described previously. In any given graph for any of the eight parameters, such as the example in Fig. 6.168A, an average line is calculated and the one, two, and three sigma values are provided so that the user can evaluate any trends or

outlying points. If an outlying point is observed, this information is printed on the final data output. In addition, a series of suggestions can be provided so that the user can assess the problem further and take preventative action if any parameters are too frequently outside of recommended limits. An example is provided in Fig. 6.168B. Possible problems that might be indicated are counting contamination, PMT failure, dirty PMTs, and electronic failures. Jaubert et al. (2006) and Chałupnik and Mielnikow (2009) provide thorough treatments of the importance of instrument performance assessment or the implementation of a quality assurance system for the monitoring of the long-term stability of LSAs.

C. Optimizing LSC performance

The procedures for determining sample activities in DPM in routine sample analysis are dealt with in detail in previous parts of this chapter. This section will describe methods used to optimize performance particularly for low-count-rate samples when LSA sensitivity is most important. There are several methods of optimizing performance, and these will be described in detail in this section.

1. Counting region optimization

If a radionuclide, such as ^{14}C , is to be analyzed and a low level of detection is required, the counting region, defined by lower level (LL) and upper level (UL) pulse height discriminators, must be optimized for best performance measured by the figure of merit (E^2/B). The figure of merit is calculated as the square of the percent counting efficiency of the radionuclide of interest divided by the background count rate expressed in CPM. Optimizing the counting

sensitivity (E^2/B) with spectrum analysis of sample and background is achieved by the following procedure:

1. Count a known activity (DPM) of the radionuclide of interest and store the sample spectrum, as illustrated in Fig. 6.169 (upper plot), in the computer memory. The sample size, sample chemistry, and amount of cocktail used should be similar to those of the experimental samples.
2. Prepare a blank sample (no radionuclide) plus cocktail in a counting vial to measure background. Count the blank sample and store the background spectrum, as illustrated in Fig. 6.169 (lower plot). It is important to prepare the sample and background (blank) counting vials in Steps 1 and 2 with the same cocktail and any other chemical components in identical amounts to provide the same chemistry and the same quench levels in both counting vials. For example, if the experimental samples will have a 50% water load (e.g., 10 mL H_2O + 10 mL cocktail), then the blank background vial should be prepared similarly, but without radioisotope. Ideally, the background counting vial should have the same chemical composition and QIP, that is, the same tSIE, SQP(E) or H#, as the sample vial with the exception that the background vial will not contain any added radionuclide.
3. Start with a wide-open counting region defined with the LL discriminator at 0 keV and the UL discriminator at the sample pulse height spectrum endpoint, and measure the count rates from the sample and background vials in the wide-open counting region. From the count rate data from the sample and background calculate the figure of merit E^2/B .

FIGURE 6.169 Pulse height spectra of a ^{14}C sample (above) and a background or blank sample (below). For this particular sample and blank, chemical composition, sample load, cocktail, and vial type, the LL (left) and UL (right) discriminator settings of 9.0–73.5 were found to provide region optimization. In this example, the reduced counting region produced a sacrifice of 18% in the ^{14}C counting efficiency but a reduction of 54% in the background counts. Region optimization is specific to radionuclide, sample-cocktail chemistry or quench level, and vial type and size (L'Annunziata, M.F., 1996, unpublished work of the writer).

- Repeat Step 3 by increasing the LL discriminator by suitable increments and calculating the E^2/B after each change of the LL discriminator setting.
- Decrease the UL discriminator by suitable increments and measure the E^2/B for each setting of the LL discriminator already tested. Record the E^2/B for each of the LL-UL counting regions tested.
- Select the optimum counting region as that region defined by the LL-UL settings that gave the highest E^2/B .

The above procedure can be carried out using a “Replay” option that is included with many liquid scintillation analyzers. This allows the variation of the LL and UL discriminator settings to obtain new count rates from computer-stored pulse height spectra without having to recount the sample or background. Also, certain liquid scintillation analyzers are equipped with SpectraWorks or similar computer program that will (1) process automatically the sample and background spectra, (2) calculate the optimum LL-UL discriminator settings for a counting region, and (3) provide a value of the E^2/B for that optimum region. SpectraWorks will also calculate the lower limits of detection (LLD) or minimal detectable activity (MDA) for a particular radionuclide, counting efficiency, and background obtained. The LLD or MDA is defined further on in this chapter. For more information on SpectraWorks, see Floeckher (1995), which is a reference available on-line.

An example of results obtained with region optimization can be taken from the following case:

A sample of ^{14}C and a background blank were prepared similarly in liquid scintillation counting vials with the exception that the background vial had no radionuclide added. For a wide-open counting region of 0–156 keV defined where LL and UL discriminators are calibrated in keV, the instrument gave a 95% counting efficiency for the ^{14}C , a background count rate of 25.0 CPM, and a calculated E^2/B of 361. After region optimization according to the foregoing procedure, an optimum counting region of

18–102 keV was found, which gave a ^{14}C counting efficiency of only 63.1% but a background of 3.38 CPM, and a calculated E^2/B of 1178. Region optimization caused a reduction by more than 30% in the counting efficiency from 95% to 63.1% but an even greater reduction of more than 10-fold in the background. The counting region of 18–102 keV is the optimum counting region for the particular sample and instrument used in this example. Region optimization is important when sample count rates are low (close to background) and low levels of detection are required.

Another strategy used to determine the optimum counting window consists of the use of the computing power to calculate the figure of merit for all combinations of counting windows (Chapon et al., 2016). This strategy permits, with the aid of 3D representation of the data obtained, to see the regions of the spectrum where figure of merit is higher and simplifies the selection of the best counting window (Fig. 6.170, Figs. 6.171 and Fig. 6.172).

It is important to emphasize here that an optimum counting region so determined is good only for the particular radionuclide, sample size, vial type, cocktail-sample chemistry (*i.e.*, quench level), and liquid scintillation analyzer used. Therefore, we should keep in mind that when samples vary in quench, the optimized counting regions (window) vary as well. If the quench level between samples varies only slightly, one can widen slightly the optimum counting region to accommodate small changes in spectral shifts.

2. Vial size and type

Optimization of performance for the LSC is achieved also by selection of the proper size of vial and vial material (*e.g.*, glass or plastic). The data in Table 6.30 provide ^3H counting efficiencies, backgrounds, and figures of merit (E^2/B) for a standard (wide-open) counting region and an optimized counting region for two counting vial types and

^a% Counting efficiency = (CPM/DPM) (100).

sizes in a particular liquid scintillation analyzer. The data in this table provide evidence of some well-known generalities that should be considered when optimizing counting performance. First, plastic vials produce a lower background count than the corresponding glass vials. In this example, a 15%–30% improvement in performance (E^2/B) was obtained with plastic vials. Second, small vials for low-

volume samples provide a lower background with about the same counting efficiency as large vials. Third, the optimized counting region gives a better performance than the standard counting region. From the example taken in Table 6.30 the total performance was enhanced with small plastic vials over large glass vials in an optimized counting region by almost a factor of 3 (E^2/B 103.9 to 306.1). The

only problem with using smaller vials is that the sample capacity is lower, and if maximum sample size is required, the larger vials should be used.

3. Cocktail choice

Choosing the proper liquid scintillation fluor cocktail optimizes counting performance in several aspects, including background, counting efficiency, stability, and loading capacity. When sample counts are low, it is best to choose a cocktail that can hold as much sample as possible and still provide the maximum counting efficiency with a minimum amount of background. Chapter 7, Volume 1 provides a great deal of information that can be helpful in selecting a cocktail as a function of sample chemical properties to optimize counting performance. Two examples of detailed examinations of the performance of several common cocktails were reported by Verrezen et al. (2008) and Komosa and Slepecka (2010). Such cocktail examinations usually take place at the same time as vial types and sizes are tested.

4. Counting time

The error associated with the measurement of sample counts and count rate is a function of counting time. As demonstrated in Chapter 8, Volume 2, the standard deviation of the counts collected and the calculation of the associated count rate are reduced according to the length of the counting time. This is particularly relevant when the sample counts are very close to background, and accurate measurements of sample counts and background counts must be made to distinguish their difference in magnitude within reasonable error limits. Therefore, liquid scintillation counting performance can be optimized by increasing the sample and background counting times. The longer the counting time, the lower is the detection level or minimal detectable activity (MDA). The MDA also referred to as the lower limits of detection (LLD) in units of Bq/L can be calculated by the following equation from Prichard et al. (1992) as described by Passo and Kessler (1993), Passo and Cook (1994), and Biggen et al. (2002):

$$LLD = \frac{L_D}{60EVTX} \quad (6.164)$$

where LLD is the lowest activity concentration in Bq/L that yields a net count above background with a 95% probability; the detection limit, L_D , according to Currie (1968) and Hurtgen et al. (2000), is the true net signal that can be detected with a given probability; 60 is a factor for conversion of DPM to Bq (i.e., 60DPM/1Bq); E is the fractional detection efficiency (CPM/DPM); V is the sample volume in liters, T is the count time in minutes; and X is any factor that is relevant, such as, decay correction, chemical yield, etc. As described by Passo and Cook (1994), when the background and sample are counted as pairs, that is, at

the same counting time, and the background counts (B) collected are > 70 , the detection limit, at a 95% confidence level, may be written as

$$L_D = 4.65\sqrt{B} \quad (6.165)$$

Other working expressions of detection limits (L_D) may be used and these are described by Prichard et al. (1992) and Passo and Cook (1994). When the lower limit of detection (LLD) is expressed in the less common units of pCi/L, the conversion factor 60 of Eq. (6.164) is replaced with the factor 2.22 for the conversion of DPM to pCi (i.e., 2.22 DPM/pCi).

To illustrate the application and interpretation of calculated lower limits of detection (LLD) and detection limits (L_D) let us take the following example to calculate the LLD and, from these calculations, determine how many sample counts must be acquired to reach a calculated LLD :

If a particular LSA counting region and cocktail chemistry in the analysis of ^3H yielded a total of 1300 background counts in a 500-minute counting time, that is, $B = 1300$ and background = 2.60 CPM, the counting efficiency for ^3H was 35% or 0.35, and the sample volume analyzed was 10 mL, the lower limit of detection according to Eq. (6.164) would be

$$\begin{aligned} LLD &= \frac{4.65\sqrt{1300 \text{ counts}}}{(60 \text{ DPM/Bq})(0.35)(0.01 \text{ L})(500 \text{ minutes})} \\ &= 1.60 \text{ Bq/L} \end{aligned} \quad (6.166)$$

In the above calculation the limit of detection is

$$L_D = 4.65\sqrt{1300 \text{ counts}} = 168 \text{ counts} \quad (6.167)$$

Therefore, to achieve the calculated LLD of 1.60 Bq/L, a minimum number of sample counts defined by

$$L_D + B = 168 + 1300 = 1468 \text{ counts} \quad (6.168)$$

must be registered with a 10 mL sample in a 500 min counting time to conclude that 1.60 Bq/L are detected with a 95% confidence level.

The denominator of Eq. (6.164) may include additional factors, such as chemical yield, if an extraction of a radionuclide is less than 100% or decay corrections, which is the variable X in Eq. (6.164). Detailed treatments of calculations involved in the determination of limits of detection are available from Currie (1968), Prichard et al. (1992), and Passo and Cook (1994). From Eqs. (6.164) and (6.165) and the calculation (6.166), we can see that increasing the counting time and reducing the background will reduce the lower limit of detection or minimal detectable activity. This is illustrated by Fig. 6.173 (Erchinger et al. 2015) where we can see that, by reducing the background count rate, we can achieve a desired LLD with a shorter counting time.

FIGURE 6.173 A “text book” example of the relation between *sensitivity* versus *background* and *count duration* with extrapolations to a shallow underground, low background liquid scintillation counter design. The “text book” example (right most panel) presents typical sensitivity levels for measurements of a 10 mL tritium sample given typical background rates and count duration and with 35% counting efficiency. The panels to the left progressively reduce the background rate in the proposed instrument and show the relevant sensitivity levels attained for differing count duration. The count duration curves derived from the Currie formulation are provided to guide the eye and may be impractical for some choices of background and count duration. In these figures the background rate is quantified in counts per minute (CPM) and the minimum detectable activity sensitivity is presented as a lower limit of detection (LLD) value. From Erchinger et al. (2015), reprinted with permission from Elsevier © 2015.

5. Background reduction

Often the easiest method of optimizing LSC performance is to reduce the background. As described previously in this chapter, region optimization, vial size, and vial material are important variables to control in the reduction of background. This section will discuss five other methods that can be used to reduce background and enhance performance for liquid scintillation analysis.

a. Temperature control

The original purpose of temperature control or cooling during the early years of liquid scintillation counting was to reduce background counts from thermal noise from the PMTs. Modern bialkali photomultiplier tubes are manufactured to have a low noise even at room temperature. The purpose of temperature control in contemporary liquid scintillation counting is to control and maintain the sample temperature, sometimes required for optimizing sample chemistry even at extremes of external temperatures. The sample chemistry in some cocktails requires lower temperature to accept more sample, and as a result, temperature control is necessary.

b. Underground counting laboratory

This method of background reduction can be used for very low-level counting and this extreme measure has been taken more often in the past for the measurement of very low levels of naturally occurring radionuclides such as ^3H in ground water and ^{14}C dating. This involves building a special counting room below the ground to reduce high-energy cosmic radiation that may cause background counts in the liquid scintillation counter. However, modern pulse discrimination electronics, described briefly in Part d following, will reduce instrument backgrounds to levels

at which underground laboratories are generally not needed for the conventional measurement of environmental radioactivity. The placement of detectors deep underground is still utilized for the liquid scintillation measurement of rare events, such as double-beta ($\beta\beta$) decay and the detection and measurement of neutrinos, etc. as described in Sections XI and XII of this chapter.

c. Shielding

Shielding the instrument from external radiation can reduce background. There are two types of shielding, passive and active shielding.

Passive shielding is the “brute force” approach. This may require lead (up to 1000 kg) barriers to reduce background. The extra lead reduces background from environmental gamma photons associated with building materials and instrument construction materials. In addition, this extra lead can reduce the “soft” cosmic muon components of background. The lead shielding is usually lined internally with cadmium and/or copper to absorb any secondary X-rays and cosmic components.

Active shielding can be one of two types, a guard detector with or without anticoincidence circuitry and components. The guard detector is an external detector [e.g., bismuth germanate (BGO)] that surrounds the area between the PMTs and the sample. The BGO has special properties described in detail in Chapter 9, Volume 1. BGO is a solid crystal scintillator with a high density and high atomic number. The high density and atomic number give BGO excellent “stopping power” for the detection of highly penetrating radiation. BGO can be used to discriminate against gamma and muon components of cosmic background. This property of BGO in combination with Time-Resolved LSC (TR-LSC) pulse discrimination electronics (described subsequently) can discriminate more background events.

Another approach to active shielding to reduce background is to manufacture a detector shield above, below, and surrounding the sample vial and PMTs consisting of an external counting chamber of a liquid or solid scintillator, such as mineral oil scintillator, plastic scintillator (*e.g.*, NE110), or even a NaI(Tl) crystal. In addition to the guard material, PMTs and an anti-coincidence circuit are added. The detector guard rejects much of the environmental gamma radiation, as well as soft and hard cosmic radiation.

d. Pulse discrimination electronics

Three different pulse discrimination methods are used, namely, pulse shape analysis (PSA), pulse amplitude comparison (PAC), and time-resolved LSC (TR-LSC).

PSA relies on the fact that a true nuclear decay signal produces a very prompt pulse in the LSC, whereas a background event produces a pulse with a longer decay time. By setting up the instrument to discriminate pulses on the basis of their shape, background can be discriminated from a true nuclear decay signal. This discrimination is specific and must be optimized for each vial material, vial size, and sample-cocktail chemistry.

The second method is PAC, which compares the amplitude of the pulse from each of the two PMTs. If the event occurs in the scintillation vial, photons of approximately the same intensity will be seen by both PMTs, but if the event originates from outside the sample, it will produce pulses in each of the PMTs of different pulse heights. If the PAC deviates significantly from unity, the pulse is discriminated as background.

The third method, TR-LSC, is a patented method of reducing background by discriminating against pulses on the basis of the number of afterpulses that occur following an initial pulse event over a given period of time. These afterpulses are most commonly created by background events. Afterpulses are generally more numerous among nonquenchable background events and less numerous with

events originating from the scintillation cocktail. With the TR-LSC technique, the liquid scintillation analyzer can be manufactured or programmed to count afterpulses, known as pulse index discrimination, which can identify background events by counting afterpulses with varying degrees of sensitivity. Therefore, among various liquid scintillation analyzers, the amount of pulse index discrimination for background rejection can be factory set or programmed to provide different sensitivities for the reduction of background (*e.g.*, high-sensitivity count mode, low-level count mode, and ultra-low-level count mode with BGO detector guard). Tables 6.31 and 6.32 illustrate how background can be reduced and performance enhanced significantly using this latter technique of background reduction. The data shown in these two tables might typically be found in a low-level counting laboratory. The samples are placed in the optimum counting geometry, optimum vial size and vial material, optimum cocktail, and counted in the optimum counting region with the TR-LSC method of electronic discrimination at various levels of pulse index discrimination with and without an active guard.

The data of Table 6.31 illustrate that the use of TR-LSC alone and in combination with an active BGO guard detector greatly increases the performance of the LSC for ^{14}C samples. This is also the case for many other radionuclide samples with low count rates. For the case of ^{14}C about 15–20 times better performance is obtained with the ultra-low-level TR-LSC and the BGO guard detector.

The data of Table 6.32 illustrate that the use of TR-LSC alone and in combination with a BGO active guard detector greatly increases the performance of the LSC for tritium samples in general with low count rates. For the case of tritium about a 10-fold better performance is achieved with the use of ultra-low-level TR-LSC in combination with the BGO guard detector.

Amount of pulse index discrimination	Detector guard	³ H efficiency (%)	Background (CPM)	Figure of merit (E^2/B)
None	No	26.50	18.45	38
Normal TR-LSC	No	26.24	12.75	54
High-sensitivity TR-LSC	No	24.68	9.25	66
Low-level TR-LSC	No	22.59	3.33	153
Ultra-low-level TR-LSC + BGO Active Guard	Yes	20.01	1.00	400

^aThe optimized counting region is 0.5–5.0 keV with various levels of TR-LSC pulse index discrimination applied to the pulse events.

For additional information on time-resolved liquid scintillation counting (TR-LSC) see papers by [Roessler et al. \(1991\)](#) and [Passo and Roberts \(1996\)](#).

6. Conclusions

In conclusion, the best ways of optimizing performance of the LSC for low-level samples are to (1) optimize counting geometry, such as optimum sample size, vial size, and vial material; (2) increase counting time; (3) optimize counting region; (4) optimize cocktail selection; and (5) use shielding together with electronic discrimination and an active guard detection method to reduce background.

Michael F. L'Annunziata

Michael F. L'Annunziata, Ph.D. is the Founding Editor and co-author of the Handbook of Radioactivity Analysis now in its Fourth Edition. His graduate thesis research at the University of Arizona, Tucson, AZ, USA in the 1960s, financed by the then U.S. Atomic Energy Commission, dealt with the analysis of ^{89}Sr and ^{90}Sr in the event of nuclear fallout. During 1970–71, he worked in the chemical industry (Amchem Products, Inc., Ambler, PA, USA) as ^{14}C -tracer chemist. Michael was then appointed Professor at the Postgraduate College, Chapingo, Mexico (1972–75) and Senior Research Scientist and graduate thesis advisor at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico City during (1975–77). Michael served as Scientific Officer in the Department of Research and Isotopes and Department of Technical Co-operation of the International Atomic Energy Agency (IAEA) in Vienna, Austria during 1977–1991 and Head of IAEA Fellowships and Training during 1987–91. Michael F. L'Annunziata was first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as the chemical pathway and origin of the various inositol phosphate stereoisomers in soils (Ph.D. dissertation, 1970, <https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum=>) and in 1975 (*SSSA Journal* 39(2), 377–379), and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–736, <https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733>). From 1977 to 2007, he served as IAEA Expert in peaceful applications of nuclear energy in over 50 countries of the

world in Europe, Asia, Africa, Latin America and the Middle East. His book entitled "Radioactivity: Introduction and History", First Edition, published by Elsevier, was on the Best Sellers List in Physics (*LibraryJournal Academic Newswire* in 2008), and his much expanded second edition entitled *Radioactivity: Introduction and History: From the Quantum to Quarks* published by Elsevier in 2016 (<https://www.sciencedirect.com/book/9780444634894/radioactivity>) was awarded an Honorary Mention in the 2017 PROSE AWARDS in the category of Chemistry & Physics.

Alex Tarancón

Alex Tarancón holds a PhD (2007) in Chemistry from the University of Barcelona. He is Serra Hunter Associate Professor of the Department of Chemical Engineering and Analytical Chemistry at the University of Barcelona. He has more than 15 years of experience in the development of innovative methodologies for the measurement of radioactivity using plastic scintillators. His experience covers several topics on the development of scintillation instrumentation, optimization of the response of scintillators, studies on the scintillation mechanism, pulse shape discrimination, LS standardization methods and the complete analysis of samples containing beta-emitting radionuclides. His current research is focused on the development of advanced strategies (fast determinations, selective analysis, on-line sensing, in-situ measurements, screening methods, ...) for radionuclide detection based on scintillation. He has been a member of the scientific committee of the two last conferences on Advances in Liquid Scintillation Spectrometry.

Héctor Bagán

Héctor Bagán received his PhD in chemistry at the University of Barcelona in 2011 working on the development of procedures to improve the selectivity in radioactivity measurements. He completed his 2 year post-doctorate at Lund University in the field of polymer synthesis for the separation and purification of biomolecules and proteins. Since then, he has been an adjunct lecturer at the Department of Chemical Engineering and Analytical Chemistry at the University of Barcelona. His research focuses on the use and development of analytical methodology for artworks characterization and also on the development of polymeric materials for the selective characterization of radioactive samples. This last topic includes the development of plastic scintillation resins that unify the separation and measurement preparation in one step, for the radionuclide measurements in environmental and nuclear power plant decommissioning samples.

José F. García

José F. García holds a PhD in Chemistry from the University of Barcelona. He is Associate Professor of the Department of Chemical Engineering and Analytical Chemistry at the University of Barcelona. José F. García has researched radioactivity analysis for the last 30 years. His work has been focused on scintillation analysis and his main contributions in this field are related to the introduction of chemometrics, the development of plastic scintillators and improvements in the continuous fluids monitoring for different radionuclide applications. These applications have included environmental and decommissioning studies and dating methods development. He has participated in several research projects at the national and international level and technology transfer contracts. José F. García has published more than 70 articles in scientific journals and has co-organized the periodical editions of the International Workshop on Plastic Scintillators.

Sample preparation techniques for liquid scintillation analysis

James Thomson and Simon Temple

Meridian Biotechnologies Ltd., Chesterfield, United Kingdom

Chapter outline

I. Introduction	804		
II. Liquid scintillation counting cocktail components	804	VII. Carbon dioxide trapping and counting	827
A. Solvents	804	A. Sodium hydroxide	827
B. Scintillators	805	B. Hyaminehydroxide	827
C. Surfactants	806	C. Ethanolamine	828
1. Nonionics	806	D. CarbonTrap and Carbo-Sorb E	828
2. Anionics	807	VIII. Biological samples encountered in absorption, distribution, metabolism, and excretion	830
3. Cationics	807	A. Urine	830
4. Amphoterics	807	1. Sample preparation	830
D. Cocktails	808	B. Whole blood	831
III. Dissolution	808	1. Sample preparation	831
A. Anions	808	C. Plasma and serum	833
B. Low ionic strength buffers	808	1. Sample preparation	833
C. Medium-ionic-strength buffers	811	D. Muscle, skin, heart, brains, and stomach	833
D. High-ionic-strength buffers	811	1. Sample preparation	834
E. Acids	811	E. Liver and kidney	834
F. Alkalis	812	1. Sample preparation	834
G. Other aqueous sample types	812	F. Fatty tissue	835
H. Selection and suitability of a cocktail based on ionic strength	813	1. Sample preparation	835
IV. Solubilization	813	G. Feces	836
A. Systems	813	1. Sample preparation	836
B. Sample preparation methods	815	H. Homogenates	836
1. Whole tissue	815	I. Solubilization and combustion	836
2. Muscle (50–200mg)	815	IX. Filter and membrane counting	837
3. Liver	815	A. Elution situations	838
4. Kidney, heart, sinew, brains, and stomach tissue	818	B. Sample collection and filters	838
5. Feces	818	C. Filter and membrane types	839
6. Blood	819	D. Sample preparation methods	839
7. Plant material	819	1. No elution	839
8. Electrophoresis gels	821	2. Partial elution	839
V. Combustion	822	3. Complete elution	840
VI. Comparison of sample oxidation and solubilization techniques	822	X. Sample stability troubleshooting	840
A. Solubilization	823	A. Decreasing count rate	840
B. What is sample combustion?	824	B. Increasing count rate	841
C. Advantages and disadvantages	824	C. Reduced counting efficiency	841
1. Solubilization methods and suitability	825	XI. Swipe assays	841
		A. Wipe media and cocktails	841

counting efficiency than the classical solvents, and the overall order is

benzene → LAB → toluene → xylene → pseudocumene → PXE → DIN
 increasing efficiency

Commercial mixtures (e.g., petroleum distillates) have been used instead of pseudocumene, but these contain many species other than alkyl benzenes and include indane, indene, methyl indane, and ethyl indane. These impurities have a detrimental effect on counting efficiency and background and can be particularly strong chemiluminescers. Indane and indene, even at the 50–100 ppm level, will produce severe chemiluminescence when contacted with alkaline materials such as tissue solubilizers. This effect is so severe that the mixture can turn brown or purple and produce backgrounds $>1 \times 10^6$ CPM (counts per minute).

These petroleum distillates can be purified by, for example, distillation, column chromatography, reactive distillation, solvent extraction, and mild sulfonation, but the final product never really approaches the pure solvent as a completely acceptable LSC solvent. An earlier approach at producing a safer solvent system was to use paraffinic and naphthenic solvents in conjunction with a secondary LSC solvent. The paraffinic and naphthenic solvents have poor

scintillation properties, but the addition of this secondary LSC solvent (sometimes referred to as an energy transfer medium) can boost the counting efficiency up to within 80% of the pure LSC solvent. This approach was largely abandoned due to the large-scale availability of the new safer solvents. A summary of the important characteristics of LSC solvents is shown in Table 7.1.

B. Scintillators

The fluor or scintillator is a light transducer that converts nuclear energy into light photons. All LSC cocktails contain at least one and usually two scintillators. The primary scintillator is responsible for the initial or primary energy exchange, but the wavelength of the emitted light does not match the optimum detection wavelength of the photomultiplier tube (PMT). Hence, a secondary scintillator (or wavelength shifter) is added to shift the wavelength of the emitted light to match the PMT. An efficient scintillator should have a high fluorescence quantum efficiency (or high photon yield); a spectrum maximally matched to the response of the photocathode, short fluorescence decay time, a large Stokes' shift, sufficient solubility, and a low sensitivity to quenching agents.

Derivatives of oxazoles, oxadiazoles, phenylenes, p-oligophenylenes, styrylbenzenes, benzoxazoles, benzoxazolyl

TABLE 7.1 Safety characteristics of scintillation solvents.

Solvent	Boiling point	Flash point (°C)	Vapor pressure mmHg@25°C	Classification (international)	Hazards
Toluene	110°C	4°C	28	Flammable	Inhalation Skin absorption Irritating to skin/eyes
Xylene	138°C	25°C	8	Flammable	Inhalation Skin absorption Irritating to skin/eyes
Cumene	152°C	31°C	5	Flammable	Inhalation Irritating to skin/eyes
Pseudocumene	168°C	50°C	2	Flammable	Inhalation Irritating to skin/eyes
LAB	300°C	149°C	<1	Harmless	None (as classified)
PXE	305°C	149°C	<1	Harmless	None (as classified)
DIN	300°C	140°C	<1	Harmless	None (as classified)
Benzyl toluene	290°C	135°C	<1	Harmless	None (as classified)
Diphenyl ethane	290°C	135°C	<1	Harmless	None (as classified)

thiophenes, pyrazolines, and nitriles have scintillation properties and are potential scintillators. The concentration of the scintillator determines the photon yield of a liquid scintillator. At optimum scintillator concentration, the light output is maximum, but beyond this point, self- or concentration-quenching occurs due to the formation of excimers. The probability of excimer formation is greater in scintillators with planar configuration than those with bulky substituent groups offering steric hindrance; for example, PPO (2,5-diphenyloxazole) exhibits a reduced quantum yield value at high concentrations. Substituted polyaryls and p-oligophenylenes currently used as scintillators can be rendered more soluble by substitution of hydrogen with alkyl or alkoxy groups. The alkyl groups tend to enhance the solubility in toluene, whereas the alkoxy groups favor an increased solubility in more polar solvents. Primary fluors are generally substituted fluorescent polyaryls and include the following:

PPO	2,5-Diphenyloxazole
PPD	2,5-Diphenyl-1,3,4-oxadiazole
PBO	2-(4-biphenyl)-5-phenyloxazole
PBD	2-Phenyl-5-(4-biphenyl)-1,3,4-oxadiazole
BBD	2,5-Di-(4-biphenyl)-1,3,4-oxadiazole
Butyl-PBD	2-(4-t-Butylphenyl)-5-(4-biphenyl)-1,3,4-oxadiazole
BBOT	2,5-Bis-2-(5-t-butyl-benzoxazolyl) thiophene
TP	p-Terphenyl

The most popular and widely used is PPO, and this preference is due to its performance, purity, cost, and availability on a large scale. Butyl-PBD is also occasionally used, but it suffers from the drawback that it yellows when in contact with alkaline species such as tissue solubilizers. The situation with secondary scintillators is similar in that there are many scintillators that are useful but only a few are in common use. The important secondary scintillators include the following:

Bis-MSB	p-bis-(o-methylstyryl)benzene
POPOP	1,4-Bis-2-(5-phenyloxazolyl)benzene
Dimethyl POPOP	1,4-Bis-2-(4-methyl-5-phenyloxazolyl)benzene
NPO	2-(1-Naphthyl)-5-phenyloxazole
NPD	2-(1-Naphthyl)-5-phenyl-1,3,4-oxadiazole
BBO	2,5-Di(4-biphenyl)oxazole
PBBO	2-(4-Biphenyl)-6-phenylbenzoxazole

The most popular and widely used is bis-MSB, and this preference is due to its performance, solubility, purity, cost, and availability on a large scale. Dimethyl POPOP is also occasionally used, but it suffers from limited solubility in organic aromatic solvents. Virtually, all commercially

available LSC cocktails are based on the combination of PPO and bis-MSB, and this has been the case now for many years.

C. Surfactants

The most efficient energy transfer takes place in aromatic organic solvents. Since the majority of radioisotopes are present in an aqueous environment that is not miscible with the aromatic solvents, detergents are used to bring the aqueous phase into close contact with the organic phase by forming a microemulsion. Such close contact allows efficient energy transfer, which means that radioisotopes in aqueous solutions can be successfully measured both qualitatively and quantitatively. In an LSC cocktail, a microemulsion is a dispersion of very small droplets (radius of approximately 10 nm) of “water-in-oil” and is achieved by the use of detergents. Many detergents have been investigated, but only a few specific types have been successfully used in LSC cocktails. The major groups are nonionics, anionics, cationics, and amphoteric, and within each group, there are certain useful or favored detergents, which are found in many LSC cocktails.

1. Nonionics

This group includes the ethoxylates; one particular type, the alkyl phenol ethoxylate (APE), is found in virtually all current LSC cocktails. However, recent studies have shown that, when APEs biodegrade in the environment, they produce endocrine disruptors. Such endocrine disruptors cause male fish to turn into female fish and produce other sexual dysfunctionality. Consequently, some countries have introduced legislation to ban the drain disposal of products containing APEs. A comprehensive review of this situation is given in [Section XIV](#) of this chapter. Until now, only one company has addressed this issue and produced a range of LSC cocktails that are completely APE-free and that company is Meridian Biotechnologies Ltd. Meridian uses alcohol ethoxylates as alternatives to APEs. The ethoxylates are the building blocks upon which cocktail performance is based. Ethoxylates are produced by the vapor- or liquid-phase ethoxylation of the free hydroxyl group of the alkyl phenol in the presence of a catalyst. Such ethoxylates are described as having a specific ethylene oxide or EO length, but this number, which refers to the length of the ethoxylate polymer chain, is in fact an indication based on properties, not on chemical structure. These ethoxylates have a range of polymer chain lengths present in a normal distribution, and the EO length is an indication of the average distribution. Commonly encountered ethoxylates include APEs, alcohol ethoxylates, amine ethoxylates, acid ethoxylates, castor oil ethoxylates, and ester ethoxylates; however, as stated above, only the APEs

and now the alcohol ethoxylates are useful in LSC cocktail formulation. These other ethoxylates are not used, because they fail to produce a stable microemulsion, are generally colored, have limited solubility in aromatic solvents, produce unacceptable chemical quench, and have poor counting efficiency properties. Historically, in the 1960s, [Patterson and Greene \(1965\)](#) examined a few nonionic detergents of the alkyl phenol type and concluded that Triton X-100 was the detergent of choice. Unfortunately, factors such as the variability of feedstock and ethoxylation conditions were not taken into account, and this resulted in a severe batch-to-batch variation in the original Triton X-100 product. When used in LSC cocktails, the result was microemulsion instability and chemiluminescence; therefore, this meant that detergent batch selection was necessary. Refinements in production methods significantly improved the quality of the APEs to the extent that standard production material can now be used in LSC cocktails without reverting to batch selection of raw materials. Due to the disposal ban, many manufacturers have dropped APEs from their product offering, but there are still some available. Sourcing acceptable raw material ethoxylate can only be achieved through a lengthy trial-and-error process. When mixed with aromatic LSC solvents, both alcohol ethoxylates and APEs are able to produce microemulsions when aqueous samples are added. The choice of solvent and ethoxylate is critical in that there is a limited range of EO chain lengths, which will work with each individual aromatic solvent, and desirable properties such as clarity of microemulsion or gelling can be chosen by careful EO selection. In addition, altering the chain length of the alkyl group of the ethoxylate affects performance. To extend or enhance performance, other detergents are needed, and these are normally selected from the other groups.

2. Anionics

This group includes, among others, alkyl and alkylaryl sulfonates, alcohol sulfates, alkyl sulfosuccinates, and phosphate esters (PEs). Of these, the sulfosuccinates have been found useful primarily due to their synergistic effect when combined with ethoxylates. Sulfosuccinates, even in relatively small quantities, are able to extend the microemulsion region of ethoxylates without affecting the other phases and have a secondary effect, in which they tend to stabilize the gel region. Various sulfosuccinates have been examined, but the most popular is sodium dioctylsulfosuccinate. This popularity is due to both its availability in a pure, water-white solid form and its ability to extend the microemulsion range of most ethoxylates. Another group of anionics, which are of exceptional benefit, are the PEs. The use of neutralized PEs has been patented ([ter Wiel and Hegge, 1983](#)), and the benefits resulting from their use include chemiluminescence

resistance and microemulsion formation with difficult sample types. In small quantities, the free acid or neutralized PEs act as hydrotropes and can remove the microemulsion instability often encountered with ethoxylates. When used as the free acid, the disadvantages are that they can react with certain metals and form colored compounds; they will protonate PPO; and they can cause cocktail degradation through reaction with the solvents. In general, the detergent properties of PEs are enhanced by neutralization, but the use of the wrong alkaline material has certain previously unreported drawbacks. If the PEs are neutralized with inorganic alkalis, the salt of the PE has a tendency to precipitate slowly out of the LSC cocktail, especially if the concentration is significant. If ammonia has been used, the presence of an alkaline sample will cause a reaction, resulting in the release of ammonia gas within the vial. Both of these situations are undesirable since they can produce variable quench conditions either in the original cocktail or within the counting vial. Other anionics that are known to have been investigated include sarcosinates, taurates, isothionates, and sulfonates, but little is reported on their benefits. If anionics are used in cocktails either alone or in conjunction with ethoxylates, then care is needed when adding cationics, such as quaternary ammonium hydroxides. There is a potential for reaction between the anionic and cationic, and insoluble compounds can form, either immediately or slowly upon standing. Thus far, the formation of an insoluble product has only been seen when sulfosuccinates are the anionic species.

3. Cationics

This class of detergents carries a positive charge on the hydrophobic portion—a property rendering it substantive to negatively charged surfaces, for example, metals and organic surfaces, in general. As stated previously, the fact that cationics form salts with anionics virtually precludes their use in cocktails since anionics are commonly present. One area that was tentatively researched was the deliberate reaction between free acid PEs and quaternary ammonium hydroxides to see if the products had any beneficial detergent properties. The results were a little inconclusive but suggested that further investigation might be worthwhile. In LSC, cationics, such as the quaternary ammonium hydroxides that are powerful bases, are used to solubilize/dissolve a host of animal fats and tissues. Although these cationics have only a limited use in LSC, they nevertheless affect many of the cocktails in use. Being very basic in nature, they have the potential to initiate chemiluminescence in many cocktails.

4. Amphotericics

This class of detergents has both positive and negative centers in the molecule, and depending on the condition

prevailing, cationic, anionic, or nonionic type properties may be exhibited. Examples of molecules peculiar to this class include betaines, imidazolines, and carboxylates. The commercially available products are at present not suitable due to problems with low concentration availability, high color, and poor solubility in aromatic solvents. Although most cocktails contain APEs, it is possible to use a mixed anionic system effectively and one such cocktail was OptiPhase RIA, which was based on sodium dioctyl sulfosuccinate and neutralized PE in pseudocumene solvent.

D. Cocktails

LSC cocktails can be categorized either as “classical” or “safer.” The classical cocktails encompass all those based on toluene, xylene, or pseudocumene, whereas the safer cocktails include those based on DIN, PXE, LAB, benzyl toluene, and 2-phenylethane. Other high flash point solvents, such as 2-ethylnaphthalene, C₅–C₁₀ alkylbenzenes, hydrogenated terphenyls (Actrel 400), high flash point aromatic fractions (Solvesso 150 and 200), ethylbiphenyl, butylbiphenyl, phenylcyclohexane, phenylnaphthalene, isopropylbiphenyl, diphenylpropane, dixylylethane (Freiberg, 1990), and dicumylethane (Mirsky, 1990), have been investigated but, for various reasons, have not been used commercially in LSC cocktails. The main reasons include purity, scintillation efficiency, cost, and availability on a large scale. Among the safer cocktails, diisopropylnaphthalene (DIN)-based cocktails, such as the Ultima Gold range from PerkinElmer and the ProSafe + range from Meridian Biotechnologies, will give high ³H efficiency, and better color and chemical quench resistance. Other safer cocktails based on DIN include some of the Optiphase Hi-Safe range from PerkinElmer and the AquaSafe and QuickSafe cocktails from Zinsser. Some cocktail manufacturers use PXE as the safer solvent base, and examples include the ScintiSafe range from Fisher and the Ecoscint range from National Diagnostics. Finally, there are many cocktails based on linear alkyl benzene (LAB), and these include Opti-Fluor and Emulsifier Safe from PerkinElmer, Bio-Safe from RPI, Ecolume from ICN, and LumaSafe from Lumac. Most LSC cocktail suppliers feature both types in their ranges, and a full table of the known equivalents is shown in Table 7.2.

III. Dissolution

The primary objective of all sample preparation procedures for LSC is to obtain a homogeneous solution for efficient energy transfer from the sample to the LS cocktail. Aqueous solutions are some of the simplest and are most commonly found in LSA. In general, they provide the environment necessary for many assays and separations, and include the most encountered solvent media for the

numerous radioisotopes used in LSC. The main methods for producing aqueous samples are by dissolution, extraction, and distillation. Dissolution simply involves dissolving the sample in water. Extraction can include solid/liquid extraction whereby the sample is extracted from a solid matrix by water, or liquid/liquid extraction, which involves the extraction of the sample from a liquid matrix by water. Distillation involves separation of the aqueous component by evaporation. A variety of LSC cocktails have evolved over the years to accommodate the diverse types, volumes, and concentrations of aqueous samples presented for analysis by LSC and some are considered by Kobayashi and Maudsley (1974a,b), ter Wiel and Hegge (1991), and Peng (1983).

A. Anions

Different types of anions encountered in LSC include chlorides, nitrates, phosphates, acetates, and formates, with sample volumes ranging from less than 100 μ L to greater than 10 mL and concentrations varying from less than 10 mM to greater than 2 M. For the purpose of cocktail selection, these aqueous samples can be roughly divided into the following categories:

1. Buffers (e.g., sodium chloride, PBS, and potassium phosphate)
 - a. Low ionic strength (less than 0.1 M)
 - b. Medium ionic strength (0.1–0.5 M)
 - c. High ionic strength (0.5 M to greater than 1 M)
2. Acids (e.g., hydrochloric acid and nitric acid)
3. Alkalis (e.g., sodium hydroxide and potassium hydroxide)
4. Other aqueous sample types (e.g., urea, sucrose, and imidazole)

By using this list of categories, it is now possible to assign cocktails for each category and therefore present a simpler and more comprehensive method of cocktail selection than was previously possible. For each category, cocktails will be recommended based on sample acceptance, performance, and safety.

B. Low ionic strength buffers

Buffers encountered in this group include 0.01 M PBS (phosphate-buffered saline), 50 mM Tris–HCl [tris(hydroxymethyl)aminoethane hydrochloride], 0.1 M NaCl (sodium chloride), 0.01 M Na₂SO₄ (sodium sulfate), etc. Since these aqueous buffers are relatively dilute, there are comparatively few problems. Both di- and trivalent anions such as SO₄ and PO₄ are potentially problematic, due in part to their charge and to their relative size (e.g., chlorides [Cl[–]] are much smaller than sulfates [SO₄^{2–}]). These characteristics can impede the formation of a stable

TABLE 7.3 Cocktail Selection for Low Ionic Strength Samples (based on the use of 10 mL of cocktail).

	Safer cocktail	Classical cocktail
Low sample volume (0–2.5 mL)	Ultima Gold, MV, AB, LLT, Opti-Fluor, Emulsifier Safe (Poly-Fluor), Gold Star, Gold Star LT, ² ProSafe+, and other equivalent cocktails	Insta-Gel Plus (Insta-Gel XF), Pico-Fluor 15, Biofluor Plus, and other equivalent cocktails
High sample volume (>2.5 mL)	Ultima Gold, XR, AB, LLT, Gold Star, Gold Star LT, ² ProSafe HC+, and other equivalent cocktails	Insta-Gel XF, Pico-Fluor Plus, and other equivalent cocktails

microemulsion and can cause phase instability, especially with high concentrations and large volumes. Surprisingly, similar problems can occur with small volumes, particularly within the range of 0.1–0.5 mL of sample in 10 mL cocktail (1%–5% sample load). The only other area of concern is color quench problems when using certain metallic salts, which are intrinsically colored (e.g., FeCl_3 [ferric chloride]). Any phase instability problem can usually be resolved by decreasing the sample volume or by increasing the cocktail volume. If the problem persists, then it may be necessary to change to a cocktail that can accept higher strength ionic samples. Color quench problems can be reduced either by diluting the sample with water (if practicable) or by using a cocktail, which is more resistant to color quenching, e.g., any of the Meridian ProSafe+ and Gold Star, PerkinElmer Ultima Gold and OptiPhaseHiSafe cocktails. Of the classical solvent-based cocktails, Insta-Gel Plus (10 mL) can accommodate greater than 2.5 mL of certain sample types and forms a stable gel (usually at greater than 3 mL sample volume), thus making large sample volumes possible. Pico-Fluor 40 (10 mL) can accommodate greater than 2.5 mL of certain samples and remains in a single liquid phase. Cocktails suitable for these samples are shown in [Table 7.3](#).

C. Medium-ionic-strength buffers

Aqueous buffer concentrations encountered in this group range from 0.1 to 0.5 M, and typical buffers are 0.1–0.5 M PBS, 0.15–0.5 M NaCl, 0.25 M ammonium acetate, etc. The cocktails suitable for these sample types are shown in [Table 7.4](#).

The cocktails are designed to overcome any phase instability problems, and therefore, cocktail selection is limited by volume and concentration factors. The Gold Star, ProSafe+, and Ultima Gold families will, in general, give higher quench resistance than the classical cocktails, i.e., higher efficiency at the same sample load. Gold Star, ProSafe+, and Ultima Gold work well with low sample volumes of aqueous buffers up to 0.5 M. Although Insta-Gel Plus will accept small volumes of certain sample types, Pico-Fluor Plus is the recommended classical cocktail for these samples.

D. High-ionic-strength buffers

With high-ionic-strength buffers, the choice of cocktails includes Gold Star, ProSafe HC+, Ultima Gold XR, Optiphase Hi-Safe 3, LumaSafe Plus, Hionic-Fluor, or Pico-Fluor Plus. Certain high-ionic-strength samples can be accommodated in other cocktails; however, the capacity is usually very low (less than 0.5 mL). The only other method of overcoming the problem of low sample acceptance of high-ionic-strength samples is to dilute the buffer sample with water and convert it into a medium-ionic-strength buffer, which simplifies cocktail selection. The sample capacity of selected cocktails for increasing ionic-strength solutions is shown in [Table 7.5](#).

E. Acids

This group includes commonly encountered mineral acids such as hydrochloric acid, nitric acid, sulfuric acid, perchloric acid, orthophosphoric acid, and hydrofluoric acid as well as some aqueous miscible organic acids such as

TABLE 7.4 Cocktail Selection for Medium-Ionic-Strength Samples (based on the use of 10 mL of cocktail).

	Safer cocktail	Classical cocktail
Low sample volume (0–2.5 mL)	Ultima Gold, XR, AB, LLT, Gold Star, Gold Star LT, ² ProSafe+, and other equivalent cocktails	Insta-Gel Plus (Insta-Gel XF), Pico-Fluor Plus, Hionic-Fluor, and other equivalent cocktails
High sample volume (>2.5 mL)	Ultima Gold XR, Gold Star, ProSafe HC+, and other equivalent cocktails	Pico-Fluor Plus, Hionic-Fluor, and other equivalent cocktails

TABLE 7.5 Sample Capacity of Selected Cocktails for Various-Ionic-Strength Buffers (sample capacities are for 10 mL cocktail at 20°C).

Ionic strength	Ultima Gold XR (mL)	Hionic-Fluor (mL)	Ultima Gold (mL)	Gold Star (mL)	ProSafe HC+ (mL)
0.5M NaCl	9.0	1.4	1.5	10.0	6.5
0.75M NaCl	6.5	2.25	0.7	10.0	3.6
1.0M NaCl	5.5	8.5	0.5	10.0	2.5

acetic acid, formic acid, and trichloroacetic acid (TCA). Acids are commonly used as extractants (Thomson and Burns, 1996a), pH modifiers, and solubilizers (Thomson and Burns, 1996b). There are a number of potential problems associated with this particular sample group, and these include quenching, reaction with cocktail components, and chemiluminescence. Strong mineral acids can also cause marked quenching effects primarily due to interaction with the scintillators. This can be overcome by using a cocktail that is known to be compatible with mineral acids or, preferably, by diluting the acid with water prior to the addition of the cocktail. Certain strong mineral acids will react with cocktail components causing both color development and changes in surfactant characteristics. For example, adding even small amounts of concentrated sulfuric acid to a cocktail will result in almost immediate color formation and eventual sulfonation of the surfactants (emulsifiers). This alteration to the surfactants will result in a change or loss of emulsifying properties and lead to phase instability. The color formation is due to sulfonation of minor impurities in the solvent and, in addition to color, significant amounts of chemiluminescence may be produced. Another example involves adding small amounts of concentrated nitric acid, which results in the formation of a yellow/brown color, due to the dissociation of nitric acid and release of NO₂. This problem can be overcome by diluting the acid with water prior to adding it to the cocktail. With some cocktails, the addition of TCA can produce chemiluminescence. Although a rare occurrence, acid-

induced chemiluminescence can be avoided by using a cocktail that is resistant to it such as Gold Star LT² or Ultima Gold LLT. An overview of suitable cocktails for acids is shown in Table 7.6.

F. Alkalis

This group of samples includes bases such as sodium hydroxide, potassium hydroxide, and ammonium hydroxide. Alkaline samples are produced from applications involving pH modification, cell lysis, CO₂ trapping (Thomson and Burns, 1994), and solubilization. The major problem normally encountered is chemiluminescence, and in general, the amount of chemiluminescence is influenced by both the volume and concentration of alkali added. The standard method of avoiding this problem is to use a cocktail that is known to be resistant to chemiluminescence. Other methods of overcoming the problem include diluting the base with water to reduce the effect, allowing the chemiluminescence to decay in the dark before counting, and neutralizing the base with acid. Prolonged storage of cocktails with alkalis present is not recommended due to the potential for color formation. Where possible, counting should be performed within 1 or 2 days.

G. Other aqueous sample types

This final group covers other aqueous samples/mixtures that are occasionally used in LSC methods and assays.

TABLE 7.6 Cocktail selection for acids (based on the use of 10 mL of cocktail).

Acid	Concentration	Safer cocktail	Classical cocktail
Mineral acids	0–2M	Ultima Gold AB, LLT, Gold Star, Gold Star LT, ² ProSafe+, and other equivalent cocktails	Insta-Gel Plus (Insta-Gel XF*), Pico-Fluor Plus, Hionic-Fluor, and other equivalent cocktails
	>2M	Ultima Gold AB, LLT, Gold Star LT ² , and other equivalent cocktails	
Trichloroacetic acid	0%–20%	Ultima Gold LLT, Gold Star LT ² , and other equivalent cocktails.	Hionic-Fluor and other equivalent cocktails

These aqueous mixtures are usually fairly specific for certain types of assays, for example, sucrose gradients in DNA and RNA separation, urea as a denaturing and reducing buffer, and imidazole as a biological buffer. Gold Star, ProSafe+, Ultima Gold, and OptiPhaseHiSafe2 are the cocktails of choice for these sample types. A slightly expanded compilation of one manufacturer's cocktails for different sample types is shown in Table 7.7 (Safer Cocktails), Table 7.8 (Safer Cocktails for Acids), and Table 7.9 (Classical Cocktails). Other available cocktails are suitable for most of these sample types, and the correct selection can be made using the cocktail equivalents table (Table 7.2). This may prove useful in providing a basic guide to cocktail selection. To further help with cocktail selection, sample capacities are presented to help with both the selection and suitability of a cocktail.

H. Selection and suitability of a cocktail based on ionic strength

1. Determine the approximate ionic strength using the sample molarity,

$$\text{Mixture Molarity} = \frac{[(v_a \times m_a) + (v_b \times m_b) + \dots]}{(v_a + v_b + \dots)}$$

where v_a is the volume of solution A, m_a is the molarity of solution A, v_b is the volume of solution B, and m_b is the molarity of solution B.

Example: 10.0 mL of 0.2 M NaCl (Solⁿ A) added to 2.0 mL of 0.5 M KH₂PO₄ (Solⁿ B):

$$\begin{aligned} \text{Mixture Molarity} &= \frac{[(10 \times 0.2) + (2 \times 0.5)]}{(10 + 2)} \\ &= 0.25 \text{ M (a medium molarity sample)} \end{aligned}$$

2. Select appropriate cocktail based on ionic strength.
3. Test for sample/cocktail compatibility.
 - a. Dispense 10.0 mL cocktail into a 20 mL glass vial. The use of a glass vial allows a clear view of the mixture.
 - b. Add the desired sample volume, cap, and shake thoroughly.
 - c. If the mixture is clear, proceed with the stability test.
 - d. If the mixture is cloudy or hazy, try increasing the cocktail volume and/or decreasing the sample volume. If the mixture does not clear, select a cocktail that can accept higher-ionic-strength samples such as Gold Star, ProSafe HC+, Ultima Gold XR, OptiPhaseHiSafe 3, or an equivalent cocktail.
 - e. If the mixture separates into two distinct phases (such as oil and water) or is milky, select a cocktail that can accept higher-ionic-strength samples.

4. Test for stability: Use a mixture that has passed the sample/cocktail compatibility test. Allow it to stand at the LSC temperature for a minimum of 2 hours or the proposed count time for the sample, if this is greater than 2 hours. If the mixture remains stable, successful counting will be possible.

5. Count.

Note: Once the proper proportions and stability of the sample/cocktail mixture have been established, plastic vials can be considered for routine counting.

IV. Solubilization²

In its simplest terms, solubilization is the action of certain chemical reagents on the chemical bonds of a macromolecular structure (such as animal or plant tissue) that affects a structural breakdown (or digestion) into smaller, simpler subunits, which can then be directly dissolved in a liquid scintillation cocktail (Kobayashi and Maudsley, 1974a,b). The tissue sample may be whole, homogenized, macerated, or in some other state of subdivision prior to solubilization. When the digested samples are added to an appropriate liquid scintillation cocktail, they should yield clear, colorless, homogeneous liquids exhibiting a minimum of quench, a minimum of chemiluminescence, and a maximum of counting stability. The chemical reagents used should be capable of rapid and complete digestion with respect to both small and large sample sizes and should not require any complex care or methodology. In addition, the combination of reagents and the method of digestion should allow an accurate determination of the isotopic content with a minimum of systematic error. Solubilizers are predominantly used for the traditional animal metabolism studies and more recently have been increasingly used in cell and tissue culture applications. Another area of growing interest is the fate of radionuclides in the environment; in this field of interest, solubilizers have been found to be an invaluable tool in sample preparation. Fundamentally, there are still only three major classifications of solubilizing reagents, and these are as follows:

1. alkaline systems (e.g., Soluene-350, GoldiSol, and Solvable & Aquigest),
2. acidic systems (e.g., perchloric acid), and
3. other systems (e.g., sodium hypochlorite).

A. Systems

The mode of action of “alkaline systems” is solubilization by hydrolysis, and a wide range of samples including animal tissues, blood, urine, bone tissue, muscle, amino acids, nucleic acids, and proteins can be digested with these

TABLE 7.7 Performance of Safer Cocktails with Various Aqueous Buffers at 20°C (based on the use of 10 mL of cocktail). Dotted lines indicate no or very limited sample capacity.

reagents. With “acidic systems,” the sample is oxidized to soluble products by the action of certain strong acids, usually oxidizing acids. Samples such as cartilage, bone, collagen fibers, and dried and hard plant samples can be digested by these reagents. Occasionally, mixed acid reagents and acids with an added oxidizing agent are preferred due to their increased oxidative power. Under “other systems,” a number of different reagents can be considered; however, the most useful reagent is sodium hypochlorite whose mode of action is by the process of oxidative bleaching. This is particularly useful when dealing with plant samples, especially those containing chlorophyll, where the sodium hypochlorite effectively prevents color quench in subsequent LSC by bleaching out all of the color present. It is not possible to cover the use of every solubilizer; the intention, therefore, is to focus on the most commonly used solubilizers and their usefulness for LSC applications. This section will identify those sample types that are routinely encountered in solubilization work and will offer helpful hints on sample preparation as well as recommending suitable reagents.

B. Sample preparation methods

The following sample preparation techniques, using the reagents detailed in Table 7.10, were carried out using high-performance glass vials. All ³H counting efficiencies presented were determined using a Tri-Carb_3100 with 67% absolute ³H efficiency (sealed argon purged standard) operating at 19°C.

1. Whole tissue

The method of solubilizing whole tissue is relatively straightforward and, apart from color formation with certain tissue types, no major problems should be encountered during sample preparation and counting. Although this section only mentions GoldiSol, Soluene-350, AqualGest, and Solvable, it is also possible in certain cases to use hyamine hydroxide.

2. Muscle (50–200 mg)

The method for processing muscle samples is shown below, and typical results are illustrated in Table 7.11. The choice of LSC cocktail influences the maximum sample size that can be processed.

Procedure:

1. Place selected sample size in a 20-mL glass scintillation vial.
2. Add an appropriate volume of solubilizer (1–2 mL depending on sample size).
3. Heat in an oven or water bath at 50–60°C for the specified time with occasional swirling.
4. Cool to room temperature and add 10 mL of a selected cocktail.
5. Temperature and light adapt for at least 1 hour before counting.

3. Liver

The method for processing liver samples (50–100 mg) is shown below, and typical results obtained are illustrated in

TABLE 7.9 Performance of Classical Cocktails with Various Aqueous Buffers at 20°C (based on the use of 10 of cocktail). Dotted lines indicates no or very limited sample capacity.

^aClears only after extended agitation.

Table 7.12. As before, the choice of LSC cocktail influences the maximum sample size that can be processed.

Procedure:

1. Place selected sample size in a 20 mL glass scintillation vial.
2. Add 1–2 mL of solubilizer.
3. Heat in an oven or water bath at 50–60°C for the specified time with occasional swirling.
4. Cool to room temperature.
5. Add 0.2 mL of 30% hydrogen peroxide in two aliquots of 0.1 mL, with swirling between additions. Allow any reaction to subside between additions of the hydrogen peroxide.
6. Heat again at 50–60°C for 30 minutes to complete decolorization.
7. Add 10 mL of a selected cocktail, then temperature and light adapt for at least 1 hour before counting.

Notes: Solubilization of liver always results in highly colored samples due to the presence of bilirubin. The above

work was therefore restricted to a viable sample size (which should ideally not exceed 75 mg). In our experience, AquiGest or Solvable has proved to be better than GoldiSol and Soluene-350 for this particular sample type, mainly due to more rapid solubilization and lower final color.

4. Kidney, heart, sinew, brains, and stomach tissue

The method for processing the above five sample types is shown below, and typical results are illustrated in Table 7.13. As previously stated, the choice of LSC cocktail influences the maximum sample size, which can be processed.

Procedure:

1. Place selected sample size in a 20-mL glass scintillation vial.
2. Add 1–2 mL of solubilizer.
3. Heat in an oven or water bath at 50–60°C for the specified time with occasional swirling.
4. Cool to room temperature.

5. Add 0.2 mL of 30% hydrogen peroxide in two aliquots of 0.1 mL with swirling between additions. Allow any reaction to subside between additions of hydrogen peroxide.
6. Heat again at 50–60°C for 30 minutes to complete decolorization.
7. Add 10 mL of selected cocktail, then temperature and light adapt for 1 hour before counting.

5. Feces

The digestion of feces (Morrison and Franklin, 1978) strongly depends on the type of animal. It is possible to use both GoldiSol & Soluene-350 and AquiGest & Solvable. However, there can be problems with residual color and incomplete digestion due to the presence of cellulose-type material present in feces from species such as rabbit. As an alternative, the use of a sodium hypochlorite solution is recommended. Sodium hypochlorite resolved a problem for one researcher (unpublished work), who was attempting to digest guinea pig feces. Sodium hypochlorite substantially digested this sample rapidly, and isotope recoveries of greater than 98% for ^3H

TABLE 7.13 Reagents for solubilization and liquid scintillation counting (LSC) of various tissues.

Sample size	Solubilizer (1.0 mL used)	Digestion time at 50–60°C	Sample Appearance ^a	LSC cocktail	^3H counting efficiency
Kidney

^bNote: It is not possible to digest stomach tissue with Solvable.

were achieved. This recovery level was confirmed by combustion in a sample oxidizer (PerkinElmer Tri-Carb Sample Oxidizer, Model 307). The solubilization method used for processing this feces sample follows.

Procedure:

1. Weigh 50–150 mg of feces into a 20-mL glass scintillation vial.
2. Add 0.5 mL of sodium hypochlorite solution and cap tightly.
3. Heat in an oven or water bath at 50–55°C for about 30–60 minutes with occasional swirling.
4. Cool to room temperature.
5. Remove the cap and blow out any remaining chlorine using a gentle stream of air or nitrogen.
6. Add 15 mL of Gold Star or Hionic-Fluor and shake to form a clear mixture.
7. Temperature and light adapt for 1 hour before counting.

Note: After digestion, a small amount of white residual matter may remain; however, this should not affect the recovery.

6. Blood

The successful preparation of blood samples (see [Moore, 1981](#)) for LSC can often be technically difficult, and successful digestion can be largely dependent on the practical experience of the researcher. The source of blood and the correct choice of solubilizer also influence the results of digestion. Consequently, methods are given for both GoldiSol & Soluene-350 and Aquigest & Solvable, and the final choice of method rests with the individual researcher. Some typical results, obtained in an independent laboratory, are shown in [Table 7.14](#).

GoldiSol and Soluene-350 method

Procedure:

1. Add a maximum of 0.4 mL of blood to a glass scintillation vial.
2. Add, while swirling gently, 1.0 mL of a mixture of either GoldiSol or Soluene-350 and isopropyl alcohol (IPA) (1:1 or 1:2 ratio). Ethanol may be substituted for the IPA if desired.
3. Incubate at 60°C for 2 hour. The sample at this stage will be reddish-brown.

4. Cool to room temperature.
5. Add 0.2–0.5 mL of 30% hydrogen peroxide dropwise or in small aliquots. Foaming will occur with Soluene-350 after each addition; hence, gentle agitation is necessary. With GoldiSol, there will only be minimal foaming. Keep swirling the mixture until all foaming subsides and then continue swirling until all of the hydrogen peroxide has been added.
6. Allow the sample to stand for 15–30 minutes at room temperature to complete the reaction.
7. Cap the vial tightly and place in an oven or water bath at 60°C for 30 minutes. The sample at this stage should now have changed to pale yellow.
8. Cool to room temperature, and add 15 mL of Gold Star or Hionic-Fluor.
9. Temperature and light adapt for 1 hour before counting.

Aquigest and Solvable method

Procedure:

1. Add a maximum of 0.5 mL blood to a glass scintillation vial.
2. Add 1.0 mL Aquigest or Solvable.
3. Incubate the sample at 55–60°C for 1 hour. Sample at this stage will be brown/green in appearance.
4. Add 0.1 mL of 0.1 M EDTA-disodium salt solution, which helps reduce foaming when the subsequent hydrogen peroxide is added.
5. Add 0.3–0.5 mL of 30% hydrogen peroxide in 0.1 mL aliquots. Gently agitate between additions to allow reaction foaming to subside.
6. Allow the sample to stand for 15–30 minutes at room temperature to complete the reaction.
7. Cap the vial tightly and place in an oven or water bath at 55–60°C for 1 hour. The color will change from brown/green to pale yellow.
8. Cool to room temperature, and add 15 mL of Gold Star or Pico-Fluor Plus.
9. Temperature and light adapt for 1 hour before counting.

7. Plant material

There are two main problems associated with the digestion of plant material: the presence of pigments (especially chlorophyll) and the difficulty of digesting cellulose. Some

TABLE 7.14 Reagents for solubilization and liquid scintillation counting (LSC) of blood.

Sample size	Solubilizer (1.0 mL used)	Sample Appearance ^a	LSC cocktail	³ H counting efficiency
0.2–0.4 mL	Soluene-350 and GoldiSol	Clear, pale yellow	Hionic-Fluor/Gold Star	29%–19%
0.25–0.5 mL	Solvable and Aquigest	Clear, pale yellow	Hionic-Fluor/Gold Star	37%–27%

0.2 mL	Solvable and Aquigest	Clear, pale yellow	Ultima Gold/Gold Star	~44%

^aAppearance after decolorization with hydrogen peroxide.

of the colored pigments can be bleached with hydrogen peroxide, but not all, and therefore, many samples will remain highly colored. The primary problem with cellulose is that it is not soluble in the alkaline solubilizers, and in general, some form of skeletal cellulose material remains after attempted solubilization. To overcome these two problems, a number of different reagent systems have been devised with the overall result that plant material can be processed. Since there is such a wide variety of plant sample types, this section will be confined to describing the solubilization methods together with their associated advantages and drawbacks. GoldiSol and Soluene-350 can be used to solubilize various plant materials, but in general the sample size must be kept small (<50 mg). With such small samples, it is often possible to achieve limited decolorization with hydrogen peroxide; however, color quenching remains a problem and the cellulose is not dissolved. This classifies the use of GoldiSol and Soluene-350 for the digestion of plant material in the "of limited use" category. Aquigest and Solvable are also not ideally suited to solubilize plant materials and suffer from the same drawbacks associated with GoldiSol and Soluene-350. Perchloric acid/nitric acid solution and perchloric acid/hydrogen peroxide solution reagent systems are suitable for digesting samples by the method of "wet oxidation" and are particularly useful for solubilizing samples such as hard and dried plant material. They have also proved useful for the digestion of cartilage, bone, collagen fibers, and even some highly colored samples such as blood and liver. The general methods for these latter two reagents are as described next.

a. Perchloric acid/nitric acid (Wahid et al., 1985)

Procedure:

1. Prepare the solubilizing reagent by adding one volume of 70% perchloric acid to one volume of 70% nitric acid.
2. Where possible, the sample should be oven-dried and then finely cut.
3. Place the prepared sample (up to 200 mg) in a glass scintillation vial fitted with a polycone-lined urea screw cap.
4. Add approximately 0.6 mL of the prepared $\text{HClO}_4/\text{HNO}_3$ reagent (1:1).
5. Digest the sample in the closed vial at 50–70°C for 1 hour or until an almost colorless solution is obtained.
6. Cool the vial to room temperature, and add 15 mL of Gold Star or Hionic-Fluor.
7. Temperature and light adapt for 1 hour before counting.

b. Perchloric acid/hydrogen peroxide (Sun et al., 1988; Mahin and Lofberg, 1966; Recalcanti et al., 1982; Fuchs and De Vries, 1972)

Procedure:

1. Where possible, the sample should be oven-dried and then finely cut.

2. Place the prepared sample (up to 200 mg) in a glass scintillation vial fitted with a polycone-lined urea screw cap.
3. Add 0.2 mL of 70% perchloric acid and swirl gently to completely wet the sample.
4. Add 0.4 mL of 30% hydrogen peroxide and again swirl gently. (This sequence of addition prevents frothing.)
5. Digest the sample in a closed vial at 50–70°C for 1 hour or until an almost colorless solution is obtained.
6. Cool the vial to room temperature, and add 15 mL of Hionic-Fluor.
7. Temperature and light adapt for 1 hour before counting.

Notes (for both methods): With both of these acidic reagent systems, if the isotope label is ^{14}C , there is a potential for loss of the label as radiocarbon dioxide ($^{14}\text{CO}_2$) during solubilization. Tritium (^3H) losses are virtually prevented due to the formation of $^3\text{H}_2\text{O}$, which condenses inside the vial. Ensure that a polycone insert is used in the cap in place of a foil lined insert, as these aggressive reagents will oxidize the foil (aluminum) insert and may contaminate the digest. Do not heat these mixtures above 90°C; perchloric acid may decompose violently above this temperature. Due to the aggressive nature of these mixtures, the use of gloves is recommended during all handling steps. The perchloric acid/nitric acid method has also been successfully used for the determination of ^{45}Ca and ^{35}S in cartilage and bone (unpublished work).

c. Sodium hypochlorite

It is also possible to use sodium hypochlorite, as reported by Fuchs and De Vries (1972), Porter (1980), and Smith and Lang (1987). Although sodium hypochlorite does not completely dissolve cellulose, it is capable of decolorizing not only chlorophyll but also almost all other pigments found in plant materials. Therefore, provided the radioisotope is not assimilated within the cellulose structure, this reagent should be considered for preparing plant materials for LSC. The advantages of using this reagent for plant solubilization are that it is simple and rapid and does not result in loss of ^{14}C as radiocarbon dioxide gas. In practice, sodium hypochlorite penetrates the plant material and rapidly decolorizes the pigments, leaving behind a white skeleton of cellulose material. The general method is described next.

Procedure:

1. Place the sample (up to 200 mg) in a glass scintillation vial.
2. Add 1.0 mL of sodium hypochlorite solution.
3. Swirl gently until the entire sample has been completely wetted.
4. Cap tightly and place in an oven or water bath at 50–60°C for approximately 1–2 hour.

5. Completeness of digestion is usually indicated by removal of pigmentation and/or the appearance of white skeleton of cellulose.
6. Cool the vial to room temperature, and carefully vent each vial under a fume hood (decolorization is by action of released chlorine and some residual chlorine remains).
7. Blow out any remaining chlorine with a gentle stream of air or nitrogen.
8. Add 15 mL of Gold Star or Hionic-Fluor.
9. Temperature and light adapt for 1 hour before counting.

Note: Sodium hypochlorite is more commonly known as bleach and should have greater than 5% available chlorine if it is to be an effective solubilizer.

8. Electrophoresis gels

Polyacrylamide gel electrophoresis (PAGE) is a technique commonly used for the separation and identification of biological species. Electrophoresis can be best described as the movement of small ions and macromolecules in solution under the influence of an electric field. The rate of migration depends on the size and shape of the molecule, the charge carried, the applied current, and the resistance of the medium. Electrophoresis is carried out in gels cast either in tubes or as slabs. A number of gel materials have been used successfully, including agar, agarose, and polyacrylamide. Agar and agarose gels are prepared by heating the granular material in the appropriate electrolyte buffer, casting the gels, and allowing them to set on cooling. Polyacrylamide gels are made from acrylamide and *N,N*-methylene bisacrylamide (bisacrylamide) mixtures dissolved in electrolyte and polymerized by the addition of chemical catalysts. Cross-linking agents other than bisacrylamide have been used and include DATDA (diallyltartardiamide), BAC (*N,N*-bisacrylylcystamine), and ethylene diacrylate (Choules and Zimm, 1965). The location of the various compounds separated within the gel is determined by staining and by the presence of radioactivity in discrete zones. Sample preparation for analysis by LSC involves either elution of the sample from the gel or complete dissolution of the gel.

a. Gel elution

The complete solution of the gel is not required for satisfactory counting. This is indicated by the observation that when acrylamide gels are treated with a solubilizer, such as GoldiSol or Soluene-350 or their equivalents, the gel swells rapidly and the entrapped macromolecules diffuse out into the solubilizer. The addition of an appropriate cocktail results in a suitable counting medium. During this diffusion process, it is presumed that the macromolecules (proteins) are partially hydrolyzed by the strong organic base (Terman, 1970; Basch, 1968).

After 10–20 hours of digestion with solubilizer at ~45°C of 1 mm gel slices, the undissolved gel can be removed after being counted and no perceptible loss of either ³H or ¹⁴C counts or changes in the isotope ratios of the samples is observed (Terman, 1970). Another method of preparing the gel slices for counting is to add the 1–2 mm gel slice to 5 mL water and macerate the slice with the aid of a stirring rod. This mixture is allowed to stand at 50°C for about 2 hours, cooled, and then 10 mL of a suitable cocktail, such as Insta-Gel Plus or equivalent, is added.

b. Gel dissolution

The alternative to elution is the complete dissolution of gels; this can be accomplished using a variety of reagents and these include hydrogen peroxide (Diener and Paetkau, 1972), periodic acid (Spath and Koblet, 1979), 2-mercaptoethanol (Hansen et al., 1980), piperidine (containing EDTA), alkalis, and ammonia. The selection of a suitable reagent depends on the gel, in which the choice of cross-linker dictates the dissolving reagent required.

Acrylamide gels cross-linked with DATDA are dissolved in 0.5 mL of 2% periodic acid in 2 hours at room temperature (Anderson and McClure, 1973), and the digest can be counted in 10 mL of a suitable cocktail such as Insta-Gel Plus, Gold Star, Ultima Gold, OptiPhase HiSafe 2, or equivalents.

Acrylamide gels cross-linked with BAC are dissolved in 2-mercaptoethanol (Hansen et al., 1980). Polyacrylamide gels that are soluble in alkalis can be constructed using ethylene diacrylate as the cross-linker instead of bisacrylamide.

Polyacrylamide gels cross-linked with bisacrylamide can be dissolved by adding the 1–2 mm gel slice to 0.5 mL of 30% (100 vol) hydrogen peroxide and heating at 50°C until the gel dissolves. Some authors use a 1-hour digestion at 55°C (Diener and Paetkau, 1972), overnight at 40°C (Benjamin, 1971), and overnight at 60°C (Dion and Moore, 1972). The hydrogen peroxide also decolorizes the stained gels. When using hydrogen peroxide, cocktail selection is extremely important due to the potential for chemiluminescence. When peroxides are present in an alkaline medium, the chances of chemiluminescence are high. Consequently, after dissolving the gel slice in hydrogen peroxide, it is advisable to add a small amount of 1–2 M HCl to keep the mixture neutral or slightly acidic. In addition, sometimes traces of copper ions have been added to aid the decomposition of the excess hydrogen peroxide, and the presence of these ions intensifies the chemiluminescence in an alkaline medium. Cocktails suitable for this type of sample include Gold Star, Hionic-Fluor, and Aquasol-2 (all acidified with 0.5 mL 2 M HCl per 10 mL cocktail). Certain researchers (Goodman and Matzura, 1971) have criticized the use of hydrogen peroxide and heat

on the grounds that during digestion, radioactive carbon dioxide and water may be lost. They proposed the digestion of 1 mm gel slices using 0.25 mL of a mixture containing 1 part of concentrated ammonium hydroxide and 99 parts of 30% hydrogen peroxide at room temperature for 4–8 hours. This method is reported to be free from the danger of loss of radioactivity because of the low-temperature digestion.

Agarose gels can be rapidly and easily dissolved by treatment with sodium hypochlorite solution for about 1 hour at $\sim 45^{\circ}\text{C}$. In this instance, cocktail selection is very important, as any residual hypochlorite solution has a tendency to decompose under slightly acidic conditions producing chlorine, and this can lead to chemiluminescence. This chemiluminescence only becomes apparent after standing for >24 hour, and therefore, cocktail selection is important. At present, the recommended cocktail for this application is Hionic-Fluor.

All of the above methods are suitable for the isotopes normally encountered in gel electrophoresis, and in one modification, ^{32}P can be detected and counted in wet gel slices, either alone or covered in buffer, by Cerenkov counting.

As an alternative to elution or dissolution, the gel slices can be combusted using a commercially available oxidizer system. Although only applicable to ^3H and ^{14}C , combustion offers a rapid and accurate means of sample preparation free from the chemiluminescence problems associated with most acrylamide gel procedures.

A variety of LSC cocktails, of both high flash point and classical solvent types, are suitable for use with the various solubilizing reagents. The information presented in this section is condensed into a quick reference guide (Table 7.15), and this may prove particularly useful in selecting the most appropriate solubilizer and cocktail for a specific sample type.

V. Combustion

Combustion (sample oxidation) is the complete combustion of a sample using the “open/closed flame combustion technique.” This technique is principally used for ^3H and ^{14}C . During combustion, the organic portion of the sample is completely converted to water and carbon dioxide, whereas the inorganic portion remains in the particle trap. The respective reactions are as follows:

Since the products of combustion are water and carbon dioxide, problems such as color quenching, self-absorption, and chemiluminescence are eliminated. The two systems operating within a combustion process are (1) water

production and incorporation into a cocktail and (2) carbon dioxide production, absorption, and incorporation into a cocktail. On the ^3H side, the process is straightforward in that the water formed is incorporated into an emulsifying cocktail such as monophasic S. On the ^{14}C side, the basic chemical reaction involves the production of carbon dioxide by the combustion (oxidation) of organic carbon, followed by absorption by an amine. The absorption reaction scheme is that 2 mol of amine reacts with 1 mol of carbon dioxide to form a carbamate. This carbamate is then added to a special cocktail (e.g., CarbonCount or Permafluor E+) for counting. Since the counting quench of the ^3H is only water and the quench for ^{14}C is carbamate/CarbonTrap or carbamate/Carbo-Sorb E, the sample size processed can be as much as 2 g for ^3H and as much as 1.5 g for ^{14}C -labeled materials.

For low-level ^3H counting, multiple combustions are possible with the collection of the combusted material (water) in the same counting vial, and hence, better counting statistics and shorter counting time. There are three principal oxidizer systems in use today, and these are the PerkinElmer Sample Oxidizer, the “Harvey Oxidizer” (also known as R.J. Harvey Biological Oxidizer), and the RaddecPyrolyser. All are able to both combust and separate ^3H and ^{14}C quantitatively, but the respective mechanisms by which this is achieved are slightly different. Differences in combustion chamber, plumbing, heating techniques, timing cycles, and reagents account for the main operational differences. Consultation with each manufacturer’s product brochures shows how these individual instruments operate. A complete description of the PerkinElmer system, together with details on alternative methods of combustion, is given in *Liquid Scintillation Analysis—Science and Technology* (Kessler, 1989). Combustion can be found in many areas, including biochemistry, metabolic studies, pharmacokinetics, and agrochemical studies. Some typical applications include the determination of ^3H and ^{14}C in waste oil and the determination of ^3H and ^{14}C in soils. Combustion is the only technique that, prior to counting, can physically separate ^3H and ^{14}C , thereby eliminating many of the errors associated with the counting of dual labeled samples.

VI. Comparison of sample oxidation and solubilization techniques³

The primary objective of all sample preparation methods is to obtain a stable homogeneous solution suitable for analysis by LSC. There are no absolutes in sample preparation; whichever method produces a sample that lends itself to accurate and reproducible analysis is acceptable. However,

TABLE 7.15 Solubilization selection guide.

Sample type	Solubilizer	Maximum sample size	Suitable liquid scintillation counting cocktails
Muscle	Soluene-350 and GoldiSol	150 mg 200 mg	Pico-Fluor Plus, Ultima Gold, Gold Star, or Hionic-Fluor
	Solvable and Aquigest	150 mg 200 mg	Pico-Fluor Plus, Ultima Gold, Gold Star, or Hionic-Fluor
Liver	Soluene-350 and GoldiSol	100 mg	Hionic-Fluor/Gold Star
	Solvable and Aquigest	50 mg 100 mg	Ultima Gold, Gold Star or Hionic-Fluor
Kidney	Soluene-350 and GoldiSol	100 mg	Hionic-Fluor/Gold Star
	Solvable and Aquigest	100 mg	Hionic-Fluor/Gold Star
Sinew	Soluene-350 and GoldiSol	150 mg	Hionic-Fluor/Gold Star
	Solvable and Aquigest	150 mg	Hionic-Fluor/Gold Star
Brain	Soluene-350 and GoldiSol	150 mg	Hionic-Fluor/Gold Star
	Solvable and Aquigest	150 mg	Hionic-Fluor/Gold Star
Stomach	Soluene-350 and GoldiSol	100 mg	Hionic-Fluor/Gold Star
Feces	Soluene-350 and GoldiSol	150 mg	Hionic-Fluor/Gold Star
	Solvable and Aquigest	20 mg	Hionic-Fluor/Gold Star
	Sodium hypochlorite	20 mg	Hionic-Fluor/Gold Star
Blood	Soluene-350 and GoldiSol	0.4 mL	Hionic-Fluor/Gold Star
	Solvable and Aquigest	0.5 mL 0.2 mL	Pico-Fluor Plus, Ultima Gold, Gold Star or Hionic-Fluor
Plant material	Soluene-350 and GoldiSol	<50 mg	Hionic-Fluor/Gold Star
	Solvable and Aquigest	<50 mg	Hionic-Fluor/Gold Star
	HClO ₄ /H ₂ O ₂	200 mg	Hionic-Fluor/Gold Star
	HClO ₄ /HNO ₃	200 mg	Hionic-Fluor/Gold Star
	Sodium hypochlorite	200 mg	Hionic-Fluor/Gold Star
Gels			
Bisacrylamide	H ₂ O ₂	1–2 mm slices	Hionic-Fluor + HCl Aquasol-2 + HCl
	Soluene-350 and GoldiSol	1–2 mm slices	Hionic-Fluor
	Solvable and Aquigest	1–2 mm slices	Hionic-Fluor or Ultima Gold
	Water	1–2 mm slices	Insta-Gel XF
DATDA	Periodic acid	1–2 mm slices	Hionic-Fluor or Ultima Gold

there will be occasions when more than one method will be both suitable and available and the selection of either method will depend on other factors. It is precisely this situation that occurs when considering solubilization and sample combustion for sample preparation. Both techniques are routinely used to process samples that are not directly soluble in LSC cocktails. There are numerous sample types that fall into this category, and typical examples include tissue, muscle, kidney, liver, feces, blood, plant material, etc. Many of these samples are encountered

in ADME (absorption, distribution, metabolism, and excretion) studies in which the biological behavior and potential toxicological effects of a test substance are investigated.

A. Solubilization

Solubilization is the action of certain chemical reagents on organic materials (such as animal or plant tissue) that affects a structural breakdown (or digestion) into a liquid

form that can then be directly dissolved in a liquid scintillation cocktail. Typical solubilizers include organic and inorganic alkalis, which act by the process of alkaline hydrolysis and certain mineral acids that affect solubilization by acidic oxidation. The solubilization process usually involves heating the sample/solubilizer at elevated temperature (40–65°C) for periods ranging from <1 to 24 hour, until a homogeneous mixture is formed. Certain samples that remain colored after solubilization are optionally treated with hydrogen peroxide, and following this, a recommended LSC cocktail is added and the sample is ready for analysis by LSC.

B. What is sample combustion?

The principle of sample oxidation is that the sample is combusted in an oxygen-rich atmosphere, and any hydrogen present is oxidized to water, whereas any carbon is oxidized to carbon dioxide. If tritium is present, then the combustion product will be $^3\text{H}_2\text{O}$, and if ^{14}C is present, then the combustion product will be $^{14}\text{CO}_2$. In the PerkinElmer Model 307 Sample Oxidizer, the water is condensed in a cooled coil and then washed into a vial where it is mixed with an appropriate LSC cocktail. The CO_2 is trapped by vapor-phase reaction with an amine, and the resulting product is mixed with an appropriate LSC

cocktail. At the end of the combustion cycle, two separate samples (a tritium sample and a ^{14}C sample) are trapped at ambient temperature, thus minimizing cross-contamination. An alternative instrument—the Pyrolyser-Trio (Radtec Ltd., Southampton, UK)—was designed to simultaneously extract $^3\text{H}_{\text{total}}$ (and ^{14}C) from virtually any type of nuclear and environmental sample. The standard methodology consists of placing weighed samples into silica glass boats that are then inserted into their own silica worktube (1 m long) containing 10 g of platinized alumina catalyst. A laminar flow of air or oxygen is passed over the sample while it is progressively ramped in temperature typically from 50 to 900°C over a period of about 3 h. This controlled oxidation ensures that decomposition is slow and does not lead to any pressure excursions as the sample components decompose and liberate CO_2 , hydrocarbons, water, etc. The oxidized combustion products (water/ $^3\text{H}_2\text{O}$ and CO_2) are collected in bubblers from which subsamples are taken for LSC measurement.

C. Advantages and disadvantages

The oxidation process described above can be compared with the steps in a typical solubilization method in Fig. 7.1. As can be seen from Fig. 7.1, there are more steps involved in solubilization as compared with combustion; while this

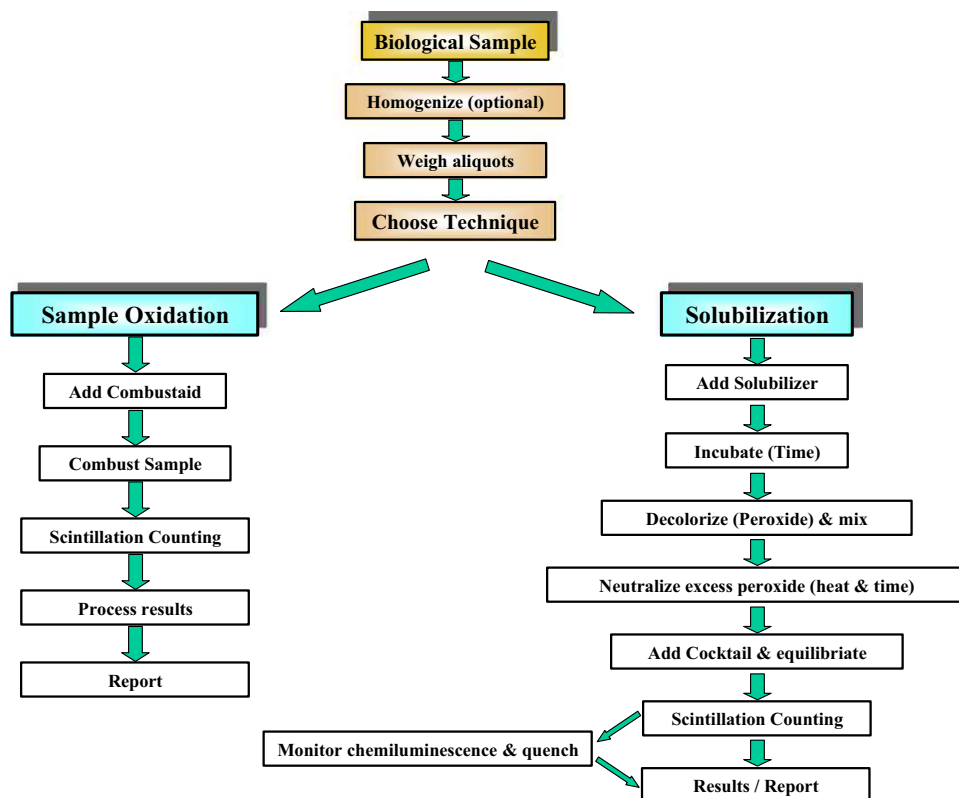

FIGURE 7.1 Sample oxidation and solubilization techniques compared. For the color version of the figure, the reader is referred to the online version of the book.

may seem less attractive, there are other important factors to consider before deciding which methodology is best.

1. Solubilization methods and suitability

The decision to use solubilization as the preferred method of sample preparation depends primarily on the nature of the sample and the number of samples that need to be processed. When the number of samples is low, then solubilization is usually the method of choice. Solubilization is suitable for many organic sample types, but certain of these are prone to problems such as color formation, limited sample size, and time to complete solubilization. These include biological samples such as whole blood, plasma, serum, liver, kidney, fatty tissue, and most plant materials. Many other biological sample types including, muscle, whole tissue, brain, stomach, intestines, nerve cells, cornea, and cartilage can be easily and rapidly processed. There is no major cost involved in setting up to do solubilization. The cost of 1.0 L solubilizer reagent and 10.0 L appropriate LSC cocktail is relatively small, and this is sufficient for 1000 analyses, assuming 1.0 mL solubilizer used with 10.0 mL cocktail. The method is relatively straightforward and is described earlier. To process a sample, simply add the solubilizer and heat at 50–60°C until the sample is dissolved. After solubilization, the sample may be colored and this color can usually be removed or reduced by treatment with hydrogen peroxide. The final step is to add the recommended LSC cocktail, and the sample is ready for counting. Using this method, many samples can be processed simultaneously and then counted sequentially.

- a. The typical advantages of solubilization
 - Capital outlay is low.
 - Homogeneous samples are produced.
 - Many samples can be processed simultaneously.
 - Color quench is corrected using a quench curve.
 - It is suitable for a diversity of isotopes.
- b. The disadvantages of solubilization
 - Sample sizes are generally ≤ 200 mg.
 - Time to complete solubilization can vary from a few hours to many hours.
 - Certain samples require modified techniques or longer solubilization times.
 - With acidic solubilizers, loss of radioactivity by volatilization may occur.

Solubilization has been in use for many years, and experienced researchers are typically able to optimize the methodologies through attention to detail and judicious selection of reagents and cocktails. Examples of sample types, reagents, and cocktails are shown in [Table 7.16](#).

2. Sample combustion methods and suitability

Since sample combustion is suitable for any organic and even some inorganic samples, the selection of this method is usually governed by the number of samples that need to be processed. When the sample load exceeds 50 per day, then sample oxidation becomes the method of choice for many sample types. In manual mode, the PerkinElmer Model 307 oxidizer can process 100 samples daily, whereas the robotic version can process 240 samples in 8 hours. High-temperature flame combustion at 1300°C enables wet, dry, or freeze-dried samples up to 1.5 g to be processed. For those samples containing dual-label $^3\text{H}/^{14}\text{C}$, the combustion cycle produces single-label ^3H and ^{14}C samples in separate vials with no cross-contamination.

- a. Advantages of sample combustion
 - Sample processing time is rapid.
 - Robotic sample processing is possible.
 - Sample can be wet, dry, or freeze-dried.
 - Any sample containing H and/or C can be combusted.
 - It is ideally suited for both single- and dual-label ^3H and ^{14}C .
 - Sample sizes up to 1.5 g are possible.
 - Radioactive recovery is excellent ($>97\%$).
 - Memory effect is $<0.08\%$.
 - There is no loss of radioactivity by volatilization.
 - There is no chemiluminescence interference.
 - There is no color quench interference.
- b. Disadvantages of sample combustion
 - Initial capital investment.
 - It is only suitable for ^3H and ^{14}C .
 - Need a gas supply (oxygen and nitrogen).
 - Must be operated in a fume hood.
 - Reagents are corrosive and flammable.

The flame combustion technology has proven to be a simple and reliable means of sample preparation and can process a diverse array of samples with a high degree of precision and accuracy. The technique requires a minimal amount of time and sample handling and eliminates any potential interference from color quenching or chemiluminescence. The diversity of samples that can be processed using flame combustion is shown in [Table 7.17](#).

Both solubilization and flame combustion are viable sample preparation techniques for a diverse array of animal and plant tissues. Flame combustion and solubilization procedures each has specific advantages and some disadvantages. Solubilization is more suited to those situations where the sample numbers are low. There can be problems

TABLE 7.16 Sample types that can be processed by solubilization.

Sample type	Solubilizer	Maximum sample size	Suitable LSC Cocktails
Muscle	Soluene-350 and GoldiSol	150 mg 200 mg	Pico-Fluor plus Ultima Gold/Hionic-Fluor/Gold Star
	Solvable and AQUIGEST	150 mg 200 mg	Pico-Fluor plus Ultima Gold/Hionic-Fluor/Gold Star

such as color formation, chemiluminescence, and sample size limitations when solubilizing with certain sample types, but by careful attention to detail and experience, these can be overcome. Flame combustion, operated in either manual or robotic format, provides a very powerful tool to rapidly process many different sample types with a high degree of precision and accuracy. The technique requires a minimal amount of time and sample handling and eliminates color quench and chemiluminescence interferences. The only limitation is the initial capital investment and the restriction to ³H and ¹⁴C. The PerkinElmer Model 307 manual oxidizer is well suited for sample loads of up to 50 per day.

Hionic-Fluor (10.0 mL)	1.0 mL	4.0 mL	8.1 mM
Hionic-Fluor (10.0 mL)	2.0 mL	6.5 mL	16.2 mM
Hionic-Fluor (10.0 mL)	3.0 mL	8.5 mL	24.3 mM

VII. Carbon dioxide trapping and counting⁴

Certain assays result in the generation of discrete gaseous ¹⁴CO₂ samples (not originating from combustion), and these require a modified approach for the trapping of the gas and subsequent LSC (Qureshi et al., 1985; Schadewaldt et al., 1983; Pfeiffer et al., 1981; Riffat et al., 1985). ¹⁴CO₂ gas samples originate from a variety of sources, including ¹⁴CO₂ in expired breath (Bird, 1997), expired by plants, expulsion from blood (Kaczmar and Manet, 1987), and release in enzymatic studies (Sissons, 1976). There are a number of potentially useful reagents available for trapping carbon dioxide, and some of these are shown in Tables 7.18 and 7.19.

A. Sodium hydroxide

Sodium hydroxide absorbs/traps CO₂ by a reaction that produces a sodium carbonate solution. Potassium hydroxide performs in a similar way by forming potassium carbonate. Some of the recommended LSC cocktails for use with this mixture include the following:

- Emulsifier Safe, which accepts up to 2 mL of 0.1 M sodium hydroxide/CO₂ in 10 mL cocktail;

- Opti-Fluor, which accepts up to 5 mL of 0.1 M sodium hydroxide/CO₂ in 10 mL cocktail;
- Hionic-Fluor, which accepts up to 5 mL of 1.0 M sodium hydroxide fully saturated with CO₂ in 10 mL cocktail;
- Ultima-Flo AF, which accepts 10 mL of 0.5 M NaOH/CO₂ or 5 mL of 1.0 M NaOH/CO₂ in 10 mL cocktail; and
- Gold Star, which accepts 5 mL of 1.0 M sodium hydroxide fully saturated with CO₂ in 10 mL cocktail.

Notes: Hionic-Fluor is suitable for use with hydroxide/carbonate solutions due to its sample capacity for concentrated solutions and alkaline pH. Ideally, the final pH should be above 9 to avoid liberation of trapped CO₂. Cocktails containing mixed surfactant systems, such as Ultima Gold, Gold Star, or Ultima Gold XR, can be used; however, counting should be performed the same day, as these cocktails have the potential for slow release of CO₂ on prolonged storage (characterized by dropping CPM levels). Cocktails containing free-acid PEs such as Aqua-Safe should not be used, as their acid nature will cause rapid loss of ¹⁴C as ¹⁴CO₂.

B. Hyaminehydroxide

Chemically, hyamine hydroxide performs similarly to sodium and potassium hydroxide, in which it forms hyamine carbonate on reaction with CO₂ (Bird, 1997). Some of the recommended LSC cocktails include Insta-Fluor Plus,

4. ©1998–2019, PerkinElmer, Inc. Printed with permission.

which will accept up to 7.5 mL of hyamine hydroxide saturated with carbon dioxide in 10 mL cocktail, and Emulsifier Safe, which will accept up to 3 mL of hyamine hydroxide saturated with carbon dioxide in 10 mL cocktail, providing a safer system due to the high flash point of this LSC cocktail.

Note: Foaming of hyamine hydroxide used to absorb carbon dioxide expelled in rat breath has been reported. This can be overcome by the addition of one drop of silicone antifoam per 10 mL of hyamine hydroxide. Both of the above cocktails are resistant to any potential chemiluminescence possible with this system.

C. Ethanolamine

Ethanolamine reacts with CO₂ in a rather different way than previously discussed reagents, in that a carbamate is formed as opposed to a carbonate. The main difference between these two species is that a carbamate is more stable under slightly acidic conditions, whereas a carbonate reacts rapidly with acids to release carbon dioxide. Ethanolamine/CO₂ is notoriously difficult to incorporate into LSC cocktails, and thus the recommended LSC solutions may seem a little unusual. The main system known, which is capable of

accepting this unusual reagent, is shown in Table 7.20. The recommended LSC cocktail requires the use of a cosolvent, for example, methyl cellosolve, to facilitate the acceptance or mixing of the ethanolamine/CO₂ with cocktail. There may be systems based on other equivalent cocktails, but at present they are unreported.

D. CarbonTrap and Carbo-Sorb E

CarbonTrap and Carbo-Sorb E will react with CO₂ to form a carbamate as well and were developed to work in the PerkinElmer sample oxidizer Model 307. It is, however, possible to use these reagents as carbon dioxide-trapping agents outside of the Model 307. As with the Model 307, the recommended cocktail is either CarbonCount or Permafluor E+, and the following conditions are recommended:

For ratios of CarbonTrap/Carbo-Sorb E to CarbonCount/Permafluor E+ from 1:10 up to 1:1, maximum saturation of carbon dioxide is possible with no phase separation of the resulting carbamate. Should any minor haziness develop, then either add 2–4 mL methanol to the mixture until a clear solution forms or add extra CarbonTrap/Carbo-Sorb E to the mixture until a clear solution forms. This latter method simply dilutes the absorption

TABLE 7.20 Reference table for CO₂ trapping and liquid scintillation counting(LSC).

CO ₂ absorber	mM CO ₂ per mL	mL required for 1 mM CO ₂	mL required for 5 mM CO ₂	mL required for 10 mM CO ₂	LSCCocktail	Cocktail Volume	mL of Absorber	Maximum CO ₂ capacity

capacity below the critical 90% level. The use of Carbon-Trap/Carbo-Sorb E is not recommended in enzymatic, plant, or human studies due to the corrosive nature of the volatile amine present.

This information is condensed into a quick reference table (Table 7.21), and it may prove particularly useful when the total trapping capacity per standard 20-mL LSC vial is required.

VIII. Biological samples encountered in absorption, distribution, metabolism, and excretion

ADME studies are a vital part of the comprehensive safety evaluation of a new chemical entity. The objective of this study is to investigate the excretion rate and tissue distribution of the chemical entity and involves the collection and analysis of urine and feces, blood, and major internal organs. Total radioactivity level in each sample is assayed, and the recovered dose is compared with the administered dose. The percentage of distribution of the administered dose in urine, feces, and each major internal organ and the half-time for excretion are calculated. Given that in ADME studies all samples are, or are derived from, biological species, the preparation of such samples has always been treated as a special case, because of the difficulties associated with their preparation for LSC. In general, all biological samples contain components not generally found in any other sample types; therefore, it is of benefit to understand the composition of these samples to fully understand the need for the slightly unusual sample preparation methods. The analysis of any biological sample is usually complicated by its complex structure. The components present in biological samples require that either specialist cocktails are needed or, more usually, modified sample preparation techniques are employed. Therefore, it is of benefit to understand the composition of these samples to fully understand the need for specialist cocktails and, in some cases, the slightly unusual sample preparation methods. Within the context of ADME, the samples generally encountered include urine, feces, blood, serum, plasma, milk, and tissue samples (liver, kidney, brain muscle, etc.), and each will be considered in its own right as a sample species.

A. Urine

Urine is formed in the kidneys. Each minute, approximately 600 mL of blood enters each kidney through the renal artery, and as the blood is filtered, water, glucose, vitamins, amino acids, and salts are reabsorbed back into the bloodstream. Normal urine consists of 95% water, and the remaining ingredients include waste products from the breakdown of protein, hormones, electrolytes, pigments, toxins, and any abnormal components. Thus, the main components of urine are (salt) water and waste products. The major waste product from cells in the body is ammonia, and the major waste product from blood is a broken form of heme called bilirubin. In the liver, each of these is converted into a less hazardous form. Ammonia is converted to urea, and bilirubin is degraded to urobilins. Salt, water, and urea are all colorless, but urobilins (which come from degraded pigments) are yellow. Freshly voided

urine is generally clear and pale to deep yellow in color. The yellow color is due to the presence of urochrome, a pigment derived from the breakdown of hemoglobin. The more concentrated the urine, the deeper the yellow color. An abnormal color may be due to certain foods or may be due to the presence of bile pigments or blood in the urine. Some drugs and vitamins may also alter the color of urine. Urine is usually slightly acidic (pH around 6) but may vary from 4.5 to 8.0 depending on the acid/base status of the body. A vegetarian diet, prolonged vomiting, and bacterial infection of the urinary tract all cause the urine to become alkaline. From the point of view of sample incorporation into a cocktail, the components present, which are likely to cause problems, are color, protein and protein breakdown products, and divalent/trivalent ions. Individually, these are relatively easy to cope with, but together they present an unusual problem. Color is present to some degree in every urine sample, and the base effect of such color is quenching. The degree of quenching is related to the color present, and therefore, whenever counting urine samples, it is critical to measure sample activities in DPM (disintegrations per minute). In addition, the volume of sample will also contribute to quenching. Since the color of urine samples is infinitely variable and sample volume can also vary, working in DPM is strongly recommended. This will ensure that the use of the correct quench curves will correct for the effect of quench and report the true activity present in the sample.

1. Sample preparation

Protein and protein breakdown products cause an interesting problem, in which, after the addition of urine to certain cocktails, a wispy precipitate forms, usually just below the surface. This can develop either rapidly (within 1 hour) or slowly (over 1 day). This phenomenon is most probably due to protein unfolding in the presence of the detergents present in the cocktail, and such unfolding causes the proteins to precipitate out, albeit slowly. This effect does not usually affect counting reproducibility, but if it is seen as a potential problem, it can be stopped usually by adding 10%–15% of IPA or ethanol. Simply add 1.0 mL IPA to the 10.0 mL cocktail prior to adding the urine sample. Since count times for urine samples in ADME are not excessive, this phenomenon can generally be dismissed unless very low levels are being measured. For low levels of activity, the count times are much longer, and therefore, stability is of major importance.

Divalent and trivalent ions (e.g., sulfate and phosphate) will adversely affect the microemulsion capability of many cocktails. However, the concentration of these ions in urine is usually so low that they should not cause a problem; however, in combination with the other ions present in urine (urea, sodium, potassium, magnesium, calcium, etc.),

there can be problems, especially in concentrated urine samples. If the urine does not mix properly with the cocktail (forms a milky mixture), then such a problem has occurred. To resolve this problem either change to a cocktail that is able to accept more concentrated solutes or dilute the urine sample with distilled or deionized water (urine:water is 1:1). Urine from small animals (e.g., rat and mouse) is usually much more concentrated than that from humans and therefore will cause all the problems mentioned above; it is recommended that the sample volume be kept below 0.5 mL per 10 mL cocktail. Specialist cocktail selection as well as dilution with water may be necessary to obtain a stable counting condition.

One final problem that can occur is chemiluminescence, and this is characterized by a dropping CPM with time. If chemiluminescence is suspected, then resolution usually involves either selecting a specialist cocktail or allowing the chemiluminescence reaction to go to completion, that is, allowing the sample/cocktail mixture to stand for a fixed time period before counting. The determination of this period is straightforward, but a nonactive urine sample is required according to the following:

1. Add cocktail to a glass scintillation vial.
2. Add a urine sample that does not contain radioactivity.
3. Place in the counter and arrange for repeat 2 minute counts.
4. Continue repeat counting until the CPM stabilizes.
5. Calculate the total time taken for CPM stabilization, and this becomes the fixed period the sample needs to stand before starting counting.

Provided attention is paid to the above, the preparation and counting of even difficult urine samples can be successfully completed.

B. Whole blood

Because whole blood contains living cells, blood is alive. Whole blood is living tissue circulating through the heart, arteries, veins, and capillaries carrying nourishment, electrolytes, hormones, vitamins, antibodies, heat, and oxygen to the body's tissues. Whole blood contains red blood cells, white blood cells, and platelets suspended in a watery fluid called plasma. Red blood cells and white blood cells are responsible for nourishing and cleansing the body. Since the cells are alive, they too need nourishment. Vitamins and minerals keep the blood healthy. The blood cells have a definite life cycle, just as all living organisms do. Red blood cells, or erythrocytes, carry oxygen throughout the body. A drop of blood, of the size of a pinhead, contains approximately 5 million red blood cells. They are small biconcave disks without a nucleus and get their red color from an iron-containing protein called hemoglobin, which is the iron-containing oxygen-transport metalloprotein in the red

cells of the blood in mammals and other animals. The molecule consists of globin, the apoprotein, and four heme groups, an organic molecule with an iron atom.

1. Sample preparation

Because of its complex nature and extreme color, blood should not be added directly to a cocktail. Such an attempt will result in a highly color-quenched and nonhomogeneous mixture that will not lend itself to accurate or reproducible counting. To prepare blood samples for counting, treatment by solubilization (digestion) is required. As described previously, solubilization is the action of certain chemical reagents on organic materials (such as animal tissue) that affects a structural breakdown (or digestion) into a form that can then be directly incorporated into a liquid scintillation cocktail. The source of blood and the correct choice of solubilizer will significantly influence the results of digestion. In general, most of the sample preparation problems occur with blood samples from smaller animals such as rats and mice. In this case, it may be necessary to consider smaller sample volumes, and even then, there can still be color quench problems. An alternative method that may be considered is sample combustion, but this is only applicable if the isotopes of interest are tritium and/or carbon-14. The principle of sample oxidation is that the sample is combusted in an oxygen-rich atmosphere, and any hydrogen present is oxidized to water, whereas any carbon is oxidized to carbon dioxide. If tritium is present, then the combustion product will be $^3\text{H}_2\text{O}$, and if carbon-14 is present, then the combustion product will be $^{14}\text{CO}_2$. In commercially available instruments, the water is condensed and then washed into a vial where it is mixed with an appropriate LSC cocktail. The CO_2 is trapped by reaction with an amine, and the resulting product is mixed with a specialist LSC cocktail. At the end of the combustion cycle, two separate samples (a tritium sample and a carbon-14 sample) are produced at ambient temperature, thus minimizing cross-contamination.

The successful preparation of blood samples for LSC counting by solubilization can often be technically difficult, and successful digestion can be largely dependent on the practical experience of the researcher. To process a sample, simply add the solubilizer and heat at 50–60°C until the sample is dissolved. After solubilization, the sample may be colored, and this color can usually be removed or reduced by treatment with hydrogen peroxide. The final step is to add the recommended LSC cocktail, and the sample is ready for counting. Using this method, many samples can be processed simultaneously and then counted sequentially. Currently available on the market are two types of solubilizers: a quaternary ammonium hydroxide in organic solvents and an inorganic alkali in water with added detergents. Examples of the former include Soluene-

350 (PerkinElmer), GoldiSol (Meridian Biotechnologies Ltd.), and ScintiGest (Fisher Scientific). Soluene-350 is based on a mixture of toluene and methanol, and as such is classified as both toxic and flammable. GoldiSol, on the other hand, is based on a mixture of IPA and water, and it is only classified as flammable. ScintiGest is similar to Soluene-350 and is based on toluene and methanol.

The only two versions of an aqueous-based solubilizer are Solvable (PerkinElmer) and AqueiGest (Meridian Biotechnologies Ltd.). The respective stepwise processes for solubilization with these different solubilizers are as follows:

a. Quaternary ammonium hydroxide method (GoldiSol and Soluene-350)

1. Add a maximum of 0.4 mL of blood to a glass scintillation vial.
2. Add, while swirling gently, 1.0 mL of a mixture of solubilizer and IPA (1:1 or 1:2 ratio). Ethanol may be substituted for the IPA if desired.
3. Incubate at 55–60°C for 2 h. The sample at this stage will be reddish-brown.
4. Cool to room temperature.

5. If using GoldiSol solubilizer, the following treatment with H₂O₂ should be followed:

Up to 0.5 mL of 30% hydrogen peroxide can be added in one addition as almost no foaming occurs. This significantly reduces the sample preparation time.

If using Soluene-350 solubilizer, the following treatment with H₂O₂ should be followed:

Add 0.2–0.5 mL of 30% hydrogen peroxide in 100 µL aliquots. Foaming occurs after each addition; therefore, gentle agitation is necessary. Keep swirling the mixture until all foaming subsides, and then repeat the process until all of the hydrogen peroxide has been added.

6. Allow to stand for 15–30 minutes at room temperature to complete the reaction.
7. Cap the vial tightly and place in an oven or water bath at 55–60°C for 30 minutes. The samples at this stage should now have changed to slightly yellow. This is important as heating destroys residual hydrogen peroxide, which, if present, can induce unwanted chemiluminescence.
8. Cool to room temperature, and add 15 mL of recommended LSC cocktail.
9. Temperature and light adapt for 1 hour before counting.

b. Aqueous-based solubilizer (AqueiGest and Solvable)

1. Add a *maximum* of 0.4 mL blood to a glass scintillation vial.
2. Add 1.0 mL *solubilizer*.
3. Incubate the *sample* at 55–60°C for 1 hour. The sample at this stage will be brown/green in appearance.

4. Add 0.1 mL of 0.1 M EDTA-disodium salt solution, which helps reduce foaming when the subsequent hydrogen peroxide is added. This reagent also complexes iron that has been released during digestion and produces a mixture that is less colored.
5. Add 0.3–0.5 mL of 30% hydrogen peroxide in 100 µL aliquots. Slight foaming will occur after each addition; therefore, gentle agitation is necessary. Keep swirling the mixture until all foaming subsides, and then repeat the process until all of the hydrogen peroxide has been added.
6. Allow to stand for 15–30 minutes at room temperature to complete the reaction.
7. Cap the vial tightly and place in an oven or water bath at 55–60°C for 1 h. This is important as heating destroys residual hydrogen peroxide, which, if present, can induce unwanted chemiluminescence. The color will change from brown/green to pale yellow.
8. Cool to room temperature, and add 15 mL of recommended LSC cocktail.
9. Temperature and light adapt for 1 hour before counting.

Both the above methods apply not only to blood but also to any other biological tissue sample, and the only modifications required are concerned with the sample sizes. Since the products of such solubilization are in an alkaline mixture, there is a high degree of probability that chemiluminescence may be present. Whenever a new method is being evaluated, it is strongly recommended that checks are carried out to confirm that the solubilizers and LSC cocktails do not produce unwanted chemiluminescence. This check should also be carried out on new deliveries of LSC cocktail to confirm quality. To determine if there is a potential problem, follow the steps below:

1. Add the appropriate volume of selected cocktail to a glass scintillation vial.
2. Add the appropriate volume of solubilizer.
3. Shake thoroughly to form a stable mixture.
4. Place in the counter, and arrange for repeat 2 minutes counts.
5. If normal background levels are observed, there is no chemiluminescence.
6. If higher than expected CPMs are observed, repeat counting until CPM falls to normal background levels.
7. Calculate the total time taken for CPM stabilization, and this becomes the fixed period that the sample needs to stand before starting counting after the solubilization process.

Chemiluminescence is produced by an interaction between free peroxides and alkaline material. The free peroxides originate from the cocktail and more specifically from the ethoxylate detergents present in the cocktail. Over

time, the ethoxylate polymer chain breaks down, and the result is a free peroxide entity. In general, freshly manufactured LSC cocktail is peroxide-free, but with prolonged storage, the level of peroxide will increase, and therefore, attention should be given to the age of the cocktail being used in solubilization studies. Although blood is a complex mixture and solubilization is an involved process, it is possible to successfully process and count blood samples both accurately and reproducibly. As with urine, it is critical that quench curves be used to record activity in DPM due to the variable quench present in solubilized samples.

C. Plasma and serum

Plasma constitutes 55% of blood volume and serves as a transport medium for glucose, lipids, hormones, products of metabolism, carbon dioxide, and oxygen. Plasma is obtained by separating the liquid portion of the blood from the cells. It is a straw-colored clear liquid made up of 90% water and rich in protein. Significant numbers of red and white blood cells as well as platelets are suspended in plasma. It also contains various proteins: albumin (the main protein), fibrinogen, and globulins (including antibodies). Serum is the same as blood plasma except that clotting factors (such as fibrin) have been removed. Serum resembles plasma in composition but lacks the coagulation factors and is obtained by letting a blood specimen clot prior to centrifugation.

1. Sample preparation

Plasma and serum samples can be added directly to LSC cocktails, but consideration needs to be given to the presence of proteins, color, sample volume, sample/cocktail compatibility, and the biological origin of the sample. The high concentration of proteins in plasma and serum usually produces a wispy precipitate, similar to that seen with urine samples. This can develop either rapidly (within 1 h) or slowly (over 1 day). This phenomenon is most probably due to protein unfolding in the presence of the detergents in the cocktail, and such unfolding causes the proteins to precipitate out, albeit slowly. This effect does not usually affect counting reproducibility, but if it is seen as a potential problem, it can be stopped usually by adding 10%–15% of IPA or ethanol. Simply add 1.0 mL or 1.50 mL IPA to 10.0 mL LSC cocktail prior to adding the plasma or serum sample.

Color is present to some degree in plasma and serum samples, and the base effect of such color is quenching. The degree of quenching is related to the color present, and therefore, whenever counting plasma and serum samples, it is important to use quench curves and report sample activities in DPM, thus ensuring that the true activity present in the sample is reported.

The complex nature of plasma and serum signifies that plasma and serum samples do not mix easily with most LSC cocktails; therefore, it is suggested that manufacturers are consulted for recommendations as to which cocktails are most suitable. Whatever cocktail is recommended, it should always be evaluated prior to commencing any work. This should be carried out in glass vials, as it allows close visual inspection of the cocktail/sample mixture. The appearance of such samples will be somewhat different from others encountered in LSC in that they will fluctuate from slightly to highly opalescent. Samples thus prepared should be allowed to stand at the counting temperature for at least 1 hour for confirmation of stability. Provided there is no obvious two-phase separation, they will remain stable. Whatever cocktail is selected, the maximum sample volume will be low; most suitable cocktails will only accept a maximum of 1.0 mL plasma or serum in 10.0 mL cocktail. Samples from small animals are considerably more problematic, and although sample volume is usually 100–250 μ L, compatibility with LSC cocktail will be an issue.

Alternative sample preparation methods include sample combustion and solubilization. If solubilization is being used, either of the methods previously detailed under blood can be used, and these are suitable for processing up to 1.0 mL of plasma or serum. Sample combustion is also suitable for processing plasma and serum samples, but it should be remembered that this is only suitable for samples containing tritium and/or carbon-14.

D. Muscle, skin, heart, brains, and stomach

The epithelium is usually the layer of cells that resides “closer” to the outside world. The outermost layer of skin is composed of dead scaly or plate-like epithelial cells. Other examples are the mucous membranes lining the inside of mouths and body cavities. Internally epithelial cells line the insides of the lungs, the gastrointestinal tract, and the reproductive and urinary tracts and make up the exocrine and endocrine glands. The primary functions of epithelial cells include secretion, absorption, and protection. As the name suggests, connective tissue holds everything together. Loose connective tissue holds organs and epithelia in place and contains a variety of proteinaceous fibers, including collagen and elastin. Ligaments and tendons are a form of fibrous connective tissue. In most vertebrate cartilage, it is found primarily in joints, where it provides cushioning. Muscle cells contain contractile filaments that move past each other and change the size of the cell, and there are three general types of muscle. The first two are “striated,” they contain filaments of striated muscle, and the third type is “smooth.” Smooth muscle differs from striated muscle in that the fibers of the smooth muscles are not arranged regularly, whereas those of striated muscles are arranged

regularly. Smooth muscles are used to sustain longer or even near-permanent contraction, whereas the striated muscles are often used for short, burst activities. The most obvious examples of nervous tissue are the cells forming the brain, spinal cord, and peripheral nervous system. The nervous system consists chiefly of two types of cells: neurons and glia. Neurons are the primary cells of the nervous system, and glia are secondary cells involved in nourishment and structural support. The next levels of organization in the body are organs, which are structures that contain at least two different types of tissue functioning together for a common purpose, e.g., heart and stomach.

1. Sample preparation

Since any radioactivity that resides within an organ cannot be accurately measured by LSC, some type of destructive sample preparation is necessary to release or convert the radioactivity into a form more conducive to analysis by LSC. Such sample preparation usually involves solubilization (alkaline hydrolysis), which is the action of certain chemical reagents on organic materials (such as animal tissue) that affects a structural breakdown (or digestion) into a liquid form that can then be directly mixed with a liquid scintillation cocktail. Since we are dealing with solubilization, the recommended reagents are the same as mentioned previously.

The method of solubilizing all of the above is relatively straightforward, and apart from possible color formation with certain tissue types, no major problems should be encountered during sample preparation and LSC. The method can be considered a general method and is as follows:

1. Place selected sample (up to 200 mg) in a 20-mL glass scintillation vial.
2. Add an appropriate volume of solubilizer (1–2 mL depending on sample size).
3. Heat in an oven or water bath at 50–60°C with occasional swirling until the sample is completely dissolved.
4. Cool to room temperature.
5. If color is present, add 100 μ L of 30% (100 vol) hydrogen peroxide and allow to stand for 10–15 minutes or until any reaction has subsided. If no color is present proceed to step 7.
6. Heat again at 50–60°C for 30 minutes to complete decolorization.
7. Add 10 mL of a recommended cocktail.
8. Temperature and light adapt for at least 1 hour before counting.

Although all of these samples can be solubilized, it is important to note that there are a few exceptions. There are two particular samples that cannot be solubilized with the aqueous-based solubilizer, and these are arteries/veins and

stomach tissue. Both of these sample types are only very slowly or partially solubilized by an aqueous-based solubilizer, and for complete solubilization, the quaternary ammonium hydroxide type must be used.

E. Liver and kidney

The liver plays a major role in metabolism and has a number of functions in the body, including detoxification, glycogen storage, and plasma protein synthesis. The kidney is part of the urinary system and filters wastes (especially urea) from the blood. It then excretes them, along with water, as urine. Renal functions include the excretion of waste material from the bloodstream, secretion of hormones, and maintenance of serum electrolyte, acid–base levels, and osmolality. Both liver and kidney samples are brownish in color and in addition contain blood or blood decomposition products. As a consequence, sample preparation by solubilization will be similar to that used for whole blood, and as with blood, it is possible to use both solubilizer types mentioned previously.

1. Sample preparation

The methods utilized for the preparation of liver and kidney samples are as follows:

a. Aqueous-based solubilizer method

1. Add a maximum of 100 mg liver or kidney to a glass scintillation vial.
2. Add 1.0 mL solubilizer (AquiGest or Solvable).
3. Incubate the sample at 55–60°C for 1 hour.
4. Add 0.1 mL of 0.1M EDTA-disodium salt solution, which helps reduce foaming when the subsequent hydrogen peroxide is added. This reagent also complexes iron that has been released during digestion and produces a mixture that is less colored.
5. Add 0.3–0.5 mL of 30% hydrogen peroxide in 100 μ L aliquots. Slight foaming will occur after each addition; therefore, gentle agitation is necessary. Keep swirling the mixture until all foaming subsides, and then repeat the process until all of the hydrogen peroxide has been added.
6. Allow to stand for 15–30 minutes at room temperature to complete the reaction.
7. Cap the vial tightly, and place it in an oven or water bath at 55–60°C for 1 hour. This is important as heating destroys residual hydrogen peroxide, which, if present, can induce unwanted chemiluminescence. The color will change to pale yellow.
8. Cool to room temperature, and add 15 mL of recommended LSC cocktail.
9. Temperature and light adapt for 1 hour before counting.

b. Quaternary ammonium hydroxide method

1. Add a maximum 100 mg liver or kidney to a glass scintillation vial.
2. Add 1.0 mL of selected solubilizer (GoldiSol or Soluene-350).
3. Incubate at 55–60°C for 2 hours.
4. Cool to room temperature.
5. *If using GoldiSol solubilizer*, the following treatment with H₂O₂ should be followed:

Up to 0.5 mL of 30% hydrogen peroxide can be added in one addition as almost no foaming occurs. This significantly reduces the sample preparation time.

If using Soluene-350 solubilizer, the following treatment with H₂O₂ should be followed:

- Add 0.2–0.5 mL of 30% hydrogen peroxide in 100 µL aliquots. Foaming occurs after each addition; therefore, gentle agitation is necessary. Keep swirling the mixture until all foaming subsides, and then repeat the process until all of the hydrogen peroxide has been added.
6. Allow to stand for 15–30 minutes at room temperature to complete the reaction.
 7. Cap the vial tightly, and place it in an oven or water bath at 55–60°C for 30 minutes. The samples at this stage will now be slightly yellow. This is important as heating destroys residual hydrogen peroxide, which, if present, can induce unwanted chemiluminescence.
 8. Cool to room temperature, and add 15 mL of recommended LSC cocktail.
 9. Temperature and light adapt for 1 hour before counting.

Solubilization of liver and kidney always results in highly colored samples due to the presence of bilirubin; in addition, such samples from small animals will produce even more color. It is strongly recommended that sample size should not exceed 75 mg for small animal samples. The aqueous-based solubilizer type has proved to be better than the quaternary ammonium hydroxide solubilizer for these particular sample types, mainly due to significantly less color development at the end of the solubilization process. If excessive color still develops, then one way of reducing the interference is to increase the volume of LSC cocktail from 15 to 20 mL. In effect, this is diluting the color, but it is nevertheless a solution to the problem. Due to the presence of color quenching, it is critical that quench curves be used to record sample activity in DPM. Do not report results in CPM, as these will vary from sample to sample.

F. Fatty tissue

Fatty tissue is a kind of body tissue containing stored fat that serves as a source of energy. It also contains adipose

tissue and serves to cushion and insulate vital organs. Fatty tissue is made up of fat cells, which are a unique type of cell. White fat cells are large cells that have very little cytoplasm (only 15% cell volume), a small nucleus, and one large fat droplet that makes up 85% of cell volume. Due to the chemical nature of fats, they are difficult to solubilize and only the quaternary ammonium hydroxide type of solubilizers are capable of solubilizing fatty tissue. Even then, the rate of solubilization is slow and may require up to 24 hours to completely solubilize animal fatty tissue.

1. Sample preparation

Fat samples can be completely solubilized, but it is a matter of time, temperature, and sample condition. Recommendations include the following:

1. cutting the fat samples into small pieces, which increases the surface area and hence the rate of reaction;
2. carrying out the solubilization at 60°C or even slightly higher; and
3. adding a small amount of IPA.

Other than the rate of solubilization, the only problem that will occur is color formation. Solubilization of fatty tissue almost invariably results in yellow coloration of the final mixture.

The recommended method is as follows:

1. Add a maximum 100 mg finely divided fat to a glass scintillation vial.
2. Add 1.0 mL of selected solubilizer and optionally 1.0 mL IPA.
3. Incubate at 60°C until the entire fat sample is solubilized (may take 10–15 hours).
4. Cool to room temperature.
5. *If GoldiSol is used as the solubilizer*, the following treatment with H₂O₂ should be followed:

Up to 0.5 mL of 30% hydrogen peroxide can be added in one addition, as almost no foaming occurs. This significantly reduces the sample preparation time.

If Soluene-350 is used as the solubilizer, the following treatment with H₂O₂ should be followed: Add 0.2–0.5 mL of 30% hydrogen peroxide in 100 µL aliquots. Foaming occurs after each addition; therefore, gentle agitation is necessary. Keep swirling the mixture until all foaming subsides, and then repeat the process until all of the hydrogen peroxide has been added.

6. Allow to stand for 15–30 minutes at room temperature to complete the reaction.
7. Cap the vial tightly, and place it in an oven or water bath at 55–60°C for 30 minutes. The samples at this stage will now be slightly yellow. This is important as heating destroys residual hydrogen peroxide,

which, if present, can induce unwanted chemiluminescence.

8. Cool to room temperature, and add 15 mL of recommended LSC cocktail.
9. Temperature and light adapt for 1 hour before counting.

As described previously, due to the presence of color quenching, it is critical that quench curves be used to record activity in DPM. Do not report results in CPM, as these will vary from sample to sample.

G. Feces

Feces are body waste formed of undigested food that has passed through the gastrointestinal system to the colon. Feces are produced and stored in the colon until eliminated. A proportion of feces is inner gut lining. Normally, when blood cells become old, they are trapped and destroyed by the spleen. When this occurs, the hemoglobin must be broken down in the liver to bilirubin to be disposed of. Bilirubin is eventually excreted in the bile and leaves the body in the feces. Its presence is the reason why feces are brown in color. Feces are mostly made of water (about 75%); the rest is made of dead bacteria that helped with food digestion, living bacteria, protein, undigested food residue (known as fiber), waste material from food, cellular linings, fats, salts, and substances released from the intestines (such as mucus) and the liver.

1. Sample preparation

The digestion of feces strongly depends on the type of animal. It is possible to use both the quaternary ammonium hydroxide type and the aqueous-based solubilizers; however, there can be problems with residual color and incomplete digestion due to the presence of cellulose-type material present in feces from species such as rabbit. The method is the same as shown previously for muscle, skin, heart, stomach, brains, and stomach tissue.

An alternative method involves the use of a sodium hypochlorite solution, and this reagent was successfully used to digest guinea pig feces. During this procedure, the sodium hypochlorite solution decomposes and a small amount of free chlorine gas is produced. Care should be taken when opening the vials after solubilization as chlorine gas will be present. It is recommended that this part of the procedure be carried out under an efficient fume hood. With this method, the choice of LSC cocktail is critical. The addition of sodium hypochlorite to almost every cocktail produces an unusual form of chemiluminescence, which manifests itself either immediately or gradually over a 24 hour period. Until now, the only LSC cocktail that is unaffected by this phenomenon is the [PerkinElmer](#) cocktail Hionic-Fluor. With this method, isotope recoveries of

greater than 98% for tritium were achieved, and these were confirmed by combusting the same sample in a sample oxidizer ([PerkinElmer](#) Tri-Carb Sample Oxidizer, Model 307).

The solubilization method used for processing the feces sample is as the following:

1. Weigh 50–150 mg of feces into a 20-mL glass scintillation vial.
2. Add 0.5 mL of sodium hypochlorite solution, and cap tightly.
3. Heat in an oven or water bath at 50–55°C for about 30–60 minutes with occasional swirling. All the brown color of the feces will disappear, and a white fibrous material remains.
4. Cool to room temperature.
5. Remove the cap, and blow out any remaining chlorine in a fume hood using a gentle stream of air or nitrogen.
6. Add 15 mL of Hionic-Fluor or Gold Star cocktail, and shake to form a clear mixture.
7. Temperature and light adapt for 1 hour before counting.

After digestion, a small amount of white residual matter (most probably undigested cellulose) may remain; however, this should not affect the recovery. Sodium hypochlorite is more commonly known as bleach and should have greater than 5% available chlorine if it is to be an effective solubilizer.

H. Homogenates

A homogenate is produced when a tissue sample has been mechanically disrupted. This releases the organelles from the cell. The resultant fluid is known as the homogenate, which is then filtered to remove any complete cells and large pieces of debris. The only problem with direct counting of homogenates is sample/cocktail compatibility. This can be resolved by either using a cocktail, which is compatible with the sample (e.g., Ultima Gold, Gold Star, ProSafe+, or Hionic-Fluor), reducing the sample size (recommended sample volume is 0–2 mL) or increasing the cocktail volume to obtain a clear mixture. Usually, the homogenate is prepared in either water or 7:3 ethanol:water, and the counting is carried out at or slightly below 20°C. With some homogenates, it may be necessary to reduce sample volume considerably or even change to the use of a solubilizer with a cocktail (e.g., GoldiSol and Gold Star or Soluene-350 and Hionic-Fluor). Alternatively, the use of combustion (sample oxidation) is a more than acceptable alternative.

I. Solubilization and combustion

Solubilization is the action of certain chemical reagents on organic materials (such as animal or plant tissue) that

affects a structural breakdown (or digestion) into a liquid form that can then be directly dissolved in a liquid scintillation cocktail. Typical solubilizers include organic and inorganic alkalis, which act by the process of alkaline hydrolysis, and certain mineral acids, which affect solubilization by acidic oxidation. The solubilization process usually involves heating the sample/solubilizer at an elevated temperature (40–65°C) for periods ranging from <1 to 24 hour, until a homogeneous mixture is formed. Certain samples that remain colored after solubilization are optionally treated with hydrogen peroxide, and following this, a recommended LSC cocktail is added and the sample is ready for analysis by LSC. The decision to use either solubilization or combustion can be a difficult one. Below is a list of the relative advantages and disadvantages of each technique, and these should help with the decision process. Whichever is chosen, careful attention to sample preparation, reagent, and LSC cocktail selection is critical to successful analysis.

The principle of sample oxidation is that the sample is combusted in an oxygen-rich atmosphere, and any hydrogen present is oxidized to water, whereas any carbon is oxidized to carbon dioxide. If tritium is present, then the combustion product will be $^3\text{H}_2\text{O}$, and if ^{14}C is present, then the combustion product will be $^{14}\text{CO}_2$. In the Model 307 Sample Oxidizer (PerkinElmer, Inc.), the water is condensed in a cooled coil and then washed into a vial where it is mixed with an appropriate LSC cocktail. The CO_2 is trapped by vapor-phase reaction with an amine, and the resulting product is mixed with an appropriate LSC cocktail. At the end of the combustion cycle, two separate samples (a tritium sample and a ^{14}C sample) are trapped at ambient temperature, thus minimizing cross-contamination. An alternative instrument—the Pyrolyser-Trio (Raddec Ltd., Southampton, UK)—was designed to simultaneously extract $^3\text{H}_{\text{total}}$ (and ^{14}C) from virtually any type of nuclear and environmental sample. The standard methodology consists of placing weighed samples into silica glass boats that are then inserted into their own silica worktube (1 m long) containing 10 g of platinized alumina catalyst. A laminar flow of air or oxygen is passed over the sample while it is progressively ramped in temperature typically from 50–900°C over a period of about 3 hours. This controlled oxidation ensures that decomposition is slow and does not lead to any pressure excursions as the sample components decompose and liberate CO_2 , hydrocarbons, water, etc. The oxidized combustion products (water/ $^3\text{H}_2\text{O}$ and CO_2) are collected in bubblers from which subsamples are taken for LSC measurement.

The typical advantages of solubilization are as follows:

- Capital outlay is low.
 - Homogeneous samples are produced.
 - Many samples can be processed simultaneously.
 - Color quench is corrected using a quench curve.
 - It is suitable for a diversity of isotopes.
- The disadvantages of solubilization are as follows:
- Sample sizes are generally ≤ 200 mg.
 - Time to complete solubilization can vary from a few hours to many hours.
 - Certain samples require modified techniques or longer solubilization times.
 - With acidic solubilizers, loss of radioactivity by volatilization may occur.
 - Excess peroxide must be destroyed after decolorization.
 - Chemiluminescence may be present.
 - If ^3H and ^{14}C are both present in the sample, then dual-label DPM calculation is necessary.
- The advantages of sample combustion are as follows:
- Sample processing time is rapid.
 - Sample can be wet, dry, or freeze-dried.
 - Any sample containing H and/or C can be combusted.
 - It is ideally suited for both single- and dual-label ^3H and ^{14}C .
 - Sample sizes up to 1.5 g are possible.
 - Radioactive recovery is excellent ($>97\%$).
 - Memory effect is $<0.08\%$.
 - There is no loss of radioactivity by volatilization.
 - There is no chemiluminescence interference.
 - There is no color quench interference.
- The disadvantages of sample combustion are as follows:
- Initial capital investment is required.
 - It is only suitable for ^3H and ^{14}C .
 - It needs a gas supply (oxygen and nitrogen).
 - It must be operated in a fume hood.
 - Reagents are corrosive and flammable.

IX. Filter and membrane counting⁵

Filter counting, or solid support counting, as it is sometimes known, is probably best described as heterogeneous counting. The main difference between homogeneous counting and heterogeneous counting is that homogeneous counting relies on 4π geometry, whereas 2π geometry applies to heterogeneous counting. An explanation of the terms 4π and 2π geometry is needed to appreciate the differences between the two counting techniques. In homogeneous counting, the sample is completely “dissolved” in the liquid scintillation cocktail; therefore, the photons of light (scintillations), which are emitted as the end result of the energy transfer process within the liquid scintillation cocktail, are free to radiate in any direction. In

geometric terms, this freedom of radiation is described by a sphere or globe whose surface area is $4\pi r^2$.² In heterogeneous counting, this freedom is restricted by the presence of the filter or membrane, which absorbs both the kinetic energy of β -particles and the photons of light passing in one plane; therefore, the emitted light can only occupy the surface area of a hemisphere, which is $2\pi r^2$.² Hence, the derivation of the expressions 4π and 2π counting geometries, and these are illustrated in Fig. 7.2.

In essence, filter counting can be a relatively simple technique where the sample is isolated or collected on a filter and usually dried. This filter is placed in a scintillation vial, a small volume of an appropriate LSC cocktail such as Ultima Gold F or ProSafe FC+ is added, and, after ensuring that the filter is completely wetted, the vial is counted.

A. Elution situations

The difficulty in counting on filters or other solid supports is that when the sample is immersed in a cocktail, four situations may develop:

1. The sample may remain bound to the filter or solid support—no elution situation.
2. The sample may be partially eluted by the cocktail—partial elution situation.
3. The sample may have certain solubility in the cocktail—equilibrium situation.
4. The sample may be completely dissolved in the cocktail—complete elution situation.

Of these, the one to avoid is partial elution as the soluble fraction is counted with 4π geometry, whereas the insoluble (filter bound) portion is counted with 2π geometry. This will make measurement under these circumstances irreproducible. However, a partial elution situation may go to equilibrium with time and therefore should not be discounted out of hand. Repeat counting of the sample, over several hours, will determine if an equilibrium situation has been reached, and this is characterized by a constant count rate being obtained over time. If the sample is insoluble (no elution), the efficiency and reproducibility of counting will depend on the magnitude of the β -energy, the nature of the filter or solid support, its orientation in the vial, and the size of the sample molecule. If the sample is completely dissolved or eluted into the cocktail (complete elution), counting considerations will be similar to those of solubilized samples, where a true homogeneous state is obtained. Other factors that affect counting are the presence and composition of the sample precipitate and the amount of sample that becomes soluble in the cocktail (Bransome and Grower, 1970).

B. Sample collection and filters

Self-absorption affects the efficiency of counting on solid supports with low-energy ^3H samples being more susceptible to self-absorption than higher-energy isotope samples such as ^{14}C . The type and amount of sample, thickness, absorption level, and the material of construction of the solid support also influence the self-absorption effect. The order of counting efficiency of solid supports is

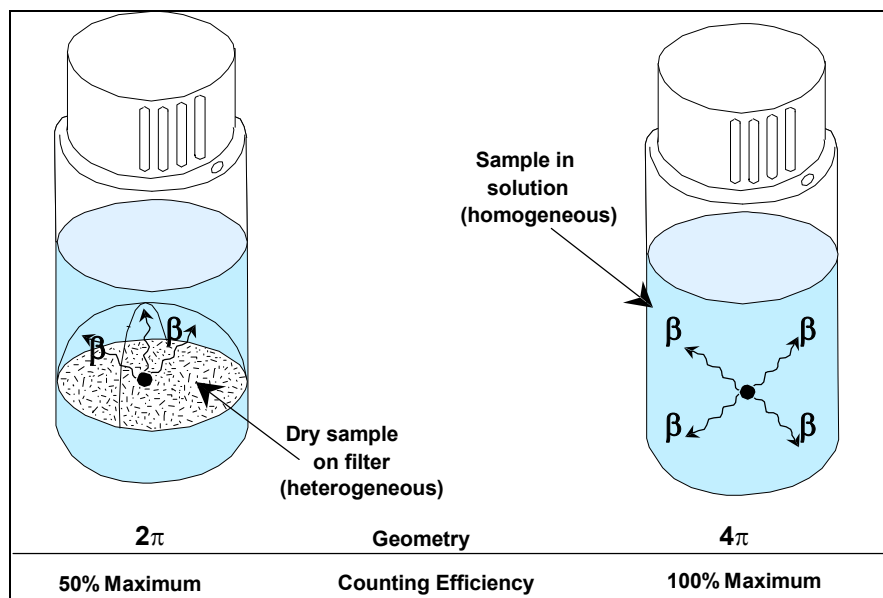

FIGURE 7.2 Sample counting geometries encountered in liquid scintillation analysis.

Glass fiber > cellulose acetate > standard cellulose > chromatographic paper

← Increasing efficiency

(Wang and Jones, 1959; Gill, 1967). This order of efficiency will vary depending on the size of the molecules. Smaller molecules can readily diffuse into amorphous regions of the cellulose fibers, whereas the larger molecules may remain on the surface. Microscopically, glassfiber filters appear as an impermeable virtual network of threads, whereas the paper filters appear as capillary tubes. For glassfiber filters, the efficiency can be markedly different for sample material trapped on the surface as opposed to that embedded in the pores. This is particularly true for low-energy betaparticles from ^3H . In some cases, reproducible counting efficiencies can be obtained by the addition of a carrier of known weight (many times more than the sample), which subsequently induces the same amount of self-absorption for each sample (Wang and Willis, 1965). The carrier must be added before the filtration step, and time must be allowed for complete mixing with the real sample. When using chromatographic paper to isolate or collect samples, one should remember that some grades contain a UV enhancer, and this can be eluted into the cocktail, producing unwanted chemiluminescence. Such spurious counts can lead to an overestimation of the activity of the sample. Provided all of these factors and effects are taken into consideration during sample preparation, successful and reproducible counting can be accomplished using this technique.

C. Filter and membrane types

In practice, there are a number of filter types, which can be used to isolate or collect various sample types for LSC. The choice of filter type will depend on both the nature and particle size of the sample; however, glassfiber filters are recommended if at all practical. Other filter types, which have been used, include cellulose nitrate, cellulose acetate, mixed cellulose esters, polyvinyl chloride (PVC), polyacrylonitrile, normal paper, polycarbonate, Teflon, nylon, and polythene terephthalate. The categories of sample types, which can be analyzed by this technique, include precipitates of macromolecules (such as nucleic acids and proteins), aquatic and terrestrial ecosystem samples (such as algae and phytoplankton), and other deposits (such as airborne particulate matter).

D. Sample preparation methods

The different elution situations influence both the choice of the sample preparation method and the recommended liquid scintillation cocktail.

1. No elution
