This situation is highly desirable since sample preparation for counting by LSC is both simple and rapid. Sample quench is constant, and a simple CPM mode on the LSC is preferred, as external standard quench correction cannot be used. With constant quench and therefore constant efficiency, the CPM results obtained are as accurate as DPM results obtained through normal 4π homogeneous counting. After collection of the sample on the filter, the filter is dried and placed in the vial. Approximately 2–3 mL of cocktail is added (ensuring that the filter is completely wet), and counting can be carried out immediately. For best counting performance using this method, it is recommended that the filter is completely dried prior to the addition of cocktail. Additionally, knowledge of the solubility characteristics of the sample will aid in the selection of the most appropriate cocktail. In general, the most applicable cocktail for dried filter counting is an organic cocktail such as Ultima Gold F or BetaPlateScint, which provides the highest counting efficiency. Occasionally, it is not practical to completely dry the filters; in these cases, a cocktail such as Ultima Gold MV should be used with the slightly damp filters for highest counting performance. The type of samples routinely counted using this method include precipitates from DNA and RNA studies, phytoplankton from seawater, algae from aquatic environments, as well as samples from enzyme activity assays, cell proliferation, and receptor-binding assays.

Note: A simple method to confirm that a no elution situation exists is to decant the cocktail into another vial and recount the cocktail—the absence of activity confirms that no elution has occurred and that the sample is completely bound to the filter. If necessary, accurate quantitation of the total isotope activity (i.e., DPM) can be carried out by removing the filter and using either solubilization or combustion techniques.

2. Partial elution

As previously mentioned, this situation is the least desirable due to the presence of both 2π and 4π geometry within the counting mixture. Any results from this situation will be inaccurate and cannot be reproduced. It is possible, however, using one or a combination of the following methods, to convert the system from a partial to an equilibrium or a complete elution situation:

1. After sample preparation, shake the contents for a fixed time period and recount. Repeat this procedure until constant CPMs are obtained (i.e., equilibrium situation).
2. Change to a cocktail in which the sample has either zero or complete solubility.
3. Extract the sample from the filter with a suitable solvent prior, and add the appropriate cocktail.

3. Complete elution

The goal with complete elution is to convert from 2π to 4π geometry. Two slightly different sample preparation methods are used, in which either the entire filter is dissolved in an appropriate cocktail or the sample is extracted or eluted from the filter prior to the addition of cocktail. In the first instance, the cocktail of choice is Filter-Count, and filter types, which can be dissolved by this cocktail, include cellulose nitrate, mixed cellulose esters, and PVC. Filter-Count will not dissolve cellulose acetate, glass fiber, normal paper, PTFE, nylon, or phosphocellulose filters. With cellulose acetate and glassfiber filters, a transparent appearance results, whereas the others remain relatively unaltered. Filter-Count will not give color formation with any filter whether soluble or insoluble. The use of Filter-Count is extremely simple, in which sample preparation involves adding cocktail (Filter-Count) to the filter, allowing it to dissolve (with optional heating), and then counting. Cellulose acetate is not dissolved by Soluene-350 or by Filter-Count. This filter type can be dissolved by strong hydrochloric acid, and after dissolution and dilution with water, the LSC cocktails Ultima Gold AB or Gold Star LT² are recommended for trouble-free counting. It is important to note that with the exception of cellulose acetate, normal paper, and PET filters, virtually all other filters produce color when used with GoldiSol and Soluene-350. In this variant of the technique, dissolving the filter overcomes the self-absorption problems, saves on drying time (accepts wet or dry filters), and provides reproducible results.

In the second case, as previously described, the sample is extracted or eluted from the filter with a suitable solvent and then counted using the appropriate cocktail.

Note: It is possible to adapt this technique for alpha/beta counting of airborne particulates. Provided the correct filter type is used, the sample filter can be dissolved in Filter-Count, and then Ultima Gold AB can be added (ratio of 2:1 Filter-Count:Ultima Gold AB).

The benefits of such a method include the removal of self-absorption problems (especially important for alphas) and significant time saved on sample preparation (ashing and acid extraction steps are eliminated).

The introduction of the [PerkinElmer](#) TopCount microplate scintillation and luminescence counters together with the development of various filter plates offers the ability to count labeled samples in filter plates (24 or 96 samples per plate), minimizing sample preparation steps and increasing sample throughput. A number of publications on the applicability of this assay method are available ([PerkinElmer](#), TopCount Topics 11, 12, and 18). A quick reference table ([Table 7.21](#)) can be used as a guide for selecting

the correct LSC cocktail type for a particular filter or membrane type.

X. Sample stability troubleshooting

Sample stability troubleshooting is the identification and resolution of problems, which can occur as a result of incorrect sample preparation. These problems become apparent during counting and are sometimes not visible during the sample preparation process. These problems can be found wherever samples are mixed with cocktail, irrespective of whether the sample is solid, dissolved in an organic solvent, or dissolved in an aqueous system.

Fundamentally, this problem becomes apparent when one or more of the following LSC situations occur:

1. unstable count rate (decreasing count rate),
2. unstable count rate (increasing count rate), and
3. reduced counting efficiency (reduced more than expected).

All the three abovementioned problems can usually be resolved by minor changes to sample preparation procedures, and/or by careful selection of the correct cocktail.

A. Decreasing count rate

Potential reasons for a decreasing count rate are a two-phase separation of the sample-cocktail mixture (sometimes described as “milky” appearance), precipitation of the radiolabeled sample, and chemiluminescence. When a two-phase situation occurs and the activity is more soluble in the aqueous phase than the organic phase, then, as the two phases separate the activity, it migrates with the aqueous phase and results in lower CPMs. This can be remedied by increasing the cocktail volume or changing to a cocktail more suited to the sample type. In addition, check that the cocktail is suitable for use at the operating temperature (both sample preparation and counting temperature). Precipitation of the radiolabeled sample can be overcome either by diluting the sample with water or a suitable cosolvent or by changing to a more suitable cocktail. A chemiluminescence problem is usually characterized by higher than expected CPMs that decay with time. Chemiluminescence can be overcome either by changing to a chemiluminescence-resistant cocktail such as Hionic-Fluor, Gold Star, Ultima Gold, or equivalent cocktail or by waiting for the chemiluminescence to decay. Additional suggestions include ensuring that the correct cocktail type is in use (i.e., do not use a lipophilic cocktail with aqueous samples) using a glass vial to check that the sample/cocktail mixture is homogeneous and checking that the sample and

cocktail have been thoroughly mixed (shaken) and formed a stable microemulsion. Finally, consult the cocktail phase diagram to verify that the selected cocktail is suitable for use with the sample type.

B. Increasing count rate

Potential reasons for an increasing count rate are a two-phase separation of the sample–cocktail mixture (sometimes described as “milky” appearance), inadequate mixing of sample and cocktail, incomplete elution of the sample from a solid support, and incomplete or slow solubilization of the sample in the cocktail. When a two-phase situation occurs and the activity is more soluble in the organic phase than in the aqueous phase, then, as the two phases separate the activity, it remains in the organic phase and results in increasing CPMs due to the reduction in quench in the organic phase. This can be remedied by increasing the cocktail volume or changing to a cocktail more suited to the sample type. Inadequate mixing of the sample and cocktail, which in essence is the same as the preceding situation, can be easily remedied by ensuring that the mixture is thoroughly shaken. If a sample is incompletely or only slowly eluted from a solid support, increasing CPM will probably result. This can be corrected by modifying the elution conditions to get complete elution. Reagents such as water, alkalisolubilizer, acid, or other solvent may be useful in this instance. In certain cases, provided the appropriate filter material is in use, it may be possible to use a cocktail such as Filter-Count to dissolve the filter and thus separate the sample from the solid support. Where the sample is not completely soluble in the cocktail, then dissolve the sample in a solvent that is more compatible with the cocktail, or add a suitable cosolvent.

C. Reduced counting efficiency

Potential reasons for reduced counting efficiency are either high color quench or high chemical quench in the samples. If the color quench is a result of solubilization, then bleach the sample with hydrogen peroxide, prior to adding cocktail. If the sample is naturally colored (e.g., some metallic salts), dilute with water or use a color-quench-resistant cocktail (e.g., Ultima Gold, Gold Star, ProSafe+ families of cocktail, or equivalent cocktail). Usually, chemical quench results from the use of an inappropriate solvent, which is highly quenching, and therefore, the remedy may simply be to change to a less chemical quenching alternative (e.g., dichloromethane is less quenching than chloroform). The sequence of chemical quench strength is shown in Table 7.22. Other remedies include either increasing cocktail volume or decreasing sample volume. Overall, if the sample preparation method cannot be changed, it may be necessary to increase the count time to obtain better statistical results.

TABLE 7.22 Strength of chemical quenchers.

Solvent	Quench strength
Nitro groups (nitromethane)	Strongest quencher
Sulfides (diethyl sulfide)	↓
Halides (chloroform)	↓
Amines (2-methoxyethylamine)	↓
Ketones (acetone)	↓
Aldehydes (acetaldehyde)	↓
Organic acids (acetic acid)	↓
Esters (ethyl acetate)	↓
(Water)	↓
Alcohols (ethanol)	↓
Ethers (diethyl ether)	↓
Other hydrocarbons (hexane)	Mildest quencher

XI. Swipe assays

All laboratories handling radionuclides are required to conduct radiation safety surveys to maintain their license. These surveys include those necessary to evaluate external exposure to personnel, surface contamination levels, and concentrations of airborne radioactive material in the facility and in effluents from the facility. In Klein et al. (1992), the wisdom of relying on wipe tests for detecting removable radioactivity due to low-energy beta emitters from surfaces has been questioned. Their opinion is that “Without considering the kind and amount of radioactivity present, wipe testing is scientifically misguided and wasteful of resources and personnel ...” They conclude by saying well-reviewed operating procedures and good working practice are the best protection in the work place. It is true that wipe testing may not be very efficient, but it does give some measure of what is removable. For weak beta emitters, especially tritium, there is little choice but to use a wipe test and a liquid scintillation counter to detect its presence. For better or for worse, wipe testing remains an important requirement for all licensees.

A. Wipe media and cocktails

Various wipe media have been evaluated for their ability to gather and release radiolabeled compounds into counting solutions and include filter paper, glassfiber filter, cotton swab, and plastic squares. Virtually, any emulsifying cocktail is suitable for use in this particular area, and the only major prerequisites are that the cocktail has a high tritium counting efficiency and is able to accommodate small volumes of aqueous and alcohol–aqueous samples in

a clear microemulsion. Paper filter circles are not soluble in any of the counting solutions used. Glassfiber filters, in general, became translucent when placed into the counting solution, and the faint outline of the glassfiber filter can be seen on the bottom of the vial. The plastic swabs show different solubility patterns depending on the LSC cocktail used. In some cases, the blue plastic stem can dissolve into a series of blue globs that adhere to the sides and bottom of the vial. When shaken, these globs remained immiscible. Other cocktails can extract the blue color from the plastic tube. The cotton swab can appear dissolved as a clear layer of fluid on top. When shaken, the sample can turn cloudy, again depending on the cocktail used. The thin plastic squares dissolve in most LSC cocktails, but the speed of dissolution depends on the type of cocktail: fast in classical and slow in a safer cocktail. The plastic wipes dissolve rapidly in classical cocktails and appear as droplets either floating on top or laying on bottom of the vial. When shaken, the samples become cloudy. In all cases, when the samples containing the swabs or plastic squares became cloudy on shaking, the count rates did not change when recounted (remained within $\pm 3\%$ of the last count rate).

For quantitation of wiped radioactive contaminants by LSC, it is essential that all the radioactive material be in solution. The contaminants are generally classified as being either water- or organic-soluble material. Organic-soluble material will normally dissolve in the organic solvents contained in the LSC cocktail. To accommodate water-soluble material, an emulsifying cocktail is used with added water. Without water, water-soluble material, such as leucine, cannot be emulsified and will remain undissolved on the solid support, resulting in poor recoveries.

B. Regulatory considerations

Any laboratory using radioactivity would be classed as a restricted area. Therefore, the action level for any α - β contamination would be the presence of radioactivity exceeding 20,000 DPM/100 cm². Assuming that the wiping procedure picked up at least 1% of the surface contamination (a very conservative estimate), there would be a minimum of 200 DPM deposited on the wipe. For tritium, 100% recovery means that 200 DPM would be recovered. With a counting efficiency of 50%, this translates into 100 net CPM. This amount of activity, being greater than five times background (about 20 CPM), can be detected easily. Even if this level of activity were quenched 50%, the activity of 50 net CPM is still easily detected. In a real situation dealing with removable contamination, it would be reasonable to expect that an amount greater than 1% would be picked up by wiping. With this assumption, it would appear that wiping is not an unreasonable method for detecting and following the removal of radioactive contamination from a surface in any biomedical laboratory.

C. Practical considerations

For most isotopes, it is important to have the sample completely dissolved in the cocktail, especially with weak beta emitters such as ³H. Wipe medium selection is largely up to the individual, but the consensus of opinion is that glassfiber filter is the best overall performer. However, paper is probably the most popular medium because of its availability, ease of use, and low cost. In one institution, waste computer paper is cut to size and used as wipes. Cotton swabs are also easy to use, but recoveries are relatively low for both paper and swabs compared with glass fiber and plastic squares. The plastic squares are principally intended for pseudocumene- and xylene-based cocktails in which they are readily soluble. Safer cocktails based on LAB, phenylxylythane, or diisopropylnaphthalene solvents slowly dissolve the plastic wipes but form an immiscible second phase. Surprisingly, it appears that the radioactivity is released into the cocktail during this process, based on reported recoveries. Klein et al. (1992) found that wetting the wipe medium greatly increased the amount of radioactive contamination removed. The problem of wetting wipes is that any solvent will increase the possibility of spreading the contamination. The solvent can cause contamination to further penetrate a surface as well as increase the probability of transfer to the hands. If paper is used, wet paper will lose its strength and tend to shred when moderate pressure, which is recommended, is applied during wiping. The contaminated surface should be exposed to solvents only during the decontamination procedure. Furthermore, it would be an added burden to control the amount of water added to each wipe before wiping a surface.

D. General procedure for wipe testing

Most regulatory guides do not contain any detail on how to conduct these surveys, and the protocols are left to the licensee. However, guidelines do suggest an area of 100 cm² be monitored and the action level of contamination for weak beta emitters to be 2000 DPM/100 cm² in unrestricted areas and 20,000 DPM/100 cm² in restricted areas. In an earlier publication, U.S.A.E.C. Regulatory Guide 1.86, the action level for removable α - β contamination was set at 1000 DPM/100 cm². Before doing any wipes, it is advisable to prepare a map of the area to be monitored. The locations to be wiped should be circled and numbered to identify the wipes after they are completed. Use the same dry wipe medium for all wipes to maintain uniform monitoring conditions. Wipe an area about 100 cm² (approximately 4 × 4 in.) using a moderate amount of pressure. The wipe can be numbered, or it can be placed directly into a numbered counting vial. After the wipe is placed into a vial, counting solution containing ~2% water

FIGURE 7.3 Quenching in the energy transfer process.

is added. The vial is capped and vortexed a few seconds to promote elution from the wipe into the counting solution. The vial is assayed by LSC. One of the most useful consequences of the presence of multichannel analyzers (MCAs) in liquid scintillation counters is that the spectrum of any sample being counted can be visualized online. An inspection of the spectrum can be very helpful in identifying the nature of the sample being counted. For example, if the contamination is due to a single radionuclide, then the visualization of the expected spectrum would confirm this fact. If the sample contained two radionuclides, then the spectrum would also reflect this fact. The ability to identify the components of a mixed sample depends on the relative content of each component. The spectrum can be visualized in either the log or linear form. In general, the log mode is more helpful in detecting the presence of more than one radionuclide in the sample. Finally, any laboratory handling radioactivity should be staffed with properly trained personnel. This assumption is generally true when laboratories first begin this type of work. However, experience has shown that, as time goes by, people tend to forget or neglect the safeguards designed into approved protocols. This is why wipe tests are necessary. Its purpose is to continually ensure safe working conditions within laboratories handling radionuclides. If contamination is detected, viewing the sample spectrum should be helpful in identifying the radionuclides present. Although the wipe test is qualitative at best, the detection of radioactivity significantly over background levels should be the cause for further investigation.

XII. Preparation and use of quench curves in liquid scintillation counting⁶

Basically, the liquid scintillation process is the conversion of the energy of a radioactive decay event into photons of light. PMTs are used to detect and convert the photons into

electrical pulses. Both the sample and the scintillator are dissolved in an aromatic solvent, which allows energy to be transferred. Any factor that reduces the efficiency of the energy transfer or causes the absorption of photons (light) results in quenching in the sample. There are two main types of quench: chemical quench (Gibson, 1980; Birks, 1971) and color quench (Gibson, 1980; Ross, 1965; Ten Haaf, 1975).

A. Chemical quench

Chemical quench occurs during the transfer of energy from the solvent to the scintillator. Any chemical species that is electronegative (electron capturing) will affect the energy transfer process by capturing or stealing the pi electrons associated with the aromatic solvent and thus reduces the availability of pi electrons necessary for efficient energy transfer.

B. Color quench

Color quench is an attenuation of the photons of light. The photons produced are absorbed or scattered by the color in the solution, resulting in reduced light output available for measurement by the PMTs. The steps in the energy transfer process affected by chemical and color quenching are indicated in Fig. 7.3.

The collective effect of quench is a reduction in the number of photons produced and therefore detected CPM. Counting efficiency is affected by the degree of quenching in the sample. To determine absolute sample activity in DPM (absolute activity), it is necessary to measure the level of quench of the samples first and then make the corrections for the measured reduction in counting efficiencies.

C. Measurement of quench

It is possible to measure quench accurately via high-resolution spectral analysis. Quenching manifests itself by a shifting of the energy spectrum toward lower-energy channels in the MCA. On PerkinElmer's Tri-Carb series LSAs, there are two methods of spectral analysis for measuring quench.

6. ©1998–2019, PerkinElmer, Inc. Printed with permission.

The first method is the spectral index of the sample (SIS) that uses the sample isotope spectrum to monitor the quench of the solution. The SIS value decreases as quench increases, reflecting the shift of the spectrum to lower energy.

The second method used to measure quench is the transformed spectral index of the external standard (t-SIE), which is calculated from the Compton spectrum induced in the scintillation cocktail by an external ^{133}Ba gamma source. The source is positioned under the sample vial, causing a Compton spectrum to be produced in the cocktail solution. From a mathematical transformation of this spectrum, the t-SIE value is determined, and t-SIE is a relative value, on a scale from 0 (most quenched) to 1000 (unquenched). The calculated t-SIE value is adjusted to 1000 when the instrument is calibrated. Like SIS, t-SIE decreases as quench increases.

Both SIS and t-SIE are used as quench-indicating parameters (QIPs). t-SIE is independent of the sample isotope and of the activity in the vial and has a large dynamic range. This makes it a very reproducible means of tracking the quench of the cocktail. SIS uses the sample isotope spectrum to track quench; it is most accurate with high-count-rate samples. The range of SIS values reflects the energy range of the isotope. Both can be used as QIPs to create quench curves, although the use of the external standard is preferred for samples containing low activity and is required for multilabeled samples.

D. Quench curve

A quench standard curve is prepared with a series of standards in which the absolute radioactivity (DPM) per vial is constant and the amount of quench increases from vial to vial. A quench curve uses the relationship between counting efficiency and QIP to correct the measured CPM to DPM. When a quench curve is made, the DPM value in each standard is known. Each standard is counted, and the CPM is measured. The counting efficiency is calculated using the following relationship:

$$\frac{\text{CPM} \times 100}{\text{DPM}} = \% \text{Counting Efficiency}$$

At the same time, the QIP is measured for each standard. A correlation is made using the QIP on one axis (X) and the % efficiency on the other axis (Y). A curve is fitted to the standard points. Fig. 7.4 shows the quench curves for ^3H and ^{14}C using SIS as the QIP, and Fig. 7.5 shows the quench curves for the same isotopes using t-SIE as the QIP. Once the quench curve is stored in the instrument computer, it can be used for automatic DPM calculations. When unknowns are counted, the sample CPM and the QIP are measured. Using the QIP, the counting efficiency is determined from the quench curve. Sample DPMs are then calculated by applying the appropriate efficiency to the CPM of the sample:

$$\text{DPM} = \frac{\text{CPM}}{\text{Efficiency (expressed as a decimal)}}$$

The standards and unknowns must be counted with the same energy regions. PerkinElmer LSCs with spectra-based libraries (2500 series, 2700 series, and the new 2900 and 3100 series) store the curve in a $0-E_{\text{max}}$ window and allow the curve to be recalculated for the windows used in the protocol. For other LSCs (1600, 1900, 2100, 2200, and 2300), the windows used to acquire the quench curve must be used in the actual DPM determination.

1. Preparation of quench curves

a. Method 1

As mentioned, a quench standard curve is prepared with a series of standards in which the absolute radioactivity (DPM) per vial is constant and the amount of quench increases from vial to vial. The quench is increased from vial to vial by the addition of a quenching agent. A quenching agent is any chemical or colored material added to the vial that causes a shift in the standard spectrum to a lower energy and a subsequent decrease in the counting efficiency of the radioactive standard.

FIGURE 7.4 Quench curves for ^3H and ^{14}C using spectral index of the sample (SIS) as the quench-indicating parameter.

FIGURE 7.5 Quench curves for ^3H and ^{14}C using transformed spectral index of the external standard (t-SIE) as the quench-indicating parameter.

Usually, a series of 6–10 quench standards are prepared per radionuclide. This series is sometimes referred to as the quench set. [PerkinElmer](#) provides factory-stored quench curves in the instrument for ^3H and ^{14}C . On occasion, it is necessary for the investigator to prepare a quench curve, for isotopes other than ^3H or ^{14}C , for example, ^{35}S . There are some basic considerations to note before preparing a quench curve, which are the following:

- It is necessary to obtain a calibrated source of radioactivity to use as the source of the activity (DPM). It is essential that a known amount of activity be added per vial. Also, the standard material must be compatible with the cocktail chosen.
- A suitable quenching agent must be chosen. It is desirable to closely approximate the chemical environment in the samples. If samples contain water with various other constituents, add the same material in increasing amounts to the standards. Additional quenching agents that are most often used, and available in the laboratory are carbon tetrachloride (CCl_4), acetone ($\text{CH}_3\text{CH}_3\text{CO}$), chloroform (CHCl_3), and nitromethane (CH_3NO_2).

To prepare the quench standards, perform the following steps:

1. Make a batch of radioactive solution in the chosen cocktail such that the desired DPMs are transferred to each individual vial when dispensing the cocktail. Prepare the standards with a sufficient level of activity, typically 50,000–200,000 DPM per vial, to be able to count the standards with good statistics in a short time. If 10 standards are to be made with 10 mL of cocktail per vial, then 100 + mL of radioactive cocktail solution is required. If 15 mL of cocktail is to be used, then 150 + mL of radioactive cocktail is required. Note: If the unknowns to be counted contain two radioisotopes (both ^3H and ^{14}C , for example), then individual standard curves must be prepared for each isotope.
2. Count the individual standards for at least 5 minutes to check for constant activity (CPM). Any sample that

deviates more than 2% from the mean should be discarded.

3. Add incremental amounts of the quenching agent to vials 2 ... n (quenching agent is not added to vial 1) to obtain the desired quench range. It may be necessary to predetermine the amounts to add per vial by testing various volumes of quenching agent added to the cocktail only (no radioactivity) and monitor the amount of cocktail quench using t-SIE; otherwise, add the suggested amounts of nitromethane based on the information given in [Table 7.23](#).
4. Count the complete set under the conditions described in the instrument operation manual for storing a quench curve. Practically, we suggest that the standards are counted to a preselected level of statistical accuracy (generally 0.5% 2 s), and this is usually achieved within 5 min per sample with the sealed standards provided.

TABLE 7.23 Volume of nitromethane needed for quench curve.

Quench level	Toluene standards (15 mL)	Ultima Gold standards (15 mL)
A (1)	0 μL	0 μL
B (2)	1 μL	5 μL
C (3)	5 μL	10 μL
D (4)	11 μL	15 μL
E (5)	17 μL	26 μL
F (6)	25 μL	45 μL
G (7)	35 μL	70 μL
H (8)	45 μL	110 μL
I (9)	55 μL	150 μL
J (10)	66 μL	230 μL

- Once the quench curve(s) are counted and stored, count unknown samples using the stored quench curve(s) to determine the DPM value for each sample.

b. Method 2

Basically, the preparation of a quench curve with any LSC cocktail is relatively straightforward, and the following procedure is given as a guideline. Many researchers use their own methods and equipment, and the procedure is therefore open to modification.

- Dispense 10.0–15.0 mL of LSC cocktail into 10 high-performance glass vials.
- Add activity to each vial (200,000 DPM for ^3H or 100,000 DPM for ^{14}C).
- Count all 10 vials to ensure that the same amount of activity is in each vial. A count time of about 5 min per vial will be sufficient. Any sample that deviates more than 2% from the mean should be discarded.
- Number the vials 1–10 or A–J, and add the suggested amounts of nitromethane based on the information given in [Table 7.23](#).
- Count the complete set under the conditions described in the instrument operation manual for storing a quench curve. [PerkinElmer](#) recommends counting each standard for 30 min or until a preselected level of statistical accuracy (using %2S terminator, generally 0.5%) is reached.

Notes:

- For dispensing the activity, use a glass-barreled micro-liter syringe fitted with a Chaney adapter. Such an adapter ensures reproducible dispensing of activity.
- After preparation, the standards should be stored in the dark, preferably at 5–10°C for best stability.

2. Notes on using the quench curves

- t-SIE is independent of the sample isotope and of the activity in the vial, and has a large dynamic range. This makes it a very reproducible means of tracking quench in the cocktail.
- SIS should only be used when there is at least 500 CPM activity in the sample. Remember that SIS uses the sample isotope spectrum to track quench; it is most accurate with high-count-rate samples. For an accurate SIS, a good sample spectrum needs to be acquired.
- SIS should not be used for low-activity samples since an accurate sample spectrum cannot be acquired.
- Most customers prefer to purchase quenched standards. For cocktails based on toluene, xylene, pseudocumene, or LAB as the solvent, toluene-quenched standards should be used. For cocktails based on DIN

(diisopropylnaphthalene) or PXE (phenylxylylene) as the solvent, Ultima Gold—quenched standards should be used. If the wrong quenched standard is used, there can be an error in DPM. This error is most pronounced with low-energy isotopes such as tritium (see [Tables 7.25–7.28](#)).

- Be sure that your prepared quench curve covers a wide t-SIE range (i.e., 800–300) to provide accurate DPM results.

3. Color quench

When a small amount of color is present in a sample, there is virtually no difference between chemical and color quenching, and the standard chemical quench curves are suitable. This applies to samples where the t-SIE is in the range of 100–400. However, if a significant amount of color is present in the sample (t-SIE is < 100), it may be necessary to consider preparing a color quench curve. When preparing a color quench curve, the selection of a suitable color quench agent is important. Aqueous soluble food dyes are usually a good choice as they provide both a stable color and a wide range of colors. The color of the sample must match the color used in the quench curve. Do not use a pH indicator since some cocktails contain acidic components, and these will alter the color. Preparing a color quench curve is very similar to the method used for a chemical quench curve, and the only difference is the quench agent. If considerable color is present in the sample, it may be wise to modify or change the sample preparation method to either remove or reduce the level of color. Some techniques that have proved useful are shown in [Table 7.24](#).

Finally, the easiest way to reduce color quench is to either decrease the sample size or increase the cocktail volume, or both.

4. Quench curve errors

The errors that can be present when the wrong quench curve is used with an LSC cocktail are shown in [Tables 7.25–7.28](#). [Table 7.25](#) shows that only Ultima Gold

TABLE 7.24 Techniques for reducing color in certain samples.

Nature of sample	Suggested remedy
Color from sample solubilization	Treat with hydrogen peroxide to bleach out the color
Plant material	Consider sample oxidation
Inorganic matrix	Change to alternate colourless anion

cocktails should be used for tritium DPM measurements with the Ultima Gold tritium quench curve. Table 7.26 shows that the Ultima Gold cocktails should not be used for tritium DPM measurements with the toluene tritium quench curve. Table 7.27 shows that only Ultima Gold cocktails should be used for carbon-14 DPM measurements with the Ultima Gold carbon-14 quench curve. Table 7.28 shows that the Ultima Gold cocktails should not be used for carbon-14 DPM measurements with the toluene carbon-14 quench curve.

5. Using a quench curve

Once the quench curve is stored in the instrument computer, it can be used for automatic DPM calculations. When unknowns are counted, the sample CPM and the QIP are measured. Using the QIP (SIS or t-SIE), the counting efficiency is determined from the appropriate quench curve.

For example:

- A tritium sample is analyzed and has the following count rate and QIP:

$$\text{Count rate} = 10,000 \text{ CPM}$$

$$\text{t-SIE} = 400$$

From the quench curve shown in Fig. 7.5, the instrument uses the t-SIE of 400 to determine that the counting efficiency is 42%. Since we now know the CPM and the counting efficiency, it is possible to calculate the DPM as follows:

$$\begin{aligned} \text{DPM} &= \frac{\text{CPM}}{\text{Efficiency (expressed as a decimal)}} \\ &= \frac{10,000}{0.42} = 23,809 \text{ DPM} \end{aligned}$$

A compilation of recommended quench curves for different LSC cocktails is shown in Table 7.29, and this will provide a basic guide to correct quench curve selection. For accurate DPM recovery, it is imperative that the quench curve selected be appropriate for the LSC cocktail being used. PerkinElmer manufactures quench curves using either a safer, high flash point (Ultima Gold) cocktail or a classical solvent (toluene) that is suitable for use with all Perkin–Elmer LSC cocktails. Whenever there is doubt about the appropriateness of a quench curve, researchers should always prepare their own using the same chemistry as that found in the sample.

E. Quench correction using selectable multichannel analyzer

The External Standard Channels Ratio (ESCR) was in frequent use in scintillation counting until the introduction

of computer-controlled spectrum analysis methods in the late 1980s when it fell into disuse. ESCR is discussed in Chapter 6 of this book in detail. The method of quench correction used in the recently introduced Hitachi Aloka LSC-8000 is ESCR. The ESCR in the Hitachi Aloka AccuFLEX LSC-8000 liquid scintillation counter uses a

FIGURE 7.6 ^3H transformed spectral index of the external standard versus External Standard Channels Ratio. PerkinElmer ^3H Standards 283,500 DPM/Std $\pm 3\%$, 30 min, three cycles, region 0–18.6 keV.DPM, disintegrations per minute.

FIGURE 7.7 ^{14}C transformed spectral index of the external standard versus External Standard Channels Ratio. PerkinElmer ^{14}C Standards 119,000 DPM/Std $\pm 2\%$, 30 minutes, three cycles, region 0–156 keV.DPM, disintegrations per minute.

selectable MCA for calculations using ESCR. Data shown in (Figs. 7.6 and 7.7) show excellent correlation between t-SIE and ESCR. This confirms the validity of ESCR as compared with another more commonly used method of quench correction. Hitachi Aloka LSC-8000 uses a selectable 4000 channel MCA with automatic gain switching and high-resolution spectral analysis.

The t-SIE is graphed against ESCR.

The selectable 4000-channel MCA allows the gain setting to be such that in the 0–20 keV region the increment is in 0.005 keV ($100\times$ gain), in the 0–200 keV the increment is 0.05 keV ($10\times$ gain), and in the 0–200 keV it is 0.5 keV ($1\times$ gain). This allows for accurate measurement of the counts in the spectrum. Fig. 7.8 shows the histogram of the spectrum of a ^3H standard counted for 10 min and the subsequent increase in data available.

XIII. Environmental sample preparation⁷

The advance of the nuclear industry in all its forms coupled with growing concerns for possible environmental contamination has led to an increased interest in the quantification of radioisotopes in the environment. Radionuclides currently present in the environment originate from a variety of natural sources such as fallout from nuclear weapons testing and in discharges from both nuclear and nonnuclear industries. Natural sources and fallout from nuclear devices provide the main input to terrestrial ecosystems, except for certain radionuclides emanating from nuclear installations.

In the late 1950s and early 1960s, during and immediately after the period of most frequent aboveground nuclear weapons testing, numerous studies were performed to determine the distribution and movement of fallout radionuclides in air, precipitation, agricultural produce, animals, and soils (e.g., L'Annunziata, 1967). Around this time, the nuclear power industry was developing, and consequently, both the diversity and amount of radioactive species in the environment increased. Currently, the majority of the high-level waste from the nuclear industry is stored for ultimate disposal in sites classified as stable, such as deep geological strata. However, as many nuclear facilities are situated in coastal areas, the bulk of low-level radioactive waste is discharged to the sea.

Because of nuclear fallout and discharges from the nuclear industry (including releases from the Chernobyl accident in 1986 and more recently from the Fukushima accident in 2011), certain radionuclides are studied more than others. This is due to either their radiotoxicity, increased presence in the environment, or ease of entry into the food chain (MAFF, 1984; MAFF, 1994; Bocock, 1981; NRPB, 1993; HMIP, 1993; MAFF, 1993; Passo and Cook, 1994); a selection of these is presented in Table 7.30. The separation and isolation of these radionuclides from the complex sample matrices often encountered are presenting researchers with a myriad of problems; however, many of these have been eased by the introduction of novel extraction chromatographic separation technology (Eichrom Industries Inc. Darien, Illinois, USA). By employing this new technology, previously difficult and time-consuming radionuclide separations are completed more effectively and efficiently. In combination with recent advances in LSC technology by the Packard Instrument Company (now PerkinElmer, Inc.), it is now possible to

FIGURE 7.8 ^3H spectrum with a 0.005 keV resolution in a 4000-channel multichannel analyzer (MCA).

consider LSC as an alternative screening tool to alpha spectrometry and gas flow proportional counting.

A. Extraction chromatographic sample preparation

A range of products that use the technique of extraction chromatography to efficiently preconcentrate and separate radionuclides from a variety of different matrices have been introduced by Eichrom Technologies LLD (Lisle, Illinois, USA) and TrisKem International (Bruz, France). Extraction chromatography combines the power and selectivity of solvent extraction with the ease of use of a chromatographic column. Through careful selection of the extractant, which is adsorbed onto the resin support, a material is produced that is highly specific for a particular radionuclide or group of radionuclides. In the majority of cases, either retention or elution of the radionuclide of interest is

achieved by modification of the concentration of the acidic eluent used. Using such technology has resulted in an accurate and reproducible sample preparation method for the determination of radionuclides in environmental samples.

Eichrom/Triskem has published methods for radionuclide separations using their chromatography technology, and these can be conveniently explained as follows:

ACW, ACS, ACU methods	Refer to actinides in water, soil, and urine
SRW, SRS, SRU methods	Refer to strontium in water, soil, and urine
TCW, TCS methods	Refer to technetium in water and soil
H3W methods	Refer to tritium (^3H) in water
OTW methods	Refer to other (e.g., lead in water)

A method for the determination of Cl-36 (and I-129) in environmental and decommissioning samples has been published by TrisKem (TKI-CL). A summary of these methods together with the recommended LSC cocktail for isotopic determination by LSC is presented in Table 7.31. Ultima Gold, Gold Star, and ProSafe+ cocktails are recommended for these applications due to the use of diisopropylnaphthalene (DIN) as the solvent base, which enhances alpha/beta resolution in LSC (Passo and Cook, 1994). The information presented in Table 7.31 shows both the eluent used in the final stripping of the radionuclide from the chromatographic column and the appropriate LSC cocktail, which will accommodate either all or at least a sizable aliquot of the eluent. Table 7.31 should be used in conjunction with Table 7.32, which demonstrates the maximum capacity of each of the LSC cocktails with the each of the eluents.

It should be remembered that the use of alpha/beta LSC for alpha determination will only provide a gross alpha measurement and is capable of limited alpha–alpha resolution. An example of such an alpha/beta LSC is the Packard Tri-Carb 2770TR/AB (now PerkinElmer), which uses time-resolved pulse decay analysis (TR-PDA) technology to separate the alpha spectrum from the beta spectrum.

An alternative method to acidic stripping of the radionuclide from the column is to elute with IPA. IPA effectively strips the resin coating (containing the radionuclide), and this can be counted with 4 π geometry in a suitable LSC cocktail. The information in both these tables is presented to help researchers investigate the use of LSC as an alternative technology for gross alpha determination. There are also methods in which the loaded resin is directly mixed with the cocktail and counted.

B. Aqueous sample preparation

Many of the radioactive species of interest to low-level radioactivity researchers are present in an aqueous medium, usually water. Therefore, any suitable LSC cocktail must not only have a high capacity for water but also be compatible with water from a variety of different sources. These include distilled, deionized, tap, rain, river, and even seawater.

In addition to high sample capacity, other preferred requirements for LSC include a very low background contribution and high counting efficiency. Ideally, the LSC cocktail should also be based on the high flash point, safer solvent DIN. Ultima Gold LLT and Gold Star LT² are such cocktails and are primarily designed for the low-level tritium (LLT) monitoring and research sectors.

Additionally, they have other unique performance characteristics that set them apart from currently available cocktails. They meet additional requirements for a low-level counting cocktail such as long-term stability and subambient temperature stability and can accept the important mineral acid species normally encountered in alpha/beta counting applications. A selection of the more important properties is illustrated in [Tables 7.33 and 7.34](#). [Table 7.33](#) shows the performance of Ultima Gold LLT in a Tri-Carb 2770 TR/SL operated in low-level count mode at 15°C. All samples were prepared in duplicate in standard polyethylene vials; background count time used was 500 min per sample. The minimum detectable activity (MDA) was calculated according to [Currie\(1968\)](#).

[Table 7.34](#) shows that Ultima Gold LLT can accept the important mineral acid species normally used in environmental sample preparation methods. In addition to these sample types, Ultima Gold LLT has a high sample capacity for urine and is therefore ideally suited for use in the bioassay of ³H in urine.

As a quick reference guide, the main radionuclides present in the environment and originating from either nuclear devices or the nuclear industry are summarized in [Table 7.35](#).

Environmental sample preparation encompasses a wide variety of techniques, including extraction chromatography, acid extraction, ashing and solvent extraction, and chemical separation.

Advances in liquid scintillation technology, together with new and emerging sample preparation techniques, now enable researchers to consider LSC as an alternative environmental sample radionuclide counting method or as a potentially useful screening tool.

XIV. Waste cocktails—environmental consequences

A. Generation of waste cocktails

Scintillation waste consists of liquid scintillation cocktails (including dissolved and suspended samples) and associated containers such as counting vials. LSC currently accounts for 65% of mixed radioactive, organic waste. Such waste is generated as a result of environmental monitoring, research, teaching, and patient care activities, and all waste that contains or is contaminated with radioactive material requires disposal. This means that if a hazardous chemical or biological hazardous waste contains or is contaminated with radioactive material, it must be disposed of as radioactive waste. However, little attention has been paid to the secondary chemical/biological hazards that may be present.

B. Disposal methods

The components of the LSC cocktail may represent a hazard or a disposal problem in addition to the radioactivity. For many experiments, only a small percentage of the samples counted will have significant radioactivity, so disposal of the LSC cocktail is the predominating issue.

Incineration is a thermal treatment technology that involves the combustion of material through contact with a controlled flame in enclosed chambers.

Chemical oxidation—The process uses UV light and hydrogen peroxide to oxidize organic compounds to carbon dioxide and water.

Steam reforming—Reforming reactions occur in a near-oxygen-free environment under high pressure and temperature and allow an extremely high conversion of organics

(wastes) to the primary conversion products of CO₂, H₂O, and H₂.

Bioprocessing is an alternative technology that involves the use of microorganisms, which can metabolize aromatic solvents of the type used in LSC waste. The use of microorganisms serving as biocatalysts in a continuous flow system designed for the processing of stored liquid scintillation waste has demonstrated success in processing stored, “hot” LSC waste. Details of the applicability of bioprocessing to treating mixed waste were presented at the third Biennial Symposium of Mixed Waste in a report entitled “‘Bioprocessing’ of Mixed Waste: A Success Story.” A bioprocess demonstration was conducted on a commercial LSC formulation; the initial results of this technology indicate that hazardous organic solvents, xylene, and pseudocumene have been removed due to processing. The process was applied to two barrels containing LSC waste with a tritium radioactive component and pseudocumene-based hazardous constituent. Further research will determine the applicability of the process to treat mixed waste. Initial results have revealed that bioprocessing can satisfactorily remove certain hazardous constituents from mixed waste. The technology is considered an alternative to incineration and could be considered a more environmentally friendly means of treating this waste.

C. Biodegradability

Biodegradation is the breakdown of organic contaminants by microbial organisms into smaller compounds. The microbial organisms transform the contaminants through metabolic or enzymatic processes. Biodegradation processes vary greatly, but frequently the final product of the degradation is carbon dioxide or methane and water. Biodegradation is a key process in the natural attenuation of contaminants at hazardous waste sites, and it is a microbial process that occurs when all of the nutrients and physical conditions involved are suitable for growth. Temperature is an important variable; keeping a substance frozen can

prevent biodegradation. Most biodegradation occurs at temperatures between 10 and 35°C. Water is essential for biodegradation, and bacteria and fungi, including yeasts and molds, are the microorganisms responsible for biodegradation. Biodegradability falls into one of the following three categories: primary biodegradation, readily biodegradable, and inherently biodegradable.

Primary biodegradation is more limited in scope and refers to the disappearance of the compound as a result of its biotransformation to another product.

Readily biodegradable refers to specific tests where a specified percentage of the compound on test must biodegrade within a fixed time period.

Inherently biodegradable is similar in specification to readily biodegradable, but there is an initial acclimation period prior to starting the biodegradability testing protocol.

Provided the sample passes one of the following tests, it can be properly described as biodegradable.

1. Testing for biodegradability

The biodegradation rate measures the speed at which microorganisms can break down the test materials. There are several ways in which this can be determined. One of the most widely accepted tests is biological oxygen demand (BOD), which measures the rate of oxygen use of microorganisms feeding on a sample of test material. The higher the rate of oxygen use, the faster the metabolism of the sample by the microorganism. Materials that are nonbiodegradable will return a very low BOD. Samples are usually tested for 28 days, with oxygen use measurements taken every 5 days. The increase in the rate of oxygen use shows that the microorganisms are acclimatizing to the sample more as a source of carbon in their diets.

There are a variety of methods used to establish biodegradability, and the most commonly used are the Organisation for Economic Cooperation and Development (OECD) methods.

One of the most important screening tests is the MITI-I test (Japanese Ministry of International Trade and Industry), also known as OECD 301C. The MITI-I is a screening test in which the test substance is initially present at 100 mg/L, and the inoculum is 30 mg sludge solids/L. The test measures BOD, and like other OECD ready biodegradability tests, it normally lasts for 28 days. If oxygen demand due to degradation of the test substance reaches or exceeds 60% of theoretical, the test substance is considered readily biodegradable. The MITI inoculum is prepared using a process of feeding a mixture of sludges from various sources for 30 days with peptone only. This standardization reduces the diversity of microorganisms in the sludge and also their ability to acclimate to and degrade

various substrates. Apparently, this reduces variability in the results and thereby makes the test of higher utility.

2. Biodegradability test methods

a. OECDTG 301 A ready biodegradability: DOCdie-away test

The biodegradation of organic products, dissolved in water, by chemicoorganotrophic microorganisms using the products as the sole source of carbon and energy is observed. The initial content of organic carbon is 40 mg/L (40 ppm). The test flasks are shaken mechanically throughout the test. The dissolved organic carbon (DOC) left in solution is measured after 3, 7, 14, and 28 days. The corresponding level of biodegradation is calculated and evaluated on the basis of this level.

Pass level is 70%.

b. OECDTG 301 B ready biodegradability: CO₂ evolution test

A chemically defined liquid medium with a carbon content of 5–20 mg/L, essentially free of other organic carbon sources, is spiked with the test material and inoculated with sewage microorganisms. CO₂-free air is bubbled through the solution. The CO₂ released is trapped as BaCO₃. After reference to suitable blank controls, the total amount of CO₂ produced is determined for the test period. It is calculated as the percentage of total CO₂ that the test material could have had theoretically.

Pass level is 60%.

c. OECDTG 301 C ready biodegradability: modified MITI test (I)

An automated, closed system device for measuring BOD is used. The samples are stirred continuously. Chemicals to be tested are the sole organic carbon sources and are inoculated with microorganisms in the testing vessels. During the test period, BOD is measured continuously. Biodegradability is calculated on the basis of BOD. Supplemental chemical analysis is undertaken to measure DOC, residual chemicals, etc.

Pass level is 60%.

d. OECDTG 301 D ready biodegradability: closed bottle test

A predetermined amount of the compound is dissolved in a mineral nutrient solution, providing a usual concentration of 2 mg/L active substance. The solution is inoculated with a small number of microorganisms from a fixed population and kept in closed bottles, without any stirring, in the dark at a constant temperature of 20°C ± 1°C. The degradation is followed by oxygen analyses over a 28-day period.

A control with inoculum, but without test material, is run in parallel for the determination of oxygen blanks.

Pass level is 60%.

e. OECDTG 301 E ready biodegradability: modified OECDscreening test

A predetermined amount of the compound is dissolved in a mineral nutrient solution, fortified with a trace element and essential vitamin solution. The concentration reached is 5–40 mg/LDOC. The solution is inoculated with a small number of microorganisms from a mixed population and aerated at 20–25°C in the dark or at least in diffuse light only. The degradation is followed by DOC analysis over a 28-day period. The procedure is checked by means of a standard. A control with inoculation, but without either test material or a standard, is run in parallel.

Pass level is 70%.

f. OECDTG 301 F ready biodegradability: also called the manometric respirometry test

This is the same test as the 301 D but automated to obtain a continuous oxygen measurement. The principal differences are that the test flasks are open, exposed to daylight, and continuously stirred. An advantage is that the test gives data on both primary and ultimate degradation.

Pass level is 60%.

g. OECD 302 A inherent biodegradability: modified semicontinuous activated sludgetest

This test is an adaptation of the semicontinuous activated sludge procedure for assessing LABsulfonate.

>20% indicates inherently biodegradable, and >70% indicates ultimately biodegradable.

h. OECD 302 B inherent biodegradability: Zahn-Wellens/EMPAtest

Modified Zahn-Wellens test (inherent biodegradability): a static test for ultimate degradation.

>20% indicates inherently biodegradable, and >70% indicates ultimately biodegradable.

i. OECD 302 C inherent biodegradability: modified MITItest (II)

Modified MITI test (inherent biodegradability): basically the same test as 301 C.

OECD 304 A inherent biodegradability in soil evaluation of the mineralization rate of a ^{14}C -labeled test chemical.

D. Incineration

Incineration reduces the volume and toxicity of waste materials by converting hazardous organic compounds to

non-hazardous products such as water and carbon dioxide. Currently, most of the LSC wastes are sent offsite to licensed facilities where they are combusted. Advantages of the technique are as follows: it is proven and well understood, it results in almost complete reduction of toxic organics if strict monitoring procedures are emphasized, it is a low-treatment technology if operated properly, and it eliminates liquids, producing a waste that is dense and easy to transport. Some of the notable drawbacks of incineration include the relatively high cost, the risks associated with transportation, the potential for release of radioactive materials into the environment, and finally the reintroduction of carbon dioxide straight back into the atmosphere. As an example, if 10 L of LSC cocktail is incinerated, it will produce ~26,000 L of CO_2 (0.05 tonnes of CO_2), which will be injected directly into the atmosphere. There are also costs associated with the disposal of the radioactive ash generated from incineration.

E. Legislation and regulatory information

Almost all currently available LSC cocktails contain nonyl phenol ethoxylates (NPEs). The NPEs are not completely biodegraded and produce metabolites that are known endocrine disruptors. Endocrine disruptors are a group of chemicals (natural, synthetic, industrial chemicals, or by-products), and exposure to which can cause adverse health effects in an intact organism or its offspring or (sub) population by altering the function of the endocrine system. In wildlife, endocrine disruptors have been clearly shown to cause abnormalities and impaired reproductive performance in some species and to be associated with changes in immunity, behavior, and skeletal deformities. In humans, endocrine disruptors have been suggested as being responsible for apparent changes seen in human health patterns over recent decades. These include declining sperm counts in some geographical regions, increased incidences in numbers of male children born with genital malformations, and increased incidences of certain types of cancer that are known to be sensitive to hormones. More controversially, links have been suggested with impairment in neural development and sexual behavior.

As a result of extensive studies, the European Community (EC) directive 2003/53/EC came into force in 2003 and put in place controls to restrict the marketing and use of nonyl phenol (NP) and NPEs. This directive covers all current 27 EC member states (as of 2011 and is the 26th amendment (Directive 89/677/EC) to Directive 76/769/EC). NPs are toxic to fish, aquatic invertebrates, and algae, affect plant growth, and impact upon the reproduction and mortality of terrestrial invertebrates. They can also affect organisms higher up the chain through consumption of lower organisms (particularly for terrestrial organisms).

Canada has also declared a ban on the use of NPEs for certain applications and is in the process of phasing them out completely (Hoponick and Sierra Club, 2005). Japan is also seriously reviewing the issue.

In the United States, the Environmental Protection Agency (EPA) will consider initiating rulemaking under the Toxic Substance Control Act (TSCA) Section 5(B) (4) to add NP and NPEs to the list of chemicals that present or may present an unreasonable risk of injury to health or the environment. The EPA initiated rulemaking in late 2011 to add NP and NPEs to the TRI (Toxic Release Inventory) list. At present, neither NPs nor NPEs are on this EPCRA (Emergency Planning and Community Right-to-Know Act) section 313 list of toxic chemicals. The EPA is supporting and encouraging the elimination of other uses of NP and NPEs, followed by regulatory actions as necessary. The EPA intends to encourage the manufacturers of all NPE-containing direct-release products to move to NPE-free formulations. For example, as the Textile Rental Services Association (TRSA) implements its phase-out commitment through SDSI (Safer Detergents Stewardship Initiative), it will provide an example for other product sectors to follow, especially those with “direct releases” to the environment. The EPA-sponsored CleanGredients database offers a source of ready alternatives—functionally equivalent to NPEs based on performance characteristics and safer, because they meet the EPA Criteria for Safer Surfactants. The EPA will develop an alternative analysis and encourage the elimination of NPE use in other industries that discharge NPEs to water, such as the pulp and paper processing and textile processing sectors, where safer alternatives may be available.

A direct consequence of EC directive 2003/53/EC is that, from 2005, cocktail waste containing NPEs cannot be drain-disposed anywhere within the 27 member states of the EC.

R.E.A.C.H: Liquid scintillation cocktails are sold globally. Their manufacture and subsequent distribution into the supply chain is highly regulated within the chemical industry, and the requirements of each country vary significantly from each other. For example, in the European Union, chemicals are regulated under REACH: **R**egistration, **E**valuation and **A**uthorisation of **C**hemicals. In the United States of America, it is the TSCA: Toxic Substances Control Act, and in China, chemicals are governed under the Provisions on Environmental Administration of New Chemical Substances. These three regulations differ greatly and highlight the complexity of bringing an LSC cocktail to a global market.

Chemical regulations are wide reaching and cover every aspect of LSC cocktail production starting with importation of raw materials, through formulation, manufacturing, packaging, classification and labeling for supply, finishing with transport and safety documentation that is sent out

with the final product. To comply with each of these development stages and with each country’s different requirements, an in-depth knowledge is required and expert help, which can be costly. For example, the cost to register a single raw material in Europe is in the region of £250k.

The overall aims of all the chemical regulations are to ultimately ensure that chemicals are safe for human health and the environment and to increase economic efficiency. However, escalating regulatory requirements and subsequent costs have, in some cases, driven up the cost of raw materials to such an extent that they are being withdrawn from the market as they are no longer viable, forcing some of the smaller chemical manufacturers to shut down. Other historic raw materials are being highlighted as being unsafe and have limited time left on the market while safer alternatives are sought.

The raw materials used in LSC cocktails are highly specialized and chosen specifically for the properties they deliver. Surfactants based on APEs that are a key component within several LSC cocktails have been highlighted in Europe as being substances of very high concern. This has recently led to several companies within the EU ceasing production of them, which will vastly reduce the portfolio of LSC cocktails on offer. At the time of printing withdrawal of APEs from the market will reduce 57 currently available LSC cocktails down to only 9 in 2021 when they can no longer be used without permission. Meridian Biotechnologies have proactively developed a range of LSC cocktails based on safer alcohol ethoxylates with equivalent performance as alternatives.

Staying abreast of chemical regulations is critical to enable targeted formulation development of LSC cocktails to keep up with global market demand.

F. Waste cocktails—the way forward

The best way forward is to reformulate the LSC cocktails using alcohol ethoxylates, which are the obvious alternatives. This approach brings both advantages and drawbacks. The significant advantage is that they are readily biodegradable and do not form endocrine disruptors upon degradation. Since the alcohol ethoxylates are aliphatic in nature, they do not contribute to the energy transfer process, and consequently, any LSC cocktail based on alcohol ethoxylates will exhibit slightly lower counting efficiency with respect to lower-energy isotopes such as tritium. For all other higher-energy isotopes, there will be equivalent performance to currently available LSC cocktails. Another consequence of this change to alcohol ethoxylates is that ease of microemulsion formation is partially compromised. The alcohol ethoxylates are slightly inferior to the NPEs with respect to incorporation of aqueous samples, and to overcome this problem, required a significant amount of research and development time.

As of early 2011, the only companies that have overcome these issues and offer NPE-free LSC cocktails are Meridian Biotechnologies Ltd. and PerkinElmer Inc.

Meridian Biotechnologies Ltd. has complete ranges, formulated in a high flash point biodegradable solvent available for both routine LSC and flow scintillation counting. These are called the ProSafe+ and Pro-Flow+ ranges, and both are completely NPE-free, readily biodegradable, and suitable for drain disposal subject to local authority approval. PerkinElmer Inc. has thus far introduced two replacement products called Pico-fluor Plus and Biofluor Plus, and although they are NPE-free, they are based on pseudocumene and therefore totally unsuitable for drain disposal.

The Meridian Biotechnologies Ltd. ProSafe+ and Pro-Flow+ ranges have been tested and been shown to be biodegradable; a further study has shown that, upon biodegradation, the only by-products, apart from water and some CO₂, are simple alcohols and glycols, with no endocrine disrupter species present. At present, many users are still using NPE-based LSC cocktails and accepting the extra costs and inconvenience of disposal by incineration. Change within the LSC community is notoriously slow, but the introduction of new regulations and a greater awareness of environmental consequences are slowly but surely driving a change to NPE-free products.

Acknowledgments

The authors would like to thank PerkinElmer Inc. for their kind permission to use excerpts from their Counting Solutions series of Application Notes. The authors are also grateful that they were able to draw upon material from the work of this chapter on "Sample Preparation for Liquid Scintillation Counting" published in 1998 and 2003 in the *Handbook of Radioactivity Analysis* for the publication of a Chapter 9 "Sample Preparation for Liquid Scintillation Counting" in the book *Radiotracers in Drug Development* by Graham Lappin and Simon Temple published in 2006 by the CRC Press.

I. Introduction

In all of its various and widespread areas of analytical applications, mass spectrometry serves as an ultimately sensitive and highly selective method for the determination of major, minor, trace, and even ultratrace components (Bacon

et al., 2008; Butler et al., 2018, and earlier issues of both annual reviews). The field of radioisotope determination primarily concerns the quantification of inorganic elemental trace and ultratrace components in lowest contaminations, frequently aside of stable isotopes of the same element. For this purpose, a multitude of highly specialized techniques

have been developed, both for analytical routine applications and for specific experiments in various fields of fundamental or applied research. Applications cover the full range of studies on radioisotope distributions in environmental and technical samples. In addition to research on the distribution of naturally occurring radioactivity and its applications in science and technology, the surveillance of anthropogenic radioactive fallout from weapon tests and the nuclear industry by nuclear safeguards is of major importance (Boulyga et al., 2015). This field has gained strong additional relevance by the public awareness to the two major nuclear accidents, in Chernobyl, Ukraine, in 1986 and Fukushima, Japan, in 2011. Also, we want to point out the increasing use of radioisotopes in medicine, in industrial production, and even applications in forensic studies (Mayer et al., 2015; Wang et al., 2018). In general, the characterization of nuclear materials, recycled products, and by-products, that is, spent nuclear fuel or depleted uranium ammunition, as well as the control and management of nuclear waste, is of highest concern regarding nuclear safety (Betti and de las Heras, 2004; Chartier et al., 1999). Industrial applications require the study of radioisotope contents in glasses, ceramics, or the semiconductor industry (Rohr et al., 1994; Fukuda and Sayama, 1997), and the sensitive characterization of highest-purity substances (Beer and Heumann, 1992; Herzner and Heumann, 1992). Finally, very specific fields of lowest-level radioisotope mass spectrometry concern the analysis of hot particles in the environment (Tamborini and Betti, 2000; Saibu et al., 2018), the surveillance of radiopharmaceuticals for nuclear–medical applications, geochronology, and cosmochemistry. Work at considerably higher radioactivities includes isotope enrichment, purification, and characterization of dedicated radioactive sources.

Obviously, radiometric techniques detecting α -, β -, or γ -radiation are the standard methods for the determination of radionuclides. Nevertheless, with respect to long-lived radionuclides and in particular those dominantly emitting β -radiation, these standard methods fall short of the detection limits required for ultratrace analyses, depending on the decay type, half-life, and numerous sources of background or noise. Trace analytical measurements of β -emitters, for example, $^{90,89}\text{Sr}$ or $^{99\text{g}}\text{Tc}$, require time-consuming chemical separations to remove any interfering source of radioactivity. With respect to α -spectroscopy, using conventional surface barrier detectors, almost carrier-free samples are a prerequisite to achieve a reasonable energy resolution for radioisotope assignment. Even then, unambiguous radiometric isotope analysis is often prevented by interferences of very similar α -energies, e.g., for $^{239}\text{Pu}/^{240}\text{Pu}$.

On the contrary, mass spectrometric techniques directly count individual atoms of the species of interest involving dedicated experimental setups and ionization methods to minimize background and interferences. In this manner, mass spectrometric methods achieve a very good sensitivity together with isotopic as well as isobaric selectivity. In addition, the recording of a full isotopic pattern of an element often provides beneficial information about the origin and composition of a radioisotope contamination. Correspondingly, mass spectrometric data are considered to be superior to radiometric data in quite many analytical cases, and its higher significance in many cases is appreciated accordingly.

The choice of the best suited analytical technique depends on a number of aspects including the following:

- Type and available amount of sample material
- Specific decay characteristics of the radioisotope in question
- Expected overall content of radioisotopes and their composition in the sample
- Possible existence of interferences, such as, molecules, or other radionuclides

An important criterion for the application of radioisotope mass spectrometry for a specific isotope is given by the following reasoning: The number of events from radioactive decay counting during a given measuring time, which should not exceed approximately 1 week, increases proportional to the number of atoms in the sample and to the decay rate (proportional to $1/\text{half-life}$). The number of counts obtained by mass spectrometry depends on the number of atoms alone and, of course, in both cases radiometric and mass spectrometric methods, on the efficiency of the detection method. Hence, mass spectrometry becomes increasingly advantageous with decreasing decay rate, that is, increasing half-life of the radionuclides, as compiled for a number of important long-lived radioisotopes in Table 8.1. In a conservative assessment, a measuring time of 24 h, an efficiency of 100% and absence of any background events are assumed for an optimum radiometric count rate to compare with the atom number present in the sample. For each of these isotopes, the number of atoms exceeds the possible decay counts by far more than three orders of magnitude.

A compilation of about 40 relevant “environmental radioisotopes” with half-lives beyond about 1 year is given in Fig. 8.1, plotted with their half-life against the proton number of the element and indicating their origin by the plotting symbols. For comparison, the age of both, the universe as well as the earth, were added, indicated as solid (age of the universe) and dashed (age of the earth) horizontal lines.

TABLE 8.1 Some selected long-lived α - and β -emitting radioisotopes.

Radionuclide	Primary decay type	Half-life $t_{1/2}$	Activity (mBq)	Ideal radiometric count rate within 24 h	Atom number for 1 fg sample content
^3H	β^-	12.3 a	$4.5 \cdot 10^4$	$3.9 \cdot 10^9$	$2.0 \cdot 10^8$
^{14}C	β^-	5730 a	$2.1 \cdot 10^1$	$1.8 \cdot 10^3$	$4.3 \cdot 10^7$
^{41}Ca	β^-	$1.03 \cdot 10^5$ a	0.38	32	$1.5 \cdot 10^7$
^{90}Sr	β^-	28.5 a	$6.7 \cdot 10^2$	$5.8 \cdot 10^4$	$6.7 \cdot 10^6$
^{99}Tc	β^-	$2.1 \cdot 10^5$ a	0.078	6.7	$6.1 \cdot 10^6$
^{129}I	β^-	$1.57 \cdot 10^7$ a	0.001	0.086	$4.7 \cdot 10^6$
^{239}Pu	α	$2.41 \cdot 10^4$ a	0.27	23	$2.5 \cdot 10^6$

Atom numbers, activities and optimally expected radiometric count rates for a sample content of 1 fg of the species are compared. Note that 10^{-2} mBq, corresponding to about 1 decay/24 h, is the absolute limit for radiometric determination under optimum conditions.

FIGURE 8.1 Relevant “environmental radioisotopes” with half-lives exceeding about 1 year. Half-lives are plotted against the proton number of the element. The origin of individual isotopes is indicated by the plotting symbols.

As noted previously, the sensitive and rapid (in case of an emergency) determination of some long-lived radioisotopes is of highest relevance in areas such as follows:

- Risk assessment
- Low-level surveillance and discrimination of environmental contaminations
- Studies of biological radiation effects and hazards
- Mid- and long-term radioactive waste control
- Fundamental research in geo- and cosmochemistry
- Investigations on the speciation and migration behavior of elements without stable isotopes, such as Pm, Tc, and the actinides

The most prominent mass spectrometric techniques used for these investigations on radioisotopes are based on

a limited set of basic instrumentation types. These include the following:

- Thermal ionization mass spectrometry (TIMS) (Platzner, 1997; Aggarwal, 2016)
- Glow discharge mass spectrometry (GDMS) (Betti and de las Heras, 2004)
- Secondary ion mass spectrometry (SIMS) (Adriaens et al., 1992; Betti et al., 1999)
- Inductively coupled plasma mass spectrometry (ICP-MS) (Kim et al., 1991; Crain, 1996; Pröfrock and Prange, 2012) or laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) (Becker, 2010)
- Resonance ionization mass spectrometry (RIMS) (Trautmann and Wendt, 2012)
- Accelerator mass spectrometry (AMS) (Fifield, 1999; Kutschera 2005, 2016)

RIMS and AMS are used for high-sensitivity mono-elemental ultratrace analyses and determinations of isotope ratios requiring specific isobaric selectivity and very high dynamical range. The other mass spectrometric methods, in general, represent sensitive multielement techniques permitting the determination of absolute concentrations and isotopic abundances of trace and ultratrace elements, which might be somewhat affected by interferences.

The different mass spectrometric methods can be categorized according to the processes used sequentially for evaporation, atomization, and ionization of the sample species. For the analysis of bulk materials, for example, compact solids or powder samples, the initial step of evaporation/atomization could involve different approaches, which include thermal evaporation, for example, from a filament or oven, evaporation and atomization in a plasma discharge, or ablation by impact of laser radiation. In contrast, the atomization may be induced by a concerted

particle interaction involving electrons or a well-controlled ion beam for initiating a sputtering process. Subsequent ionization is achieved by different processes among which are the following: as a side effect of this atomization process, for example, directly on a hot surface, by collisional ionization induced by the electrons, ions, or in the plasma, or finally, by resonant or nonresonant single- or multi-photon absorption processes induced by laser light. Simultaneous or quasisimultaneous evaporation and ionization occurs commonly in the ion sources of TIMS, SIMS, ICP-MS, and AMS apparatuses. An incremental procedure, separating evaporation and atomization from ionization of the atomic species in time and/or space, is arranged in TIMS by using multiple filaments, and this occurs in GDMS, LA-ICP-MS, and RIMS.

Ion acceleration, ion beam formation, and guidance into the subsequent mass dispersive system are chosen in a way that is well adapted to the specific properties of the ions formed. Furthermore, possible interference by elemental, molecular, and cluster ions that may occur in large surplus determines the choice of the optimum technique. Both static magnetic sector-field and combinations of electric and magnetic sector-field systems, for example, in Mattauch-Herzog or Nier-Johnson type mass spectrometers (Prohaska et al., 2015), which apply high ion acceleration energies in the range of several keV, are in use. Such a combination of a magnetic mass analyzer with an electrostatic analyzer leads to a so-called double-focusing sector-field mass analyzer. The electrostatic sector establishes ion trajectories by energy only. In contrast, the magnetic sector determines trajectories by both mass and energy, that is, momentum. When these two ion-optical elements are combined, ions are sorted by mass only while the two sectors provide angular focusing. In this way, the total system is considered to be double-focusing. Resulting mass resolutions are sufficient to separate interfering isobaric components and even study elements affected by elemental or molecular isobaric interferences.

For many applications, dynamic ion separation systems such as compact but powerful radiofrequency quadrupole-mass filters (Paul and Raether, 1955; Dawson, 1976), time-of-flight (TOF) systems, or the variety of different ion trap mass spectrometer designs are highly competitive. These most often very compact devices in most cases use ion sources operating near ground potential, which makes them beneficial for a number of routine or specific applications, for example, when continuous sample supply is required.

Ion detection after mass separation is performed by a variety of detector types. Historically, mass spectrometry started using ion-sensitive photographic emulsion plates to record full mass spectra. Unfortunately, these systems were limited in their sensitivity, linearity, and dynamical range. In addition, they required time-consuming photographic

development before data analysis. Faraday cups, measuring directly and quantitatively the ion current, became the workhorses of mass spectrometry for long time. For this purpose, the efficient suppression of any emitted secondary electrons, which would falsify a quantitative reading, was mandatory. Today, highly sensitive detectors, most often capable of recording single ions, revolutionized the field with respect to sensitivity and background suppression. The far majority of detector devices in the field are based on the technique of secondary electron generation and multiplication in discrete electrode arrangements, in microstructured channel plates, or in single-channel multipliers (channeltrons). Fully enclosed, more durable, and protected scintillation type detectors with photomultipliers (Daly detectors) are advantageous for some specific tasks in radioisotope detection (Daly, 1960). In addition, pixel-based solid-state detectors are in use, which offer spatial resolution for imaging applications (Jungmann and Heeren, 2013).

A direct analysis of the sample material without any preparatory chemical separation, as practicable in the case of GDMS, SIMS, or LA-ICP-MS, is very favorable but only possible in a few cases and specific samples. In such circumstances, possible inevitable contaminations, which could be introduced during chemical pretreatment, for example, in TIMS, RIMS, or AMS measurements, or which might result from interferences within the required aqueous solutions (ICP-MS), are prevented. However, the quantification in such direct, solid-state mass spectrometric analyses is much more difficult than in chemically pretreated samples, since often there is no suitable standard reference material available in the same form as the sample (Becker et al., 2000). Correspondingly, usual quantification methods such as the addition of internal or external standards or the use of isotope dilution techniques (Muccio and Jackson, 2009; Garcia Alonso and Rodriguez Gonzalez, 2013) might fail. In recent years, an increasing number of so-called hyphenated techniques were developed and used routinely. These techniques combine a (often chemical) preselection step, usually involving chromatographic separation, to produce pure fractions, which afterward are online coupled to the analyzing mass spectrometric methods (Bürger et al., 2007; May et al., 2008).

In the following sections of this chapter, a short introduction into the relevant figures of merit of mass spectrometric techniques, the most prominent approaches used in radioisotope analysis and a set of specific, yet typical applications for the determination of long-lived radioisotopes and related isotope ratio measurements will be presented.

II. Figures of merit

Mass spectrometric techniques are characterized by a set of basic specifications regarding the performance of the

instrumental setup with respect to individual aspects of analytical relevance. Also, for radioisotope mass spectrometry, these numbers are associated with the common figures of merit typical for conventional mass spectrometry, that is, the mass resolution, the dynamical range, the selectivity, and finally the sensitivity. The latter is often expressed by the level of detection (LOD). In general, the experimental information, which is extracted from any mass-dispersive spectrometric system, is just a raw mass spectrum. Such a spectrum gives intensities and positions of most often irregularly shaped peaks along a sequence of masses. These data are afterward converted into useful results via blank measurements, the recording of a calibration curve as well as by systematic studies on the technology at hand. The understanding of the specific performance of the setup is mandatory, and the related parameters are common for all different techniques and are defined as follows:

- The basic quantity **mass resolution** is given by the ratio of the mass number divided by the width of the mass peak as

$$R = \frac{m}{\Delta m}.$$

It determines the location in the mass spectrum and defines the precision, with which a specific mass value can be assigned to a recorded peak. In the analysis of radioisotopes, as for similar studies in inorganic mass spectrometry of atoms and small molecules, a rather low and easily achievable resolution with values beyond 500 is sufficient for the mass dispersive element. This is easily achieved by magnetic sector fields, TOF, or most quadrupole mass filters. Only in the case of high-precision mass determination or in studies on the radioisotope content on large biomolecules, much higher values of mass resolution in the order of 10^5 and more are needed, which are provided by ion trap spectrometers.

- The **dynamical range** of a mass spectrometer is given by the specifications of the detector—or possibly different detector channels—for the maximum permissible count rate, considering dead time corrections, versus the unavoidable background count rate. It is determined experimentally from the calibration curve, which ideally is taken from the lowest detectable concentration up to the maximum permitted count rate. Under optimum conditions, it should confirm a linear response in this full range of up to many orders of magnitude and, for multicollector systems, relate the readings of the different channels.
- The **selectivity** of a mass spectrometric device is loosely related to the resolution but quantitatively specified by the inverse of the abundance sensitivity. The latter is

given by the contribution of a chosen interfering peak—not necessarily from a directly neighboring mass—to the desired mass peak, which easily could amount to many orders of magnitude surplus. Due to the usually irregular, asymmetric, and not analytically reproducible mass peak shape, this quantity cannot be predicted theoretically but must be determined experimentally under operation conditions. In addition, it must be clarified if its value is based on a ratio of peak heights or integrated areas, which could well deliver significant variations. According to the experimental conditions, it usually differs toward the lower or higher side of a mass peak and is strongly affected by specific experimental conditions such as residual vacuum pressure, ionization technique, mass analyzer type, and preconditioning of the sample.

- The **sensitivity** is an experimentally defined quantity, which depends on the efficiencies of the individual process steps: sample preparation, evaporation and atomization, ionization, mass spectrometer transmission, and detection. Quantitatively, it is often defined in a relative form, giving a detected number of ions (or charges) versus the sample amount used. The sensitivity is related to the **LOD**. This quantity is the smallest (true) value of the measurand that can be detected with high reliability. The LOD is calculated based on the background or blank measurement. Furthermore, the expected best estimates and uncertainties of the measurand's assumed true value (ion counts) are needed. Using the probability distribution of the measurand's value (e.g., a Gaussian), the probability $(1-\gamma)$ for the true value to lie inside the coverage interval is calculated. Since the width of this Gaussian probability function decreases with increasing number of counts, the LOD decreases. It thus defines the lowest relative contents m/M of the species m under study, which can be reliably determined in the sample of a given size M .
- A final specification is the **precision**, which can be achieved in the measurement of isotope ratios. It is significantly dependent on the dynamical range, which must be covered for the determination of the different trace and reference isotopes, and usually lies in the range of few percent for RIMS or AMS up to better than 0.1% for TIMS.

More details on the figures of merit of analytical techniques are found in textbooks on statistics, analytic chemistry, or specifically mass spectrometry, e.g., [Prohaska et al. \(2015\)](#). For radioisotope mass spectrometry, concentrations commonly in the range of ng/g to pg/g for solids and down to sub-pg/L for aqueous solutions can be detected. Exceptional precision of 0.02% relative standard deviation (RSD) for isotope ratio measurements has been demonstrated using TIMS and ICP-MS ([Becker, 2002](#)), whereas RIMS and AMS can detect 10^6 – 10^7 (fg) and 10^4 atoms (ag) per

sample, respectively, for which sample sizes in the μg (RIMS) up to mg (AMS) range are used after chemical pre-separation. These values correspond to lowest isotope ratios in the 10^{-15} range and below, but with reduced precision in the low percentage range.

III. Thermal ionization mass spectrometry

A. Principle of surface ionization

TIMS is well suited for very sensitive and, at the same time, precise measurements of isotope ratios, achieving overall detection efficiencies in the region of 0.1% and precision values of even better than 0.01% (Platzner, 1997; Bürger et al., 2015). Usually, it is performed with sector-field mass spectrometers providing acceleration voltages in the order of 3–10 kV. For TIMS measurements, a small volume ($\sim 10 \mu\text{L}$) of an aqueous solution is deposited on a filament, that is a thin ribbon made of a refractory metal (Kawai et al., 2001). In many cases, the ion source contains an arrangement of two or even three filaments. The first filament is used for exhaustive and smooth evaporation of the analyte by careful thermal heating and the additional filaments produce the efficient ionization of the evaporated atoms or molecules on an extra hot surface. Ion acceleration toward the mass spectrometer is carried out using an extraction electrode together with a beam-forming electrostatic lens.

The release of atoms or molecules from a hot surface populates final states according to their excitation energies following statistical thermodynamics. As described by the Saha-Langmuir equation, positively ionized states are preferred for species with low ionization potential I_p as compared with the work function Φ of the ionizer material, which determines electron emission or capture at the - usually metallic - surface (Dresser, 1968). The ratio of positive ions to neutrals in thermal equilibrium is expressed by

$$\frac{n_+}{n_0} \propto e^{(\Phi - I_p)/kT}.$$

Negative surface ionization only occurs for those elements exhibiting a high electron affinity E_a , and it is determined by the relation

$$\frac{n_-}{n_0} \propto e^{(E_a - \Phi)/kT}.$$

In both cases, T is the temperature of the filament and k is the Boltzmann constant.

In vacuum, all elements with ionization potentials I_p well below 7 eV may be efficiently evaporated and are ionized positively at temperatures around $T \approx 1000\text{--}2500 \text{ K}$, respectively (**p-TIMS**). Generally,

filaments manufactured of the refractory elements Ta, Re, or W are in use. These exhibit comparably high electron work functions Φ around 5 eV, which slightly depend on the electronic configuration at the surface, together with ultimate temperature stability expressed by the highest melting points of all the elements lying beyond 3000 K. In this way, singly charged positive ions are obtained with high efficiency for alkali and alkaline earth elements, lanthanides, and actinides. Background from molecular hydrocarbons present in the vacuum system is strongly suppressed (Jakopic et al., 2010). For elements with a first ionization potential above 7 eV, special ion emitting reagents such as silica gel and H_3PO_4 and/or H_3BO_3 are used to stimulate the formation of MO_x^+ ions.

Negative ions of only a very few elements, i.e., the halogens, S, Se, Os, Re, and Te, are accessible by thermal ionization with reasonable sensitivity (**n-TIMS**), most often studied in the form of an oxide molecule MO_x^- (Liu et al., 2000). For the determination of precise isotope ratios of Os and Re, specific corrections on the oxygen isotope are required (Liu et al., 1998). Thoriated W or LaB_6 surfaces with low electron work functions $\Phi \approx 2.7 \text{ eV}$ are used frequently. Similarly, when volatilizing refractory metal elements in the form of MO_x molecules, corresponding negatively charged oxide ions are produced by thermal ionization and may be studied. On the other hand, n-TIMS quite often exhibits memory effects, and the stable and reliable operation of the ion source is much more delicate than in the case of p-TIMS. Thus, in general, it is not of practical relevance for radioisotope studies, as discussed in a direct comparison between the pros and cons of both technologies, i.e., p-TIMS and n-TIMS (Heumann et al., 1995). Also, the application of inductively coupled plasma mass spectrometry (see Section VI) on negative ions has been reported, but it is a similarly exotic system (Vickers et al., 1988).

Here, we consequentially limit the discussion of TIMS to the generation and study of positive ions in p-TIMS. A sketch of a p-TIMS system using a 90 degrees sector-field magnet is given in Fig. 8.2. Typical arrangements for single, double, or triple filaments are included schematically in the inlay aside of the source. Before use, filaments are thoroughly cleaned and thermally conditioned by controlled heating sequences in high vacuum, including short excess heating to maximum temperature just before destruction.

Samples for TIMS, containing rare radionuclides, must be particularly well prepared using pure reagents to avoid isobaric contaminants. These controlled conditions reduce errors due to fractionation of the isotope content during the measurement (Johnson and Beard, 1999). The correction for the isotope fractionation occurring in thermal ionization has been investigated in detail (Ramakumar and Fiedler, 1999; Habfast, 1998), whereas isobaric interferences in the sample could significantly

FIGURE 8.2 Schematic view of thermal ionization at a sector-field mass spectrometry. The inset shows details of a single filament (left), as used, for example, for alkali elements, or of multiple filaments (middle and right) as used for alkaline earth, lanthanides, and actinides.

affect and limit investigations, for example, for measurements of Pu in the presence of a vast surplus of U (Kumar et al., 1995).

B. Applications

High-precision TIMS measurements for the determination of radioisotope contents and isotope ratios in a sample imply a proper quantification. In most cases, this is done via isotope spiking to apply isotope dilution techniques, as pointed out in detail in Fassett and Paulsen (1989), Heumann (1992), Muccio and Jackson (2009) and Garcia Alonso et al., (2013).

Fast magnet switching and multicollector detection, as developed by Wieser and Schwieters (2005), and applied in total evaporation TIMS (Fiedler, 1995), was demonstrated for the determination of ^{187}Re as well as the actinide isotopes ^{238}U and ^{239}Pu , to minimize errors introduced by instabilities in the ion source and the overall operation of the mass spectrometer (Ramakumar and Fiedler, 1999). For measuring radioactive isotopes of alkaline earth elements, that is, radium, pre separation using chromatography is coupled to total evaporation TIMS, achieving detection limits as low as 0.1 pg/g and a precision in isotope ratios better than 1% for ^{226}Ra in silicate rocks (Yokoyama and Nakamura, 2004). Analytics in geochronology or in nuclear industry—related applications comprise high-precision isotope ratio determination with medium to high sensitivity, which is ensured by the good overall efficiency of the technique with correspondingly achievable high statistics (Richter and Goldberg, 2003). For these tasks, a high dynamic range and specifically high stability of the thermal

ionization process are required for proper quantification of the element/isotope under investigation versus the reference.

1. Isotope ratio determination with thermal ionization mass spectrometry

Geochronology based on ^{39}Ar and ^{40}K decay has been reported exhibiting a reproducibility of 0.03% for measurements on sub- μg samples (Nägler and Villa, 2000). Studies on Li isotopes have included investigations of nucleosynthetic processes in the solar system and the precise measurement of Li in open seawater and several international rock standards (James and Palmer, 2000). The monitoring of accidental Pu intake of workers has been performed by TIMS at different laboratories (Inkret et al., 1998; Ham and Harrison, 2000; LaMont et al., 2005; and Hare et al., 2010). The Institute for Reference Materials and Measurements IRMM at Geel, Belgium, reports on U abundances and isotope ratios in natural U (Richter et al., 1999, 2010) as well as in nuclear materials (Richter and Goldberg 2003). A direct and fast TIMS method was developed to overcome the influence of impurities on the measurement in $^{235}\text{U}/^{238}\text{U}$ isotope ratio measurements in nuclear spent fuel safeguards by using refractory metal oxide (Al-Nuzal, 2011). The interlaboratory and other errors in Pb isotope analyses were carefully investigated with a combined TIMS and GDMS study using a ^{207}Pb — ^{204}Pb double spike (Thirlwall, 2000). A reliable analytical technique for Mo isotope abundances in fission products (Wieser and De Laeter, 2000) and also in samples for double-beta decay studies (Wieser and De Laeter, 2001) was tested on molybdenites and other high-purity metals and was compared with IUPAP reference materials. A modified thermal ionization mass spectrometer with deceleration components was presented in measurements on $^{234}\text{U}/^{238}\text{U}$ standards and on $^{230}\text{Th}/^{232}\text{Th}$ samples (Van Calsteren and Schwieters, 1995), delivering an abundance sensitivity in the order of 10^{-8} . In parallel for the isotope ratios of $^{234}\text{U}/^{238}\text{U}$ of $\sim 0.7\%$ and $^{230}\text{Th}/^{232}\text{Th}$ of 6.1×10^{-6} , a precision of 1.3% was obtained.

2. High-sensitivity measurements with thermal ionization mass spectrometry

Interesting work has been reported on TIMS applications regarding high-sensitivity measurements at lowest concentrations, for which any kind of isobaric interference must be reliably suppressed (Taylor et al., 1998). One example is the precise counting of atom numbers for half-life determination of extremely long-lived isotopes, undertaken, for example, in the case of ^{126}Sn (Oberli et al., 1999) and ^{244}Pu (Aggarwal, 2006). Other applications concern radiogenic isotope geology and geochronology, as described in detail in textbooks, such

as Dickin (2018). Sensitive ultratrace determinations in the attogram per liter level in seawater have been reported for the actinide isotope ^{231}Pa , demonstrating overall efficiencies exceeding 0.5% (Shen et al., 2003), whereas an overall efficiency of 2.7% for femtogram level studies on Pu isotopes was demonstrated for TIMS, including separation recovery from an initial chromatographic preseparation step (Grate et al., 2011).

IV. Glow discharge mass spectrometry

A. Principle of ionization in a glow discharge

Glow discharge mass spectrometry (GDMS) represents a very powerful and efficient analytical method for direct trace analysis and depth profiling (Harrison, 1988; Betti and de las Heras, 2004; Venzago and Pisonero, 2015). It has found widespread applications in the determination of trace-level distributions at surfaces and within conducting and nonconducting solids or dispersed liquids (Duckworth et al., 1993; Barshick et al., 1993, 2000). It is also frequently applied to the characterization of nuclear samples (Betti, 1996) as well as nuclear forensics (Betti et al., 1999). GDMS has the advantage of almost entirely avoiding sample preparation, as measurements are carried out directly on the initial sample material. This serves as the cathode for a low-pressure argon plasma, burning at a pressure of ca. 1 mbar. The Ar^+ ions are accelerated by the source potential of a few hundred volts and sputter off sample constituents as atoms, ions, molecules, and clusters. The plasma conditions ensure an efficient dissociation and atomic ion formation by Penning and/or electron impact ionization. Positive ions from the glow discharge are emitted via an exit aperture through the anode and are analyzed usually by a double-focusing mass spectrometer, for example, in reverse Nier–Johnson geometry like the commercial VG-9000 instrument (Winsford, UK), as sketched in Fig. 8.3. Such a system provides high transmission ($>75\%$) and a mass resolution of up to $m/\Delta m \approx 10,000$. For the handling of highly radioactive nuclear materials, GDMS systems are operated in sealed glove boxes (Betti et al., 1994). Depending on the specific sample material, either a direct current (dc) or radio-frequency (RF) power is used as the ion source. With dc-GDMS in electrically conducting materials, LODs in the ng/g range with a reproducibility of $\sim 10\%$ were reported (Van Straaten et al., 1994; Venzago and Weigert, 1994). Due to electrical charging of the sample surface, the analysis of nonconducting materials is more demanding. Admixtures of nonconducting powders with high-purity metal or graphite powder (De Gent et al., 1995) or alternatively the use of an electron flooding secondary cathode (Schelles et al., 1996) was applied successfully. RF-GDMS permits the analysis of conducting as well as semiconducting or

FIGURE 8.3 Schematics of a glow discharge mass spectrometry system in reverse Nier–Johnson geometry. The glow discharge source is shown enlarged and worked out in more detail.

nonconducting materials without major restriction (Marcus, 1996).

B. Applications

In the fields of nuclear technology, the characterization of nuclear fuels with respect to elements and individual isotopes is highly relevant. This includes high-temperature metallic cladding materials, before and after exposure, nuclear waste, and undeclared nuclear material, often on high to highest activity levels. On the other hand, the direct determination of suspected low-level radiocontamination in environmental samples and hot particles is of major concern. GDMS is successfully applied in both fields.

1. Trace and bulk analysis of nuclear samples

Metallic alloy fuels consisting of UNdZr and UPuZr with uranium content of up to 81% were analyzed semi-quantitatively by GDMS using the signal intensity of the analyte and taking into account the specific element sensitivity of uranium. The relative sensitivity factor (RSF) values were obtained from a comparison with other methods such as ICP-MS and ICP-AES in analyzing uranium metal specimens of different origin. A good agreement between concentration values as determined directly by GDMS and other techniques, which involve specific chemical sample preparation, was found (Betti, 2002, 2005). Further applications of GDMS include the analysis of zirconium alloys, which are used as cladding materials for nuclear fuel elements. Quantitative data on these zircaloy cladding materials were obtained in agreement by applying either matrix specific or RSF values for a uranium metal sample. In this way, GDMS meets the requirements

for bulk solids analysis in nuclear systems, providing a full elemental analysis at major, minor, and trace concentration levels with lowest matrix dependency (Robinson and Hall, 1987).

Nonconductive nuclear samples, especially oxide-based compounds such as uranium and plutonium oxide samples, are investigated by GDMS (Betti, 1996; Betti and de las Heras, 2004). Different arrangements were developed for this purpose and are in use, often in combination with each other, such as the following: (1) a secondary cathode is placed directly in front of the (nonconductive) sample surface (Tong and Harrison, 1993); (2) a powder sample is mixed with a conducting host matrix in an appropriate ratio (Winchester and Marcus, 1988); and (3) in a modern approach, a pulsed glow discharge source combined with time-of flight mass spectrometry is used (Ganeev et al., 2017).

Oxygen as a major element in the matrix causes problems due to its release during the discharge process. Introduced into the plasma, it influences the signal by quenching metastable atoms and by forming oxide complexes with the analyte. Tantalum and titanium are thus well suited as host matrix, because these materials significantly reduce the formation of UO^+ and PuO^+ species. Due to its getter capability for oxygen, tantalum is used specifically as a secondary cathode material as well. It was shown that, for several elements, the RSFs strongly depend on the oxygen content in the sample (Betti 1996), which implies a specific matrix reference sample for the quantitative analysis of oxygen-containing samples. A good agreement for plutonium oxide samples using ICP-MS and GDMS with tantalum as secondary cathode was obtained for a number of radioisotopes (De las Heras et al., 2000).

Using a pulsed glow discharge, U contents and $^{235}\text{U}/^{238}\text{U}$ isotope ratios were studied in Chernobyl microparticles (Ganeev et al., 2017). Routinely, materials used for nuclear fuel production are tested by dc-GDMS on their isotopic composition of major elements and the concentration of trace elements, which might lead to severe radiocontaminations by neutron capture in the reactor. Both, initial raw materials and fuel pellets were studied (De la Heras et al., 2000). Data from a uranium oxide reference sample analysis (Morille, CEA, France) taken by secondary cathode GDMS gave precisions of $\sim 10\%$ RSD or better (Betti, 2002). LODs for GDMS in the low $\mu\text{g/g}$ level are reported for most elements, including stable as well as radioactive isotopes (Zhang et al., 2016).

2. Determination of radioisotopes in the environment

In the safety assessment of repositories for highly radioactive waste, the study of the potential migration behavior

of the enclosed radionuclides into the nearby environment is a major focus. In this respect, GDMS is in use for the detection of anthropogenic uranium (Duckworth et al., 1993) as well as other radioisotopes in soil, sediment, and vegetation samples (Betti, 1996). The determination of ^{237}Np in Irish Sea sediment samples is another example for such measurements using secondary electrode GDMS (De las Heras et al., 2002). The influences of host matrix interferences must be considered, for example, in the determination of ^{236}U , which leads to detection limits in the pg/g range. This purely anthropogenic isotope indicates the presence of irradiated uranium in a sample.

3. Determination of isotopic compositions

The precise and accurate measurement of isotope ratios is a further application of GDMS, which is of high relevance, for example, in nuclear forensics. Here, the main interest is the isotopic composition of all types of declared or undeclared nuclear materials with respect to U and Pu isotopes. Direct investigations are carried out by means of GDMS (Barshick et al., 1998), whereas a comparison with TIMS once again showed that GDMS is competitive in terms of precision and accuracy for the relevant elements (Mayer et al., 2005).

4. Depth profiling measurements

Depth profiling by GDMS is in use for the study of the mechanism of corrosion of zircaloy cladding of nuclear fuels by measuring the diffusion of impurities in the ZrO_2 layers (Actis-Dato et al., 2000). In general, the investigation of the diffusion mechanism of trace elements is an important aspect in the characterization of environmental processes. An example is the sorption or desorption of actinides in various host rocks or technical barrier materials. These types of studies, which imply depth information, are important for the conception and planning of nuclear waste repositories, and GDMS is a highly versatile tool for that purpose (Betti and de las Heras, 2004).

V. Secondary ion mass spectrometry

A. Principle of ionization through ion impact

SIMS is a surface imaging technique, mainly applied for mono- and multielement trace analysis of solid materials or thin layers, depth profiling, and mapping of elemental and isotopic distributions with high sensitivity. A beam of primary ions with energy ranging from about 1 to 25 keV is focused onto the sample. The ions transfer their kinetic energy to the atoms of the solid by sputtering neutral particles from the surface and—to a lesser extent—positively or negatively charged secondary ions, from which the name of the technique is derived (Benninghoven et al., 1992).

The emitted secondary ions can be atomic, molecular, or cluster ions. They are separated in a mass spectrometer according to their mass-to-charge ratio and are measured with a sensitive ion detection system. To cover a wide dynamic range, often both an electron multiplier and a Faraday cup are installed as sensitive ion detection systems. For a given element, the yield of secondary ions depends on its ionization potential and on the physicochemical properties of the specimen such as its chemical composition, thickness, and even surface quality. Hence, SIMS efficiencies strongly depend on element and sample composition, making it hard to obtain absolute concentrations. Therefore, SIMS is primarily used for element imaging by measuring relative quantities such as isotope ratios or for depth profiling of trace elements in the form of relative abundances.

There are two operational regimes in SIMS, namely, *dynamic SIMS*, which uses a high primary ion current density for LbL erosion and depth profiling studies, and *static SIMS*, which operates at a low primary ion current. *Dynamic SIMS* is restricted to elemental and isotopic analysis but allows the three-dimensional characterization of the sample composition by scanning the primary ion beam over the surface and combining this imaging with depth profiling. Furthermore, the sample is ablated, that is, destroyed in the course of the measurement. Imaging can be performed either via the so-called microscope or the microprobe mode. In the microscope mode, the sample is illuminated by a broad beam of primary ions and the produced secondary ions are accelerated by an electrostatic field and focused with an electrostatic lens. Here, the lateral resolution is about 0.4 μm and determined by the ion optics. For microprobe investigations, a tightly focused illuminating beam is used and an immersion lens acts as the collecting optical system. In this mode, the resolution is defined by the beam diameter (Chabala et al., 1995); 50 nm and below is achieved by standard commercial instruments (e.g., CAMECA nano-SIMS, <https://www.cameca.com/>, accessed November 29, 2018)).

In addition to element and isotope analysis, *static SIMS* (Van Vaeck et al., 1999; Adriaens et al., 1999) enables the detection of structural ions from organic compounds with an information depth limited to the uppermost surface layer, that is, speciation and organic analysis are feasible. The very low sample consumption makes static SIMS a quasi-nondestructive method. However, depth profiling is possible only by using an additional sputtering ion beam.

With both types of SIMS, primary ions are produced in so-called “ion guns” by either electron or plasma ionization of both, reactive or inert gases (e.g., O_2^+ , Ar^+), by surface ionization of alkalis (Cs^+), or by liquid metal ion field emission (Ga^+). Depending on the energy of the ions and the nature of the sample, the primary ions penetrate only fractions of a nanometer up to about 10 nm into the solid.

The primary ion’s kinetic energy is transferred to the atoms of the sample in a cascade process producing the secondary atoms and ions only in a thin layer. This makes SIMS a surface-sensitive technique with depth resolution in atomic dimensions.

For many sample materials, the majority of sputtered entities remains neutral and hence is lost to MS detection, which most often limits the sensitivity for trace analysis determination. By use of pulsed lasers, these neutral atoms are postionized in a technique called secondary neutral mass spectrometry (SNMS). For many years, neutral species were ionized in a nonselective process by high-energy ultraviolet photons (Hayashi et al., 1991; Kaesdorf et al., 1990). However, ionization can also be performed in a multistep resonant process (see the Section VII) by using up to three well-tuned photon energies of high-repetition-rate tunable pulsed lasers. Based on an early study by Erdmann et al. (2008, 2009), the multistep resonant process was further developed (Franzmann et al., 2017) and is now applied at several laboratories (Franzmann et al., 2018; Savina et al., 2017; Stephan et al., 2016).

In most modern instruments, the secondary ions are analyzed by single focusing magnetic sector fields or using radiofrequency quadrupoles for compactness. Time-of-flight mass spectrometers allow imaging of a wide range of mass-to-charge ratios simultaneously. A few highly sophisticated SIMS instruments use a high-resolution double-focusing mass separation system. These were developed for resolution of interferences from molecular or cluster ions with respect to atomic ions. A schematic representation of a secondary ion mass spectrometer equipped with sector-field analysis is provided in Fig. 8.4.

FIGURE 8.4 Schematic representation of the secondary ion mass spectrometry principle.

With a double-focusing mass spectrometer or, more commonly, TOF analyzers, resolutions exceeding $m/\Delta m = 10,000$ are routinely achieved. A detection limit for SIMS in the ng/g to pg/g range can be achieved (Tamborini et al., 1998; Tamborini and Betti, 2000). While element imaging and relative abundance measurements are easily carried out, quantification of the analytical results obtained by SIMS is a challenging task. The ion count rates must be corrected with relative sensitivity coefficients (RSCs), which vary, among others, as a function of the primary ion beam, the physical and chemical properties of the element to be investigated, the composition of the matrix, and the charge of the secondary ions. Many of these parameters have to be determined by using standard reference materials. However, successful use of SIMS for the quantitative analysis of partly oxidized uranium surfaces was demonstrated (Kuruc et al., 2011).

B. Applications

SIMS has many applications in the field of radioisotope analysis. Due to the good lateral resolution of the primary ion beam, SIMS is successfully applied for particle identification down to micrometer size and for isotope analyses in astrophysics, for example, of presolar dust grains (Savina et al., 2003). The characterization of environmental samples, possibly contaminated by radioisotopes, studies for nuclear medical applications using, that is, ^{99}Tc , ^{89}Sr , and ^{76}Br as radiotracers (Fourre et al., 1997), investigations on surface compositions, depth profile measurements, and material science studies are examples for the wide range use of SIMS. In the following paragraphs, some important applications are exemplified without any claim to be exhaustive.

1. Radioecology

SIMS has been applied to the identification of single uranium particles and for the determination of their isotopic composition (Tamborini et al., 1998). This is an important issue in environmental monitoring and radioprotection. Such particles can be released from nuclear installations either during regular operation or in the case of accidents. Due to their small size, they are transported as aerosols and are recovered in environmental samples or collected, for example, in air filters. The isotopic composition serves as a fingerprint characteristic of the origin of the particles. From certain isotope ratios, such as $^{241}\text{Pu}/^{241}\text{Am}$, the age of the particle can be calculated (Jernstrom et al., 2006). Furthermore, the properties of these particles allow conclusions on the course of the accident itself as, for example, in the case of micrometer-sized fuel debris released from the Chernobyl nuclear power plant in 1986 (Salbu et al., 2001). To understand weathering mechanisms, UO_2F_2

particles were stored in environmental samples, and the alterations were investigated by SIMS (Kips and Kristo, 2009).

Many military actions and accidents led to the release of U- and Pu-bearing material, spanning the range from depleted uranium ammunition (Danesi et al., 2003a,b; Lind et al., 2009) to highly enriched weapons grade materials (Lind et al., 2008). One of the most prominent cases is the Thule accident. By means of SIMS, particles extracted from marine sediments were traced back to this origin (Nielsen et al., 2009). Plutonium released from the underground nuclear weapon tests in the Nevada test site were shown to be much more mobile than expected, which is ascribed to colloid-mediated transport (Kersting et al., 1999). At the same time, large amounts of actinides were released from the Mayak reprocessing plants during several accidents in the 1950s and 1960s. Speciation of these radionuclides and evidence of colloid-mediated transport were provided by using SIMS, X-ray absorption fine structure, and X-ray photoelectron spectroscopy as described by Kalmykov et al. (2007). SIMS applied in combination with electron probe microanalysis and glow discharge mass spectrometry allowed the characterization of environmental samples contaminated with traces of radioisotopes (Lefèvre et al., 1996). Here, the main emphasis was put on the radionuclides ^{127}Cs , ^{129}I , and ^{238}U , localized in soil and grass samples.

2. Safeguards and nonproliferation control

SIMS was applied to the characterization of plutonium and highly enriched uranium particles with a diameter of $\sim 10\ \mu\text{m}$ in nuclear forensic studies (Betti et al., 1999; Tamborini and Betti, 2000). The isotopic composition of these particles was measured with an accuracy and precision of 0.5%. Furthermore, trace elements were determined in the particles by SIMS, and their composition revealed the history of the sample. SIMS was also applied to the identification of plutonium particles and their characterization according to the isotope ratios, especially with respect to the ratio $^{239}\text{Pu}/^{240}\text{Pu}$. Other examples are the isotopic determination of uranium and plutonium in glass microparticles (Simons, 1986) and in clay microspheres (Stoffels et al., 1994). The high efficiency of large geometry SIMS for safeguard purposes was reported by Ranebo et al. (2009). The isotopic composition of laboratory synthesized monodisperse uranium oxide particles could be verified with SIMS (Erdmann et al., 2000; Ranebo et al., 2010). The dependence of sputtered molecular ions on the stoichiometry of the uranium particle (Hocking et al., 2012) provides forensic evidence for chemical processing of a sample, even if the isotope ratio was not changed (Schuler, 2010).

3. Cosmochemistry

The chemical analysis of meteorites and the isotope analyses of presolar dust grains (Stephan et al., 2018; Trapitsch et al., 2018) are two examples for the application of SIMS in astrophysics. Results from such analysis make it possible to detect the origins and pathways through the interstellar medium and thus give new insights into the cosmic nucleosynthesis (Diehl and Hillebrandt, 2002). For the isotope analyses of dust grains consisting mainly of SiC, nanoscale secondary ion mass spectrometry (nano-SIMS) has enabled investigations with spatial resolution in the range of 100 nm. Calcium–aluminum-rich inclusions (CAIs) from the Allende Meteorite were investigated by means of SIMS to get information on the $^{11}\text{B}/^{10}\text{B}$ and $^9\text{Be}/^{11}\text{B}$ compositions. The $^{10}\text{B}/^{11}\text{B}$ values from various spots show ^{10}B excesses, which are correlated with the beryllium to boron ratio in a manner indicative of the in situ decay of the radioactive isotope ^{10}Be ($T_{1/2} = 1.6 \times 10^6$ a). ^{10}Be is produced only by nuclear spallation reactions and not by stellar nucleosynthesis, so its existence in early solar system material (CAI) attests to intense irradiation processes in the solar nebula (McKeegan et al., 2000). The technique also has been useful in the investigation of indigenous hydrocarbons in extraterrestrial material, possible essential precursors to the formation of life on earth (Stephan, 2001).

4. Geosciences

In the geosciences, radionuclides are used for dating purposes and for the investigation of erosion rates. Recent SIMS developments in geoscience applications include (1) the lowering of the total sampling mass down to the 10 fg range, (2) the enhancement of spatial resolution to better than 100 nm, and (3) a reduction in the uncertainties on major element isotope ratios to well below $\pm 0.2\text{‰}$ (Linge et al., 2017; Wiedenbeck, 2008).

5. Trace analysis

The application of the SIMS technique for the assessment of trace concentrations of uranium and plutonium in urine samples was explored (Amaral et al., 1997). Concentrations in the order of 10^{-10} g/L of ^{238}U and 10^{-11} g/L of ^{239}Pu can be determined with this method. The accurate quantification of a number of elements among them Th and U in complex matrices is another example (Ottolini and Oberti, 2000). Among the physical methods for in vitro analytical imaging in the microscopic range, SIMS plays an important role because it images the isotopes of quite a number of elements with good detection limits and an excellent spatial resolution (Thellier et al., 2001).

6. Radiochemistry and material sciences

Within the context of the disposal of radioactive waste, radionuclide migration and mobilization and retention mechanisms need to be understood. In a combined scanning electron microscopy and SIMS study, Ra in contact with already existing barite in aqueous solution was shown to undergo recrystallization into a $\text{Ba}_{1-x}\text{Ra}_x\text{SO}_4$ solid solution (Klinkenberg et al., 2014). While considerably slower than coprecipitation, as used for Ra removal from naturally occurring radioactive materials, recrystallization forms long-term stable phases, which is desirable for the safe disposal of long-lived radioactive waste. The investigation of uranium solids for use as fuels was investigated in many studies. An additional application is the proof of uranium passivation by carbon implantation (Nelson et al., 2006).

VI. Inductively coupled plasma mass spectrometry

A. Principle and instrumentation

Inductively coupled plasmas (ICPs) were introduced into analytical applications in the early 1960s, when powerful radiofrequency generators became available (Reed, 1961). The technique, in general, is based on a flame-like electrical discharge that operates at ambient air pressure. It has revolutionized the practice of elemental and isotope ratio analyses, in particular by the use of argon ICPs. In addition to applications in atomic emission spectrometry (AES) and atomic fluorescence spectrometry, ICPs were established as universal and most efficient ion sources for mass spectrometry in 1980 (Houk et al., 1980), combining the processes of vaporization, atomization, excitation, and complete ionization of a vaporized sample within the hot plasma. A comprehensive presentation of ICP-MS is found in various textbooks and review articles (see, e.g., Montaser, 1998; Ammann, 2007; Beauchemin, 2010). Only a brief introduction to the general principle and the relevant instrumentation is provided here. The plasma torch is formed by a stream of high-pressure argon gas of typically 8–20 L/min, flowing through an assembly of usually three concentric quartz tubes. The analyte is introduced through the central bore after nebulization of initially liquid solutions as aerosol particles or droplets. Most common for ICP-MS is a torch diameter of 18 mm. The torch is encircled at the top by a cooled induction coil, called the load coil, connected to a free-running or crystal-controlled radiofrequency (RF) generator. Most ICP-based mass spectrometers use an RF of either 27 or 40 MHz with typical output powers in the kilowatt range. The magnetic field generated by the RF current through the load coil

induces a strong electrical current in the argon gas stream. A plasma is instantaneously formed and afterward self-sustained, when the Ar gas is seeded with energetic electrons from a high-voltage discharge or from a solid-state piezoelectric transducer. The largest current flow occurs in the periphery of the plasma, which gives the ICP a distinctive annular doughnut-type structure and ensures the efficient introduction of the sample material through the central channel into the plasma. Due to highest gas temperature in the range of up to 8000 K and still higher electron temperatures up to 10,000 K in the plasma, the Ar-ICP is capable of ionizing a wide range of elements, in particular entirely all metals. As a prerequisite, these conditions together with the comparably long plasma-to-sample interaction time in the range of some milliseconds lead to complete vaporization and atomization of the sample aerosols. ICP-MS thus permits a simultaneous multielement determination with lowest LODs.

ICP-MS exhibits a number of special attributes, which are among the following: As a result of the axial sample inlet arrangement into the core of the ICP discharge, the sample aerosols do not undergo any kind of interactions with the surrounding hot walls or a possibly reactive atmosphere. On the contrary, the argon gas and the plasma effectively isolate the analyte's pathway. This enclosure of the analyte ionic species provides optimum conditions for transfer from the ICP on ambient air pressure into the evacuated mass spectrometer system. For this purpose, a sampling cone orifice together with, typically, a two-stage interface, formed by a sampler and a skimmer aperture, is positioned in front of the torch on its central axis. The sampler provides the first differential pumping aperture of approximately 1 mm resulting in a pressure of typically 5 mbar downstream. Behind the sampler, a concentric shock wave is formed. This structure surrounds the

so-called zone of silence and terminates in a perpendicular Mach disc of the gas stream. The skimmer orifice is located in the zone of silence for optimal extraction of the analyte ions into the mass spectrometer. The velocity of the particles passing through the MS interface is around 2.5×10^5 cm/s resulting in a mass-dependent axial kinetic energy in the range 0.5–10 eV for ions of 6–240 u. Final acceleration and ion beam formation is achieved by the acceleration potential and an electrostatic lens system. The longitudinal distances of the arrangement are chosen in a way to exhibit maximum analyte signal together with minimal background in the subsequent high vacuum mass spectrometer section. Fig. 8.5 sketches the principal components of an ICP-MS arrangement, illustrating the plasma torch and the interface system in some detail. As the plasma properties and analytical characteristics of the AR-ICP are not significantly affected by a variation in the sample composition, a wide range of elements contained in major, minor, trace, and ultratrace concentration levels in a variety of liquid or easily vaporable matrices can be studied.

Most spectroscopic studies of the ions produced by an ICP discharge are conducted using compact quadrupole mass spectrometers, which offer the advantages of easy use by operating the ion source near ground potential and low cost. Nevertheless, there are some major drawbacks: a poor peak shape, as compared with magnetic double-focusing mass analyzers, and an intrinsically low mass resolution in the range of 0.1 u. This is insufficient to separate analyte ions from isobaric interferences generated by the ICP ion source. These may arise from molecular species formed, for example, by a reaction of sample, plasma gas, and matrix or solvent constituents. Examples are the interferences of $^{40}\text{Ar}^{16}\text{O}$ with ^{56}Fe , or $^{35}\text{Cl}^{16}\text{O}$ with ^{51}V or numerous hydrides, which might generate signals at the same nominal masses as the analyte.

FIGURE 8.5 Principal components of a quadrupole inductively coupled plasma mass spectrometry (ICP-MS) system. Ions are created in the ICP plasma torch and transferred into the quadrupole mass spectrometer through the MS interface. This involves sampler and skimmer apertures and the ion transfer lens arranged inside a differentially pumped vacuum section. After separation according to the mass-to-charge ratio, indicated here by a quadrupole mass filter, ions are recorded at the detector.

To overcome the drawbacks described above, various refinements of the basic ICP-technique have been developed which include

- the use of non-Ar or mixed gas plasmas (Montaser, 1998; Balcaen et al., 2007),
- electrothermal vaporization (Becker and Hirner, 1994),
- laser ablation (Gray, 1985; Richner et al., 1994; Becker et al., 1998),
- matrix separation by chromatography and preconcentrations within hyphenated techniques (Ebdon et al., 1993),
- shielded torches (Gray, 1986; Uchida and Ito, 1994),
- cold plasma operation (Jiang et al., 1988; Tanner, 1995),
- the introduction of collision or reaction cells (Feldmann et al., 1999 a,b; Tanner et al., 2002),
- the use of tandem mass spectrometry (Balcaen et al., 2015), or
- the use of multiple ion collectors (Yang, 2008).

Using a single ion detector, optimum figures of merit in isotope ratio measurements by ICP-MS were achieved by the introduction of a collision cell interface. This device serves to dissociate or neutralize disturbing argon gas-based molecular ions from the plasma torch and to reduce the kinetic energy of the ions. Its application results in higher ion transmission, improved sensitivity, and better precision of isotope ratio measurements compared with conventional ICP-MS (Boulyga and Becker, 2002a). A further significant instrumental improvement for isotope ratio measurements by sector-field ICP-MS was the implementation of multiple ion collectors. In this way, a precision of isotope ratios of up to 0.002% was demonstrated (Becker, 2002).

Apart from all the modifications to ICP-MS, the most effective approach for the improvement of ICP-MS analyses is the use of a high-resolution sector-field mass analyzer (Becker and Dietze, 1999b). This configuration allows for the proper separation and interpretation of spectral interferences in elemental analyses and generally permits the operation of the plasma in its normal “hot” mode in which the level of oxides and hydrides is much higher as in the cold, but inefficient plasma operation. Even though experimentally much more extensive, the use of a high-resolution system is the preferred method for investigating low levels of ultratrace components, that is, radioisotopes in complicated matrices. They also serve best for precision measurements of isotope ratios by ICP-MS. Less common mass analyzers used in ICP-MS include ion cyclotron resonance mass spectrometers, ion trap mass spectrometers, for example, the Orbi trap, as well as time-of-flight mass spectrometers (Olesik, 2000).

B. Sample introduction

Regarding ICP-MS, the introduction of the sample into the plasma plays a key role in the production of ions and interfering species as discussed in numerous publications (Greenfield and Montaser, 1992; Montaser, 1998). Generally, the sample can be introduced in gaseous, liquid, and solid form. Here, we restrict ourselves to liquids and solids and those techniques that have been applied in the analysis of long-lived radionuclides.

1. Nebulization

Liquids are dispersed into fine aerosols before being introduced into the ICP by using different nebulizers: pneumatic (PNs), ultrasonic (USNs), or thermospray nebulizers are in use. Although a large variety of individual sample introduction devices are commercially available (Sharp, 1988), they all are formed on two basic designs: in the concentric type, the sample solution passes through a capillary surrounded by a high-velocity gas stream, which flows parallel to the gas stream axis. Alternatively, the cross-flow type has a liquid-carrying capillary set at a right angle to the tube carrying the high-velocity gas stream. In both configurations, a pressure differential created across the sample draws the solution through the capillary. The analyte transport efficiency of commonly used PNs reaches a few percent, limited by nebulizer clogging due to excessively concentrated solutions. In ultrasonic nebulization, the sample solution is applied onto the surface of a piezoelectric transducer driven by an ultrasonic generator at a frequency of several 100 kHz. The total production rate of droplets generated by the USN is significantly higher than that obtained with PNs, and desolvation is essential to remove excess solvent and prevent plasma cooling. Analyte transport efficiencies approaching 20% are reached for USNs operating at an uptake rate of 1 mL/min. This value can be further optimized if the spray chamber is heated or if the solution uptake rate is reduced to a few microliters per minute. For example, analyte transport efficiencies close to 100% are achieved with a microflow USN at solution uptake rates of 5–20 $\mu\text{L}/\text{min}$ (Montaser, 1998; Beauchemin, 2010). Direct injection nebulizers introduce 100% of the aerosol into the plasma, thereby increasing the solvent load. Most recent versions of these include microconcentric pneumatic nebulizers positioned directly inside the ICP torch. Further developments include a specific high-efficiency nebulizer or a direct injection high-efficiency nebulizer (DIHEN), as reviewed in textbooks (Montaser, 1998; Prohaska et al., 2015).

2. Hyphenated systems

The combination of liquid chromatography (LC) with ICP-MS is a straightforward approach, which provides attractive opportunities for element speciation. In most cases, a direct transfer of the eluate from the column through a nebulizer into the torch (Ebdon et al., 1993) provides the interfacing of LC to the ICP. Similarly, capillary electrophoresis, being another attractive separation technique with excellent speciation capabilities, is hyphenated to ICP-MS. This was reported first in 1995 using a conventional concentric nebulizer and a conical spray chamber as an interface to the ICP. LODs in the low pg/g range and precision in the range of 1%–5% RSD were reported (Olesik et al., 1995).

3. Laser ablation

Laser ablation is the most versatile sampling technique used for solid materials in ICP spectrometry. Laser ablation was first introduced into ICP-MS in 1985 (Gray, 1985). When sufficient energy in the form of a focused laser beam is directed onto a solid sample, material from the surface is sputtered and vaporized. The plume of vapor and particulate matter is transported within an argon carrier gas to the ICP plasma torch for atomization and ionization, as sketched in Fig. 8.6.

The specific strength of the combination of LA-ICP-MS is found in the ability to directly study diverse materials ranging from conducting and nonconducting inorganic and organic compounds available as solids or as powders (Becker et al., 1998). In addition to conventional bulk analysis, the focusing characteristics of lasers permit sampling of small areas, such that localized microanalysis and spatially resolved studies are feasible (Krachler et al., 2018).

C. Applications to radionuclides

A number of reviews summarize recent applications of ICP-MS in environmental sciences, including radioecology (Pröfrock and Prange, 2012) and with a focus on uranium analysis (Tissot and Dauphas, 2015; Bu et al., 2017).

1. Methodical developments on isotope ratios

The early application of a double-focusing sector-field ICP-MS for ultratrace and isotopic analysis of uranium in radioactive waste samples was performed in high-purity water, showing a detection limit in the low fg/mL range (Kerl et al., 1997). Under optimum experimental conditions, a precision in $^{235}\text{U}/^{238}\text{U}$ isotope ratio determinations was 0.07% for ratios around unity. For the isotopic standard U-020 ($^{235}\text{U}/^{238}\text{U} = 0.0208$), a precision of 0.23% RSD at the 100 pg/mL level using ultrasonic nebulization was achieved. With $^{234}\text{U}/^{238}\text{U}$ ratios as low as 10^{-5} , data obtained by ICP-MS and α -spectrometry were shown to agree well. Nuclide analysis in a tantalum target, which was used in a spallation source by irradiation with 800 MeV protons, is another early example. Concentration of radionuclides within a highly radioactive matrix in the range from 1 ng g^{-1} to $50 \text{ } \mu\text{g g}^{-1}$ was performed to verify the theoretical predictions for spallation yields. Double-focusing sector-field ICP-MS was used in combination with liquid–liquid extraction from the tantalum matrix to remove the ^{182}Ta activity, and results were compared with quadrupole ICP-MS. Comparison of the ICP-MS results to radiometric data on some nuclides, obtained by neutron activation analysis, yielded reasonable agreement (Becker and Dietze, 1997; Becker and Dietze, 1998). Precise long-term measurements of uranium and thorium isotope ratios

FIGURE 8.6 Principle of the laser ablation inductively coupled plasma (ICP) coupling. By the interaction of a focused laser beam with a solid surface, sample material is ablated and vaporized, and the ablated material is transported using argon as the carrier gas into the ICP.

were carried out in standard 1 µg/L solutions, using a conventional ICP-MS (Becker and Dietze, 1999a). Uranium isotope ratios of $^{235}\text{U}/^{238}\text{U} = 1, 0.02, \text{ and } 0.00725$ were determined, using different approaches for nebulization: either a cross-flow nebulizer (CFN) at a solution uptake of 1 mL/min or a low-flow microconcentric nebulizer (MCN) at a solution uptake of 0.2 mL/min over 20 h. For an isotope ratio $^{235}\text{U}/^{238}\text{U} \approx 1$, RSDs of $\leq 0.05\%$ using both, CFN and MCN, were achieved. Additional isotope ratio measurements using a DIHEN at a solution uptake of 0.1 mL/min on the same uranium solution yielded a RSD of 0.06–0.08%. The sensitivity of the solution introduction for uranium, thorium, and plutonium was increased significantly compared with CFN and MCN. In parallel, the solution uptake could be reduced to 1 µL/min in DIHEN-ICP-MS. Isotope ratio measurements at an ultralow concentration level (e.g., determination of $^{240}\text{Pu}/^{239}\text{Pu}$ isotope ratio in a 10 ng/L Pu waste solution) were carried out for the characterization of radioactive waste and environmental samples. Recently, Pu isotope ratio studies were reported in different environmental and biomedical samples using ICP-MS (Evans et al., 2003). In a study utilizing IAEA standard soils, it has been shown that a uranium surplus of about six orders of magnitude prohibits any suitable application of ICP-MS (Xu et al., 2014). On the other hand, Pu isotope ratio determinations for the isotopes $^{239,240,241}\text{Pu}$ in marine sediments near the Fukushima Dai-ichi nuclear power plant were successfully achieved after uranium decontamination by about six orders of magnitude (Bu et al., 2014).

Systematic investigations were undertaken on the capability of double-focusing sector-field ICP-MS coupled with a plasma-shielded torch using different nebulizers. A total amount of analyte between 0.4 and 10 pg was used for a number of long-lived radionuclides (^{226}Ra , ^{230}Th , ^{237}Np , ^{238}U , ^{239}Pu , and ^{241}Am ; each available at concentrations of 1 ng/L in aqueous solution) with different nebulizers (Becker and Dietze, 1999b). Detection limits in the sub-pg/L range and precisions ranging from 1% to 2% RSD for a 1 ng/L concentration level were reported. At lowest solution uptake rates (down to 1 µL/min), uranium solutions were analyzed by DIHEN-ICP-MS using the double-focusing sector-field instrument, which exhibits significantly higher transmission and sensitivity than the conventional quadrupole ICP-MS. Using the shielded torch arrangement, a precision of Pu isotopic analysis of 0.2%, 2%, and 14% RSD for 1000, 100, and 10 pg/L was obtained.

The performance of a specific ICP-MS system with a hexapole collision cell (HEX-ICP-QMS) was studied to obtain figures of merits and to prepare for real applications (Boulyga and Becker, 2001). A significant improvement in sensitivities and detection limits was achieved in particular for those ions affected by interferences with argon or argon-based molecular ions due to the removal of Ar^+ and ArX^+

ions (with $\text{X} = \text{H}, \text{C}, \text{N}, \text{O}, \text{Ar}$). Investigation on heavier elements generally profited due to an enhanced ion transmission by the hexapole ion guide. Subsequent applications of HEX-ICP-MS were focused on the determination of uranium in soil samples from the Chernobyl area (Boulyga and Becker, 2002b). A limit of the $^{236}\text{U}/^{238}\text{U}$ ratio determination in 10 µg/L uranium solution of 3×10^{-7} was measured, corresponding to a detection limit of 3 pg/L. The precision of uranium isotope ratio measurements in 10 µg/L standard solutions was 0.13% ($^{235}\text{U}/^{238}\text{U}$) and 0.33% ($^{236}\text{U}/^{238}\text{U}$).

A very specific application of ICP-MS has developed in the separation of individual radioisotopes for the production of ultrapure targets for fundamental research and calibration purposes (Liezers et al., 2015). Both actinide isotopes ^{238}Pu and ^{241}Am could be purified with a signature of more than a factor of 100, and subsequently, background-free α -spectrometry at the intrinsic resolution of the detector could be realized. The limitation remaining is the low efficiency of the process (Dion et al., 2015).

2. Radioecology

Soil samples from the former Semipalatinsk nuclear test site (SNTS) in Eastern Kazakhstan were investigated using double-focusing ICP-MS to determine the contamination level and isotope ratios of plutonium (Yamamoto et al., 1996). After dissolution of the samples, the Pu fraction was purified by anion exchange chromatography, evaporated to dryness, and dissolved in nitric acid for introduction into the ICP-MS. Isotope ratios were determined using an ultrasonic nebulizer. High transmission measurements were carried out at relatively low resolution of $m/\Delta m \approx 400$ (by opening slits), and isotope ratios were determined at a level of about 0.1 pg/g solution. Low $^{240}\text{Pu}/^{239}\text{Pu}$ ratios of 0.036(1) and 0.067(1) were found at different test sites and $^{242}\text{Pu}/^{239}\text{Pu}$ ratios of $4.8(4) \times 10^{-5}$ and $2.9(5) \times 10^{-4}$, respectively. These values are significantly different to the values commonly accepted for global fallout from the atmospheric nuclear weapons tests, but they represent the situation after a Pu weapon explosion similar to data from the Nagasaki area. Recently, this work was extended to the study of altogether 32 human tissue and bone samples collected by autopsy from individuals that lived near the SNTS. A significant difference in the $^{240}\text{Pu}/^{239}\text{Pu}$ isotope ratios for tissue samples and for the global fallout value indicated that weapons-grade plutonium was incorporated into the human tissues, especially lungs (Yamamoto et al., 2008).

3. Treatment and storage of nuclear waste

ICP-MS was also used for the characterization of long-term storage and geological isolation by vitrification of highly

radioactive waste, that is, defense-related material, at the Defense Waste Processing Facility (DWPF), Savannah River Site in South Carolina, United States. Safety considerations require the verification of repository criteria for 24 radioisotopes, including major fission products, activation products, actinides, and their daughter nuclei that grow in the waste. Based on a routine determination of four isotopes, that is, ^{90}Sr , ^{137}Cs , ^{238}U , and ^{238}Pu , it was found that the concentrations of the other radiocontaminations in the final glass product can be predicted. For that, a thorough characterization of the high-level waste tanks and a knowledge of the concentrations of the predominant nonradioactive components in the vitrification process are sufficient (Kinard et al., 1997).

The capability of LA-ICP-MS was systematically investigated for measurements of long-lived radionuclides, for example, in nonconducting concrete matrices that are common in nuclear waste packaging. The LODs of long-lived radionuclides were determined in the low pg/g range using a quadrupole LA-ICP-MS or a double-focusing sector-field LA-ICP-MS. For both systems, different calibration procedures, including the correction of analytical results with experimentally determined RSCs and the use of calibration curves or solution calibration by coupling LA-ICP-MS with an ultrasonic nebulizer, were compared and applied to the determination of long-lived radionuclides, that is, Th and U in different solid samples (Becker et al., 2000). The application of dedicated hyphenated systems, that is, ion chromatography (IC) attached on-line to ICP-MS (IC-ICP-MS), for the determination of the quality achieved in separation of fission products and actinides and the determination of trace elements in the different nuclear waste solutions, is reviewed (Betti, 1997). The coupling of IC and a low-resolution ICP-MS has been found to be effective in eliminating isobaric interferences in the determination of, for example, ^{90}Sr , ^{137}Cs , lanthanides, and actinides (Barrero Moreno et al., 1996). This online coupling has been installed inside a glove box for the determination of the complete inventory of fission products and actinides in spent nuclear fuel and high-level liquid waste samples. With this system, for example, for the radioactive isotopes of $^{134,135,137}\text{Cs}$, isobaric interferences by stable isotopes of Ba were eliminated giving a detection limit of 16 pg/g for total Cs with a precision of 2.5% at a concentration level of 10^{-7} (Barrero Moreno et al., 1999). The accuracy of the ratio $^{134}\text{Cs}/^{137}\text{Cs}$ was found to be 2.5%. The same system was applied successfully to the determination of actinides in aqueous leachate solutions from uranium oxide (Solatie et al., 2000). The results were compared with those of classical radiometric methods and determinations by α -, γ -spectrometry, and liquid scintillation counting (LSC). The comparison confirmed that IC-ICP-MS is a powerful method for the detection of long-lived radionuclides. IC-ICP-MS was found to be the most

convenient choice being much less time-consuming than the radiometric methods with respect to sample preparation (α -spectrometry) as well as counting time (γ -spectrometry and LSC).

4. Application to Chernobyl and Fukushima samples

Numerous specific studies on environmental contamination by different radionuclides using different ICP-MS systems were published after the occurrence of the two major reactor accidents at Chernobyl in 1986 and Fukushima in 2011. Concentrations of the isotopes ^{239}Pu and ^{240}Pu and their isotope ratios were determined by ICP-MS in soil samples collected from three forest sites of the Chernobyl 30-km exclusion zone. Overall, $^{239,240}\text{Pu}$ activity levels of 1 up to above 10 kBq/m² were measured, whereas the isotope ratio of $^{240}\text{Pu}/^{239}\text{Pu} \approx 0.4$, which is well above the value for nuclear fallout of 0.18, confirmed the origin of the contamination and the high burn-up grade of the nuclear fuel (Muramatsu et al., 2000). The highly mobile fission fragment ^{99}Tc was analyzed in soil and in plant leaf samples similarly taken from the 30 km zone around Chernobyl. Strongly varying ^{99}Tc activity levels in the order of 1–15 Bq/kg in soil and 0.2–6 Bq/kg in plants were measured, and soil-to-plant transfer factors of similar magnitude such as for radiocesium have been extracted (Uchida et al., 2000).

To study contaminations around Fukushima, radioisotope ratios of $^{129}\text{I}/^{127}\text{I}$ in iodine (Ohno et al., 2013) and $^{134}\text{Cs}/^{137}\text{Cs}$ and $^{135}\text{Cs}/^{137}\text{Cs}$ in cesium (Ohno and Muramatsu, 2014) were analyzed with ICP-MS in collected rainwater from the vicinity within and around the 30 km exclusion zone. To suppress fully isobaric interferences from Xe, Ba, and molecular ions in both studies, tandem mass spectrometry at a triple quadrupole system equipped with an octopole reaction cell was used. For iodine, the measured isotope ratios in the order of $^{129}\text{I}/^{127}\text{I} \approx 10^{-7}$ are in good agreement with independent AMS studies, whereas the determined cesium ratios were verified with radiometric data from a germanium semiconductor detector. The Cs results differ from global fall-out values and from that of Chernobyl, indicating that measurements of rainwater samples can be used as a radiocesium tracer in the environment. Hyphenated ICP-MS-based techniques were applied to study the role of organics for iodine transport in Japan after the Fukushima accident (Xu et al., 2016). Uranium and plutonium isotope ratios in environmental samples collected close to the Fukushima Dai-ichi Nuclear Power Plant (FDNPP) were determined by a number of groups (Zheng et al., 2012a, 2012b; Yang et al., 2017). A general overview of mass spectrometric activities in the assessment of the radiocontamination around the Fukushima accident site is found in Bu et al. (2018).

VII. Resonance ionization mass spectrometry

A. Principle and requirements for the laser light sources

The different mass spectrometric methods discussed so far, in general, apply to conventional ionization processes. Most of these show strong variations in the ionization efficiency depending on the element, which is expressed, for example, by the RSF factor in GDMS, and might even exhibit isotope fractionation. Thus, these techniques are generally limited in their sensitivity as well as in the significance of their data by the occurrence of isobaric interferences. In addition, due to finite abundance sensitivity values, cross-contaminations, present in the form of peak wings from the neighboring masses, could obscure the mass spectra and limit the precision of results on overall contents and isotope ratios. In contrast, RIMS, using a stepwise resonant excitation and ionization process of specific atoms of the analyte by well-tuned laser light, achieves highest elemental and, if needed, even may contribute additional isotopic selectivity on top of the mass separation. It is a dedicated single-element determination technique and not suitable for simultaneous multielement analysis in one sample; however, it can be adapted to the majority of elements by appropriate tuning of the lasers. Due to the high cross sections for resonant optical processes, that is, the individual excitation steps, and the availability of well-controllable high-power tunable lasers, RIMS offers outstanding properties. These include

- complete suppression of atomic and molecular isobaric interferences,
- very good overall sensitivity in the fg range down to $\sim 10^6$ atoms per sample,
- feasibility of ultrahigh isotope selectivity by taking advantage of the isotope shift in the atomic transitions in addition to the abundance sensitivity of the mass spectrometer, and
- universal applicability to the far majority of elements as a single-element determination technique.

The principle of a typical three-step resonant excitation process leading to final ionization is shown in Fig. 8.7. The initial step is a preferably complete conversion of the sample material into individual atoms within a hot furnace or in free vacuum above a heated filament. Starting from the atomic ground state (or from a thermally populated low-lying state), the sample atoms are excited stepwise to a high-lying excited state along strong optical resonance lines. As illustrated in the figure, usually at least two resonant photon absorption steps are required. Either a real or a virtual (indicated as dotted line) intermediate state can be involved. Finally, the highly excited atoms are ionized

FIGURE 8.7 Principle of a three-step resonant excitation of an atom by light of tuneable lasers. Inefficient nonresonant ionization (center) can be circumvented by addressing autoionizing levels (left) or high-lying bound Rydberg states. For the efficient ionization from the highly excited atomic state besides photon absorption from a laser beam, additional processes may be interjected as discussed in the text.

by absorption of another laser photon or by an alternative process as discussed below.

The probability for induction of one of the individual excitation and ionization steps, W_{opt} , determines the final ionization rate. It is given by the simple formula

$$W_{\text{opt}} = \sigma_{\text{res}} \cdot n_{\text{photons}} \cdot t_{\text{int}},$$

where σ_{res} is the absorption cross section, n_{photons} is the number of photons per cm^2 per second, and t_{int} is the interaction time. In resonance, the cross section σ_{res} for a strong optical transition between two bound atomic states is in the order of $\lambda^2/2\pi$, where λ is the wavelength of the transition, corresponding to about 10^{-9} cm^2 (or $\sim 10^{15} \text{ b}$). Total laser intensities, measured as photon flux, of 10^{15} – 10^{18} photons/ $(\text{cm}^2 \cdot \text{s})$ are easily available from continuous wave lasers or during pulses of pulsed laser systems. In a cloud of free atoms, that is, an atomic vapor, thermally expanding above a filament or within a heated atomizer furnace, interaction times in the order of few microseconds to milliseconds are common. Correspondingly, saturation of the optical excitation with maximum transition rate and an efficiency near 100% in each individual step toward ionization are easily realized in such a sequential process. This makes it one of the most efficient ionization processes for atoms (Hurst et al., 1979).

A bottleneck exists in the ionization step into the ionization continuum. Nonresonantly raising the electron energy beyond the ionization limit (I_p) is very inefficient with low cross sections in the order of 10^{-17} cm^2 and requires very high laser power. Resonant population of an autoionizing level or, alternatively, a high-lying bound Rydberg state in the final excitation step can circumvent this shortcoming. An atom in an autoionizing level immediately decays into a positively charged ion under emission of an

Data were taken on technetium (Mattolat et al., 2010), astatine (Rothe et al., 2013), and 11 of the 14 actinide elements up to einsteinium (Erdmann et al., 1998; Peterson et al., 1998, Rossnagel et al., 2012). For most of these cases, data were taken on samples in the pg range ($\sim 10^{12}$ atoms). A further application concerns the high precision measurement of atomic and nuclear masses, which is carried out at online facilities using Penning-type ion trap or multireflectron mass spectrometers (Dilling et al., 2018).

In the field of analytical applications, RIMS is well established for the fast and sensitive ultratrace determination of long-lived α - and β -emitters, providing LODs in the fg range (10^6 – 10^7 atoms) and, in addition, providing the isotopic composition as valuable information on the source of a contamination (Kluge et al., 1994; Trautmann et al., 2004; Trautmann and Wendt, 2012). Beyond that, the ultratrace determination of long-lived radioisotopes is also applied in biomedical tracer investigations involving highest isotopic and/or elemental selectivity (Ham and Harrison, 2000; Bushaw et al., 2001; Müller et al., 2001; Hennessy et al., 2005; Denk et al., 2006) and in cosmochemistry (Geppert et al., 2005).

B. Resonance ionization mass spectrometry systems and applications

1. Elemental-selective resonance ionization mass spectrometry using pulsed lasers

For studies involving high sensitivity but only moderate demands on isotopic selectivity, which is accomplished by the mass dispersion of the mass spectrometer, pulsed lasers are regularly in use for RIMS. In this way, saturation of all optical excitations and the ionization step and corresponding high efficiency in the ionization process can be ensured. The resulting pulsed generation of ions is most easily combined with mass separation in a time-of-flight mass spectrometer, where the laser pulse delivers the start signal and a complete mass spectrum is recorded for each laser pulse. The temporal and spatial overlap of the evaporated atoms from the sample and the laser pulses needs to be adapted properly:

- For low-repetition-rate pulsed-laser operation at around 10–200 Hz, sample volatilization by pulsed laser desorption is favorable to prevent significant duty cycle losses of up to some orders of magnitude in efficiency (Krönert et al., 1991; Maul et al., 2006). As the process is furthermore strongly affected by the pulse-to-pulse stability of power and spatial profile of the desorption laser, it is not well suited for quantitative ultratrace determinations. With the advent of reliable laser systems, it was almost entirely replaced by high-repetition-rate pulsed-laser RIMS.
- For high-repetition-rate pulsed-laser operation in the 10 kHz range, duty cycle losses during laser pulse pauses are negligible due to the relatively slow movement of atoms with thermal energies, even for continuous evaporation of the sample from an electrothermally heated oven or filament (Grüning et al., 2001). In combination with a TOF-MS, an easy-to-handle and reliable analytical apparatus is formed, which just requires advanced data acquisition to manage the high throughput with refreshment of entire mass spectra in the kilohertz range. Alternatively, high-repetition-rate pulsed-laser RIMS is performed in combination with well-synchronized sample volatilization by ion beam sputtering or laser ablation. This approach not only gives complete temporal overlap of atomization to the laser pulses but even ensures a direct and spatially resolved analysis of surfaces and particles avoiding chemical preparation steps. This technique of SNMS was already discussed in the section on SIMS of this chapter together with some prominent applications in radioisotope determination.

Although not commercially available, analytical systems based on the concept of pulsed laser RIMS are routinely in use for the ultratrace determination of actinides, primarily plutonium, in environmental and biological samples (Passler et al., 1997; Trautmann et al., 2004; Kratz, 2015). After an initial chemical preseparation step extracting predominantly the plutonium content from the sample, plutonium hydroxide is formed and electrolytically deposited on a tantalum filament, which subsequently is covered with a thin titanium layer ($\sim 1 \mu\text{m}$) by sputtering technique. This so-called sandwich filament is inserted into the TOF-MS and heated to about 1000 °C. During this procedure, plutonium hydroxide is converted into the oxide, which immediately releases free atoms through the reducing titanium layer. These atoms are ionized near the filament surface by a three-step three-color laser excitation/ionization process. The ions formed are accelerated in the two-stage electric field of the TOF mass selection, and the mass selectively is recorded by a multichannel plate detector at the end of the time-of-flight drift tube, which is operated either in linear mode or as a reflectron by using an electrostatic ion reflector to further improve mass resolution. For quantification, an internal standard tracer isotope - usually ^{244}Pu in the case of environmental samples - is added to the sample prior to the chemical treatment. Independent monitoring of the chemical yield is carried out by α -spectroscopy on ^{236}Pu added as second tracer. Fig. 8.9 shows the setup with details of the filament, the two suppression electrodes preventing electrons and surface ions from entering the laser ionization region, the transversal laser beam overlap, and the different components of the TOF-MS. The latter include two acceleration grids for

FIGURE 8.9 Sketch of a typical setup for pulsed-laser resonance ionization mass spectrometry with time-of-flight mass analysis, used, for example, for sensitive and isotope-selective determination of plutonium and other actinides.

double-stage acceleration, the reflector unit, and the two detectors used either in linear mode or in reflectron geometry.

A similar technique is also used for ultratrace determination of ^{99}Tc , while an application to minor actinides is under development, for example, for Np, where process efficiencies of 0.3% were reported (Raeder et al., 2011). For the determination of ^{99}Tc in soil, a resonant laser excitation scheme was developed (Wendt et al., 2012) and the rare isotope ^{99}Tc was used as a tracer for quantification. A LOD for ^{99}Tc determination of 0.5 fg was determined, which compares favorably with the competing techniques TIMS and AMS (Schönberg et al., 2017).

A way to overcome limitations inherent in the filament-based sample evaporation, that is, incomplete temporal and spatial overlap of the expanding atom vapor cloud in front of the filament with the beams of the pulsed lasers, is the “laser ion source” technique. By means of this technique, the sample atoms are confined inside a narrow heated furnace cavity of typically ~ 3 mm diameter and >30 mm length, wherein they are resonantly ionized by the laser beams entering through the ion exit hole. The sample atoms are evaporated from a heated reservoir, enter the atomizer cavity at the rear end, and are “stored” inside the cavity by multiple wall collisions before escape. Once ions are generated by the laser radiation or spurious effects, these are guided along the cavity by the field leakage of the acceleration voltage and efficiently extracted toward the subsequent ion beam/mass separator system. The laser ion source is used for analytical applications in combination with a high-transmission radiofrequency quadrupole filter or a magnetic sector-field instrument. In this case, a significantly higher efficiency in the order of 1% and beyond has been demonstrated for technetium and plutonium determination as compared with TOF-RIMS, but spectra are obscured by unspecific background contributions, which brings the LOD to similar values as discussed above (Raeder et al., 2012; Wendt et al., 2012).

Due to the high ionization efficiency and isobaric selectivity demonstrated, hot cavity-type laser ion sources today are standard at the different isotope separator online (ISOL)-type facilities for the artificial production of short-lived radioactive isotopes (Barzakh et al., 1997; Marsh, 2014). Similarly, also at radioactive ion beam facilities, which use the in-flight fragment separator technique (Blumenfeld et al., 2013), resonance ionization is used in gas cells and jets. In this case, the highly energetic products from nuclear reactions are thermalized and neutralized in a high-pressure noble gas for selective resonant laser ionization carried out before or during flushing out by a gas jet toward the mass spectrometer (Kudryavtsev et al., 2002). A combination of a gas-filled ion guide with a laser ion source enabled the first analysis on fermium (Backe et al., 1997; Sewtz et al., 2003) and served as a prototype for combined laser spectroscopic and mass spectrometric investigations on the heaviest actinides toward the transactinides (Laatiaoui et al., 2016). At a pressure of about 35 mbar, the storage time within the interaction volume illuminated by the laser light is about 40 ms, limited by diffusion and thermal convection in the buffer gas. Yet, at 200 Hz repetition rate, a tunable high-power laser system is well suited for efficient resonant ionization. The ions are guided by electric fields to a nozzle and flushed out of the cell by a gas jet. By means of skimmers, a quadrupole ion guide, and mass filter structures, separation from the buffer gas and mass selection is achieved with highest overall sensitivity.

To date, hundreds of radioisotopes of more than 50 different elements have been ionized at the different online facilities by laser resonance ionization, and these were studied after mass separation in high transmission magnetic sector-field spectrometers with respect to their atomic and nuclear properties, that is, mass, size, and shape of the nucleus (Fedosseev et al., 2012). For mainly all those elements, the ionization efficiencies of laser ion sources are generally in the order of 20%–50% and thus more than comparable with conventional ion sources (e.g., surface or plasma ion sources) (Fedosseev et al., 2017). The additional specific advantage of the laser ion source, that is, the drastically improved selectivity in suppression of isobars and neighboring masses, is only limited by interfering of nonspecific ionization processes—primarily thermal ionization at the cavity walls. To achieve the highest isobaric selectivity by complete prevention of these effects, the so-called laser ion source trap has been developed, which combines mass spectrometric, ion trap, and laser spectroscopic aspects (Blaum et al., 2003; Schweltnus et al., 2008). In this approach, the laser ionization takes place just when the atoms have effused out of the hot ion source cavity within a quadrupole structure. Spurious ions are repelled and driven back into the hot source, whereas laser

ions are produced inside the radiofrequency quadrupole trap structure, where they are accumulated and possibly cooled and bunched within buffer gas, for optimum mass resolution and background reduction (Fink et al., 2015). The enrichment and purification of rare radioisotopes for specific applications in fundamental research is a further upcoming application, where mass spectrometry profits from the high-efficiency selectivity and reliability of laser resonance ionization. One particular example is the implantation of ^{163}Ho ions into microscopic detector pixels for the determination of the neutrino mass (Dorner et al., 2018).

2. Highest isotopic selectivity using continuous wave lasers

There are a number of analytical challenges, where exceptionally high isotopic selectivities are required. This is the case, for example, in the determination of a rare radioisotope at ultratrace level aside of a vast surplus of neighboring stable isotopes of the same element. The latter could be numerous orders of magnitude higher in number than the isotope of interest and, in addition, could even be accompanied by additional molecular interferences. Isotopic selectivities in the range well above 10^9 are, in general, not achievable by conventional inorganic mass spectrometry due to the omnipresence of elements and the ubiquitous formation of small molecules such as hydrides or oxides (Heumann et al., 1995). Using narrow-bandwidth laser radiation, as delivered by continuous wave lasers, in a suitable experimental geometry, high-resolution (HR) RIMS contributes a remarkable additional isotopic selectivity of up to multiple orders of magnitude already within the ionization process. By taking advantage of the isotope shift in well-chosen atomic transitions, this optical selectivity enhances the abundance sensitivity of the mass spectrometer, reduces molecular interferences, and leads to extremely high isotopic selectivities, which can be estimated to reach up to 10^{15} .

Sensitive laser mass spectrometric investigations directed toward achieving such high isotope selectivities have been carried out on a long list of ultrarare radioisotopes. Early studies concerned the radioisotopes ^{81}Kr and ^{85}Kr of the noble gas krypton, which either are of relevance for radioisotope dating or are of environmental concern as a major fission product release after a possible nuclear reactor disaster or from nuclear reprocessing, respectively. RIMS determination techniques for noble gases use fully encapsulated vacuum chambers and refrigeration or recirculation of the sample material to obtain extremely low LODs in the low fg (10^{-15} g) to ag (10^{-18} g) region and even beyond (Payne et al., 1994; Crowther et al., 2008; Iwata et al., 2010; Strashnov et al., 2011). Due to these outstanding specifications, unusual applications of this technology, for

example, for the detection of exotic species like dark matter are envisaged (Iwata et al., 2015).

Regarding the surveillance of the use of nuclear power and possibly associated lowest-level contaminations in the environment, dedicated RIMS techniques have been developed for a number of fission products, which are radiometrically not easily accessible. These include the alkaline isotopes ^{135}Cs , which is one of the only seven long-lived fission products existing, and ^{137}Cs . Both isotopes were measured at a surplus of about six orders of magnitude of stable ^{133}Cs . Results showed good agreement with TIMS studies (Pibida et al., 2004). Significantly higher isotopic selectivity is required for investigations on the alkaline earth isotopes ^{41}Ca , ^{89}Sr , and ^{90}Sr , which we shall discuss in detail below, as well as for analytical studies of ^{210}Pb and ^{236}U . The determination of traces of the long-lived lead isotope in the range of few fg per g of sample material from human hair was investigated as an indicator for accumulated radon exposure (Bushaw, 1992).

The artificial isotope ^{236}U is frequently used to distinguish anthropogenic material, stemming from the nuclear fuel cycle, from natural uranium. For the sensitive surveillance of ^{236}U content in environmental samples, an isotopic selectivity of a minimum of 9 up to 14 orders of magnitude is needed (Schumann et al., 2005). For most of these studies, a quite similar compact analytical setup is used, which applies three-step optical resonance ionization induced by small diode lasers and ionization at a compact quadrupole mass filter. This apparatus will be described in the example of ^{41}Ca determinations as follows: For selective ultratrace determination of the long-lived radioisotope ^{41}Ca ($T_{1/2} = 1.04 \times 10^5$ a) aside a huge surplus of stable calcium, an excellent overall isotope selectivity $> 10^{12}$ has been demonstrated at an LOD of well below 10^6 atoms ^{41}Ca (Müller et al., 2001). This enables various applications, for example, using ^{41}Ca as a biomedical tracer isotope for (1) in vivo studies of human calcium kinetics, (2) cosmochemical investigations on the ^{41}Ca content in meteorites (together with related studies on the production cross section in nuclear reactions), and finally, (3) the determination of ^{41}Ca activity in reactor concrete and other materials for an integrated neutron dosimetry. For these studies, ^{41}Ca abundances of 10^{-9} to 10^{-12} relative to the predominant stable isotope ^{40}Ca (96.94%) were addressed. Due to the much lower estimated ambient ^{41}Ca concentrations of only about 10^{-15} , radioisotope dating by ^{41}Ca , which would open up a new time window around 10^6 years before present, is not in reach by HR-RIMS. In addition to the sophisticated laser system, the setup for ultratrace determination of ^{41}Ca consists of a vacuum recipient with a graphite furnace for efficient atomization of the sample and a quadrupole mass filter for mass-selective detection of the ions ionized via the selective laser excitation process. The calcium atomic beam is crossed perpendicularly by the

laser beams at a minimum distance in front of the orifice to ensure highest overall efficiency. For maximum isotope selectivity, a three-step three-color excitation scheme is used to populate a high-lying Rydberg state, from where efficient nonresonant ionization is induced by a 10.6- μm CO_2 laser. All three resonant excitation steps are driven by narrow-bandwidth radiation from compact extended cavity diode lasers, which can be tuned well onto the respective Ca resonances and kept well controlled in resonance. For quantification of the ^{41}Ca content, the low abundance isotope ^{43}Ca (0.134%) is used as a reference, which significantly reduces the required dynamic range by three orders of magnitude. In samples of concrete from the shield of a nuclear research reactor, very low relative abundances in the order of a few 10^{-10} corresponding to contents of only ~ 20 mBq/g, were determined by quantifying the total calcium content via X-ray fluorescence spectroscopy (Müller et al., 2000). In the frame of biomedical and nutritional studies in connection with osteoporosis prevention and therapy, human urine samples were measured by this technique with somewhat equally low abundances (Denk et al., 2006).

In strontium, a desired fast and sensitive determination of the radiotoxic isotopes ^{89}Sr and ^{90}Sr in air samples, for example, after a nuclear accident, would require an overall selectivity of $\text{Sr} \geq 10^{11}$ (Monz et al., 1993). For instance, about 10^8 atoms of ^{90}Sr and ^{89}Sr need to be detected among some 10^{18} atoms of stable strontium, mainly ^{88}Sr , assumed for a collection of 1000 m^3 of ambient air. Due to a very small optical isotope shift in Sr, this requirement is not met by the triple-resonance diode laser-based RIMS on a thermal atomic beam, as discussed previously for the ^{41}Ca determination (Bushaw et al., 2001). In contrast, the complex setup of resonance ionization mass spectrometry on a fast atomic beam has been adapted and applied. Sample atoms are initially ionized in a conventional thermal ion source and undergo sector-field mass spectrometry at an ion beam energy of about 30 keV. After neutralization in a cesium vapor cell, resonance ionization is carried out in collinear geometry between laser and atomic beam, which is applied on the resulting fast neutral atomic beam by utilizing the strong Doppler shift for optical isotope selection. Highly excited Rydberg atoms are generated, selectively field-ionized, and counted by a channeltron detector after passing an electrostatic energy filter for further background suppression. With this approach, an overall efficiency of 1×10^{-5} and a selectivity for $^{90}\text{Sr}/^{88}\text{Sr}$ of well above 10^{10} have been demonstrated and ^{90}Sr measurements within a variety of environmental and technical samples were reported (Wendt et al., 1997). The LOD for ^{90}Sr has been determined to be 3×10^6 atoms, corresponding to an activity of 1.5 mBq per sample.

VIII. Accelerator mass spectrometry

A. Principle

AMS is a modern and sophisticated mass spectrometric technique, specialized to provide highest absolute sensitivity and selectivity with respect to isobaric and isotopic contaminations. Individual ions are detected after acceleration to energies in the hundred keV to few MeV range. Any interferences from atomic or molecular species are efficiently suppressed in the different stages of the mass spectrometric measuring process. Thus, AMS permits the determination of ultrarare radioisotopes with abundances far below 10^{-9} of a dominant neighboring isotope and surpasses the usual selectivity limits in isotope ratio measurements of conventional mass spectrometric techniques by far (Purser et al., 1981). AMS data provide relative isotope abundances but do not give absolute concentrations of an element or isotope. Hence, AMS in most cases is combined with an absolute concentration measurement of at least one stable isotope by, for example, ICP-MS. The development of AMS has been boosted primarily in connection with the determination of the cosmogenic radioisotope ^{14}C . The numerous applications include (1) radioisotope dating, (2) atmospheric and oceanographic circulation studies, (3) determination of anthropogenic radioactive contamination levels, particularly as a consequence of the atmospheric nuclear weapons tests, and (4) biomedical applications, for example, in studies on cancer prevention by using ^{14}C labeled compounds (Hellborg and Skog, 2008). Many of these fields have only become possible as a result of the development of AMS, which has partly replaced the formerly used technique of low-level radiometric counting (Libby, 1955; García-León, 2018) and also neutron activation analysis (Szidat et al., 2000) due to its higher sensitivity, smaller sample size requirement, and faster response. Radiocarbon dating, carried out on ^{14}C isotopic levels as low as 10^{-15} , is the broadest field of application of AMS with thousands of samples per year. Further applications on many other radioisotopes have been developed, which contribute to the value and acceptance of the technique (Michel, 1999).

Following a suggestion by Oeschger and coworkers (Williams et al., 1969), which was triggered by a first, very early mass spectrometric experiment at an accelerator by Alvarez and Cornog (1939), it was realized in the late 1970s that isobaric contaminations can often be eliminated very efficiently by performing mass spectrometry with high-energy ($\sim \text{MeV}$) ion beams (Müller, 1977; Nelson et al., 1977; Bennett et al., 1977). In this regime, a variety of experimental techniques can be applied and quantitative, and highly selective counting of the species of interest with

unrivalled background suppression is enabled, including the following:

- Already in the ion source of the mass spectrometer, unwanted atomic isobars can be suppressed by using negative ions in the first stage of a tandem accelerator. Many interfering elements do not form such anions. For example, $^{14}\text{N}^-$, the only abundant atomic isobar of $^{14}\text{C}^-$, is not stable and consequently is neither produced nor accelerated.
- A second technique to suppress interfering ions directly inside the source is laser-induced photodetachment. If the wanted species' electron affinity exceeds that of the unwanted species, the latter can be neutralized by photodetachment, and hence it is removed from the beam. At the Vienna Environmental Research Accelerator at University of Vienna, this isobar suppression was demonstrated successfully for ^{63}Cu (Forstner et al., 2015), ^{93}Zr , and ^{93}Nb (Martschini et al., 2015).
- Furthermore, chemical reactions in gas-filled cells might prove a very universal tool for removal of interfering ions in the future (Eliades et al., 2015).
- Molecular isobars can be efficiently removed by passing the accelerated beam through a thin foil or a gaseous target inducing a so-called stripping process. Here, negative atomic ions are efficiently converted into positive ones by stripping off some electrons. Due to the high energy transfer from the collisions, molecules are effectively dissociated, removing an additional source of interfering ions.
- Finally, versatile and discriminatory ion detection techniques, for example, elemental selective energy-loss measurements in ionization chambers, are applied on high-energy ions ($\sim\text{MeV}$) to identify the species via its mass and proton number and further reduce the influence of isobaric interferences.

Examples for such interferences in the case of the $^{14}\text{C}^+$ ion are $^{28}\text{Si}^{2+}$, $^{14}\text{N}^+$, or $^{13}\text{CH}^+$. Other limiting effects include background effects originating from gas kinetics, wall scattering, and charge exchange collisions. Nevertheless, these contributions can be strongly suppressed by optimizing the experimental conditions. A typical AMS system is based on a tandem accelerator with a terminal voltage of 2.5–10 MV, usually involving a beam line length of several tens of meters. On the side of the ion source, the so-called low-energy side, intense beams of negative atomic or molecular ions of the species to be analyzed are produced. This is accomplished usually by sputtering, applying Cs^+ ion bombardment with about 10 keV energy, focused onto the target of the analyte. The latter is introduced in the form of about 10 mg of material, fixed within a target wheel or a sample exchange mechanism with more than 60 positions, which enables rapid changes between analytical sample, blank, and standard.

The importance of a proper chemical pretreatment of the sample, including removal of extraneous material, dissolution, and, when appropriate, addition of carrier, separation of the element of interest, and conversion into the most suitable form for the sputtering process, must be emphasized (Tuniz et al., 1998; Lopez-Lora et al., 2018).

A minor drawback of the AMS technique is the fact that rather large sample sizes around 10 mg are required for the initial ionization process. Negative target ions from the sputtering process are accelerated toward a first low-energy (typically $\sim 50\text{ keV}$) mass separator for an initial mass selection. By varying the electric potential applied at the magnet chamber, a rapid change from one mass to another is possible, avoiding complications that arise from the scanning of the magnetic field, for example, hysteresis or slow switching speed. Subsequently, acceleration to the high terminal voltage of several megavolts takes place within the first half of the tandem accelerator. On the high positive potential of the terminal, the ions undergo a stripping process in a thin foil ($\sim 5\text{ }\mu\text{g}/\text{cm}^2$) or a gas target, and a spectrum of positive charge states is populated. Now positively charged, these ions are accelerated a second time, this time from the terminal voltage down to ground; for example, in the case of carbon, typically charge states between C^{2+} and C^{7+} are populated, depending on the ion velocity. For the case of the C^{5+} ion, this leads to a total beam energy of 15 MeV on the high energy side, when a typical 2.5 MV tandem accelerator is used. All molecular ions are dissociated during the stripping process, and remaining fragments have significantly altered mass-to-charge ratio and can easily be separated afterward. For this purpose, the high-energy ion beam undergoes another mass selective step in a second sector field magnet as well as charge state and energy filtering within an electrostatic deflector before reaching the detectors. Due to the high energy of the incoming ions, some kind of selectivity via species identification with respect to charge number Z and mass A is possible by measuring energy and specific energy loss in a sensitive semiconductor telescope or an energy-sensitive ionization chamber. A typical layout of an AMS machine, which shows these individual components, is given in Fig. 8.10.

Generally, AMS determines the relative abundance of the rare radioisotope under study by comparing its count rate with the ion current of an abundant stable (or reference) isotope of the same element. The measured quantity is therefore, in most cases, an isotope ratio, which might cover many orders of magnitude. In most applications, a high accuracy in the order of $\leq 1\%$ for this value is required. Such precise isotope ratio measurements with unrivalled dynamical range of up to 15 orders of magnitude are accomplished experimentally by accelerating both isotopes alternately in a fast-cyclic mode. While the transmitted atoms of the rare ultratrace isotope are counted

FIGURE 8.10 Schematics of the primary components of a typical accelerator mass spectrometry machine. Details are provided in the text.

individually as ion counts in a two-dimensional Z versus A plane, the reference isotope, which typically is up to a factor of 10^{12} more abundant, is measured as electrical current using a Faraday cup detector for this intense beam. Proper calibration and stability of both detectors during the measurement is mandatory. Hence, each analytical measurement is flanked by measurements on blanks and calibration samples for background surveillance and proper quantification of results. For the heavier isotopes, the energy resolution of semiconductor detectors or ionization chambers is not sufficient for a proper species identification and reasonable suppression of isobars and/or neighboring isotopes. A better background suppression is possible by combining the energy determination in the detector with a velocity analysis of the incoming ions by an additional time-of-flight measurement (Coffin and Engelstein, 1984). In a different approach, a gas-filled magnet in front of the detector leads to a spatial separation of projectiles with different proton number Z and hence significantly increases the selectivity with respect to those isobars, which have not been filtered out sufficiently during the stripping process (Paul, 1990). For some isotopes, the process of fully stripping the ions after gaining sufficient high energy is favorable for complete background suppression, but this can only be realized at large accelerators.

During the last decade, enormous effort can be observed within the AMS community to reduce size and cost of AMS systems. By incorporating well-matched technical features such as gas strippers and state-of-the-art silicon detectors, very compact low-voltage (300 kV – 1 MV) AMS machines have been developed (Synal et al., 2000). By now, these systems have demonstrated their broad range of applicability not only for ^{14}C measurements but also in the analysis of other radioisotopes such as ^3H , ^{26}Al , ^{41}Ca ,

^{129}I , and Pu isotopes with selectivities close to that of a standard large-frame AMS machine (Suter et al., 2000).

The technique of AMS has currently become a standard method, applied for investigations on a variety of long-lived radioisotopes. Commonly utilized isotopes in routine operation are ^{10}Be , ^{14}C , ^{26}Al , ^{36}Cl , ^{41}Ca , and ^{129}I . Many other isotopes, namely ^3H , ^3He , ^7Be , $^{22,24}\text{Na}$, ^{32}Si , ^{39}Ar , ^{44}Ti , ^{53}Mn , $^{55,60}\text{Fe}$, $^{59,63}\text{Ni}$, ^{79}Se , ^{81}Kr , ^{90}Sr , ^{93}Zr , ^{93}Mo , ^{99}Tc , ^{107}Pd , ^{151}Sm , ^{205}Pb , ^{236}U , ^{237}Np , and $^{238-244}\text{Pu}$ have also been investigated by AMS during recent years. Most of the radioisotopes mentioned in both categories have natural abundances in the range of 10^{-9} down to 10^{-18} , as illustrated in Fig. 8.11. Here some isotopes are missing, as their natural abundance is either not known precisely or it varies across the earth, due to an inhomogeneous distribution of natural or anthropogenic

FIGURE 8.11 Natural radioisotopes with abundances below 10^{-9} together with their process of origin.

sources. The isotopes shown in Fig. 8.11 are produced by cosmic radiation, neutron capture, or as fission product. More details about AMS and a compilation of the different AMS versions for individual radioisotopes can be found in the textbook on AMS (Tuniz et al., 1998) and a number of review articles (Litherland et al., 1987; Elmore and Philips, 1987; Hotchkis et al., 2000; Woelfli, 1987; Vogel et al., 1995; Fifield, 1999; Kutschera et al., 2000; Synal, 2013). The application of AMS in various fields is increasing rapidly since the late 1970s (Kutschera, 2016). Since the year 2012, there were approximately 110 uniquely dedicated AMS facilities in use around the world, whereas quite some more nuclear physics accelerator facilities have been adapted to perform AMS measurements, often also on a routine basis (Kutschera, 2012). Whereas some facilities measure the full spectrum of “AMS nuclides,” many others focus on a subset such as the lighter ones up to ^{129}I (Rugel et al., 2016) or the actinides (Hotchkis et al., 2018).

B. Applications of accelerator mass spectrometry

1. Radioisotope dating in archeology and other applications of the isotope ^{14}C

AMS has become best known due to its application to the analysis of the isotope ^{14}C , where thousands of samples per year are investigated worldwide. Carbon-14 is produced by the neutron component of cosmic rays from ^{14}N in the upper atmosphere with a rate of about 2 atoms/cm²/s. Through the formation of CO_2 , it is very homogeneously distributed worldwide and is easily assimilated by living organisms. With a half-life of $T_{1/2} = 5730$ years and an average abundance in living organisms of about 10^{-12} , the determination of the remaining ^{14}C in fossils not only gives access to a dating range of about 40,000 years before present but also opens up a broad field of further investigations, for example, circulation studies in the atmosphere or the oceans, authentication of minerals, plants, and even human artifacts such as precious artworks. Most important is the fact that a well-adapted continuous calibration curve of the ^{14}C content in the biosphere, dating back to 7000 BC can be established from counting tree rings. Outstanding applications for ^{14}C radiodating by AMS include the dating of the Ice Man from the Tyrolean Alps (3120–3350 BC), the Shroud of Turin (1260–1390 AD), as well as numerous approaches of dating ice cores from the arctic regions or glaciers. Novel hyphenated techniques are continuously developed. At the University of Bern, a continuous flow gas interface was coupled to a low-energy AMS of TANDY type for online measurements of CO_2 gas, for instance, produced by organic/elemental carbon analyzers (Agrios et al., 2017).

2. Accelerator mass spectrometry applications in geo- and cosmoscience

Numerous additional studies in the field of geosciences currently are carried out with the AMS technique with respect to radioisotopes other than ^{14}C . The cosmogenic production mechanism and the short residence time of ^{10}Be in the atmosphere make it an ideal cosmic ray and hence solar activity monitor, which is preserved in arctic ice for hundreds of years and serves as a paleoclimatic archive. Together with data on a few other long-lived radionuclides, for example, ^{26}Al (Auer et al., 2009) and ^{36}Cl both measured by AMS, further information such as the strength of the earth's magnetic field, the mode of the atmospheric mixing, and precipitation patterns are extracted. In this way, for example, the 11-year solar cycle as well as severe changes during the end of the last glacial period, 40 ka back, have been obtained. From investigations of the same three isotopes, the age of the Arizona Meteor crater has been determined to about 49,000 years (Vogel et al., 1995). As a different AMS application in geosciences, ocean currents were probed by detecting actinides and long-lived fission products released from reprocessing plants (Christl et al., 2015). Abundance of ^{60}Fe in sea sediments yielded findings on the history of supernova explosions in the vicinity of our solar system during the past 10 Mio. years (Wallner et al., 2016).

The production mechanisms for long-lived radioisotopes are significantly different in space than on the earth's surface, due to the different composition of cosmic radiation (Michel, 1999). Thus, AMS analyses in supposed extraterrestrial material like micrometeorites, which exhibit isotopic anomalies from the well-known terrestrial abundances, serve as the most stringent test for its authenticity. In addition, if data of at least some of the different routine AMS isotopes, that is, ^{10}Be , ^{14}C , ^{26}Al , ^{36}Cl , ^{41}Ca , and ^{129}I , are combined, these measurements provide valuable information, for example, on the terrestrial age of the material, the exposure age, and the geometrical conditions of exposure (Herzog, 1994). Recent reviews summarize the use of AMS and other techniques in the field of geo- and cosmosciences (Linge et al., 2017; Wiedenbeck et al., 2012, 2014).

3. Noble gas analysis

Due to their chemical inertness, noble gases form an ideal tracer for dating ground- and surface waters, for performing related circulation studies or for the analysis of gaseous inclusions in ice cores. Since noble gases generally do not form stable negative ions, long-lived noble gas isotopes, for example, ^{39}Ar or ^{81}Kr , cannot be analyzed by standard AMS facilities. Thus, W. Kutschera and coworkers used an electron cyclotron resonance source instead, to produce

positive ions and a high-energy cyclotron accelerator to accelerate them. To separate ^{81}Kr from its abundant isobar ^{81}Br , they applied the full-stripping technique, accelerating the ions up to a 4-GeV beam energy and removing all electrons of the ions (Collon et al., 1997). Once fully stripped, $^{81}\text{Kr}^{+36}$ can be well separated from the maximum charge stage of $^{81}\text{Br}^{+35}$ with $Z = 35$. With a detection efficiency of $\sim 1 \times 10^{-5}$, a 10% precision measurement required 0.5 cc STP of a krypton sample (Collon et al., 2000). For groundwater dating, this amount had been extracted from 16 tons of groundwater. In a closely related development, ^{39}Ar has been detected at an isotopic abundance level of 1×10^{-16} with an efficiency of 1×10^{-3} using a high-energy (~ 200 MeV) linear accelerator (Collon et al., 2004). Since the charge number of ^{39}Ar ($Z = 18$) is lower than that of its abundant isobar, ^{39}K ($Z = 19$), the full stripping technique cannot be used here. Instead, ^{39}Ar has been separated from ^{39}K using the standard technique of a gas-filled magnet, which exploits the fact that the energy loss of ^{39}K is significantly different from that of ^{39}Ar .

4. Accelerator mass spectrometry in life sciences

Research with tracer isotopes has become enormously relevant for various kinds of in vivo studies concerning influences of nutrition or deficiencies as well as analyzing the cause and prevention of numerous diseases. In most cases, no suitable enriched stable isotopes for such studies are available, and radioisotopes must be chosen. However, radionuclide concentrations as high as required by radiometric detection techniques would cause a significant radiation dose to the test person. Furthermore, such high doses could affect the proper physiological response itself. Hence, AMS with its high sensitivity and selectivity has become a valuable system for analyzing biomedical samples (Jackson et al., 2001). Again, ^{14}C is the key isotope, used for labeling numerous biomedically relevant compounds, while their influence can be studied by AMS measurements on their content in bodily excretions or blood (Vogel, 2000). Other radioisotopes used in this field are ^{10}Be , ^{26}Al , ^{41}Ca , ^{79}Se , and ^{129}I . Aluminum was considered an essential trace element, while, only in the late 1990s, its toxicity has been recognized. A number of AMS studies with ^{26}Al on gastrointestinal and intravenous absorption have been carried out, which indicated pathways and established exchange rates for Al crossing the blood–brain barrier (Tuniz et al., 1998). ^{41}Ca has become extremely versatile in the measurement of nutritional and other effects on calcium kinematics and the prevention of diseases such as osteoporosis (Freeman et al., 1997). The high demand on determining the capacity for these life science applications in the field of biomedical and nutritional research has led to the recent commissioning of dedicated commercial AMS instruments

(Barker and Garner, 1999). Additional biomedical applications comprise the uptake and retention of Pu in living organisms (Fifield, 2000).

AMS is used for so-called retrospective dosimetry. The release of ^{131}I from nuclear installations can cause significant dose to the human thyroid. Due to its short half-life of only 8 days, screening is often not performed fast enough, as was the case in the Chernobyl accident and also partly in Fukushima. However, measuring the long-lived fission product ^{129}I in environmental compartments permits a determination of the thyroid doses with rather high accuracy (Michel et al., 2005, 2015).

AMS-based measurements gained new insight into the function of the human brain. Contrasting up to then assumption of little or no renewal of so-called hippocampal cells in the adult human brain, Spalding et al. (2013) proved an annual turnover of almost 2% of the cells by measuring the concentration of nuclear bomb test–derived ^{14}C in genomic DNA.

5. Accelerator mass spectrometry measurements on long-lived radionuclides in the environment

Most of the anthropogenic long-lived radioisotopes in the environment arise from the nuclear fuel cycle or nuclear explosions. They are produced either by neutron capture (e.g., actinides) or as fission products (e.g., ^{90}Sr , ^{99}Tc , ^{135}Cs). The determination of low-level contaminations of these isotopes is of major importance for nuclear safeguards; however, it is often complicated by the necessity to distinguish these contributions from the naturally existing levels. A few high-transmission, high-voltage AMS instruments are specialized for measuring these radioisotopes (Hotchkis et al., 2000). Overall efficiencies of up to 10^{-4} enabling measurements with as few as 10^6 atoms of the radioisotope of interest have been demonstrated in favorable cases with typical selectivities above 10^{10} (Fifield, 2008). A recent review summarizes selected radioecological studies on ^{14}C , ^{36}Cl , ^{129}I , ^{236}U , and Pu (García-León, 2018). Further AMS investigations in this field have been reported for ^{90}Sr (Paul et al., 1997), ^{99}Tc (Fifield, 2000; Bergquist et al., 2000), ^{129}I (Daraoui et al., 2016) (Daraoui et al., 2012; Michel et al., 2012), ^{135}Cs (Lachner et al., 2015), ^{206}Pb (Paul et al., 2000), ^{236}U (Zhao et al., 1994, 1997; Berkovits et al., 2000), and Pu isotopes (Fifield et al., 1996; Wallner et al., 2000; McAninch et al., 2000; Hotchkis et al., 2000; Lachner et al., 2010). Plutonium and Americium transport and scavenging by snow was investigated by Gückel et al. (2017). The isotope abundance of ^{236}U in depleted uranium particles was used as an indicator that the material originates from the enrichment of reprocessed uranium (Danesi et al., 2003a, 2003b). Several of the investigations on Pu and ^{236}U release from the

Fukushima Daiichi accident used AMS (Schneider et al., 2013, 2017). Applications of AMS in the nuclear field include trace detection of activation products in shielding material to be decommissioned (Warwick et al., 2009) and highly sensitive and selective detection of Am and Cm (Christl et al., 2014). In a field experiment, colloid-mediated transport of ^{233}U , ^{237}Np , ^{242}Pu , and ^{243}Am was monitored at ultratrace concentrations (Quinto et al., 2017). AMS was also used in the search for naturally occurring superheavy elements (Dellinger et al., 2011) and in the precise measurement of the half-lives of long-lived nuclides (Vockenhuber et al., 2004).

Clemens Walther

Clemens Walther studied Physics (thesis on metal cluster physics using laser spectroscopy in an ion trap) at Mainz University and University of Seattle, WA. He completed his habilitation in Nuclear Chemistry in Mainz in 2008, where he also served as lecturer. From 1999 to 2011, he was employed at the Karlsruhe Institute of Technology, Institute for Nuclear Waste Disposal, serving as group leader “Actinide Nanoparticle Analysis” and deputy department head of “Actinide Speciation” where he headed a group developing and applying mass spectrometric and laser spectroscopic techniques. He is currently full professor, head of the Institute of Radioecology and Radiation Protection, and dean at the Leibniz University Hannover. CW is member of the German Commission of Radiation Protection (and head of the subgroup “Radioecology”), former chair of the mass spectrometry section of the German Physical Society (DPG), chair of the NRC section of the German Chemical Society (GDCh), and chair

of the European Network on Nuclear and Radiochemistry Education and Training.

Klaus D.A. Wendt

Klaus Wendt studied physics at Johannes Gutenberg University of Mainz, where he got attracted to laser physics and quantum optics. After receiving his diploma in 1981, he went on to CERN to complete a PhD on the study of nuclear structure using laser spectroscopy and mass spectrometry at the radioactive ion beam facility ISOLDE. After graduation, he stayed as CERN Fellow up to 1986. He then returned back to Mainz University, and the Chernobyl nuclear disaster and its consequences motivated him to establish a research group working on ultratrace isotope determination using dedicated laser mass spectrometric techniques. Today, he is full professor and group leader in the field of laser resonance ionization spectroscopy and its applications. In addition, he strongly addresses aspects of teacher education and physics didactics.

Chapter 9

Solid scintillation analysis

I. Introduction

Solid scintillation is a process whereby the absorption of energy from ionizing radiation (e.g., alpha particles, beta particles, heavier charged particles, and X- or gamma rays) by certain crystalline inorganic or organic materials results in the emission of photons of light from the solid absorbing material. Neutron radiation, which is nonionizing, can produce indirectly the scintillation effect in certain solid scintillators, which may be used specifically for the detection and measurement of neutrons. The effect of neutrons in scintillators is generally the result of ionization and scintillation caused by (n,p) or (n, α) nuclear reactions within the scintillator material, which will be described further on in this chapter. Even neutrinos, which are nonionizing and, in addition, of very low rest mass, cause detectable interactions in scintillators, via neutrino-electron scattering, neutral current excitation of nuclei, and inverse beta decay. These processes are discussed in Chapter 6, Volume 1, and Chapter 6, Volume 2, and expounded further in this chapter.

An excellent account of the discovery of solid scintillation is given by [Kolar and den Hollander \(2004\)](#). Henri Becquerel, who was awarded the Nobel Prize in Physics for the discovery of radioactivity as Professor at the Ecole Polytechnic in Paris (An historical account is provided by the writer, [L'Annunziata, 2007, 2016](#)), was aware of the phosphorescent properties of crystalline zinc sulfide, referred to as “Sidot’s blende”, as related in his Nobel Lecture ([Becquerel, 1903](#)). “Sidot’s blende” was named after Théodore Sidot of France, who established a procedure for the preparation of crystalline zinc sulfide. In historical accounts by [Fricke \(2001\)](#) and [Kolar and den Hollander \(2004\)](#), a pioneer in research on radioactivity by the name of Friedrich Oskar Giesel (1852–1927), while an employee of the Quinine Factory Braunschweig Buchler & Co. in Braunschweig, Germany, synthesized his own “Sidot’s blende” by heating zinc and sulfur in a copper vessel. The crystalline zinc sulfide thus contained traces of copper, which Friedrich Giesel mixed with gelatin and spread the mixture over glass plates to manufacture phosphorescent screens. The “Sidot’s blende” or zinc blende is reported to have a hexagonal (wurzite) crystalline structure with traces of copper ions ($\text{ZnS}:\text{Cu}^{2+}$), which is responsible for its yellow-green luminescence ([Bol et al., 2002](#); [Kolar and den Hollander, 2004](#)). In a biography by [Fricke \(2001\)](#), Friedrich Giesel was under the impression that the light emitted by the ZnS screens was not continuous but appeared to flicker when exposed to radioactivity, and on December 9, 1902, he wrote to Julius Elster (1854–1920) to encourage him to research this phenomenon. Thus, Julius Elster teamed up with his friend Hans Geitel (1855–1923), both of whom were working in Wolfenbüttel, Germany, to scientifically investigate the luminescence. Shortly

thereafter, the phenomenon of solid scintillation was reported by Julius Elster and Hans Geitel in both German and English scientific journals ([Elster and Geitel, 1903a,b](#)). With the aid of a magnifying glass they were able to see the individual flashes of light emitted by a ZnS screen placed in front of a sample emitting alpha particles.

Also in 1903, Sir William Crookes (1832–1919) in London studied the scintillations systematically, and he developed the apparatus for counting the light flashes ([Crookes, 1903a,b](#)). It consisted of a brass tube fitted with a lens at one end and a ZnS screen at the other. The position of the radioactive source, radium, from the ZnS screen could be adjusted by means of a thumbscrew. The closer the radium was adjusted to the screen, the more numerous and frequent were the flashes of light. He named the apparatus the Spintharoscope from the Greek “spintharis” meaning spark. The instrument was used by [Rutherford \(1919, 1920\)](#) and his students Hans Geiger and Ernest Marsden. They were able to visibly count the individual scintillations produced by alpha particles as the particles bombarded the ZnS screen. It was a crucial instrument in their research with alpha particles, leading to Rutherford’s discovery of the atomic nucleus described in Chapter 1, Volume 1.

The first report of scintillation in organic compounds was documented much later in a thesis by [Herforth \(1948\)](#), who studied under the leadership of Hartmut Kallmann. An historical account of this discovery is related by [Niese \(1999, 2003\)](#). In her thesis presented on September 13, 1948, at the Technical University Berlin—Charlottenburg, Herforth reported that certain crystalline organic compounds could convert absorbed energy of alpha and beta particles. The discovery of this solid scintillation phenomenon in organic crystals led to liquid scintillation analysis through the work of [Kallmann \(1950\)](#) and [Reynolds et al. \(1950\)](#), which is covered in Chapter 6, Volume 1. The advances made in the solid scintillation analysis of nuclear radiation detection since these early discoveries are astounding. These may be best compared with advances made in development from the abacus to the modern electronic computer.

This chapter focuses mainly on solid scintillation analysis with inorganic crystalline materials. Certain solid inorganic crystalline materials have a high “stopping power” for X- and gamma radiation because of the high densities and high effective atomic numbers (Z_{eff}) that these inorganic crystals possess. Therefore, many inorganic scintillators are used throughout many fields of basic and applied research and applications ([Diehl et al., 2017](#); [Glodo et al., 2017](#); [Moszyński et al., 2016, 2003](#); [van Eijk, 2014, 2001](#); [Ghelman et al., 2011](#); [Novotny, 2005](#); [Nikl et al., 2006](#); [Higgins et al., 2006, 2008](#); [van Eijk et al., 1994](#)) and in almost all medical diagnostic imaging instrumentation ([Ghabrial et al., 2018](#); [Kertzschner and Beddar, 2018](#);

Germano et al., 2016; Lecoq, 2016; Slomka et al., 2016; Llosá, 2015; Deprez et al., 2011; Heller and Zanzonico, 2011; Ninos et al., 2010; Bieberle et al., 2007; Korzhik et al., 2007; Kandarakis et al., 2005; Ricard, 2004; van Eijk, 2003) for the detection and measurement of penetrating X- and gamma radiation. Depending on detector types and properties, solid inorganic scintillators are also applied to the detection and measurement of particulate radiation, such as alpha particles, beta particles, and neutrons. Neutrons are detected indirectly through nuclear reactions in crystal detectors. Special applications with solid scintillation detectors used for the analysis of alpha, beta, and neutron radiation will be discussed in this chapter. Applications of solid scintillation analysis are broad. We can find applications in the measurement of radioactivity and radionuclides in almost every field of science, including physics, chemistry, industry, space exploration, and the clinical and biochemical fields. This chapter will cover the basic principles and current practice of solid scintillation for the analysis of nuclear radiation and radionuclides.

II. Principles of solid scintillation

A. Inorganic crystal scintillators and their properties

Chapter 6 of Volume 1 dealt with the scintillation phenomenon that occurs when radiation energy is absorbed by certain organic materials (fluors) such as anthracene, PTP, and PPO dissolved in suitable organic solvents. The interaction of radiation with the organic solvents and the transfer of that energy to the organic fluors occur at the molecular level; that is, the organic molecules in a ground energy state absorb radiation energy and are elevated to an excited energy state. On returning to its ground state, the molecule emits absorbed energy as photons of visible radiation. The detection and analysis of electromagnetic radiation (i.e., X- and gamma-ray photons) by these organic materials, either solid or liquid, generally are not efficient due to the high penetrating power of the electromagnetic radiation. The relatively low density of organic materials (e.g., anthracene, 1.3 g/cm³ and PTP, 1.2 g/cm³) and their low effective atomic number (Z_{eff}) diminishes the “stopping power” of these scintillators for X- and gamma radiation.

The higher density (ρ) and higher effective atomic number (Z_{eff}) of certain inorganic crystalline materials such as NaI (3.7 g/cm³), CsI (4.5 g/cm³), and bismuth germanate (Bi₄Ge₃O₁₂), also known as BGO (7.1 g/cm³), give these solids a greater gamma-ray stopping power, that is, a greater ability to absorb energy of impinging gamma radiation. In addition to the higher density and atomic number offered by these inorganic crystalline scintillators, there are other basic properties of scintillators in general that are desirable for applications involving gamma and neutron

radiation measurements. The desirable properties of a scintillator, which would constitute an “ideal” scintillator, are reviewed in detail by Derenzo et al. (2003) and Melcher (2005) and listed in Table 9.1. These properties of the ideal scintillator are the following:

- **High detection efficiency.** A scintillator of high density (ρ) and high effective atomic number (Z_{eff}) will provide the optimum stopping power for gamma radiation, whereas a scintillator enriched in isotopes with high neutron-capture cross-section (e.g., ⁶Li, ¹⁰B or ¹⁵⁷Gd) would yield improved neutron detection.
- **Low cost of manufacture.** The cost of manufacture is governed by difficulties of crystal growth and their production into various shapes and sizes.
- **Chemical stability and resistance to thermal and mechanical shock.** Many inorganic crystal detectors are hygroscopic and must be protected from the atmosphere, and must be handled with care to avoid fracturing to preserve their optical properties. Resistance to environmental effects and high mechanical strength are desirable properties.
- **High count rate capability and coincidence timing.** Short decay times and minimal afterglow would permit higher count rates. Afterglow, which is caused by relatively long-lived excitation states, is the emission of light after radiation excitation in the crystal has terminated. Strong afterglow can cause pulse pileup at high count rate applications and reduced energy resolution.
- **Good spatial resolution and signal-to-noise ratio.** A high light yield (i.e., high photon emission per radiation excitation energy deposited in the crystal scintillator or photons/MeV) with low noise will yield best spatial resolution.
- **Good energy resolution.** A light yield that is both high and proportional to the radiation energy deposited in the crystal will provide the best energy resolution.
- **Suitable emission wavelength.** The optimum wavelength of spectral emission of the crystal scintillator is the wavelength most efficiently detected by the photodetector, be it the photocathode of the photomultiplier tube (PMT) or by the photodiode (PD) detector.
- **Radiation resistance.** This refers to resistance to damage by high levels of ionizing radiation particularly in the field of high energy physics.
- **Good light transmission from scintillator to photodetector.** Optimization of light transmission from the scintillator to the photodetector is achieved by matching as close as possible the index of refraction of the scintillator at its maximum wavelength of emission to the index of refraction of the optical coupling of the photodetector, such as the PMT or PD window.

Crystal scintillators will not possess all of the optimum properties, and a tradeoff is made in selecting a scintillator

TABLE 9.1 Properties of the ideal scintillator.

Performance criteria	Scintillator properties	Notes
Detection efficiency	High density and Z for gamma-rays; or high cross-section for neutrons	$\rho > 7 \text{ g/cm}^3$, $Z > 60$; ${}^6\text{Li}$, ${}^{10}\text{B}$, ${}^{157}\text{Gd}$
Practical manufacturing at low cost	Low cost raw materials; practical growth technique; congruent melting; acceptable melting point.; no phase transitions	Usually Czochralski or Bridgman growth techniques are the most practical
Chemical, thermal, and mechanical stability	Inert/non-hygroscopic; light yield insensitive to temp.; low/uniform thermal expansion; no cleavage; shock resistant	Facilitates fabrication of practical detectors
High count-rate capability and coincidence timing	Short decay time; low afterglow	$T < 10 \text{ ns}$ Afterglow $< 0.1\%$ at 100
Good spatial resolution; good signal-to-noise	High light yield	Definition of “high” varies widely according to appl.
Good energy resolution	High light yield and proportional response to energy of excitation	
Suitable emission wavelength	Near 400 nm for use with PMTs; Near 600 nm for use with PD/APDs	
Radiation resistant	Insensitivity of optical properties to ionizing radiation and light	Considerable success has been achieved in improving radiation hardness
Good transmission of light to photodetector	Low index of refraction	$n \sim 1.5$ is usually considered to be optimal in order to match PMT windows

From Melcher (2005); reprinted with permission from Elsevier © 2005.

according to its properties and the particular application for which it is needed. Some of the scintillators possess one of the properties listed in Table 9.1, that are at the optimum or at what is considered currently to be the theoretical limit of that property. Some scintillators that exhibit an optimum or near optimum value for one of the qualifying properties are listed in Table 9.2.

There are basic requirements of inorganic crystal scintillators, which are principally a fast response or decay time for light output (10–100 ns) and high light yield ($\geq 20,000$ photons per MeV of gamma-ray or particle energy absorbed), and many of these scintillators are described in review papers, by Gundacker et al. (2018), Yanagida (2016, 2013), Ahmed (2015), Ghelman et al. (2011), Higgins et al. (2006, 2008), Nikl et al. (2006), Novotny (2005), van Eijk et al. (1994), and van Eijk (1993, 1997a,b, 2001). As characterized by van Eijk (1997a,b, 2001), these inorganic scintillators can be placed into two groups. In the first group are included NaI:Tl, CsI:Tl, CsI:Na, BGO, and CdWO₄ with light yields of $\geq 10^4$ photons per MeV and decay times of $> 200 \text{ ns}$. The second group includes BaF₂, CsF, CeF₃, and CsI with faster decay times ($\sim 1\text{--}30 \text{ ns}$), but lower light yields (a few thousand photons per MeV). The GSO:Ce scintillator (i.e., Gd₂SiO₅:Ce) falls in between these two groups with a 60 ns decay time and 8000 photons per MeV

light output (see Table 9.3). The use of a colon in the nomenclature of these detectors separates the molecular formula from the atomic activation sites or luminescence centers of the detector, respectively. Parentheses are also used. For example, thallium activated sodium iodide may be represented as NaI:Tl, NaI:Tl⁺, or NaI(Tl). The mechanisms of activation and luminescence in inorganic scintillators are described further on in this chapter. To improve solid scintillation performance for the measurement of gamma radiation in many applications, researchers are searching actively for a scintillator that meets all of the basic requirements of fast response, high light yield, high density, and high effective Z.

Table 9.3 lists the properties of several commercially available and commonly used inorganic crystalline scintillators. Many other crystal scintillators are available, and some of these scintillators and their specific applications will be described further on in this chapter. Scintillator research is directed toward the development of more efficient scintillators with faster response, higher light yields and energy resolution, and low production costs. Examples are the high energy resolution of YAP:Ce, LaCl₃:Ce, LaBr₃:Ce, and SrI₂:Eu²⁺ which show a good proportionality of the light output in a large range of gamma-ray energies (Moszyński, 2010; Neal et al., 2011; Quarati

^aLight yield is the number of generated UV/visible photons within a certain time gate (typically 1 μs), after the high-energy photon absorption.

^bTotal scintillation efficiency is given by all of the generated UV/visible light, which is usually obtained by an absolute comparison of radio-luminescence spectra against a “standard scintillator sample”.

^cNot measured.

et al., 2011). For example, the europium-activated alkaline earth halide SrI₂:Eu²⁺ is reported by Neal et al. (2011) to exhibit a light yield of 81,400 photons/MeV with an associated energy resolution of 3.7% (FWHM for 662 keV gamma rays) with measured decay times from 1.1 to 2.0 μs. Many industrial, research, and medical applications have different demands for detector characteristics and efficiencies. Nevertheless, the basic properties of fast response (10–100 ns), high light yield (>25,000 photons/MeV), high density, and high effective atomic number (Z_{ef}) are required for many applications. Several inorganic crystal

scintillators are available commercially and under research as efficient detectors for positron emission tomography (PET) and other nuclear medical imaging applications in which stopping power, speed, and energy resolution are crucial (Ghabrial et al., 2018; Kertzschner and Beddar, 2018; Germano et al., 2016; Lecoq, 2016; Slomka et al., 2016; Llosá, 2015; Deprez et al., 2011; Ninos et al., 2010; Korzhik et al., 2007; Valais et al., 2007; Ricard, 2004; van Eijk, 2003; Korzhik and Lecoq, 2001). Some of these scintillators together with their properties are listed in Table 9.4.

The inorganic atoms in the solid crystalline state are usually “doped” with varying concentrations (mol %) of an element impurity such as thallium, cerium, or other elements, which act as centers of activation or luminescence centers in the crystal. For example, one of the oldest and most commonly used crystal detector of this type is NaI:Tl, which is sodium iodide activated with approximately 1.3×10^{-3} mol fraction of thallium (Mundy and Rothman, 1983) referred to as a thallium-activated sodium iodide detector. The concentration of element impurity, that creates the luminescence centers in the crystal detector, will affect the light output or pulse heights. For example, Hamada et al. (2001) demonstrated that increasing the Tl^+ concentration from 10^{-3} to 10^{-2} mol in CsI:Tl detectors increased the pulse heights originating from heavy particle (alpha) excitation compared with those of electron excitation. The optimum concentration of dopant is determined experimentally. For example, Balamurugan et al. (2006) determined that a 0.06 mol% of Tl doped CsI crystal yielded optimum gamma-energy resolution of the detector and increasing the Tl^+ doping concentration decreased the hardness of the crystal. Another example can be taken from the work of Fukabori et al. (2011a) where Ce^{3+} doping of LiYF_4 single crystals was tested over the range of 0.1–10 mol% of Ce content. They found that energy resolutions of the crystal for ^{137}Cs gamma quanta would decrease at Ce concentrations that would exceed 2 mol%. Co-doping of inorganic crystal scintillators with a second dopant can affect also the efficiency of the scintillator. The addition of Eu^{2+} codopant to thallium doped CsI (i.e., CsI:Tl) crystal reduces the intensity of the scintillator afterglow by two orders of magnitude in the time range of 10 μs –100 ms (Nagarkar et al., 2005; Ovechkina et al., 2007). Strong afterglow is a deleterious effect, as it can cause pulse pileup in high count rate applications, reduce energy resolution in radionuclide imaging, and produce reconstruction artifacts in computed tomography (CM) (Ovechkina et al., 2007). Europium-doped polycrystalline lutetium oxide scintillator at 0.5 mol% Eu^{3+} was co-doped with promethium over the range of 0–0.5 mol% Pr^{3+} by Jie et al. (2011) to give a crystal detector abbreviated as $\text{Lu}_2\text{O}_3:(\text{Eu},\text{Pr})$ whereby the added promethium reduced the crystal afterglow. Neal et al. (2011) improved the performance of europium-activated (or europium-doped) strontium iodide crystals, $\text{SrI}_2:\text{Eu}^{2+}$ with the divalent europium at 3%–6% by substituting 30 atom% of the strontium ions with Mg^{2+} , Ca^{2+} or Ba^{2+} . They achieved improved light yields of 81,400 photons/MeV with an associated energy resolution of 3.7% (FWHM for 662 keV gamma rays) and fast decay times of 1.0–2.0 μs . Several examples of ion-activated inorganic scintillators are listed in Tables 9.2–9.4, where a colon separates the element acting as the center of activation from the detector formula. The thallium (Tl^+) or other such ions (e.g., Ce^{3+} , Eu^{2+} or Pr^{3+} ,

among others) serve as activation centers in the inorganic crystals, where deexcitation of absorbed energy from interacting nuclear radiation and subsequent emission of visible light occur. Other scintillators do not require doping with element impurities to improve the scintillation efficiency. Some of these scintillators are also described in Tables 9.2–9.4.

The mechanisms of the conversion of nuclear radiation energy to photons of visible light in such crystal detectors are described subsequently.

B. Scintillation mechanisms in inorganic crystals

The mechanisms of scintillation in inorganic crystal detectors have been studied by Pejchal et al. (2018), Sun et al. (2018), Liu et al. (2017), Drozdowski et al. (2016), Nikl et al. (2016, 2013), Sahi et al. (2016), Yang et al. (2016), Bartosiewicz et al. (2015), Bizarri (2010), Alexandrov et al. (2008), Pidol et al. (2005), Weber (2002, 2004), Belsky et al. (2001), Hamada et al. (2001), Rodnyi (2001), Zazubovich (2001), Saoudi et al. (1999), Wojtowicz et al. (1994b, 1995, 1996), Lempicki (1995), Lempicki et al. (1993), Heath et al. (1979), Kabler (1975), and Dietrich et al. (1973), among others. Bizarri (2010) and Lempicki (1995) outline the scintillation process in three stages: (1) creation of electron-hole pairs by an absorbed gamma- or X-ray photon, (2) energy transfer after electron-hole pair propagation to a luminescent center, and (3) light emission at a luminescent center. The treatment that follows will refer at times to the interaction of electromagnetic gamma or X-radiation with the crystal detector. However, the same basic principles apply to any type of radiation, that produces ionization and electron-hole pairs in matter, such as electrons, protons, alpha particles and other heavy ions.

As described in Chapter 1, Volume 1, the principal mechanisms of the interaction of gamma- or X-ray photons with matter are the Compton effect, photoelectric effect, and pair production. In each of these mechanisms of interaction with scintillating crystals, photon energy is absorbed by the crystal. As a result of the initial interaction of each gamma photon in the crystal, an electron will be produced, either a Compton electron, photoelectron, or an electron from pair production. The Compton and photoelectrons are the result of ionization producing electron-hole pairs. A Compton scatter photon will travel on and produce further ionization and additional electron-hole pairs in the crystal detector until its energy is absorbed or until it exits the crystal detector. Electron-hole pair production is, therefore, the first step in the absorption of gamma or X-radiation in crystal scintillators.

Let us now look at the mechanisms whereby the electron-hole pairs produced in the crystal scintillators can result in the emission of visible light photons from the

crystal lattice. To explain this process we should consider first that there are two types of crystal scintillator detectors. Lempicki (1995) and Weber (2002, 2004) classify the detectors into the following two types:

1. **Intrinsic (i.e., Self-activated).** These crystals do not contain any doped elements as centers of activation. Examples are BGO ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$), PbWO_4 , CdWO_4 , BaF_2 , and CsI , among others listed in Tables 9.2–9.5. In these cases, luminescence may be considered a property of the lattice itself.
2. **Extrinsic (i.e., Activated).** These crystal detectors generally are doped with a trace amount of element, such as Tl^+ , Ce^{3+} , Pr^{3+} , which are introduced into the crystal lattice to serve as centers of activation and luminescence. Examples of this type are NaI:Tl , CsI:Tl , $\text{LuAlO}_3\text{:Ce}$ (LuAP), and $\text{Lu}_2\text{SiO}_5\text{:Ce}$ (LSO), among others listed in Tables 9.2–9.5.

The luminescence resulting from nuclear radiation energy deposition and ionization in the intrinsic or self-activated crystal detectors may involve electron–hole (e–h) recombination, self-trapped and defect-trapped exciton luminescence, charge transfer transitions (metal-to-ligand, ligand-to-metal) within the crystal molecule, or core–valence band transitions (Weber, 2004). The emission transitions, listed in Table 9.5, have characteristic emission wavelengths and decay times, which are described in detail by Weber (2004). Excitation and luminescence in the extrinsic (activated) crystals occurs at a site of the dopant ion (e.g., Tl^+ , Ce^{3+} , Eu^{2+}), which undergoes excitation following the capture of ionization holes and electrons (Weber, 2004; Bizarri, 2010, See also Fig. 9.1).

One of the oldest crystal detectors still in extensive use today since its discovery by Nobel Laureate Robert Hofstadter in 1948, while at Princeton University (Hofstadter,

TABLE 9.5 Scintillator materials and their radiative transitions.

Scintillator material	Emission transition
Intrinsic (self-activated)	
CeF_3	5d–4f
$\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (BGO)	6p–6s
CsI , BaF_2 , LaF_3	Self-trapped exciton

1948, 1950), is thallium-activated sodium iodide [NaI(Tl) or NaI:Tl]. We can confine our explanation of scintillation to this crystal, because of its widespread use and the extensive study devoted to this detector, and the general mechanisms apply to other activated inorganic scintillators.

In brief, the principal mechanisms of photon emission subsequent to electron-hole production in the NaI(Tl) crystal occur in the following two sequences: (1) electron and hole trapping processes and (2) radiative recombination mechanisms (Lempicki, 1995; Weber, 2004; Alexandrov

FIGURE 9.1 Basic scheme of various stages involved in scintillation. From Bizarri (2010); reprinted with permission from Elsevier © 2010.

et al., 2008; Bizarri, 2010). Predominate electron-hole trapping processes are explained as follows:

The Tl is normally found in the crystal lattice as TI^+ ions. Electrons, e^- , are trapped by TI^+ to form TI^0 as described by

and holes (h^+) are trapped by TI^+ to form TI^{++} according to

The predominate radiative recombination mechanisms then come into play to include the interaction of trapped electrons with free holes to form activated thallium or $(\text{TI}^+)^*$ followed by the emission of visible light upon thallium deactivation according to

and the interaction of trapped holes with free electrons (e^-) to produce activated thallium or $(\text{TI}^+)^*$ followed by the emission of visible light upon thallium deactivation as illustrated by

The luminescence at dopant activation centers is illustrated in Fig. 9.1 where the scintillation scheme is depicted to occur in three stages, as described by Bizarri (2010). Firstly, the high-energy particle (HEP) deposits energy in the scintillator crystal forming N number of electron-hole pairs ($N_{e/h}$) in Stage 1. The electron-hole pairs travel to luminescent centers depicted in Stage 2, where the major constraint is the transport or transfer efficiency S of the crystal of the $e-h$ pair energy to the luminescence centers. Finally the Stage 3 occurs when the dopant ions act as the centers for electron-hole trapping and dopant ion excitation and deexcitation with photon emission, governed by the luminescence efficiency, Q , of the scintillation crystal. The overall light yield (LY) in units of photons emitted per MeV of energy deposited in the crystal by the nuclear radiation is a function of the transport efficiency of the $e-h$ pair energy (S) and the luminescence efficiency (Q) of the crystal detector, as described by Eq. (9.8) further on in this chapter.

Although of lower density than other available inorganic scintillator crystal detectors, the NaI(Tl) crystal in combination with low-noise photomultipliers remains among the most commonly used today for X- and gamma-ray photon measurements as well as other particulate radiation and as a promising tool for the detection of the nuclear recoil (NR) events from weakly interacting massive particles (WIMPs) interactions (Bayat et al., 2018; Gütlein et al., 2017; Kasban et al., 2017; Oliván et al., 2017; Varley et al., 2017; Kim et al., 2015; Amaré et al., 2014;

Bezuidenhout, 2013; Cuesta et al., 2013; Parker et al., 2013; Cacioli et al., 2012; Peebles and Gardner, 2012; Ianakiev et al., 2009; Alexandron et al., 2008; Hell et al., 2000). The popularity of this detector is due partly to the development of polycrystalline NaI(Tl) by Harshaw/Filtrol Partnership (Solon, OH) under the trade name Polyscin, which is prepared by the recrystallization of single-crystal ingots under heat and pressure and other more modern techniques of producing large ingots of NaI(Tl) detector material (Taranyuk et al., 2011). The ingots are more durable than single-crystal material and can be fabricated in a wide range of sizes and shapes to accommodate specific applications without any cost to scintillation performance. Mechanical and thermal shock inflicted on single-crystal NaI(Tl) can cause fractures, which can cleave among many planes and propagate across the entire crystal, resulting in an overall reduction in light output efficiency and pulse height resolution. Fractures in the single-crystal ingots, however, usually remain confined to localized areas of the crystal with no overall interference with light collection efficiency and pulse height resolution.

Other important factors that have contributed to the popularity of NaI(Tl) are the relative short decay time of this detector and its high light output or relative scintillation conversion efficiency. The decay time is the time necessary for deactivation. Shorter decay times permit greater resolution of succeeding deactivation events, referred to as resolving time, in the crystal detector. The resolving time of an NaI(Tl) crystal detector is reported to be around 10 ns (Seo et al., 2010).

Optical emission in the scintillation process is governed by an exponential decay with decay constants varying with detector type (see Table 9.3). Heath (1983) explained the effect of variable optical emission decay on the basis of detector afterglow. That is, although most excited states of a scintillator or phosphor may have the same lifetime, phosphors are characterized by the presence of long-lived states referred to as afterglow. Grabmaier (1984) defines afterglow as the emission of light from the scintillator after the cessation of radiation excitation. This is a property of all scintillation crystal phosphors, and NaI(Tl) and BGO display this property to a minimal degree. The high density and atomic number of BGO give it a greater stopping power than NaI(Tl) for electromagnetic radiation. This is of particular importance in improving detection efficiencies of high-energy gamma radiation. Therefore, BGO has become a very popular detector. The properties of BGO detectors and their applications are provided in Tables 9.3 and 9.4, and they are discussed further on in this chapter.

Research has produced scintillation crystal detectors with higher density, higher light yields, and faster responses than BGO. Some of these fast solid scintillation detectors are the Ce^{3+} -activated crystals found in Tables 9.3 and 9.4 among others activated by Pr^{3+} and

Eu^{2+} . The properties and the scintillation processes in these materials are described by Khan et al. (2018), Kim et al. (2016), Sun et al. (2015), Gundiah et al. (2014), Samulon et al. (2014), Derenzo et al. (2011), Neal et al. (2011), Bourret-Courchesne et al. (2009, 2010), Mares et al. (2005), Belsky et al. (2001), Korzhik and Lecoq (2001), Rodnyl (2001), van Loef et al. (2001), Pauwels et al. (2000), Saoudi et al. (1999), Wojtowicz et al. (1994a, 1995, 1996), and Lempicki et al. (1993). The scintillation mechanism at sites of Ce^{3+} in crystal detectors is similar to that of Tl^+ described previously. Following the production of electron-hole pairs by the impinging gamma radiation, a two-step scintillation process involves first the trapping of holes by Ce^{3+} according to

and the interaction of the trapped holes with conduction band electrons yielding excited Ce^{3+} ions (Ce^{3+})* as follows

The excited cerium ion (Ce^{3+})* falls to a stable ground state with the emission of a scintillation photon, $h\nu$, according to

where h^+ and e^- represent a valence band hole and conduction band electron, respectively (see Fig. 9.1). Wojtowicz et al. (1994a,b) demonstrated that the high hole-capture cross section of the Ce^{3+} ions and good transport properties of electrons are responsible for the high scintillation light yield of these Ce-doped crystals, which are properties yielding high light yields with other dopants, such as Eu^{2+} .

The scintillation processes previously described with Tl^+ and Ce^{3+} activation centers can be described similarly with other ions doped in a crystal lattice to serve as centers of luminescence. Bressi et al. (2001) modeled the scintillation process in the following steps: (1) absorption of radiation, (2) production of an electron-hole pair, (3) thermalization of the electron and hole, (4) energy transfer to a luminescence or activation center, and (5) emission, which is similar to that described by Bizarri (2010) and depicted in Fig. 9.1. Bressi et al. (2001) define the light yield (LY) in units of photons/MeV as

$$\text{LY} = 4.35 \times 10^5 \frac{\beta S Q}{E_g [\text{eV}]} \frac{\text{photons}}{\text{MeV}} \quad (9.8)$$

where β is the conversion efficiency (Step 1), E_g is the band-gap energy (Step 2), that is, the energy difference between the valence and conduction band of the detector, S is the transport or transfer efficiency of the e-h pair/energy to the luminescence center (Steps 3 and 4), and Q is the luminescence efficiency (Step 5). A similar definition for photon

production or light yield is provided by Rodnyi et al. (1995) and van Eijk (2001). The light yield could be controlled by the selection of a scintillation detector with a small band gap (Kurudirek et al., 2018; Wang et al., 2018; Kowalski et al., 2017; Shendrik et al., 2017; Yanagida et al., 2017; Auffray et al., 2016; Wu et al., 2016; Shwetha et al., 2015; Ninos et al., 2010; Hawrami et al. 2008; van Loef et al., 2005). Band-gap energies may vary from <1 eV to several eV. Values are provided by van Eijk (2001) for several types of detectors. Bizarri (2010) points out, that for an efficient Q , the ground state of the dopant ion should be above the valence band, and the excited state of the dopant below the conduction band (see Fig. 9.1).

The relative light output of all scintillation crystal detectors is a function of temperature, and the effect of temperature varies significantly from one detector type to another over the temperature range -100 to $+140^\circ\text{C}$. These temperature effects are generally less significant for NaI(Tl) detectors in normal room measurements of radionuclides, because this detector displays a rather stable light output response at $\pm 20^\circ\text{C}$ at either side of room temperature (Heath et al., 1979; Sabharwal et al., 1982; Ianakiev et al., 2009). In space exploration and borehole logging, where more extremes in temperature are experienced, temperature effects on the light output of scintillation crystal detectors are very significant. NaI(Tl) is often the detector of choice for in-situ gamma spectroscopy including borehole logging, because of its high light output (40,000 photons/MeV), high effective atomic number (Z_{eff}), and high scintillation efficiency (Asfahani, 1999; Rudin et al., 2001). However, Rudin et al. (2001) demonstrate that $\text{CaF}_2(\text{Eu})$ may be a suitable replacement for NaI(Tl) particularly as groundwater probes and at liquid waste sites. The $\text{CaF}_2(\text{Eu})$ detector has a lower light yield (24,000 photons/MeV), but it is nonhygroscopic and more fracture resistant. The low effective atomic number of $\text{CaF}_2(\text{Eu})$ renders it less suitable for gamma-ray spectroscopy at energies above a few hundred keV.

C. Conversion of detector scintillations to voltage pulses

The utilization of the solid scintillation phenomenon for the analysis of nuclear radiation requires the conversion of the visible photon emissions of the inorganic scintillator crystal to voltage pulses. The voltage pulses can be measured to determine their magnitude and number. As in the case of liquid scintillation analysis, a PMT with a photosensitive cathode is used in many instruments to convert a given photon emission to photoelectrons, which are amplified by a series of dynodes to an avalanche of electrons (see Fig. 6.4, Chapter 6, Volume 1). Other types of photomultipliers can also do this job, and these are described in Section III.B of this chapter. The magnitude of the resulting

pulse height produced by the PMT is proportional to the photon intensity emitted by the crystal scintillator. The photon intensities depend, in turn, on the amount of nuclear radiation energy absorbed by the scintillator. In Table 9.3 it is noted that NaI(Tl) produces around 40 photons per keV absorbed. Therefore, in summary, we can state that a given pulse height in volts produced by the PMT (within the resolving time of the PMT, e.g., 5 ns) is proportional to the scintillation photon intensity, and the scintillation photon intensity is, in turn, proportional to the energy of the nuclear radiation absorbed by the crystal detector. The following equation can be written to describe this process, which is the basis of the principle behind solid or liquid scintillation analysis of the energies of nuclear radiation:

$$\begin{aligned} \text{Pulse height (volts)} &\propto \text{scintillation photon intensity} \propto \\ &\text{gamma-ray energy absorbed} \end{aligned} \quad (9.9)$$

The absorption of a monoenergetic beam of gamma radiation by the crystal detector is governed by the exponential attenuation Eq. (1.442) (Chapter 1, Volume 1), $I = I_0 e^{-\mu x}$, and the attenuation coefficient, μ , is a sum of the independent coefficients due to the Compton, photoelectric, and pair production effects in the crystal, defined by Eq. (1.454) (Chapter 1). The magnitude of the attenuation coefficients for these radiation absorption processes in a given absorber material is a function of the incident gamma-ray energy. Attenuation coefficients due to the Compton, photoelectric, and pair production processes as well as the total attenuation coefficient (sum of these three processes) in NaI as a function of gamma-ray energy are plotted in Fig. 1.127 of Chapter 1, Volume 1.

Because gamma rays, originating either from the sample or from annihilation radiation, and X-radiation, produced in the crystal and detector shielding, may impart any fraction of their energy in Compton interactions, a wide spectrum of photon intensities of visible light are emitted from the crystal detector. Consequently, a spectrum of pulse magnitudes in volts is produced as an output from the PMT. Pulses low in magnitude are also produced by thermal noise, that is, thermionic emission of electrons from the cathode of the PMT. All pulses produced may be amplified and then registered as counts over a period of time to provide a count rate, and the pulse events may be analyzed by a multichannel analyzer (MCA) to determine the spectrum of pulse heights produced and gamma-ray energies absorbed by the crystal detector. The principles of operation and applications of the PMT as well as other photomultipliers and the MCA as components of the solid scintillation analyzer are discussed further on in this chapter and other parts of this book.

III. Solid scintillation analyzer

From the information provided up to this point of the chapter we might conclude that inorganic crystal scintillators are used most often for the measurement of electromagnetic X- and gamma radiation. This is the case; however, these detectors are also commonly used to measure other ionizing radiations such as electrons, heavy ions and elementary particles as well as non-ionizing radiations such as neutrons and neutrinos. The latter are detected indirectly via the reactions they produce within the inorganic crystal scintillators. This section of the chapter will focus mostly on the analysis of electromagnetic X- and gamma radiation. Special applications of solid scintillation to the measurement of charged-particle radiation and the neutrally charged neutrons and neutrinos are covered separately in this chapter.

Automated modern state-of-the-art solid scintillation analyzers are computer controlled to enable the automatic hands-off analysis of many samples, sample data processing, instrument calibration and control, and programmed instrument performance assessment (IPA). Linked to the computer are the hardware components, including the sample changer, solid scintillation detector, or even several detectors in one instrument to enable the high-throughput simultaneous analysis of multiple samples, and the electronic components required to convert scintillation photons to voltage pulses, and pulse height MCAs required to correlate these voltage pulses with radiation energies and to quantify their intensities. The basic components of the solid scintillation analyzer will be discussed subsequently.

A. Scintillation crystal detectors

The chemical structure, properties, and performance of a wide range of inorganic crystal scintillation detectors are provided in Tables 9.2–9.4 of this chapter. The properties of many other inorganic scintillators will be discussed further on in this chapter.

Scintillation crystal detectors may be employed in various shapes or geometries. Among these are (1) the planar detector, (2) the well-type detector, and (3) the through-hole detector. The crystalline scintillation detectors are discussed in this section of the chapter. Yet other detector formats exist including the noncrystalline plastic or glass type. There are commercially available 24- or 96-well plastic microplate solid scintillators and microsphere plastic or glass scintillators for high-throughput scintillation counting and scintillation proximity assay (SPA). Also, there are plastic and glass fiber-optic scintillators. These, as well as other scintillator detector types, are discussed separately further on in this chapter.

1. Planar detector

The planar solid scintillation detector usually consists of an inorganic crystal that is cylindrical in shape, and NaI(Tl) is the most commonly employed detector material. The dimensions will vary as described subsequently. One flat surface of the cylindrical crystal detector is exposed to the radiation source and the other end of the crystal is connected to a PMT by means of a light pipe and light-transmitting grease. The PMT converts the individual scintillation events into measurable voltage pulses as described later in this section. The crystal surfaces that are not in contact with the PMT are covered with a protective coating (e.g., aluminum ~ 0.5 mm thick), which blocks out external light and protects the scintillation crystal detector from atmospheric moisture (particularly hygroscopic crystal detectors) and from physical damage. The detector coating, if sufficiently thick, may also serve as a shield against alpha and low-energy beta radiation. The inner part of the coating is often whitened or covered with a reflector material (e.g., MgO) in order to reflect photons of visible light toward the PMT.

The surface of a crystal of this type can receive, at best, only 50% of the radiation emitted from a given sample, since the crystal can be exposed to a maximum of 180 degrees of a possible 360 degrees of radiation emission. This counting geometry is often referred to as 2π geometry. This is not a very efficient counting geometry, because of the very limited exposure the detector can have to the sample radiation, as this type of detector can “see” only 50% of the sample at best. Detection efficiencies with this counting geometry are relatively low compared with other detector geometries. Consequently, planar detectors are generally not used for the analysis of samples, which are handled and prepared in the laboratory, as more efficient detector geometries are available for sample analysis. The planar detector is used in other applications such as the monitoring of surface radioactivity, area monitors, space exploration, and imaging detectors used in medical diagnosis, such as single-photon emission computed tomography (SPECT) and PET, which require the detection of gamma-ray photons from only one direction (Knoll et al., 2016; Phillips et al., 2015; Retière et al., 2012).

The crystal detector is most commonly 75×75 mm in size. Smaller crystals are used, but they provide lower gamma-ray detection efficiencies, because the probabilities become greater that a gamma ray may pass through the crystal detector without dissipating its energy within. Belle et al. (1974) demonstrated that oversized crystals are characterized by an enhanced background without increased sensitivity. They concluded that a 70×70 mm ($\sim 3 \times 3$) NaI(Tl) crystal is best with gamma-ray energies up to 0.4 MeV, whereas a 150×150 mm ($\sim 6 \times 6$)

crystal is recommended for gamma-ray energies between 0.4 and 3.0 MeV.

2. Well-detector

The well-type detector consists of a crystal detector with a cavity drilled at the center of the crystal to form a well within which a sample may be placed in a suitable sample tube or other container for radiation analysis and counting, as illustrated in Fig. 9.43 further on in this chapter. For example, a cavity of 15 mm diameter (~ 0.6 in dia.) may be drilled into the center of a 75-mm-diameter (3 in dia.) cylindrical crystal. The crystal surfaces not in contact with the PMT are covered with a thin aluminum coat for the reasons given previously in Section III.A.1. The sample to be counted is enclosed within a plastic tube and placed within this cavity, which is referred to as the detector well. This detector geometry was designed in the early years of solid scintillation analysis and used by the writer in the early 1960s. Manufacturers of this type of detector utilize a very thin aluminum coat (0.25–0.5 mm) to achieve the highest counting efficiency possible. The detector becomes vulnerable to damage if the sample tube is dropped into the well. Contamination of the well cavity or coating over long-term use is also a concern.

The well-type detector was envisaged with the objective of surrounding the sample with detector as much as possible. Optimum counting geometry is obtained when a sample is only a point source and that source is at the very center and completely surrounded with a radiation detector. Such an arrangement enables the detector to receive all of the possible radiation emissions, which may emanate in all directions (360 degrees) from a given sample. This is referred to as a 4π counting geometry. Obviously, such a counting geometry with a well-detector is not possible. The well-type detector was designed to try to approach, as closely as possible, a 4π counting geometry.

The well-detector remains a commonly used counting geometry. In this counting geometry there is a higher degree of variability in detection efficiency as a function of sample size or volume. For example, if the sample is a point source at the bottom of a sample tube and the tube is inserted into a well-detector, the sample is as far as possible from the well opening. As the sample size or volume is increased, the surface of the sample in the tube approaches the well entrance. Consequently, as the sample volume is increased, the detection efficiency will vary. It may increase and then diminish, as illustrated in Fig. 9.2 for ^{65}Zn ; or the detection efficiency may remain stable for small volumes of sample and then drop as the sample volume is increased, as in the case of ^{22}Na (Fig. 9.2). The different response of the well-type detector to counting geometry is due to the

FIGURE 9.2 Changes in detection efficiency of a $6 \times 6''$ (150×150 mm) NaI(Tl) well-type detector for the analysis of ^{22}Na and ^{65}Zn as a function of sample volume. From L'Annunziata, M.F. (1965) unpublished work of the writer for ^{22}Na and Garcia Burciaga (1976) and Garcia Burciaga et al. (1978) for ^{65}Zn .

energies of the photon or charged-particle emissions and the volume of crystal detector exposed to radiation emissions from a sample. As the sample volume increases beyond a certain point, there is increasing probability of radiation escape without penetrating or interacting with the crystal detector. The two radionuclide samples, illustrated in Fig. 9.2 serve as examples. If we compare the gamma-ray emissions of ^{22}Na and ^{65}Zn , it is possible to explain the different sample geometry effects on detection efficiencies in the well-type detector. The decay schemes of the two radionuclides are given in Chapter 1, Volume 1 (see Eqs. (1.224)–(1.227) of Chapter 1, Volume 1). Sodium-22 emits a relatively high-energy gamma of 1.275 MeV with 100% intensity and 0.511-MeV annihilation gamma with 180% intensity (90% of the ^{22}Na radionuclides decay by

positron emission). On the other hand, ^{65}Zn emits a lower energy gamma ray (1.115 MeV) with an intensity of 50% and a lower abundance of 0.511-MeV annihilation gamma (3.0% arising from the 1.5% of the ^{65}Zn nuclides decaying by positron emission). Most of the ^{65}Zn nuclides (98.5%) decay by electron capture (EC), which give rise to a large number of low-energy X-rays of the copper daughter nuclide. See Table A.1 of the Appendix for data on radiation types, energies, and radiation intensities of many of the radionuclides. The effect of sample volume on the detection efficiency of the well-type detector varies significantly with radionuclide radiation emissions and energies.

El-Khatib et al. (2016), Pommé (2012, 2009) and Pommé et al. (2009) have elaborated analytical models and software for the calculation of detection efficiencies of well-type detectors for photons, electrons, and positrons for a radioactive source at an arbitrary position relative to the detector and sample well. These calculations are used in the standardization of radionuclides. In the routine measurement of radionuclide activities, the optimum volumes for measuring the activities of radionuclides can be determined by simple measurements of count rates as a function of sample volume such as illustrated in Fig. 9.2. Ramadhan and Abdullah (2018) carried out thorough studies on the effects of gamma-ray photon energy and sample geometry on the gamma-ray full energy peak absolute efficiency. They used the following equation for the calculation of gamma-ray energy peak efficiencies (ϵ) of various radionuclides:

$$\epsilon = \frac{N}{A \times t \times f_{\gamma}} \times 100 \% \quad (9.10)$$

where N is the net peak area for each photopeak (see Fig. 9.3), A is the radionuclide activity and f_{γ} is the probability of a gamma-ray line for a particular radionuclide.

FIGURE 9.3 Gamma-ray spectrum of Na-22 obtained with a 3×3 inch (7.6×7.6 cm) NaI(Tl) well-type scintillation detector. From Ramadhan and Abdullah (2018); reprinted with permission from the Korean Nuclear Society © 2018.

Various photopeaks are found in the Na-22 gamma spectrum illustrated in Fig. 9.3. The photopeak at 511 keV arises from positron annihilation photons and that at 1022 keV arise from the coincident detection of two 511 keV photons. The photopeak at 1274 keV is that of the gamma-ray photon emission of Na-22, and the photopeak at 1785 KeV is a result of the detection in coincidence of a 1274 keV gamma-ray photon and 511 keV annihilation photon.

The distance of the source from the bottom of the sample well will affect the photopeak detection efficiency, and this effect is more prevalent for photopeaks of the lower gamma-ray photon energy lines, as depicted in Fig. 9.4. Gamma-ray photons of lower energy have a greater probability of absorption and energy loss in the scintillation detector; whereas, those of higher energy have a greater probability of traveling through the detector with less energy loss. When measured at a specific distance from the bottom of the sample well, the relationship of the detection efficiency of a point source as a function of gamma-ray energy line is illustrated in Fig. 9.5. The analysis of samples do not generally involve point sources; however, the Figure illustrates the higher probability of gamma-ray photon energy absorption in the scintillator for gamma-ray photons of lower energy.

For consistent results in the routine measurement of radionuclide activities, sample volumes should be maintained constant to assure constant sample counting geometry. For all radionuclides measured including the low-energy radionuclides, such as, ^{57}Co , with gamma energies of 0.122 MeV (87% intensity) and 0.014 MeV (9% intensity) and Fe daughter K X-rays ($\sim 55\%$ intensity), and ^{125}I , with gamma energy of 0.035 MeV (7% intensity) and Te daughter K X-rays (138% intensity), sample volumes should be maintained constant and the optimum volume determined, which may be under 1 mL for the 15-mm detector well dimension in the 75-mm diameter cylindrical crystal cited previously or corrections can be made for changes in detection efficiency as a function of sample volume. Hunter et al. (1975) demonstrated significant

FIGURE 9.5 Detection efficiency of a 3 × 3 inch NaI(Tl) well-type scintillation detector as a function of gamma-ray energy with a source placed at a 2.5 cm height above the bottom of the sample well. From Ramadhan and Abdullah (2018); reprinted with permission from the Korean Nuclear Society © 2018.

decreases in detection efficiency of these radionuclides with the well-type detector with sample volumes over 1 mL. In many cases where detector dimensions will vary, the user should plot the detection efficiencies against sample volume for the particular radionuclide. Corrections for the effect of sample geometry on detection efficiency can then be made. Automatic gamma analyzers, which can analyze up to 1000 samples automatically, with well-type detectors are available commercially with up to 10 detectors to provide for the simultaneous analysis of 10 samples in tubes of variable dimension.

3. Through-hole detector

The through-hole solid scintillation detector consists of a cylindrical crystal with a hole machined all the way through the center of the crystal. Fig. 9.6 illustrates four crystal detectors of the through-hole type with a sample tube in the central cavity of each detector. Such a detector geometry

FIGURE 9.4 Experimental absolute efficiency measured with point gamma-ray sources for gamma-ray energy lines at 86.5, 105, 662, 1274 and 1785 KeV with a 3 × 3 inch NaI(Tl) well-type scintillation detector as a function of the source location (b) from the bottom of the well. Arrows were added by the writer to point to curves derived from sources at various distances from the well bottom. For the color version of this figure, the reader is referred to the electronic version of the book. permits the automatic loading of samples from the bottom and automatic instrument adjustment of the sample elevation to position the sample at the very center of the crystal detector. The four samples illustrated in Fig. 9.6 are of different volume, but positioned automatically by the instrument to provide optimum detection efficiency and minimal variation of detection efficiency as a function of volume.

Automatic gamma analyzers with through-hole detectors have been produced commercially with up to 10 detectors to provide for the simultaneous analysis of 10 samples in tubes of variable dimension up to a maximum size of 14×100 mm for a 1.5-inch (3.8 cm) diameter crystal. Other models of automatic gamma analyzers can accommodate sample tubes up to 10×100 mm in size for crystal detectors 2 or 3 inches (5 cm or 7.6 cm) in diameter. The larger crystal detectors provide higher detection efficiencies, particularly desirable for the higher energy gamma-emitting radionuclides. These gamma analyzers have automatic sample changers, which can accommodate up to 1000 samples for hands-off analysis.

B. Photomultipliers

A photomultiplier is an electronic device used to measure low intensities of visible radiation by converting the photons, which strike the light-sensitive surface of the photomultiplier, into a photocurrent (e.g., flow of electrons). The magnitude of the electric pulse produced by the photomultiplier is a function of the intensity of the light that strikes the photosensitive surface of the photomultiplier. The most common type of photomultiplier used with commercial automatic laboratory gamma analysis instrumentation is the dynode photomultiplier, more commonly known as the PMT. Other types of photomultipliers may be used where resistance to magnetic fields are required or

where miniature devices are needed for field applications, space exploration, and so on. Various types of photomultipliers are described in this section.

1. Dynode photomultiplier or PMT

The dynode photomultiplier or PMT is placed in direct contact with the solid scintillation crystal via a plastic light pipe and clear translucent grease to ensure optimum light transmission from the scintillation crystal to the PMT. The PMT is constructed of an outer glass surface with an inner photocathode (see Chapter 6, Volume 1, Fig. 6.4). The photocathode consists of a photosensitive substance (e.g., bialkali alloy, Sb–K–Cs) that produces photoelectrons when bombarded with photons of visible light. The photoelectrons produced at the photocathode are then accelerated toward a positively charged dynode in the PMT. The dynode is a metal plate given a positive potential, which emits secondary electrons upon impact with accelerated electrons. The acceleration of the photoelectrons and the impact of these on the dynode produce multiple secondary electrons. A series of several additional dynodes are contained in the PMT, and each subsequent dynode is given a higher positive potential to further accelerate and produce a larger number of secondary electrons. The final outcome is an avalanche of electrons at the last dynode. This final avalanche of secondary electrons is collected as a current pulse, which is of a magnitude that can be handled by the electronic circuitry and further amplified, counted, and analyzed for its pulse height.

From the description of the dynode photomultiplier or PMT provided in the previous paragraph, it is easy to see why this electronic component is also referred to as an electron multiplier phototube. Therefore, from the preceding account, we can state that the PMT has a twofold purpose: (1) to convert any given scintillation of visible light emission from the scintillation detector into a current pulse of secondary electrons and (2) to amplify the current pulse to a magnitude that can be handled by the counting and pulse height analysis circuitry associated with the radiation analyzer. It is important to note at this point that the number of photoelectrons produced at the PMT photocathode and the magnitude of the final current pulse collected after the series of dynode amplifications are a function of the light intensity, which is in turn a function of the radiation energy absorbed by the scintillation detector. As a consequence, the current gain from the PMT will depend on the initial scintillation photon intensity, and it will vary within the range 10^6 to 10^9 . This range of current gain provides a source of variable pulse heights, which may be analyzed by other components of the radiation analyzer, such as the pulse height analyzer and multichannel analyzer (MCA) discussed further on in this chapter.

2. Hybrid photomultiplier tube

The hybrid photomultiplier tube (HPMT) is constructed as a vacuum tube with a photocathode face as in the classical PMT. The HPMT differs from the classical PMT in that it does not contain dynodes for electron amplification, found in the classical PMT; rather, the HPMT uses high accelerating voltages (10–20 kV) and a high focusing voltage to accelerate the photoelectrons produced at the photocathode onto a small anode consisting of a Si p-i-n diode or avalanche photodiode (PD) only a few mm² in area, as illustrated in Fig. 9.7. The gain or electron amplification achieved by the HPMT is a consequence of both the high voltage applied to the tube for electron acceleration and the energy needed to create one electron–hole (e–h) pair in the p-i-n diode (3.6 eV). Thus, ~ 280 (e–h) pairs are produced for a 1 kV accelerating voltage; and a typical gain from a 12 kV accelerating voltage would be ~ 3000 due to some energy loss in the diode entrance window (Mares and D'Ambrosio, 2007; Burger et al., 2008). Amplifications of 5000 are reported with the silicon diode anode and an accelerating field of 20 kV; and a yet higher gain of 10^5 with an avalanche PD anode would allow simpler readout electronic circuits (Iijima, 2011; Korpar, 2011 and Renker, 2004, 2007).

The hybrid photomultiplier can be equipped with a pixelated silicon PD anode capable of high resolution imaging as required in medical imaging. Depending on the pixel size, single photon detection is possible (D'Ambrosio et al., 2006; Burger et al., 2008; Anton et al., 2009). A hybrid photomultiplier concept employing the pixelated semiconductor detector Timepix for the detection of photoelectrons and resultant imaging is described by Llopart et al. (2007), Anton et al. (2009), and Medipix Collaboration (2011). Timepix comprises 256×256 pixels with a pixel pitch of 55 μm electronically connected to a 300 μm

FIGURE 9.7 Scheme of the hybrid photomultiplier (HPMT); and an experimental setup for scintillator response measurement with the HPMT. From Mares and D'Ambrosio (2007); reprinted with permission from Elsevier © 2007.

thick silicon layer developed by the MEDIPIX, which is a worldwide collaboration of institutes producing and evaluating semiconductor pixel detectors for tracking applications in high energy physics including medical imaging. Canberra Industries has coupled pixelated PDs, illustrated in Fig. 9.8, which can be mounted in an HPMT. In the vacuum tube the photoelectrons produced at the photocathode are accelerated by the electric field whereby the electrons penetrate into the depleted region of the silicon diode (Burger et al., 2008). High resolution permitting single photon counting is possible subject to pixel size.

FIGURE 9.8 (Left) Artistic view of an array of hexagonal pixels of a pixelated PD and (Right) An HPMT with Si pixelated detector. (Left) From Burger et al. (2008); reprinted with permission from Elsevier © 2008; (Right) From Fontanelli (2009); reprinted with permission from Elsevier © 2009.

A pixelated hybrid photomultiplier is employed in the Ring-Imaging Cherenkov (RICH) detector at the CERN Large Hadron Collider (LHC). The hybrid photomultiplier, illustrated in Fig. 9.8 converts the Cherenkov photons to photoelectrons in a multialkali photocathode; and the photoelectrons are accelerated and focused by an electrostatic field of ~ 20 kV onto a reverse-biased silicon pixel detector, which is bump-bonded onto a 40 MHz read-out chip (Fontanelli, 2009). The kinetic energy of each accelerated photoelectron is dissipated in the silicon with the creation of ~ 5000 electron-hole pairs, estimated as $20 \text{ kV}/3.6 \text{ eV/e-h pair}$ with some energy lost in the diode entrance window. The RICH detectors, described by Fontanelli (2009), utilize 484 pixelated hybrid photomultipliers covering a total surface area of $\sim 3.3 \text{ m}^2$; and the granularity of the pixels is $2.5 \times 2.5 \text{ mm}^2$ resulting in approximately half a million pixels. RICH detectors are described in Chapter 6, Volume 2.

Advance designs of the HPMT with Si diode, also referred to as the hybrid Si photomultiplier (SiPM) and vacuum silicon photomultiplier tube (VSIPMT) have been designed and are described by Barbarino et al. (2018, 2013a,b), Barbato et al. (2017), Berneking et al. (2018), Suda (2014), Ko et al. (2013), Sanfilippo et al. (2013). The first 1-inch industrial VSIPMT is illustrated in Fig. 9.9. The VSIPMT, as described by Barbarino et al. (2018) is a silicon photomultiplier (SiPM) intended to replace the classical dynode PMT with unprecedented performance capabilities, including negligible power consumption, single-photon emission resolution, low voltage-based stabilization, and good timing performance. The 1-inch SiPM contains a pixelated PD with an array of 54 SiPMs $3 \times 3 \text{ mm}^2$.

3. Microchannel plate photomultiplier

Microchannel plate photomultipliers (MCP-PMs) can have advantages over the conventional multidynode PMTs described previously, particularly when the size of the photomultiplier is critical (Fraser, 2002; Lees and Fraser, 2002; Nappi, 2009; Wetstein, 2011), and when low susceptibility to magnetic fields ($<2 \text{ T}$) is a requirement (Barnyakov et al., 2010; Baturin et al., 2006; Iijima, 2009; Kosev et al., 2010; Lehmann et al., 2008). A microchannel plate (MCP) consists of closely packed and fused micro lead glass capillary tubes ($\sim 10 \mu\text{m}$ in diameter and $\sim 400 \mu\text{m}$ in length) with inner walls containing a material that can easily yield secondary electrons (Iijima, 2011). A photocathode is placed at the entrance of the fused capillary tubes and an anode collector at the exit to produce an MCP-PM. Certain MCPs are manufactured as radioactivity detectors and imagers (Lapington et al., 2009; Lees and Fraser, 2002; Lees and Hales, 2001; Lees et al., 1997; Price and Fraser, 2001). These are referred to as MCP detectors,

FIGURE 9.9 A schematic cutaway of the VSIPMT showing the interior composition of the device. On the top there is the light entrance window, then a photocathode for the conversion of photons to electrons (yellow). In the middle there is a focusing ring (dark gray) producing an electric field which accelerates and focuses the photoelectrons on the SiPM surface (yellow square at the bottom). On the bottom the SiPM acts in this configuration as a (photo)electron detector and (photo)electron current amplifier. Everything is assembled into a hermetically sealed container. Lettering was added by the writer. For the color version of this figure, the reader is referred to the electronic version of the book. From Barbarino et al. (2018); reprinted with permission from Elsevier © 2018.

which are manufactured to detect directly nuclear radiation (e.g., beta particles and X-rays) when the entrance to the MCP is made of a nickel-based electrode, which may be coated also with an alkali halide (e.g., CsI) capable of producing electrons directly from the impinging nuclear radiation.

Light photons emitted from a scintillation crystal detector are first absorbed by the photocathode, yielding photoelectrons in the process. The photoelectrons are then accelerated across the ends of MCP capillary tubes by a voltage potential applied across the channels. As the photoelectrons travel through the microchannels, secondary electrons are produced via impact or collisions with the inner walls of the channels. These secondary electrons, in turn, produce other secondary electrons through further collisions with the capillary walls. The result is a cascade or avalanche of electrons. An illustration of the production of secondary electrons and consequent electron amplification in a microchannel is illustrated in Fig. 9.10. For clarity, only a few secondary electrons are illustrated; the avalanche of electrons or output charge cloud produced at the end collector plate is not shown. Various MCP-PM designs can provide electron multiplications in the range

FIGURE 9.10 Signal amplification in a microchannel. K_p and α_p are the energy and grazing angle for the incident primary electron initiating the avalanche. θ_i ($i = 1, 2, \dots$ in the schematic shown here) and $(K_e)_i$ are the emission angles and energies of the emitted secondaries. From Price and Fraser (2001); reprinted with permission from Elsevier © 2001.

of 10^5 – 10^6 (Pfaffinger et al., 2019; Hirose et al., 2015, 2014; Matsuoka, 2014; Kim et al., 2012a,b; Iijima, 2009, 2011; Kosev et al., 2010; Nappi, 2009); and gains of almost 10^7 have been reached with MCPs of $6\mu\text{m}$ pore size (Lehman et al., 2008). MCP-PMs are very compact in size relative to a classical PMT. The MCP-PMs vary in dimensions with diameters of 25–100 mm, channel pore (channel) sizes of 3–25 μm , and are 0.5–1.5 mm thick (Korpar et al., 2008; Kosev et al., 2010; Lapington et al., 2009; Lees and Fraser, 2002; Lees and Hales, 2001; Lehmann et al., 2008; Leutz, 1995; Nappi, 2009).

Dual MCP-PMs are constructed to augment electron amplification; and such an arrangement is illustrated in Fig. 9.11. An incident photon of light is converted to a photoelectron at the photocathode via the photoelectric effect. The photoelectron is accelerated across a potential gap toward a dual set of MCPs. Approximately a 1 kV potential is applied across each plate causing a photoelectron entering a pore to accelerate and strike the pore walls and thus create an avalanche of secondary electrons (Wetstein, 2011). The amplified pulse of secondary electrons exits from a pore of the MCPs; and the electrons are collected on the anode and the signal digitized. Time resolutions of the dual microplate photomultiplier, reported by Brook et al. (2019), Pfaffinger et al. (2019), Harnew et al.

(2016) and Wetstein (2011), are ~ 10 ps, which are under development for application in time-of-flight RICH detectors described in Chapter 6, Volume 2. The relative dimensions of the MCP PMT with 4×4 anodes yielding excellent position resolution and imaging capabilities to the photomultiplier is illustrated in Fig. 9.12; and an example of its application in the detection of Cherenkov photons in a time-of-propagation (TOP) counter for particle identification (PID) is illustrated in Fig. 9.12. TOP counters are

FIGURE 9.12 (A) Photograph of the MCP-PMT with dimensions and its cross-section view; and (B) schematic drawing of a TOP counter illustrating the path of an incoming particle, the production of a Cherenkov photon cone, and the propagation of the Cherenkov photon along the quartz bar and its final detection by an MCP-PMT. FIGURE 9.11 The structure of a generic MCP-PM tube. From Wetstein (2011); reprinted with permission from Elsevier © 2011.

described in detail in the chapter on Cherenkov Counting (Chapter 6, Volume 2).

The MCP-PM offers certain advantages over the classical PMT; among these are the following: (1) small size (0.5–1.5 mm thick); (2) low background noise; (3) capable of detecting single photons with pore diameters $< 10 \mu\text{m}$; (4) operational in magnetic field up to 2 T with appropriate orientation; (5) improved timing resolutions (~ 10 – 20 ps) suitable for time-of-flight RICH imaging; and (6) high quantum efficiency (QE) with use of appropriate photocathode (e.g., GaAsP) of $\sim 40\%$ at 500 nm and extending up to 700 nm (Brook et al., 2019; Harnew et al., 2016; Hirose et al., 2015, 2014; Wetstein, 2011; Iijima, 2009; Lapington et al., 2009; Nappi, 2009). The principal disadvantages of MCP-PMs compared with conventional PMTs are (1) their relatively high cost of fabrication, (2) lower gains or electron magnifications, (3) magnetic fields (> 2 T) prevent electrons from hitting the MCP walls and, therefore, stop electron multiplication, (4) they exhibit a lower photon detection efficiency, and (5) they have a reduced lifetime (Nappi, 2009). The feasibility of MCP-PMs for the coincidence detection of 0.511 keV annihilation gamma rays in PET has been tested by Kim et al. (2012a,b, 2010a). Their initial findings resulted in an energy resolution of $\sim 11\%$ at 511 keV, a coincidence timing resolution of ~ 323 ps, and a coincidence detection efficiency of $\sim 40\%$.

MCP-PMs led to the development of MCP detectors. MCP detectors were developed originally for their use in photon counting in astronomical X-ray telescopes (Weiskopf et al., 1995). MCP-PMs are applied as imagers (e.g., beta autoradiography) for commonly used radioisotopes in the biological sciences and other radiation sources, including neutron, gamma, and particle beam imaging (Tremisn et al., 2018; Wiggins et al., 2017, 2018; Ackermann et al., 2016; Wang et al., 2015a,b; Cazalas et al., 2014; Lapington, 2012). For radionuclide imaging, these detectors contain a nickel-based electrode at the face or entrance to the microchannel, which may be also coated with an alkali halide (e.g., CsI) as a photocathode. Beta particles originating from a radionuclide (e.g., ^3H , ^{14}C , ^{35}S , ^{32}P) or gamma- or X-ray radiation from certain radionuclides (e.g., ^{125}I) are capable of producing primary electrons upon colliding with the microchannel photocathode. Low-energy beta-emitting radionuclides (e.g., ^3H) are measured by the MCP in a windowless fashion where the beta-particles (electrons) interact directly with the MCP to produce the avalanche of electrons along the microchannel (Lees et al., 2005). The primary electrons collide with the walls of the microchannels resulting in an electron multiplication or avalanche as described in the previous paragraph for the MCP-PM. MCPs of this type may be only 1.5 mm thick with channel diameters ranging from 6 to $12.5 \mu\text{m}$. The microchannels are bundled side by side to form a relatively large area detector with dimensions of

100×100 mm (Lees and Hales, 2001). This forms a radioactivity imaging device, as each microchannel acts as an individual detector. Spatial resolutions of $\sim 70 \mu\text{m}$ full width half maximum are reported (Lees et al., 1997, 2005) for the large area 100×100 mm detector. The detectors have proven to be useful devices for the imaging of radionuclides in the biological sciences (Lees and Fraser, 2002; Lees et al., 1997, 1998, 1999, 2005). MCP detectors have also been employed as neutron imaging devices when the MCPs are doped with a suitable converter, which have high interaction cross-sections for low-energy neutrons, such as ^{10}B or ^{157}Gd (Tremisn et al., 2018, 2008, 2005; Wiggins et al., 2018; Wang et al., 2015a,b; Cazalas et al., 2014; Siegmund et al., 2007).

4. Channel photomultiplier

The channel photomultiplier (CPM) is a light detector, which contains a photocathode to convert light photons to electrons, and an electron multiplier consisting of a single narrow and hollow semiconductive curved channel through which the photoelectrons are accelerated. A diagram of the CPM is illustrated in Fig. 9.13. The CPM is very distinct from the MCP-PM, as the CPM consists only of a single curved channel rather than a more complex sheet of numerous and straight microchannels. Thus, the CPM, as an individual unit, cannot provide spatial resolution of radiation sources. Light photons produce photoelectrons at the photocathode. The photoelectrons are accelerated under vacuum in an electric field along a narrow curved semiconductive channel. Collisions of the electrons on the walls of the channel create secondary electrons, which terminate in an avalanche of electrons collected at the anode with a gain exceeding 10^8 (Ivan et al., 2008). The tortuous path of the curved channel increases the number of electron collisions with the glass wall of the channel and the consequent multiplication effect of the electron avalanche.

The CPM is produced by several commercial suppliers; and some specifications are the following: alkali photocathode, cerium-activated yttrium aluminum perovskite [YAP(Ce)] scintillator faceplate, 10–19 mm diameter faceplate, 300–650 nm spectral sensitivity, 22.2% QE at 410 nm, and a single photoelectron gain of 3.3×10^8 at

FIGURE 9.13 Diagram of the channel photomultiplier (CPM). From Grimm et al. (2003); reprinted with permission of Elsevier © 2003.

3.0 kV (Grimm et al., 2003; Ivan et al., 2010). The YAP(Ce) faceplate avoids considerable light loss due to the large difference in index of refraction (n of YAP = 1.95) and a typical borosilicate glass (n = 1.49) or UV-glass window (Grimm et al., 2003). CPM tubes were successfully utilized by Ivan et al. (2008, 2010) for the standardization of radionuclides in a TDCR liquid scintillation counter containing three and six photomultipliers in lieu of the classical dynode PMTs. As described by Ivan et al. (2008) the CPM operates in a saturated mode, so a photoelectron peak is a signature of any number of photoelectrons created at the same time at the photocathode. Thus, unlike the classical dynode PMT, the pulse amplitude is not the function of the number of photons reaching the photocathode. This feature prohibits the use of the CPM for spectroscopy, which is a useful but unnecessary feature of scintillation counters (Ivan et al., 2008).

5. Semiconductor photomultipliers

There is much ongoing research into the development of photodetectors that are good substitutes for the relatively large albeit very efficient PMT in applications of radioactivity analysis particularly in situations that demand small size and low weight such as in the fields of nuclear medicine and space exploration, and resistance to magnetic fields often required in studies of high-energy physics. In particular, imaging technologies, such as PET and computed tomography (e.g., SPECT), are advancing rapidly placing a high demand for efficient and small photomultiplier detectors, that can provide high resolution images. Research is underway at improving the performance of semiconductor photomultipliers (PDs) for this purpose. Although PDs have yet to serve as general replacements for the commonly used dynode PMTs in the general laboratory analysis of radionuclides, PDs are more widely utilized in many fields of radiation detection and measurement due to their very compact size, less bias to operate, resistance to magnetic fields, and excellent X- and γ -photon energy resolutions achievable with matching crystal scintillators (Kim et al., 2010b). For example, PDs with wafer dimensions are used as substitutes for PMTs in high-energy physics experiments where intense magnetic fields and space limitations preclude the use of PMTs (Lee et al., 2019; Legou et al., 2019; Whitaker et al., 2018; Li et al., 2017; Ohno et al., 2016; Cooper et al., 2012; Monteiro et al., 2012; Nelson et al., 2012; Brown and Cockerill, 2011; Nakamura et al., 2011; Hobson, 2009; Renker, 2009; Badalà et al., 2008; Beznosko et al., 2006; Fernandes et al., 2003). In the field of nuclear medicine imaging, in particular, PET and SPECT, there is increased demand to improve on image resolution from photon emissions, which only miniscule PDs can provide. Research in the improvement of PD performance in

conjunction with scintillation detectors in nuclear medicine imaging of X- and gamma radiation with SPECT and PET is intense (Samson et al., 2018; Herzog and Lerche, 2016; Kang and Choi, 2016; Schaart et al., 2016; Slomka et al., 2014; Rato Mendes et al., 2013; Shimazoe et al., 2013; Hu et al., 2012; Schneider et al., 2012; Beltrame et al., 2011a,b; Kato et al., 2011; Moadel, 2011; Yoshino et al., 2011; Bolle et al., 2010; Nishikido et al., 2010; Bérard et al., 2009; Braem et al., 2009; Kataoka et al., 2009). In space exploration, the characteristics of low weight, small volume, and low power consumption generally exclude the use of the bulky PMTs. Compact X- and gamma-ray spectrometers consisting of scintillators resistant to intense cosmic radiation coupled to small wafer PDs are in use on planetary probes and orbital vehicles. Research on the discovery of new PDs and their applications in astrophysics and planetary exploration is ongoing (Ohno et al., 2016; Boll et al., 2015; Kasahara et al., 2012; Monteiro et al., 2012; Anderhub et al., 2011a,b,c; Leroy et al., 2010; Kataoka et al., 2010a,b; Braun et al., 2009; Koteswara Rao et al., 2009; Labanti et al., 2009; Otte et al., 2009).

a. p-i-n photodiodes

The classical dynode PMT can be substituted, at least for certain applications, by the solid-state light amplifier (Orphan et al., 1978). As described by Heath et al. (1979), the light amplifier consists of a conventional photocathode coupled to a silicon diode. The photoelectrons produced at the photocathode of the device are accelerated at a potential of 15 keV and focused on to the reverse-biased p-i-n silicon junction diode. Because about 3.6 eV is required to produce an electron-hole pair in silicon, the light amplifier produces a net single-stage gain of about 4000 (i.e., 15,000 eV/3.6 eV). A subsequent slight gain produces an amplification equivalent to that of a PMT. A photocathode need not be used in conjunction with the p-i-n semiconductor diode, because photons with energies not much in excess of 1 eV can produce electron-hole (e-h) pairs directly in a semiconductor diode with nearly 100% efficiency (Groom, 1983, 1984). These devices are called p-i-n diode detectors, when particles are detected directly without the aid of a scintillator crystal. For example, PIN-diode detector arrays were used by Laitinen et al. (2002) directly without a scintillator to determine the depth profile of ^{31}Si radiotracer (β^- , $E_{\text{max}} = 1.5$ MeV) in amorphous ceramic. Such detectors were used by Wauters et al. (2009) to accurately measure the beta-spectra of ^{60}Co with a 500 μm -thick Si PIN PD with a sensitive area of 81 mm^2 exposed directly to the β -particle emissions of a ^{60}Co source in an experimental arrangement that would prevent beta-particle backscatter and under vacuum (10^{-4} torr) to prevent absorption by air molecules. The β spectrum is illustrated in Fig. 9.14. The endpoint energy of 318.1 keV of the principle beta branch is shown in the Figure. Cobalt-60 decays by two beta

FIGURE 9.14 ^{60}Co β spectrum obtained with a “scattering free” source and the Si PIN PD. The regions below and above the endpoint energy of 318.1 keV are labeled as 1 and 2, respectively. The Si PIN detector energy resolution is 7 keV. From Wauters et al. (2009); reprinted with permission from Elsevier © 2009.

branches of the following decay energies and intensities: 318.2 keV (99.9%) and 1491.4 keV (0.1%), as reported in the database of the National Nuclear Data Center, Brookhaven National Laboratory (NuDat 2.7, 2018). The higher decay energy is of insignificant intensity to interfere with the determination of the principle beta decay spectrum. The region of the spectrum beyond the 318.1 keV endpoint energy, illustrated in Fig. 9.14 as region 2, is attributed to Compton scattering of the 1173 and 1332 keV γ lines, which follow the ^{60}Co decay (Wauters et al., 2009).

The direct measurement of the energies of α -particles by the PIN PD can yield highly resolved energy lines, as the PIN PD absorbs directly the α -particle energy instead of measuring the photons of visible light from a crystal scintillator. Martín-Martín et al. (2006) devised a method of measuring ^{222}Rn in air with an 18×18 mm PIN PD. Air was passed at a given flow rate through a light-tight chamber containing the PIN PD; and the daughter nuclides of the ^{222}Rn were collected electrostatically on the surface of the PD. The close proximity of the daughter nuclides on the PD surface permitted their energy dissipation directly into the PIN PD. The highly resolved α spectra of the daughter nuclides ^{218}Po and ^{214}Po are illustrated in Fig. 9.15. Barlas et al. (2013) devised a hemispherical collection chamber to force the electrostatic collection of alpha particles to the surface of a windowless PIN PD resulting in highly resolved alpha spectra of the ^{218}Po and ^{214}Po radon progeny.

Although certain applications may call for the measurement of nuclear radiation directly with the PIN PD, most applications employ the efficient conversion of the radiation energy into photons of visible light by crystal scintillators, which are subsequently measured with the PIN

FIGURE 9.15 Pulse height spectra of alpha particles from radon daughter products with an inverse bias voltage of -9V applied to the PIN photodiode. From Martín-Martín et al. (2006); reprinted with permission from Elsevier © 2006.

PD coupled to the scintillator. When a PIN diode is coupled to a scintillation detector they are more often referred to as PIN PDs rather than PIN diode detectors. The photodiodes (PDs) are exposed directly to photons of visible light emitted by the crystal scintillation detector. The e-h pairs produced in the depletion layer are collected to provide what is referred to as a photocurrent signal. The principle of the PD is described by Lorenz (1983). In brief, the PDs, made of high-resistivity silicon ($>1\text{ k}\Omega\text{ cm}$), have a very thin p-type diffusion front layer and an n-type diffusion layer on the back of the wafer. A reverse bias voltage of a few tens of volts generates a depletion layer over nearly the entire depth of a $200\text{-}\mu\text{m}$ -thick diode.

A common PD similar to that used by Lorenz is the Hamamatsu p-i-n-PD or PIN PD. Electron-hole pairs are produced in these diodes when photons are absorbed by the diodes as illustrated in Fig. 9.16. The electron-hole pairs

FIGURE 9.16 Cross-section of a p-i-n semiconductor photodiode illustrating photon interactions with different components of the diode including the migration of electron-hole pairs formed in the depletion layer of the diode. From Lorenz (1983).

formed in the depletion layer are separated by the electric field; and a photocurrent is generated when the electrons and holes migrate to the n- and p-regions, respectively. The e-h pairs formed in the p and n regions recombine and produce no charge effects (see Fig. 9.16). Surface reflection of photons, illustrated in Fig. 9.16, accounts for a reduced QE. Silicon PDs, at optimum photon wavelengths, exhibit QEs in the range of 70%–80% (Renker, 2004). In Si, 3.62 eV of energy on the average must be deposited in the PD to create an e-h pair. This would translate into $\sim 2.76 \times 10^5$ e-h pairs (i.e., 10^6 eV/3.62 eV/e-h pair) produced for each MeV of energy deposited in the Si PD (Yang et al., 2011). Thus, a 59 keV γ photon from ^{241}Am , fully absorbed in the depletion layer of a Si PIN PD, would produce $\sim 16.3 \times 10^3$ e-h pairs (Otte et al., 2006). The pulse height is dependent on the number of electron-hole pairs produced and, in turn, dependent on the intensity of photons emitted from the solid scintillation detector. See Chapter 4, Volume 1 of this book for additional reading on the mechanisms of interaction of radiation with semiconductor materials.

Meisner et al. (1995) report the application of two side-mounted PIN PDs as photomultipliers for a cylindrical (15×61 mm) CsI(Tl) scintillation detector. The detector was used successfully in a soil probe as a rugged and magnetic field-insensitive means of identifying gamma ray-emitting ^{137}Cs and ^{60}Co contaminants at soil depths of 20 m. Schotanus (1995) of SCIONIX Holland BV demonstrated the energy resolutions achieved with the coupling of a small 1-cm³ CsI(Tl) crystal to a 10×10 mm² silicon PIN PD. The resolutions reported were 8.7% and 4.7% FWHM for 511- and 1275-keV photopeaks of ^{22}Na , respectively. For 662- and 1332-keV photopeaks of ^{137}Cs and ^{60}Co sources, energy resolutions obtained from the coupled miniature crystal and PD were 7.4% (662 keV) and 4.4% (1332 keV). Typical pulse height spectra obtained from a CsI(Tl) activated crystal with an entrance area of 25×25 mm² and 10.0 mm thickness coupled to a Si-PIN PD 300 μm thick and active area of 18×18 mm² is illustrated in Fig. 9.17. Energy resolutions of $\sim 3.6\%$ for ~ 5 MeV α particles and $\sim 7.8\%$ for 1.33 MeV γ rays are reported (Gupta et al., 2011). Comparable resolutions for γ -ray energy lines were measured by Kim et al. (2009, 2010b) with a CsI(Tl) scintillator and PIN PD. An energy resolution of 2.7% was obtained for the 662 keV γ ray from a ^{137}Cs source coupled to a LaBr₃ crystal scintillator Moszyński et al. (2009).

PMTs are sensitive to weak magnetic fields and can be shielded to only a few hundred gauss, whereas PDs are considered insensitive to magnetic fields. The insensitivity to magnetic fields has been placed at a theoretical limit of 15 T (Renker, 2004). PMTs also occupy much more space than PDs, and applications employing many crystal detectors and their individual PMTs are bulky and awkward,

FIGURE 9.17 Pulse height spectra for α particles from ^{241}Am – ^{239}Pu and γ rays from ^{60}Co obtained with a CsI(Tl) crystal scintillator detector coupled to a Si-PIN PD. The broad peak below 1.17 MeV is due to Compton scattering of γ rays of 1.17 and 1.33 MeV. From Gupta et al. (2011); reprinted with permission from Elsevier © 2011.

particularly when shielding is also required. PD wafers are small and can be placed in direct intimate contact with the crystal detector.

Silicon PDs can display high electronic noise due to capacitance and dark leakage current. As explained by Holl et al. (1995), the PD noise can be reduced by introducing long filter time constants unfit for high-count-rate applications. In addition, the PDs are highly sensitive to charged particles that may pass the depletion layer and produce false signals of magnitude similar to that of expected signals from the incident photon radiation. With a PIN PD readout coupled to a CsI(Tl) scintillator, Mikhailov and Panteleev (2001) observed a long-lasting “light noise” originating from the crystal similar to a crystal afterglow. This noise together with PD leakage current are contributing factors that define the energy resolution of the CsI(Tl)-PD gamma detector. Reduced temperature can improve energy resolution. They report a resolution of $<5.5\%$ FWHM for the 1275 keV γ line of ^{22}Na at 5°C.

An efficient handheld portable neutron detector consisting of a $^6\text{LiI}(\text{Eu})$ crystal scintillator enriched to 96% ^6Li coupled with a light guide to two silicon PD detectors sandwiched on both sides of the crystal scintillator is described by Yang et al. (2011). Such an arrangement enabled a coincident double PD readout to permit the discrimination of gamma-ray background from neutron-capture events in the detector. It is very compact, as the scintillator is only 3 mm thick and 1 in. (2.54 cm) diag.; and the PDs measured 10×10 mm in active area with a 0.3 mm depletion layer thickness. The high enrichment of ^6Li makes the crystal essentially opaque to thermal neutrons with an intrinsic thermal neutron detection efficiency of 99.3%. The small thickness of the scintillator minimizes γ -energy dissipation while maximizing thermal neutron stopping power. The $^6\text{Li}(n,\alpha)^3\text{H}$ reaction has a high Q -value of

4783 keV (QCalc, 2018), which attributes the light yield of a neutron capture signal equivalent to a 3–4 MeV gamma photon making discrimination against gamma necessary (Yang et al., 2011). Pulse-shape n/γ discrimination is possible; but this would require more cumbersome electronics for a handheld portable device. In lieu of pulse-shape discrimination, gamma-ray interference was reduced to natural background by employing a coincidence output from the two Si PD detectors coupled to both sides of the scintillator. The schematics of the coincidence electronics is illustrated in Fig. 9.67 much further on in this chapter. Neutron capture events produce significant coincidence signals in both PDs; whereas, with a ^{137}Cs gamma source, it was demonstrated by Yang et al. (2011) that the probability of an interfering γ -ray interaction producing a detectable pulse in both PDs was very low ($1.69 \times 10^{-6}\%$).

Another novel design of a sandwiched scintillator crystal between two Si PIN PDs was devised by Kah et al. (2011). A CsI(Tl) crystal was sandwiched between two silicon photostrip sensors whereby the p+ strip arrays of each sensor were oriented orthogonally to each other. Such a configuration provided the two-dimensional position information and depth of interaction of the radiation particle in the crystal scintillator by measuring signal ratios between the two photostrip sensors.

Lioliou and Barnett (2016) used GaAs p-i-n PDs to measure directly ^{55}Fe X-ray and ^{63}Ni beta spectra with p-i-n PDs. Highly resolved K_α and K_β X-ray spectra are reported by Singh et al. (2017) with a Si p-i-n diode detector. The X-rays were produced by bombardment of 25 keV electrons on Ti and Cu targets. A resolution of 165 eV at 5.9 keV is reported.

Pixelated Si PIN PDs coupled to inorganic crystal scintillators can provide gamma-camera imaging in nuclear medicine applications (Kang and Choi, 2016; Schaart et al., 2016; Huh et al., 2015; Michail et al., 2010, 2011; Park et al., 2009; Safavi-Naeini et al., 2008; Kim et al., 2006). The pixelated Si PIN PDs coupled to scintillator crystal segments provide imaging information due to the different origins of nuclear events from the emitted γ -ray photons within a patient administered an appropriate radiopharmaceutical or imaging provided by the varying intensities of X-ray photons traversing the patient.

b. Avalanche photodiodes

Advances continue to be made in the development of avalanche photodiodes (APDs) for scintillator readout capable of accepting high-count-rate applications for large multichannel systems used in PET, studies of HEP physics, and general radiation detection and measurement. Multi-dynode PMTs are the classical readouts and are commonly used for scintillation detectors in many fields; however, many advances have made the APD photomultiplier a preferred substitute to the PMT in many applications.

FIGURE 9.18 (A) Schematic cross-section of a Large Area Avalanche Photodiode (LAAPD) up to 16 mm diameter, and (B) electric field profile according to Advanced Photonics, Inc. From Moszyński et al. (2003); reprinted with permission from Elsevier © 2003.

As described by Holl et al. (1995) and Moszyński et al. (2002a), light photons produce electron-hole pairs as they penetrate the silicon of the APD, illustrated in Fig. 9.18. The depth of photon penetration is dependent on the wavelength and governed by their attenuation coefficients. The e–h pairs combine instantaneously in the very thin p+ front layer, while electrons in the depleted volume drift toward the n+ layer under the applied electric field potential. When the electrons enter the high-field region of the pn transition, impact ionization occurs. Impact ionization refers to collisions of electrons with other electrons, whereby more e–h pairs are produced and an avalanche multiplication of e–h pairs occurs. Only electrons are able to produce the e–h pairs at a certain field strength. Therefore, the initial e–h pairs produced by the incident photon, which penetrates only a shallow depth, result in an avalanche of electrons (pulse amplification). A relatively wide depletion layer extends into the n-type region resulting in a low dark current. The broad gain region of the electric field profile (Fig. 9.18) permits operation at high gain with low excess noise.

The advantages of the APD over the conventional PD described in the previous section are much lower noise for fast readout and lower interference (by a factor of 10–100) from charged particles that traverse the APD. Moszyński et al. (2002a) outline the advantages and limitations of the APD compared to the conventional dynode PMT. Among

FIGURE 9.19 Pulse height spectrum of ^{137}Cs measured with $\text{LaCl}_3(\text{Ce}^{3+})$ ($\varnothing 8 \times 5$ mm) coupled to an APD no. 70-73-510 from Advanced Photonix, Inc. The energy resolution (FWHM) at 662 keV is $3.65 \pm 0.05\%$. From Allier et al. (2002), reprinted with permission from Elsevier ©2002.

the advantages are high QE, good spatial uniformity, insensitivity to magnetic fields, compactness, low power consumption, rugged, and flexible geometrical configuration. Some limitations to performance are lower gain, higher noise contribution, and susceptibility to radiation damage.

For the measurement of gamma radiation, the APD is used in conjunction with a solid scintillator whereby the photons from the scintillator are detected by the APD. The APD coupled to an appropriate solid scintillator can yield energy resolutions for X- and γ -ray photons superior to those provided by the conventional PMT (Grodzicka-Kobylka et al., 2017; Silva et al., 2015; Sasano et al., 2013; Cooper et al., 2012; Sato et al., 2006; Yatsu et al., 2006; Kataoka et al., 2005; Ikagawa et al., 2003, 2005; Kaputsa et al., 2003; Moszyński et al., 2002a, 2003; Allier et al., 2002; Balcerzyk et al., 2002). An energy resolution of 3.65% FWHM for the 662 keV gamma ray from ^{137}Cs measured with a small ($\varnothing 8 \times 5$ mm) $\text{LaCl}_3(\text{Ce}^{3+})$ scintillator coupled to an APD serves as an example (Fig. 9.19) of the application of an APD in lieu of a PMT.

BGO scintillator has favorable properties for gamma-ray photon measurements, including high density and a high photon absorption coefficient at 0.511 MeV, which is the positron annihilation photon energy of interest in PET. Grodzicka-Kobylka et al. (2017) demonstrated the excellent gamma-ray spectra obtained with various scintillators, including BGO, LSO, and CsI(Tl) coupled to APD cells. Examples of gamma-ray photon spectra of gamma emissions from ^{157}Eu , ^{22}Na , and ^{137}Cs obtained with APDs coupled to a BGO scintillator crystal detector are illustrated in Fig. 9.20.

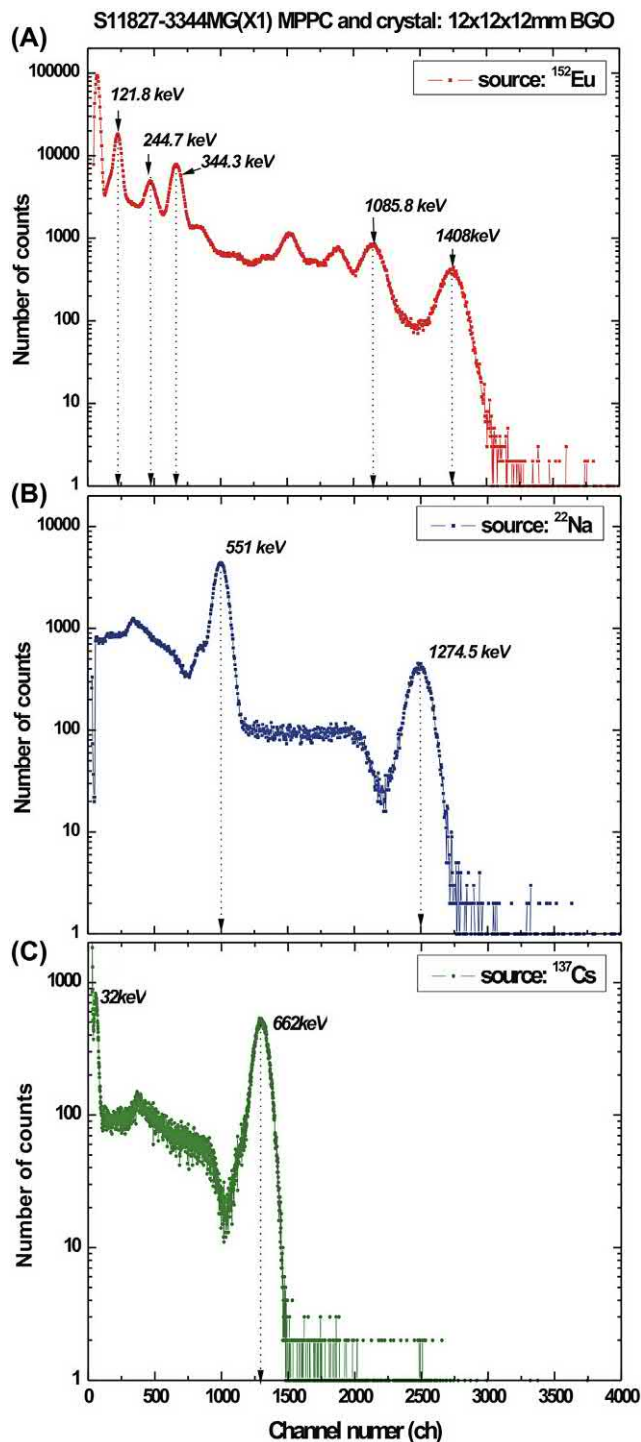

FIGURE 9.20 The energy spectra measured with a $12 \times 12 \times 12$ mm BGO crystal coupled to 4×4 inch Hamamatsu SiPM (silicon photo-multiplier) consisting of arrays of APDs. Radioactive sources: (A) ^{152}Eu , (B) ^{22}Na , (C), and ^{137}Cs . From Grodzicka-Kobylka et al. (2017); reprinted with permission from Elsevier © 2017.

The APD can be used directly as a radiation detector without the use of a scintillation detector such as in the measurement of β -emitting radionuclides (Kriss and Hamby, 2004) and spectra of low-energy X-rays (Yatsu et al., 2006; Kataoka et al., 2005; Fernandes et al., 2003; Ikagawa et al., 2003; Kaputsa et al., 2003; Moszyński et al., 2000a,b; 2002a). Typical X-ray photon and β -particle spectra obtained from direct measurement with an APD are illustrated in Fig. 9.21. The β -particle spectra of ^{14}C , ^{36}Cl , $^{90}\text{Sr}/^{90}\text{Y}$, and ^{99}Tc were measured with a 16-mm diameter LAAPD by Kriss and Hamby (2004). They observed that the active thickness of the LAAPD is only $\sim 15\ \mu\text{m}$; and thus, most of the β -particles of the higher-energy emitters (e.g., ^{36}Cl and $^{90}\text{Sr}/^{90}\text{Y}$) pass through the active thickness, depositing some energy behind. These nuclides exhibit the same endpoint on the MCA). However, they report that the lower-energy radionuclides ^{14}C and ^{99}Tc retained their characteristic spectral shapes. Thus, the LAAPD can function as a general β -particle counter; however, its usefulness as a spectroscopy tool would be limited to very low energy beta emitters (Kriss and Hamby, 2004). The X-ray spectrum of ^{55}Fe , illustrated in Fig. 9.21 was measured

by Kataoka et al. (2005) with a 3-mm diameter Hamamatsu APD at -20°C . The effect of temperature on resolution of the 5.8 keV X-ray line of ^{55}Fe at -20 , 0 and 20°C was studied by Yatsu et al. (2006). The resolution (% FWHM) was optimum at -20°C ; and the % FWHM increased by only $\sim 1\%$ at 0°C and by another $\sim 2\%$ increase at 20°C .

Due to the penetration power of higher-energy γ -rays, the use of the LAAPD for the measurement of most γ -emitting radionuclides is performed with the coupling of the APD and a scintillation crystal detector. For example, the experimental arrangements for measuring directly the soft 5.4 keV X-rays from ^{54}Mn with an LAAPD is illustrated in Fig. 9.22A; and the indirect measurement of the 835 keV γ -rays from ^{54}Mn by measurement of the visible-light photons from an inorganic crystal scintillator by the LAAPD is illustrated in Fig. 9.22B. The LAAPD detects the crystal scintillator light output at $\sim 520\ \text{nm}$ produced by the γ -ray interactions (Fernandes et al., 2003); and the amplitude of the LAAPD output is proportional to the scintillation light intensity and the γ -ray photon energy absorbed by the crystal scintillator.

FIGURE 9.21 (Left) Energy spectrum of 5.9 keV X-rays at -20°C from an ^{55}Fe source measured directly with a 3-mm diameter “reach through” type APD. The energy threshold is $\sim 0.5\ \text{keV}$. The K-shell peaks of the Mn K_α and K_β (small peak at the right) are marginally resolved in the line profile. The resolution (FWHM) of the 5.9 keV peak was $\Delta E \sim 379\ \text{eV}$ or 6.4%; (Right) Beta-particle pulse height spectra of ^{14}C (stars) and ^{99}Tc (diamonds) measured directly with a 16-mm diameter LAAPD. FIGURE 9.22 Source/detector arrangements for LAAPD detection of (A) X-rays and (B) visible-light photons. From Fernandes et al. (2003); reprinted with permission from Elsevier © 2003.

FIGURE 9.23 Internal structures of three different types of APDs (i) beveled-edge, (ii) reach through, and (iii) reverse type (from left to right) The electric field profiles and gain profiles in each type of APD are shown in the middle and bottom rows. From Kataoka et al. (2005); reprinted with permission from Elsevier © 2005.

The spectrometric measurement and analysis of X-ray and α -emitting radionuclides by the APD measurement of the liquid scintillation photon spectral intensities from liquid Xe (Fernandes et al., 2003; Ni et al., 2005) and from liquid scintillation fluor cocktails (Reboli et al., 2005) is also possible. This is discussed in Chapter 6, Volume 1.

APDs are commercially available as three types, namely (i) “beveled edge”, (ii) “reach through”, and (iii) “reverse type”. These are illustrated in Fig. 9.23 and described by Kataoka et al. (2005) and Yatsu et al. (2006). The three types of APDs are the following:

i. The “beveled-edge” type This type of APD is a traditional p+n junction in which the n-type resistivity is selected to require a very high breakdown voltage, which is ~ 2 kV (Kataoka et al., 2005). The beveled-edge APDs have advantages of high gain and a low excess noise factor due to the broad multiplication region (Yatsu et al., 2006). Examples are described and tested by Moszyński et al. (2001, 2002c, 2003). An energy resolution of 4.9% for the 662 keV line from a ^{137}Cs source was observed with a CsI(Tl) crystal scintillator coupled to a beveled-edge LAAPD (Moszyński et al., 2001). Other examples reported by Moszyński et al. (2003) are 550 eV for the 5.9 keV X-ray energy line from an ^{55}Fe source is reported from the direct interaction of the X-rays with a beveled-edge LAAPD; and a 4.3% energy resolution for 662 keV gamma rays with the LAAPD coupled to a YAP:Ce crystal detector. The broad gain region enables the operation of this device at high gain with low excess noise and excellent gain uniformity (Moszyński et al., 2003).

ii. The “reach through” type The reach-through type of APD contains an avalanche region consisting of a p-type

and n-type semiconductor layers; the depletion layer consists of a relatively wide drift region of low field (~ 2 V/ μm) and a relatively narrow region (25–30 V/ μm) for impact ionization (Kataoka et al., 2005). The depletion region is separated into two regions: (i) a thick drift region, comprising $>90\%$ of the APD volume, where photons and charged-particles are absorbed, and (ii) a thin multiplying region where electrons are multiplied (Yatsu et al., 2006). The reach-through APD offers an advantage of direct X-ray detection (i.e., no scintillator required) due to the thick depletion layer (≥ 100 μm) in front of the amplification region; and this APD is sensitive to weak scintillation photons from γ -ray interactions with scintillators at a high QE of $\sim 80\%$ at ~ 500 nm of scintillation photon wavelength (Tanaka et al., 2007). Optimum energy resolutions (FWHM) at $+20^\circ\text{C}$ with the APD coupled to a $4 \times 4 \times 4$ mm³ CsI(Tl) scintillator reported by Tanaka et al. (2007) for 5.9 keV X-rays, 32 keV X-rays, and 662 keV γ -rays were 15%, 6.6%, and 7.6%, respectively; and X-ray and γ -ray signals can be discriminated using pulse shape discrimination (PSD) applied to the APD output. An X-ray and γ -ray imaging spectrometer over the energy range of 1 keV to 1 MeV with a 5×5 mm² reach-through APD coupled to a CsI(Tl) scintillator is reported by Nakamori et al. (2010).

The thin-surface dead layer (~ 340 Å) and a thick depletion layer (140 μm) of the reach-through APD permit the measurement of low-energy electrons from 3 keV up to 100 keV with good linearity and excellent energy resolution of 4 keV at 100 keV electrons (i.e., 4%); and measurements may be made over a wide range of temperatures (Ogasawara et al., 2008, 2009). The measurement of heavier ions is also possible. Ogasawara et al. (2010) demonstrate the pulse height distribution of the reach-

FIGURE 9.24 Schematic structure of a reach-through APD with an ion trajectory. Electrons of the e–h pairs drift in the direction of the avalanche layer due to the electric field in the depletion layer. Electron-hole (e–h) pairs are represented as dots and circles along the ion trajectory. From Ogasawara et al. (2010); reprinted with permission from Elsevier © 2010.

through APDs with active layers or depletion-layer thickness of $\sim 150\ \mu\text{m}$ show a significant peak for energies $>2.5\ \text{keV}$ for protons and $3.4\ \text{keV}$ for helium ions with a noise level of ~ 300 electrons. Energy resolutions are 15% for $58\ \text{keV}$ protons, 16% for $56\ \text{keV}$ helium ions, 43% for $55\ \text{keV}$ nitrogen ions, and 46% for $55\ \text{keV}$ argon ions. A schematic illustration of the reach-through APD and ion trajectory is illustrated in Fig. 9.24. The p+ or dead layer of the APD was measured by Ogasawara et al. (2010) to be $340\ \text{\AA}$ thin. The dead layer is followed by the depletion layer ($\sim 150\ \mu\text{m}$ thick), which provides an appreciable depth for absorption of high-energy particles. Electron-hole (e–h) pairs are formed throughout the particle or ion trajectory; and the electrons drift toward the avalanche layer where they undergo multiplication.

iii. The “reverse” type The reverse-type of APD is designed to be coupled to scintillators, as the multiplication region is very close to the detector surface ($\sim 5\ \mu\text{m}$) where absorption of photons of visible light from scintillators is effective. The peak emission wavelength of many inorganic crystal scintillators is at $\sim 550\ \text{nm}$ or less, and thus most photons of visible light are absorbed in the first $1\text{--}3\ \mu\text{m}$ of the depletion layer and electron generation undergoes full multiplication (Kataoka et al., 2005). The reverse-type of APD exhibits very low noise. This is due to the multiplication region being just behind the detector surface and the dark current undergoes only hole multiplication and not amplified (Kataoka et al., 2005; Yatsu et al., 2006). Advantages of the reverse-type APD, summarized by Yoshino et al. (2011), are the efficient detection of weak scintillation light signals due to the narrow high field amplification region close to the front end, a high QE of $\geq 80\%$ over the wavelength range of $500\text{--}830\ \text{nm}$, operation at a low bias voltage ($\sim 400\ \text{V}$ for an avalanche gain of 100), and excellent noise characteristics.

Reverse-type APDs, coupled to inorganic scintillators, have been developed for high-resolution X-ray and γ -ray spectrometers in satellite space research (Arimoto et al., 2018; Saito et al., 2013; Ikagawa et al., 2005; Kataoka et al., 2005, 2010a). A typical energy resolution for the $662\ \text{keV}$ ^{137}Cs γ -ray absorption peak with a $5 \times 5 \times 5\ \text{mm}^3$ BGO crystal scintillator is 8.3% (Sato et al., 2007). Pixelated reverse-type APDs are developed for high resolution X-ray imaging and PET (Kataoka et al., 2009, 2010b; Yoshino et al., 2011). Coupled to appropriate crystal scintillators they report energy resolutions of 7% FWHM for $662\ \text{keV}$ γ -rays and a coincidence timing resolution of 4 ns (FWHM) for $511\ \text{keV}$ annihilation photons, which is a vital measurement in PET. Because the APDs are not affected by high magnetic fields, these can be applied in detectors providing combined PET and MRI imaging.

c. Geiger-mode avalanche photodiode (GM-APD) — silicon photomultiplier (SiPM)

An APD is operated in the Geiger-mode when the applied bias voltage is raised above the avalanche breakdown point — the threshold voltage for Geiger discharge; and the avalanche process is stopped by momentarily reducing the electric field in the amplification region by means of an active circuit or a quench resistor (Korpar, 2011). This process introduces dead time when the PD recovers to its operating voltage. The Geiger-mode avalanche photodiode (GM-APD) was devised to obtain single-photon sensitivity; however, dark counts, dead time, and recovery time following a breakdown permitted PD areas of only $\sim 100\ \mu\text{m}$ (Renker, 2009). Such a device is very small; and PDs of larger area of this type are subdivided into many PD cells connected in parallel via an individual limiting resistor (Renker, 2009). Simultaneous signals from the numerous subdivided PD cells add up to a multiple of a single cell resulting in a gain of up to 10^7 . These devices are reviewed by Huh et al. (2015), Pellion et al. (2015), Berra et al. (2013), Barbarino et al. (2012), Korpar (2011) and Renker (2009). An array of small GM-APDs, which operate in parallel, is illustrated in Fig. 9.25; and because such an array serves as a photomultiplier, the device is very often referred to as a SiPM, which is currently the name most commonly applied to this device. Other names, that have been applied to this photomultiplier are the multi-pixel photon counter or MPPC (Huh et al., 2015; Kato et al., 2011), the micropixel avalanche PD or MAPD (Sadygov et al., 2006, 2009a,b), the solid-state photomultiplier or SSPM (Chen et al., 2010), and the avalanche microchannel PD or AMPD (Britvitch et al., 2007).

The operation of the SiPM is described by Korpar (2011), which is basically as follows: A single incoming photon, such as that arising from an inorganic crystal

FIGURE 9.25 Silicon photomultiplier (SiPM) consisting of an array of Geiger-mode avalanche photodiode (GM-APD) cells with a magnified or close-up image of one of the GM-APD cells. From [Korpar \(2011\)](#); reprinted with permission from Elsevier © 2011.

scintillator or a photon of Cherenkov light, produces an electron-hole pair in one of the GM-APD microcells. This initiates the avalanche process; and the microcell discharges to the breakdown voltage, which stops the avalanche. The microcell then recharges to the bias potential. A signal is produced by this discharge/recharge process; and as all quenching resistors are connected to a common terminal, simultaneous signals from various microcells of the array add up to an integer multiple of the single cell signal.

The summing of signals from the various APDs of the SiPM array produces a final signal proportional to the photon intensity. The amount of X-ray or γ -ray energy deposited in an inorganic crystal scintillator will govern the photon intensity emitted by the scintillator and, in turn, govern the signal output from the SiPM. The process of this solid-state scintillation measurement of nuclear radiation is depicted in [Fig. 9.26](#). The figure illustrates a low-energy (i.e., longer wavelength) γ -ray interacting with a crystal scintillator; and, on the right, a γ -ray of higher energy (i.e., shorter wavelength) depositing energy in another

scintillator. The visible light emitted from the scintillator on the left is of lower intensity than that produced on the right. Both scintillators are coupled with a SiPM array depicted just below each scintillator. The scintillator emitting the brighter or more intense light emission on the right triggers a larger number of GM-APD cells of the SiPM array; and the corresponding amplitude of the pulse event registered by the SiPM array on the right is larger than that on the left.

The field of application, which is currently the most demanding of the SiPM, is nuclear medicine. Research is intensely focused on the production of the next generation of nuclear medicine X-ray and γ -ray imaging detectors, which utilize the SiPM in lieu of the classical dynode photomultiplier tube, i.e., PMT ([Legou et al., 2019](#); [Samson et al., 2018](#); [Herzog and Lerche, 2016](#); [Kang and Choi, 2016](#); [Schaart et al., 2016](#); [Huh et al., 2015](#); [Silva et al., 2015](#); [Rato Mendes et al., 2013](#); [Shimazoe et al., 2013](#); [Hu et al., 2012](#); [Schneider et al., 2012](#); [Beltrame et al., 2011a,b](#); [Kato et al., 2011](#); [Lee et al., 2011](#); [Powolny et al., 2011](#); [Roncali and Cherry, 2011](#); [Verheyden et al., 2011](#); [Zorzi et al., 2011](#); [Bolle et al., 2010](#); [Efthimiou et al., 2010](#);

FIGURE 9.26 Concept of the solid-state scintillation detection with a silicon photomultiplier (SiPM). The crystal scintillator converts an X-ray, γ -ray, or neutron event into an optical pulse (i.e., photon emission of given intensity). The optical pulse is detected by the SiPM array of GM-APDs; and the number of GM-APDs that are triggered by the optical pulse is proportional to the amplitude of the optical pulse (i.e., proportional to the photon intensity emitted by the scintillator). CMOS is an acronym for Complementary Metal-Oxide-Semiconductor, which is a technology for constructing integrated circuits used in microprocessors. Pestotnik et al., 2010; Persson et al., 2009). Imaging techniques in which the SiPM may be utilized are X-ray CT, SPECT, and PET. The SiPM offers numerous advantages including high gain, low noise, low voltage, excellent energy resolution and timing properties, and insensitivity to magnetic fields. Excellent energy resolution for the 511 keV annihilation γ -ray detected in PET with the SiPM coupled to an appropriate crystal scintillator is reported by Legou et al. (2019), Huh et al. (2015), Silva et al. (2015), and Efthimiou et al. (2010), among others. The insensitivity of the SiPM to magnetic fields offers the added advantage of the development of the emerging hybrid PET/MRI imaging systems (Mannheim et al., 2018; Ferda, 2017; Herzog and Lerche, 2016; Rato Mendes et al., 2013; Roncali and Cherry, 2011; Efthimiou et al., 2010).

There is a temperature dependence when making energy calibrations of crystal scintillators with gamma emitters. A temperature-dependent light yield of the crystal scintillator results in a gain shift of the detector system. Fig. 9.27 illustrates the temperature dependence with a CsI(Tl)

FIGURE 9.27 Upper frame: Energy spectra of ^{22}Na measured at different temperatures using as detector a CsI(Tl) crystal coupled to a PMT sensor. The spectra are not calibrated to illustrate the temperature gain dependence. Lower frame: Energy spectra measured at different temperatures using as detector a CsI(Tl) crystal coupled to an APD sensor. Shifts in the 0.511 MeV positron annihilation gamma peak and the 1.275 MeV gamma emission of ^{22}Na are clearly observed. From Silva et al. (2015); reprinted with permission from Elsevier © 2015.

scintillator coupled to either a PMT or APD as photosensor readouts for the crystal scintillator. Silva et al. (2015) utilized pulse shape analysis to classify the pulse shape with respect to the internal temperature of the crystal detector to compensate for the resultant gain shift; and they report that gain shifts due to temperature variations can be corrected to a precision of better than 1% with either a PMT or APD as photosensor. Compensation for temperature dependence is particularly relevant when making coincident detection of the 0.511 MeV gamma photons emitted in opposite directions required in PET in nuclear imaging for medical diagnosis and treatment monitoring. Huh et al. (2015) developed a compensation method for the stabilization of the temperature-dependent performance of Geiger-mode APD sensor arrays coupled to scintillator crystals in PET. Fig. 9.28 illustrates the PET detector arrangement with associated electronics for temperature compensation. The positron annihilation gamma emissions are detected by two arrays of 4×4 channels of LYSO scintillator crystal detectors facing each other and a positron emitter. An array of Geiger-mode APDs are coupled to the crystal scintillator as MPPCs. The bias voltage of each APD is controlled by the DC power supply; and preamplifier gains are controlled by a digital potentiometer with microprocessor (MICOM). Huh et al. (2015) demonstrated that the photopeak variation can be stabilized by adjusting the preamplifier gain within a specified bias voltage range for the development of PET systems with Geiger-mode APD arrays.

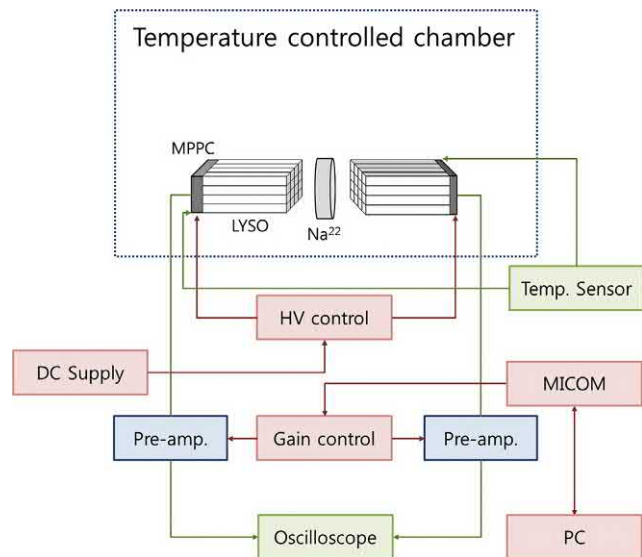

FIGURE 9.28 Experimental setup for the measurement of temperature-dependent performance of PET detectors using Geiger-mode avalanche photodiodes (APDs) as photosensors as multi-pixel photon counters (MPPCs) coupled to the LYSO crystal scintillator arrays facing the ^{22}Na positron emitting source in opposite directions for the detection of 0.511 MeV positron annihilation gamma-rays. The SiPM offers promise as a photodetector when coupled to appropriate crystal scintillators in radionuclide and radiation metrology. Research in the development of inorganic crystal scintillator detectors coupled to the SiPM are under development (Czyz et al., 2018; Morishita et al., 2018; Park et al., 2017; Ginzburg et al., 2015, 2011; Bellini et al., 2010; McClish et al., 2007).

In the field of astroparticle physics, energetic phenomena, and rare events are measured with detectors of very large volume, which may involve the measurement of scintillation or Cherenkov photons. Currently very large dynode PMTs are used for this purpose, as described in Chapter 6, Volume 1 and Chapter 6, Volume 2. The vacuum silicon photomultiplier tube (VSiPMT) shows promise as a potential substitute for the classical PMT, for a photodetector that can view and detect large volumes with high gain and single-photon counting capability (Barbarino et al., 2009, 2018, 2013a,b; Barbato et al., 2017; Berneking et al., 2018; Suda, 2014; Ko et al., 2013; Sanfilippo et al., 2013; Russo et al., 2010, 2009). The VSiPMT is a large hemispherical vacuum tube capable of viewing large active areas with a photocathode face. The photoelectrons emitted from the photocathode are then accelerated toward an SiPM (see Fig. 9.9 illustrated earlier in this chapter). The SiPM offers several advantages such as small size, low cost, high gain, absence of external voltage divider, and no passive power consumption (Russo et al., 2010).

The SiPM is capable of measuring the low-intensity levels of Cherenkov photons; and the employment of the SiPM in RICH detectors has been demonstrated (Balossino et al., 2017; Barnyakov et al., 2016; Contalbrigo et al., 2014; Tahirović et al., 2015; Gamal et al., 2011; Korpar et al., 2010, 2009). The insensitivity of the SiPM to magnetic fields is a key advantage, as subatomic particles identified by RICH detectors often utilize magnetic fields to determine particle momentum, as described in the chapter on Cherenkov Counting (Chapter 6, Volume 2).

C. Pulse height discriminators

Subsequent to amplification and pulse shaping, pulse height discriminators come into play. A pulse height discriminator is an electronic gate that permits pulses of a certain magnitude to continue on in the circuit to be registered and counted. In general, there are two discriminators, which are used to identify the pulses, which may continue on to be registered. These are the lower level (LL) and the upper level (UL) discriminators. The LL discriminator can be used to eliminate electronic noise from the photomultiplier. The settings of both the LL and UL discriminators can be used to define a counting region or counting window. The heights of the LL and UL discriminators may be input manually when setting up a computer-controlled counting protocol. According to the settings of the LL and UL

discriminators, the instrument circuitry will allow only pulses of magnitude (volts) higher than the LL discriminator and lower than the UL discriminator to continue on to be registered or counted by the scalar. Although the amplifier output pulse heights are measured in volts, the LL and UL discriminator settings may be calibrated in other units, such as, kiloelectron volts (keV), which allows correlation between amplifier output pulse heights from the crystal scintillator detector and the actual gamma-ray energies absorbed by the detector.

D. Single-channel analyzer

The correlation between the gamma-ray energy dissipation within the crystal scintillation detector and pulse height amplitude output from the PMT or PD, preamplifier, and linear amplifier are used to measure the gamma-ray energies emitted by a given radionuclide or mixture of radionuclides in a sample. For this purpose a single-channel analyzer (SCA) may be employed.

An SCA contains two electronic pulse height discriminators described in the previous section of this chapter, namely the LL and UL discriminators. The output pulses from the amplifier, that have heights or amplitudes below the LL discriminator setting or above the UL discriminator setting, are rejected. Only pulses that have magnitudes higher than the LL discriminator setting and lower than the UL discriminator setting, referred to as the discriminator window, pass the discriminator circuit and go on to be registered by a scalar circuit. If we expose a solid scintillation detector to a sample containing gamma ray-emitting radionuclides, we may use the LL and UL discriminators to analyze the pulse heights produced and consequently the energies of the gamma ray photons emitted by the sample. For example, if we begin by arbitrarily setting the LL discriminator at its lowest possible pulse height, namely 0.0 keV, and the UL discriminator at 1.0 keV, the discriminator circuit will allow only pulses of magnitude between 0.0 and 1.0 keV equivalents to go on to be registered and counted by a scalar circuit. A time interval may be selected to give the instrument a specific time to register pulses passing the discriminator circuit between 0.0 and 1.0 keV. The pulses collected by the scalar circuit in the allotted time interval are summed. The total counts collected in the 0.0–1.0 keV counting region (window) are registered; these counts may also be reported as a count rate (e.g., counts per minute, CPM), if the total counts collected are divided by the time interval. The procedure as described will produce one data value, the total number of counts or count rate in the one counting region (channel) defined by the discriminator settings of 0.0–1.0. We may repeat this counting procedure after changing the LL and UL discriminator settings to 1.0 and 2.0 keV, respectively. This will provide a second value of counts or count rate

FIGURE 9.29 Gamma-ray spectra of ^{137}Cs and ^{65}Zn as separate radiation sources and as a mixture measured with a NaI(Tl) detector. The lines A and B represent LL and UL discriminator settings for a counting region which receives all the pulses arising from the photopeak of 0.662-MeV gamma rays from the ^{137}Cs sample in secular equilibrium with its daughter radionuclide $^{137\text{m}}\text{Ba}$. The lines A' and B' represent LL and UL discriminator settings for another counting region, which receives pulses from the photopeak of the 1.08-MeV gamma rays of ^{65}Zn . From L'Annunziata, M. F. (1965), unpublished work of the writer.

collected of pulses in the energy range 1.0–2.0 keV. The procedure may be continued as described by collecting counts in the regions 2.0–3.0, 3.0–4.0, 4.0–5.0, and so on up to a maximum, for example, 1999–2000 keV. The counts or count rate collected in each channel selected are then plotted against the window height or channel height, which is the LL discriminator setting in keV of each selected channel. This plot will produce a spectrum of gamma-ray photon energies absorbed by the scintillation crystal detector and consequently a spectrum of the gamma-ray energies emitted by a given sample. Fig. 9.29 provides an example of gamma-ray spectra plotted using an SCA according to the procedure described. The use of two discriminators in this fashion is referred to as single-channel gamma-ray analysis. The difference between LL and UL in keV is referred to as the window width or channel width, and the LL discriminator setting for a given channel setting is referred to as the window height or channel height. Manual variation of the channel height while maintaining the channel width constant permits scanning of the entire spectrum of pulse heights produced by a given gamma radiation source. The procedure is simple but tedious and time consuming for the measurement of γ -ray spectra. On the other hand, the SCA is a simple, relatively inexpensive, and a popular component used to analyze radionuclide activities by counting the scintillation pulse events within a given energy region defined by the LL and UL discriminator settings (Zhao et al., 2013; Zafrir et al., 2011; Kumara et al., 2010; Toyohara et al., 2006; Vrinda Devi et al., 2010; Cendre et al., 2005; Kraus et al., 2005; Dupasquier et al., 2004). For example, the SCA may be used to conveniently count all pulse events arising from the photopeak of a ^{137}Cs source in the counting window defined by LL and UL discriminator settings A and B (i.e., 550–800 keV) of Fig. 9.29 for the particular scintillation analyzer used in this

example. A wide counting window defined by LL and UL discriminator settings between zero and 800 keV would encompass all events arising from β -particle, X-ray, and γ -ray interactions in the scintillator crystal from $^{137}\text{Cs}/^{137\text{m}}\text{Ba}$ decay. The LL discriminator is generally set somewhere above zero to discriminate against background noise. In such a case, the precise setting of the LL discriminator above zero, would be determined according to the background count rate. Background count rates due to photomultiplier noise occur at the lower end of the pulse height spectrum.

Scintillation analyzers may also be equipped with an MCA, which provides automatically the gamma-ray spectrum of a sample. The MCA is described subsequently.

E. Multichannel analyzer

With the SCA previously discussed, one can count at one time only the pulses received by a given channel (counting window or region) after selection of the channel position (window height) and channel width. Numerous channel positions corresponding to definite pulse height ranges must be tediously chosen in order to construct energy spectra similar to those illustrated in Fig. 9.29. For example, approximately 40 channel heights of 80 keV width were manually selected to produce the gamma-ray spectrum of $^{137}\text{Cs}/^{137\text{m}}\text{Ba}$ in Fig. 9.29. At each of these channel positions the count rate was determined for a 1-minute time interval. A minimum of 40 minutes was thus necessary to scan the ^{137}Cs gamma-ray spectrum, exclusive of the time involved in changing the channel heights. If a narrower channel width is selected (e.g., 20 keV rather than 80 keV), as many as 160 count rate determinations in the same number of counting channels would be required.

On the other hand, the MCA permits the simultaneous accumulation of pulses in as many as several thousands of energy levels (channels) in a semiconductor core memory. The stored spectra of pulses in the core memory may be viewed simultaneously in real time on the computer monitor of a solid scintillation analyzer and saved on disk or printed whenever desired.

The following is a description of the basic principle of operation of a MCA. Gamma rays from a sample dissipate energy in the crystal scintillator, e.g., NaI(Tl), CsI(Tl), or other scintillator detector. A wide spectrum of photon intensities will be emitted by the scintillator according to the amount of energy dissipated in the crystal by each γ -ray interaction in the crystal according to photoelectric and Compton scattering interactions among other mechanisms of gamma-ray energy dissipation. The PMT or PD will then convert the photon intensities to voltage pulses of various magnitudes as a function of the various photon intensities emitted by the scintillator. As previously described in this chapter, pulses of different magnitude arise from different energy quanta absorbed by the solid scintillation crystal detector. The pulse events of various magnitudes produced by the photomultiplier undergo amplification and pulse shaping before processing by the MCA, as depicted in the pulse amplification and detection circuit illustrated in Fig. 9.30. Multichannel analysis involves processing the pulses onto an analog-to-digital converter (ADC), where each pulse amplitude in volts is converted into an equivalent time interval by the production of an equivalent number of pulses from a periodic oscillator. An address register then counts the number of pulses produced by the periodic oscillator, which gives a quantified measure of the amplitude of each input signal. This quantification identifies the channel among many thousands within which the pulse is to be stored in the core memory. In most MCAs, counts in excess of 10^9 can be stored in each channel. The contents of the core memory are viewed on the computer monitor as a spectrum of pulse heights while the sample is being counted, as illustrated in Fig. 9.30; and, if desired, the spectrum is saved on disk or printed.

MCAs are available commercially with thousands of channels. Scintillation analyzers are equipped with a computer-controlled MCA, which can provide automated sample processing and spectral analysis over the gamma-ray energy range (e.g., 0–2000 keV). An example of gamma spectra produced by an automatic modern solid scintillation analyzer is illustrated in Fig. 9.31. The simultaneous accumulation and readout of pulses in many thousands of channels corresponding to pulses of defined amplitudes are very timesaving, and the hands-off construction of the gamma spectra is effortless (Neal et al., 2011; Quarati et al., 2011; Bourret-Courchesne et al., 2009, 2010; Limkitjaroenporn et al., 2010).

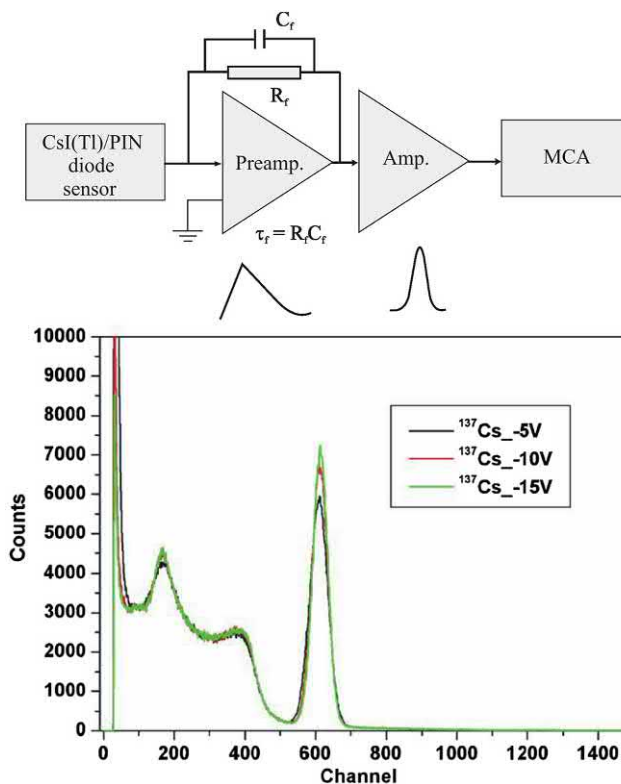

FIGURE 9.30 (Top) Pulse amplification and detection circuit for the multichannel analysis of pulse events produced by a CsI(Tl) scintillator coupled to a Si-PIN photodiode photomultiplier. Preamp and AMP are the preamplifier and shaping amplifier; and C_f and R_f are the feedback capacitor and resistor, respectively. (Bottom) Typical gamma spectra provided by the multichannel analyzer (MCA) at three bias voltages to the Si-PIN photodiode. From Kim et al. (2009); reprinted with permission from Elsevier © 2009.

Research is underway in the development of digital multichannel analyzers (DMCAs) based on a field programmable gate array (FPGA), as described by Garcia-Duran et al. (2019), Becker and Farsoni (2014), and Zeng (2012). As described by Zeng (2012), the signals from the scintillation detector and photo detector (PMT or APD) are processed by the FPGA, which utilizes the signals acquired by the analog-to-digital converter to perform the calculus, identify spectral peaks, determine the threshold, and plot the energy spectrum utilizing a personal computer for energy spectrum processing. As underscored by Garcia-Duran et al. (2019), the MCA embedded into an FPGA is a virtual instrument for the handling and visualization of the pulse height spectrum. An example of the output of the multichannel analysis obtained with a commercial ORTEC MCA and that from the MCA embedded into an FPGA is illustrated in Fig. 9.32. The two pulse height spectra illustrated in Fig. 9.32 are similar in terms of resolution of the 0.662 MeV photopeak and the appearance of the Compton shoulder; however, as underscored by Garcia-Duran, the embedded MCA offers the advantage of

FIGURE 9.31 Multichannel gamma spectra of ^{125}I over the energy range 15–100 keV as seen on the computer monitor of a solid scintillation gamma analyzer. A gamma spectrum of a given sample is determined by MCA and plotted and analyzed in real time. © 1998 PerkinElmer, Inc. Printed with permission.

FIGURE 9.32 Upper panel: The pulse height spectrum of ^{137}Cs from a NaI(Tl) scintillator obtained with an MCA from ORTEC. Lower panel: The pulse height spectrum of ^{137}Cs obtained with the embedded MCA. The differences in channel numbers of the two spectra are due to the embedded MCA scaling; and the differences in counts of the two spectra are due to counting time. From Garcia-Duran et al. (2019); reprinted with permission from Elsevier © 2019.

optimization of hardware use related to the programmable logic device, that is, only 9% of the hardware available in the FPGA is used. This provides the possibility to add other components to improve the MCA or develop a network involving several detectors. With this objective in mind,

Becker and Farsoni (2014) developed an FPGA-based miniature gamma-ray spectrometer, which may be accessed wirelessly by mobile phone providing a device with applications in emergency response, Battlefield assessment and personal dosimetry. They report excellent

resolution of 5.9% FWHM for the 662 keV photopeak of ^{137}Cs gamma spectrum and 54.3% FWHM for the 32 keV X-ray peak from the Ba K X-rays of the ^{137}Cs daughter nuclide utilizing CsI(Tl) scintillator coupled to a SiPM photodiode.

F. Other components

The previous paragraphs in this section have provided details of the physical crystal scintillator detector, the scintillation process, the photodetector, and the electronic components needed to convert X- or γ -ray photon emissions into voltage pulses that may be analyzed in terms of number (counts) and magnitude (pulse height or keV energy) and the data converted into count rate (CPM) or gamma spectra. There are other components of the modern solid scintillation analyzer that are vital to the automatic processing and analysis of samples. These components include (1) computer system control for the hands-off analysis of samples and processing of data; (2) a sample changer for the automatic unattended analysis of up to 1000 samples tubes; (3) automatic and adjustable counting regions for single-, dual-, and multiple-radionuclide measurements; (4) many (up to 60) different analysis protocols that can be set by users for the automatic analysis of samples; (5) automatic protocol-adjustable sample positions in detectors for optimum sample counting geometry (for through-hole detectors); (6) live real-time spectral display with an MCA; (7) computer, hard disk, and printer for the processing, storage, and recording of data; (8) computer-controlled automatic IPA, detector normalization, decay corrections, background reductions, spillover calculations, and radionuclide activity (DPM) calculations; and (9) computer-controlled special application programs for instrumental analysis of samples, such as single- and multiple-site receptor binding assays, radioactive waste tracking, radioimmunoassay data processing, chromium release assays, hepatitis screening, and traditional and radioallergosorbent test (RAST) allergy screening, among other assays. These components, among others, that are characteristic of automatic gamma analyzer systems are discussed in Section V of this chapter.

IV. Concepts and principles of solid scintillation analysis

A. Gamma-ray spectra

The spectrum of pulse heights, being directly proportional to the gamma-ray energies dissipated in the crystal detector, provides a measure of the gamma-ray energy spectrum of the radiation source. Such energy spectra are illustrated in Figs. 9.3, 9.17, 9.19, 9.20, 9.27 and 9.29–9.32 in previous parts of this chapter. The gamma-ray spectrum is simply a

plot of the relative abundances of the pulses versus the pulse heights calibrated in gamma ray energies in units of keV or MeV. Two spectral peaks of Fig. 9.29 are enclosed within the A and B and A' and B' discriminators, which represent the LL and UL discriminator settings of two counting regions. These two peaks are referred to as photopeaks because they are the result of the interaction of 0.662 MeV gamma rays from $^{137}\text{Cs}/^{137\text{m}}\text{Ba}$ or 1.08 MeV gamma rays from ^{65}Zn with the crystal detector via the photoelectric effect or a combination of Compton effects resulting in the total dissipation of the gamma-ray energy in the crystal.

Gamma-ray spectra are very useful for the identification of radionuclides. For example, the photopeak is usually the highest energy peak. An exception is the “doubles peak,” which can occur at a higher energy, as it is due to the coincidence detection of two gamma-ray photons (see Section IV.C of this chapter). The photopeak gives a measure of the gamma-ray energy, which is a characteristic of each radionuclide, and may be used to identify unknown radionuclides.

Gamma-ray spectra may also be characterized by several other peaks such as those illustrated in Fig. 9.33. These are often not well defined because of the Compton

FIGURE 9.33 Segmentation of a spectral curve showing the case of a typical spectrum for gamma rays of about 2 MeV. From Tominaga (1983); reprinted with permission from Elsevier © 1983.

smear or background produced by a wide spectrum of Compton electron energies. The Compton edge and backscatter peaks are characteristic of most gamma-ray spectra. Compton electrons of maximum energy produce the Compton edge. A portion of the radiation, which may pass through the detector without interaction, may be scattered at 180 degrees by the detector shielding back into the detector. Absorption of the backscattered radiation by the crystal detector produces the backscatter peak.

Three other peaks illustrated in Fig. 9.33 may also be observed in gamma spectra. These are the annihilation peak, double-escape peak, and single-escape peak. These peaks are the result of pair production in the crystal detector and cannot be observed in the spectra of gamma rays of energy below the theoretical threshold of 1.02 MeV. In practice, significant numbers of pair production events are confined to high-energy (>1.5 MeV) gamma ray—photon interactions. The annihilation peak is located at an energy value of 0.51 MeV; and it is the result of the absorption of one of the two 0.51-MeV gamma-ray photons following positron annihilation accompanying pair production. When one of the two annihilation gamma rays escapes from the detector without interaction, the single-escape peak is produced at an energy level of $E_\gamma - 0.51$ MeV, where E_γ is the gamma-ray energy characterized by the photopeak. Both of the annihilation gamma rays may escape the detector without interaction and produce the double escape peak at the energy level of $E_\gamma - 1.02$ MeV.

Gamma-ray spectrometry may also be applied to the assay of more than one gamma ray—emitting nuclide in a mixture. If these nuclides emit gamma rays of characteristic energies where photopeaks of the gamma spectra are well separated, they may be assayed separately by setting the counting regions or windows directly over the photopeak of each nuclide. For example, Fig. 9.29 illustrates the combined spectrum of a mixture of ^{137}Cs and ^{65}Zn and discriminator settings that encompass the photopeak of each nuclide. The ^{65}Zn activity can be determined with LL and UL discriminator settings A' and B' providing a 0.950–1.25 MeV counting window; whereas the 0.550–0.800 MeV counting window defined by LL and UL discriminator settings A and B provides pulse contributions from both nuclides. The contribution due to ^{65}Zn in this window, which may be determined with a pure ^{65}Zn standard of known activity, must be subtracted from the total number of counts in this counting region to provide the net counts due to the nuclide ^{137}Cs . The determination of the gamma spectrum of a sample and the analysis of the gamma-emitting nuclides in a given sample are most effectively carried out with a MCA. The use and mode of operation of a MCA are discussed in Section III.E of this chapter.

B. Counting and detector efficiencies

Solid scintillation gamma counting fortunately does not have the disadvantages of quenching normally associated with the liquid scintillation counting technique. The sample is physically separate from the crystal scintillator, which prevents any possible physical or chemical interference with the gamma energy transfer and scintillation processes. Nevertheless, the sample composition and the counting geometry, namely the sample's shape, density, and volume as well as its distance from the scintillation detector, can have a marked effect on the count rate or the counting efficiency of a particular sample. Also, in the literature it is possible to encounter several terms related to counting and detection efficiency, which can be confusing. These terms and the factors that affect counting and detection efficiency will be discussed in more detail in this section.

1. Counting efficiency

The counting efficiency is defined as the ratio of the number of counts collected in a given period of time (count rate) to the disintegration rate or activity of the source. This is the detection efficiency that is used generally for routine measurements of radionuclide activities, such as in applications involving radionuclide tracers. It is calculated as

$$E = \text{cpm}_{\text{std}} / \text{dpm}_{\text{std}} \quad (9.11)$$

where cpm_{std} is the count rate in counts per minute of a standard source measured by the analyzer and dpm_{std} is the disintegration rate in disintegrations per minute or activity of the radiation standard source. The value of the counting efficiency, also expressed as a percentage, is a characteristic of a particular detector, the counting region selected as defined by the LL and UL discriminator settings, the radionuclide, and the counting geometry. The counting geometry will include the sample, its composition (e.g., density governing self-absorption), geometry (e.g., point source, shape, or volume and distance from the detector), and the combined geometry of the sample, sample tube or container, and detector.

The counting efficiency of a single-nuclide sample is easily determined from the count rate of an internal radionuclide standard of known disintegration rate. By internal radionuclide standard it is meant a radionuclide of known activity that is added to the sample. The internal standard is counted with counting conditions and geometry similar to those of the sample when it is counted alone without the internal standard. The procedure involves first counting the sample without the standard. This is followed by adding the internal standard to the sample and counting a second

time. The counting efficiency of the sample can be calculated as follows:

$$E = \frac{\text{cpm}_{s+i} - \text{cpm}_s}{\text{dpm}_i} \quad (9.12)$$

where cpm_s is the count rate of the sample, cpm_{s+i} is the count rate of the sample after the addition of the internal standard, and dpm_i is the disintegration rate or activity of the internal standard. This method of determining counting efficiencies is valid when the following conditions are met: (1) The volume and composition of the internal standard have no effect on the counting geometry and counting efficiency of the sample; (2) The internal standard is counted with the same instrumental parameters (e.g., LL and UL discriminator settings) as the sample; and (3) The standard used is the same nuclide as that of the sample of unknown activity.

Once known, the counting efficiency for a particular sample can be used to convert the count rate of the sample to disintegration rate (activity) according to the equation

$$\text{dpm}_s = \text{cpm}_s / E \quad (9.13)$$

For certain radionuclides the disintegration rates of unknown sample activities can be determined directly by the “doubles-peak” method, which does not require any measure of counting efficiency. This method is described in [Section IV.C](#) of this chapter.

2. Detector efficiency

Detector efficiencies are often used to compare and evaluate different types of solid scintillator crystals and counting geometries. Detector efficiency may be referred to as the full-energy peak efficiency, photopeak efficiency, or photoelectric efficiency. These terms are used to define detector efficiency, and these will be discussed subsequently.

a. Full-energy peak efficiency

The full-energy peak efficiency or photopeak efficiency is defined as the ratio of the number of gamma-ray photons detected in the photopeak to the number of gamma rays of the photopeak energy emitted by the source ([Scafè et al., 2011](#); [Anil Kumar et al., 2009a,b](#); [Abbas, 2007](#)), which may be written as described by [Anil Kumar et al. \(2009b\)](#) as

$$\varepsilon = \frac{\text{no. gammas detected under the photopeak}}{\text{no. of gammas emitted by the source}} \quad (9.14)$$

The full-energy peak efficiency can be measured according to the equation

$$\varepsilon = \frac{N}{AP_\gamma} \quad (9.15)$$

where N is the gamma count rate in the full energy peak, A is the activity of the source during the measurement time in Bq, and P_γ is the gamma emission probability ([Abbas, 2001a, 2007](#)). The same equation can be expressed in terms of the total number or counts of the gamma-rays detected in the photopeak rather than count rate as follows

$$\varepsilon = \frac{N_{\text{peak}}}{AtP_\gamma} C_i \quad (9.16)$$

where N_{peak} is the number of net counts in the photopeak, A is the radionuclide activity, t is the time or duration of the measurement, P_γ is the emission probability, and C_i is the correction factor due to dead time ([Anil Kumar et al., 2009a,b](#); [Hurtado et al., 2004](#)).

The value of the full-energy peak efficiency of a given source is a function of the distance from the radiation source to the scintillator detector, the path length that the photon traverses within the active volume of the gamma detector, and the solid angle subtended by the front surface of the crystal detector ([Abbas and Noureddeen, 2011](#); [Abbas, 2006](#); [Moss et al., 1984](#)). It can be used to evaluate the properties of the solid crystal detector to fully stop or absorb impinging gamma radiation by the photoelectric effect or a series of Compton interactions resulting in complete absorption of the gamma-ray energy. [Evans \(1980\)](#) compared the full-energy peak efficiencies of BGO and NaI(Tl) detectors of the same dimensions with radionuclides that span a wide range of gamma energies. The full energy peak efficiency is inversely proportional to the gamma-ray energy ([Evans, 1980](#); [El-Khatib et al., 2017](#)). The work of [Evans \(1980\)](#) indicated that the photopeak resolution of BGO was only about half as good as that obtained with equivalent NaI(Tl) detectors; however, the higher photopeak efficiency of BGO and the near absence of Compton continua (Compton smear) make BGO the detector of choice when a high-resolution detector is not needed. Both density (g/cm^3) of the scintillator and effective atomic number (Z_{eff}) are important properties that can govern the gamma radiation stopping power and photopeak efficiency. For a given optimized detection geometry and given γ -energy, the photopeak efficiency will be a function of the density and effective atomic number of the scintillator, as the probability of the photoelectron effect rises with Z ([Valentini and Vianden, 2010](#)). For example, the photopeak or full-energy peak efficiency of BGO ($\rho = 7.1 \text{ g/cm}^3$, $Z_{\text{eff}} = 75$) is greater than that of NaI(Tl) scintillator ($\rho = 3.7 \text{ g/cm}^3$, $Z_{\text{eff}} = 51$) for a given γ -energy and detector size and geometry ([Evans, 1980](#)). Also, [Valentini and Vianden \(2010\)](#) demonstrated a considerably higher photopeak efficiency of LSO scintillator ($\rho = 7.4 \text{ g/cm}^3$, $Z_{\text{eff}} = 65.8$) over that of BaF_2 ($\rho = 4.89 \text{ g/cm}^3$, $Z_{\text{eff}} = 52.2$).

b. Total or absolute efficiency

The total or absolute efficiency, which should not be confused with the counting efficiency previously discussed (Eq. 9.11), is defined as the probability that the incident gamma rays will interact with the crystal detector via at least one of the predominate mechanisms of gamma-ray energy absorption, namely the photoelectric effect, Compton effect, or pair production. It is defined as the ratio of the number of gamma-ray photons detected by the scintillator to the number of gamma rays emitted by the source (in all directions). This detector efficiency may be written, as described by Anil Kumar et al. (2009b), according to the expression

$$\varepsilon_{\text{abs}} = \frac{\text{total no. of gammas detected}}{\text{no. of gammas emitted by source}} \quad (9.17)$$

The total efficiency is different from the counting efficiency defined earlier in the chapter by Eq. (9.11) because the counting efficiency calculated according to Eq. (9.11) is calculated on the basis of (i) the possible detection of other particles from the source and (ii) the disintegration rate (dpm) of a source; whereas the absolute efficiency is calculated on the basis of the number of gamma rays emitted per radionuclide disintegration. Because gamma emission is often characteristic of the daughter nuclide in various decay processes, gamma emission may occur via

several energy states and may not occur with each disintegration of a given radionuclide, as described in Chapter 1, Volume 1. According to the radionuclide, the gamma rays emitted per disintegration may vary in number as well as probability of emission.

The relationship between photopeak efficiency and total efficiency can be expressed by peak-to-total ratio (photo-fraction) and expressed as

$$P/T = \frac{\varepsilon_P}{\varepsilon_T} \quad (9.18)$$

where P/T is the peak-to-total ratio, and ε_P and ε_T are photopeak or full-energy peak efficiency and the total efficiency, respectively (Abbas, 2001b).

The magnitudes of the photoelectric efficiency (or photopeak efficiency) and total detector efficiency diminish as the photon energy increases. The relationship between photon energy and detector efficiency for a detector of given geometry is nearly linear when plotted on a logarithmic scale (Sudarshan et al., 1992; Suzuki, 1982; Brinkman and Veenboer, 1979). As illustrated in Fig. 9.34, the photoelectric and total detection efficiencies decrease as the photon energy increases. Thus, nuclides that emit high-energy gamma radiation (e.g., ^{24}Na , 1.38 and 2.76 MeV) are detected with lower efficiencies than nuclides that emit lower energy gamma radiation (e.g., ^{54}Mn , 0.83 MeV). The inverse relation between gamma energy and detector

FIGURE 9.34 Photoelectric, e , and total efficiency, t , curves for samples placed on the bottom of the well of a 60×60 mm NaI(Tl) crystal. Diameter of well is 17 mm, depth of well is 38 mm. From Brinkman and Veenboer (1979); reprinted with permission from Elsevier © 1979.

efficiency can be extrapolated to counting efficiency. Such comparisons can be made, of course, when there is negligible self-absorption among the nuclide samples. The relationship between counting efficiency and photon energy is explained by the fact that most of the photons of low energy (<0.100 MeV) hitting the detector are absorbed due to high absorption coefficients (Sudarshan et al., 1992; Holmberg et al., 1972). As the photon energy increases, the absorption coefficients decrease or, in other words, the stopping power of the detector crystal decreases.

For a given radionuclide source, the total or absolute detection efficiency is dependent on the source and detector counting geometry (Abbas and Noureddeen, 2011; Enqvist et al., 2010; Yalcin et al., 2007); and it can be a measure for evaluating and comparing various scintillator materials (Ayas-Maierhafer and DeVol, 2007).

C. Sum-peak activity determinations

The activity or disintegration rate of some radionuclides may be determined directly from the X- or gamma-ray spectra, without the use of standards, if they decay by the emission of two photons in coincidence (i.e., X- or gamma-ray photons). The technique, known as the sum-peak or doubles-peak method, was developed following the pioneering work of Brinkman and Alten (1963, 1965), Brinkman et al. (1963a,b, 1965), and Eldridge and Crowther (1964). The method has been applied often to the activity analysis of ^{60}Co and ^{125}I (Marsoem et al., 2014; Sahagia et al., 2008; Capogni et al., 2006; da Silva et al., 2006; Kim et al., 2003; Miyahara et al., 2000; Pommé et al., 2005; Yuan and Hwang, 2000; Kawano and Ebihara, 1990, 1991, 1992). In the case of ^{60}Co , the nuclide decays by β emission with the concomitant emission of two gamma rays from the daughter nuclide ^{60}Ni in coincidence, namely, 1.17 and 1.33 MeV gamma rays of equal intensity. The radionuclide ^{125}I decays exclusively by EC followed by a 35 keV gamma-ray emission of the daughter nuclide ^{125}Te . Following EC the K X-rays of 27.4 and 31 keV are emitted in coincidence with the 35 keV gamma-ray photons of the ^{125}Te daughter.

Based on the pioneering work of Brinkman et al. (1963a,b), the disintegration rate of a nuclide source emitting two gamma rays in coincidence or an X-ray and gamma ray in coincidence, such as the cases for ^{60}Co or ^{125}I , can be determined by the sum-peak equation

$$N_0 = T + \frac{A_1 A_2}{A_{12}} \quad (9.19)$$

where T is the total count rate of the entire spectrum extrapolated to zero energy (or the area under the total spectrum), A_1 , A_2 , and A_{12} are the count rates of the photopeaks (or areas under these peaks) of γ_1 , γ_2 , and the sum-peak, respectively. The photopeaks of γ_1 and γ_2 are also referred

to as the singles peaks, and these may consist of two separate photopeaks of two gamma rays of different energy as for the case of ^{60}Co or, they may consist of a gamma-ray and X-ray peak or two X-ray peaks as in the case of ^{125}I . The sum-peak is also called the doubles-peak, as it is the result of coincidence summing of two photons. High-purity germanium (HPGe) semiconductor detectors yielding well-resolved singles and doubles peaks have been applied to the sum-peak method of activity analysis of the following radionuclides: ^{22}Na (Ogata et al., 2016, 2015; de Oliveira et al., 2012), ^{57}Co (Novković et al., 2012; Iwahara et al., 2009), ^{60}Co (Ogata et al., 2016, 2015; Marsoem et al., 2014; Bikit et al., 2009a; Vidmar et al., 2009; Kim et al., 2003; Miyahara et al., 2000), ^{65}Zn (Oliveira et al., 2012), ^{125}I (Marsoem et al., 2014), ^{133}Ba (Nadder et al., 2013; Bikit et al., 2009a,b; Novković et al., 2009), ^{134}Cs (Ogata et al., 2018a; b, 2016), ^{139}Ce (Korun and Martinčič, 1993), and ^{152}Eu (Ferreira Filho et al., 2018; Nemes et al., 2011). The classic NaI(Tl) crystal scintillation detector can be used to measure the activities of ^{60}Co and ^{125}I by photon energy spectral lines with poorer resolution than that provided by semiconductor detectors; and Eq. (9.19) serves as the basis for working equations used in these experimental activity determinations, subsequently described.

An example of a typical gamma spectrum of ^{60}Co measured with a NaI(Tl) detector is illustrated in Fig. 9.35. Kawano and Ebihara (1990, 1991, 1992) measured the activity N_0 of ^{60}Co according to Eq. (9.19) and the measured gamma spectrum according to the following calculated spectral areas:

$$T = I_T - B_T \quad (9.20)$$

$$A_1 = A_2 = \frac{(I_{1+2} + B_s)}{(2 + \alpha)} \quad (9.21)$$

$$A_{12} = I_{12} - \frac{1}{2}(\text{Ch}_5 - \text{Ch}_4 + 1)(C_5 + C_4) \quad (9.22)$$

where I_T and B_T are the area and background, respectively, under the entire spectrum; I_{1+2} is the total area between channel 1 (Ch1) and channel 2 (Ch2) of the spectrum illustrated in Fig. 9.35, and B_s is the background for the same area; α is the ratio of the area of the Compton scattering of γ_2 under the photopeak of γ_1 to A_2 ; I_{12} is the total area between channel 4 (Ch4) and channel 5 (Ch5), and C_4 and C_5 are the counts in channels Ch4 and Ch5, respectively.

The sum-peak method for the activity analysis of ^{125}I has been used by several researchers (Marsoem et al., 2014; Sahagia et al., 2008; Capogni et al., 2006; da Silva et al., 2006; Pommé et al., 2005; Wang et al., 2001; Yuan and Hwang, 2000; De Felice and Myteberi, 1995; Dias and Koskinas, 1995; Martin and Taylor, 1992). The case of ^{125}I

FIGURE 9.35 Typical gamma spectrum of ^{60}Co as measured with a NaI(Tl) crystal. The photopeaks are identified as follows: A_1 , photopeak of γ_1 (G1); A_2 , photopeak of γ_2 (G2); A_{12} , sum peak. From Kawano and Ebihara (1990, 1992); reprinted with permission from Elsevier © 1990.

is treated differently than the previous example, as it decays by EC into the 35.5 keV excited state of ^{125}Te with the emission of a 27.4- and 31-keV X-rays in coincidence with the 35-keV gamma-ray photon emitted by the excited state of the ^{125}Te daughter (6.67%) or by emission of conversion electrons (CEs) (93.33%), as illustrated in Fig. 9.36. The photopeak at the lower end of the spectrum occurring at ~ 28.5 keV is due to the unresolved single-photon detection of the X-rays and the 35-keV gamma rays, while the coincidence photopeak (sum peak) occurring at ~ 56.8 keV is the result of coincident summing of two X-rays or an X-ray and a 35-keV gamma ray. The singles peaks for the two X-rays and the one gamma ray remain unresolved under one peak at ~ 28.5 keV. Only with the use of a high-resolution semiconductor detector can the singles peaks for each of the photon emissions be observed (Wang et al., 2001).

FIGURE 9.36 Typical ^{125}I spectrum taken from a NaI(Tl) well-type detector. From Capogni et al. (2006); reprinted with permission from Elsevier © 2006.

For the case of the unresolved singles peaks of ^{125}I , as illustrated in Fig. 9.36, Capogni et al. (2006) define the count rates under the two photopeaks of Fig. 9.36 as

$$A_1 = \varepsilon N_0 P_1 (1 - \varepsilon P_2) + \varepsilon N_0 P_2 (1 - \varepsilon P_1) \quad (9.23)$$

$$A_{11} = \varepsilon^2 P_1 P_2 N_0 \quad (9.24)$$

where A_1 is the count rate under peak 1 (the more intense peak at the lower end of the spectrum (see Fig. 9.36) corresponding to the count rate of the unresolved K X- and gamma-ray singles peak area, A_{11} is the count rate under the coincident event peak (the lesser intense peak at the higher-energy end of the spectrum (see Fig. 9.36), ε is the detection efficiency for 30 keV photons, as it is assumed that the detection efficiency would be constant for all photons between 27.2 and 35.5 keV, N_0 is the decay rate or activity of the ^{125}I , P_1 is the K X-ray emission probability per EC decay, i.e., $P_1 = P_K \omega_K = 0.6990 \pm 0.0056$ where P_K is the K shell EC probability and ω_K is the fluorescence yield of K X-ray, and P_2 is the sum of the K X-ray emission probability for internal conversion events plus the 35 keV gamma-ray emission probability; i.e., $P_2 = (1 + \alpha_K \omega_K) / (1 + \alpha) = 0.7624 \pm 0.0075$ where α and α_K are total and K shell conversion coefficients (Capogni et al., 2006; Wang et al., 2001; Yuan and Hwang, 2000; Dias and Koskinas, 1995; Martin and Taylor, 1992).

From Eqs. (9.23) and (9.24) Capogni et al. (2006) derive the following equation of Eldridge and Crowther (1964) as

$$N_0 = \frac{P_1 P_2}{(P_1 + P_2)^2} \frac{(A_1 + 2A_{11})^2}{A_{11}} \quad (9.25)$$

De Felice and Myteberi (1995) demonstrated the application of the sum-peak method to the absolute activity

measurement of ^{125}I with an overall uncertainty of 0.3% (1σ). Capogni et al. (2006) report an experimental standard uncertainty of 0.14% for various instrumental setups used with two NaI(Tl) crystal detectors of different volumes. Marsoem et al. (2014) report total relative standard uncertainties of 0.39% and 0.36% for the standardization of ^{125}I and ^{60}Co by the sum-peak method. Also, Dias and Koskinas (1995) and Yuan and Hwang (2000) found excellent agreement between the sum-peak method and other methods of radionuclide standardization of ^{125}I .

In the case of ^{22}Na sum peak activity measurements with a NaI(Tl) detector, de Oliveira et al. (2012) reported combined uncertainties in the analysis to be only 0.15% and 0.11% depending on the detector geometry of $< 4\pi$ or 4π , respectively. A counting geometry of $< 4\pi$ is that of a single well-type NaI(Tl) detector; and the 4π detector geometry was achieved by placing a planar NaI(Tl) detector directly over the well-type NaI(Tl) detector thereby completely surrounding the sample with detector. A typical gamma-ray spectrum of the ^{22}Na with the NaI(Tl) detector in the 4π geometry is illustrated in Fig. 9.37. Sodium-22 decays principally by positron emission with 90% intensity and EC with 10% intensity followed by gamma-photon emission at 1274 keV with 100% intensity. The various peaks in the gamma spectrum of ^{22}Na are identified by in Fig. 9.37 as the annihilation photopeak at 511 keV, the coincident detection of two annihilation photons at 1022 keV, the gamma photopeak at 1274 keV, the coincident detection of the 1274 keV gamma-photon and annihilation photon at 1785 keV and the coincident detection of two annihilation photons and a 1274 keV gamma photon producing a peak at 2296 keV. The basic equations used for the sum-peak activity measurement of ^{22}Na are described by de Oliveira et al. (2012), namely,

$$N_0 = N_T + \frac{A_1 A_2}{A_{12}} \quad (9.26)$$

where $N_T = T$ of Eq. (9.19) described previously and N_T is the number of rate interactions under the total spectrum, A_1 and A_2 are the count rates of two photopeaks, and A_{12} is the sum-peak count rate resulting from the coincident interactions of the two radiation photons represented by peaks

A_1 and A_2 . Eq. (9.26) is expressed by de Oliveira et al. (2012) as

$$N_0 = N_T + R \quad (9.27)$$

where, namely,

$$R = \frac{A_{1274} A_{1022}}{A_{2296}} = \frac{A_{1274} A_{511}}{A_{1785}} \quad (9.28)$$

where A_{511} = the count rate under the 511 keV annihilation photopeak, A_{1022} = the count rate under the 511 + 511 keV sum peak, A_{1274} = count rate under the 1274 gamma emission photopeak, A_{1785} = the count rate under the 511 + 1274 keV sum peak, and A_{2296} = count rate under the 511 + 511 + 1274 keV sum peak. A third ratio of count rates under the singles and sum peaks may be used for the ratio R , which is the following:

$$R = \frac{A_{511}^2}{A_{1022}} \quad (9.29)$$

where A_{511}^2 = the square of the count rate under the 511 keV annihilation photon peak, and A_{1022} = the count rate under the 511 + 511 keV sum peak. de Oliveira et al. (2012) note that the R value defined by Eq. (9.29) can be used in the above Eq. (9.27) only in the case of 4π counting geometry where the detector completely surrounds the sample. This is clear in light of the positron annihilation phenomenon which results in the emission of two 511 keV gamma photons in opposite (180 degrees) direction. When using a well counter, which is $< 4\pi$ counting geometry, a coincidence factor W must be included in Eq. (9.27) or

$$N_0 = W \left(N_T + \frac{A_{511} A_{511}}{A_{1022}} \right) \quad (9.30)$$

where $W = 1$ in 4π counting geometry. The reader may refer to de Oliveira et al. (2012) for the working equation in the calculation of W when the detector provides $< 4\pi$ counting geometry.

Taking advantage of the high resolution and efficiency for X-rays and low-energy gamma rays provided by a well-type HPGe semiconductor detector, Wang et al. (2001) was

FIGURE 9.37 Gamma spectrum of ^{22}Na obtained by a well-type NaI(Tl) detector covered by another NaI(Tl) detector in 4π counting geometry. From de Oliveira et al. (2012); reprinted with permission from Elsevier © 2012.

FIGURE 9.38 Spectrum of ^{125}I obtained with a well-type HPGe semiconductor detector. The singles peaks are identified as $K_{\alpha}\text{X}$, $K_{\beta}\text{X}$, and γ , while the doubles or sum peaks are denoted as $N_{\alpha\alpha}$, $N_{\alpha\beta}$, $N_{\beta\beta}$, $N_{\alpha\gamma}$, and $N_{\beta\gamma}$. From Wang et al. (2001), reprinted with permission from Elsevier © 2001.

able to define the count rates of the individual resolved single peaks for two K X-rays and the gamma ray as well as the sum peaks for the ^{125}I spectrum illustrated in Fig. 9.38. The spectrum illustrates the three singles peaks for the two K X-ray emissions ($K_{\alpha}\text{X}$ and $K_{\beta}\text{X}$) from the EC decay of ^{125}I as well as the 35-keV gamma emission line. The five sum peaks for all probabilities of coincidence summing between the two K X-rays and the one gamma ray are also discernible. From the peak areas and the following equation derived by Wang et al. (2001), the ^{125}I activity was calculated:

$$N_0 = T + \frac{N_{\gamma}N_{\alpha\beta}}{N_{\beta\gamma}(2N_{\alpha\alpha} + N_{\alpha\beta})} \left[N_{\alpha} + N_{\beta} - N_{\gamma} \left(\frac{N_{\alpha\beta}}{2N_{\beta\gamma}} + \frac{N_6}{N_{\beta\gamma}} - \frac{N_{\alpha\alpha}}{N_{\alpha\beta}} \right) \right] \quad (9.31)$$

where N_{α} , N_{β} , and N_{γ} are the singles peaks for the 27.3 keV K_{α} X-ray, 31.0 keV K_{β} X-ray, and 35.49 keV γ -ray, respectively, $N_{\alpha\alpha}$, $N_{\alpha\beta}$, $N_{\beta\beta}$, $N_{\alpha\gamma}$, and $N_{\beta\gamma}$ are sum peaks for all possible combinations of coincidence detection of the two X-ray emissions or one of the X-ray emissions with the gamma ray, and N_6 represents the unresolved sum peak of K_{β} X-rays ($E_{\beta\beta} = 62.0$ keV) and sum peak of K_{α} X-rays and γ -rays ($E_{\alpha\gamma} = 62.8$ keV), which could not be separated and therefore treated as one peak, $N_6 = N_{\beta\beta} + N_{\alpha\gamma}$. With this method, Wang et al. (2001) determined the ^{125}I activity with 0.6% uncertainty.

Nemes et al. (2016) demonstrate the use of pileup peaks for corrections of accidental coincidences and Monte Carlo techniques for angular correlation, and lower-level discriminator corrections, the source activity can be measured by the sum-peak method with an accuracy and reproducibility below 1%. Further studies by Nemes et al.

(2018) show, that at high count rates, random coincidence corrections must be considered and provide an equation for the sum-peak activity calculations that include these corrections.

In Chapter 1, Volume 1, examples were provided of radionuclides that exhibited different electron-capture decay rates as a function of the chemical environment of the radionuclide. Because EC involves extranuclear atomic electrons, which can be affected by chemical environments, the decay rates of EC radionuclides can be affected. Singh et al. (2001) utilized this phenomenon and the sum-peak method (gamma-gamma summing) to correlate variations in nuclear precession frequencies with electric field gradient components in different chemical environments. They measured the variations in the ^{75}Se sum-peak intensity at the 400 keV line due to the simultaneous detection of the 121 + 279 keV gamma rays relative to the singles peak intensities at 121 and 279 keV.

D. Modified sum-peak activity determinations

Ogata et al. (2015, 2016) developed a modified sum-peak method, which simplifies activity determinations requiring only the singles peak and sum-peak count rates and permitting the activity determinations of a radionuclide within a mixture of radionuclides. Ogata et al. (2016) confirmed the technique with known activities of ^{60}Co , ^{22}Na , and ^{134}Cs . They used HPGe detectors for gamma-ray spectrometry; however, a solid scintillation spectrometer could be used if the singles and sum peaks can be accurately defined and measured. As noted by Ogata et al. (2016), the conventional sum-peak method requires the total count rate (See N_T of Eqs. (9.26) and (9.27) described previously); and when the sample contains radionuclides other than that of interest, the total activity of the radionuclide of interest cannot be easily determined. In contrast to this, the modified sum-peak method requires only the count rates of the singles peak(s) and that of the sum peak.

Ogata et al. (2016) break down the basic equation that defines the sum-peak method as follows:

$$N_0 = R + T = \left[\frac{N_1 N_2}{N_{12}} + N_t \right] \overline{W}(0) = \frac{N_1 N_2}{N_{12}} \overline{W}(0) + N_t \overline{W}(0) \quad (9.32)$$

where N_0 is the sample activity, as described previously, R is the ratio of count rates in the singles and sum peaks, T is the total count rate under the entire spectrum, N_1 and N_2 are the count rates of the photopeaks for the single gamma-ray photons, N_{12} is the sum-peak count rate, N_t is the total count rate under the spectrum, and $\overline{W}(0)$ is the angular correlation of successive gamma-ray emissions (Evans, 1955; Frauenfelder and Steffen, 1965; Visinelli, 2014). The angular correlation of 1.111 was used by Ogata et al.

FIGURE 9.39 Semitheoretical plots estimated by the typical efficiencies for HPGe detector of 40% relative efficiency (RE), where (A) represents the partition of the activity R , T , and $(R + T)$ as a function of S–D distance, and (B) represents the dependences of N_0 and N'_0 on N_1 , where A_0 is assumed to be 10 kBq of ^{60}Co . From Ogata et al. (2016); reprinted with permission from Elsevier © 2016.

(2016). As noted by Agata et al. (2016), the value of T in Eq. (9.32) decreases almost proportionally to the total efficiency, which is inversely proportional to the square of the source-to-detector (S–D) distance; however, the value of R is not proportional to the efficiency because the efficiency cancels in the ratio term $N_1 N_2 / N_{12}$. The activity N_0 is a constant value if there is negligible decay during the assay; and thus, R becomes a dominant variable with increasing source-to-detector distance, as illustrated in Fig. 9.39A, in light of the fact that R/N_0 becomes dominant with increasing distance from the source, Ogata et al. (2016) modified Eq. (9.32) by removing N_t , to provide the following solution to the sample activity:

$$N'_0 = \frac{N_1 N_2}{N_{12}} \overline{W}(0) = R \quad (9.33)$$

As depicted in Fig. 9.39A, N'_0 approaches N_0 with increasing sample-to-detector distance where the curve R/N_0 approaches 1.0 at infinite distance. Thus, by taking several measurements at various source-to-detector distances, the value of N_0 is obtained at the extrapolated value of N'_0 at infinite distance. Ogata et al. (2016), simplified the method yet further, by plotting N'_0 as a function of one of the singles peak count rates, N_1 , as a function of sample-to-detector (S–D) distance to yield the following relation:

$$N_0 = N'_0(N_1), N_1 \rightarrow 0 \quad (9.34)$$

In the case of ^{60}Co taken as an example, the source activity A_0 is 10 kBq determined by the conventional sum-peak method as N_0 , Ogata et al. (2016) illustrate the dependence of N_0 and N'_0 on N_1 as plotted in Fig. 9.39B where N'_0 can be extrapolated to A_0 with decreasing count rate of N_1 . An added advantage of this method is that the removal of N_t from the equation of the sum-peak method permits the activity measurements of a radionuclide containing other radionuclides in the sample. This modified sum-peak method was verified with activity determination of ^{60}Co , ^{22}Na , and ^{134}Cs .

E. Self-absorption

The counting efficiencies of samples can be affected significantly by self-absorption, particularly when the radionuclide emits low-energy X- or gamma radiation. Self-absorption may be defined as the attenuation of radiation by the sample emitting the radiation. This absorbed radiation does not reach the detector and, if appreciable, counting efficiencies can be markedly reduced. Self-absorption is a function of the sample composition and geometry, namely its effective atomic number, density, thickness, and the X-ray or gamma-ray photon energy (Lopes et al., 2019; Carrazana González et al., 2016; Długosz-Lisiecka and Ziomek, 2015; Dziri et al., 2014; Landsberger et al., 2013). Photons of low energy such as the 28- and 32-keV X-rays and 35-keV gamma rays emitted from ^{125}I are much more susceptible to self-absorption than the higher energy gamma ray photons of, for example, ^{60}Co (1.17 and 1.33 MeV).

The X- and gamma rays of ^{125}I can be attenuated significantly before escaping from a typical 1-cm-diameter sample tube (Malcolme-Lawes and Massey, 1980), which is a common sample geometry with crystal scintillator well detectors. The effect of salt concentration and ions of different atomic mass absorption coefficients on the solid scintillation counting efficiency of ^{125}I is illustrated in Fig. 9.40. Pommé et al. (2005) emphasize the importance of maintaining constant counting geometry and self-absorption in the analysis of ^{125}I .

Rieppo et al. (1975) and Rieppo (1976a,b) have studied extensively the relationship of counting efficiency and

FIGURE 9.40 Variation of counting efficiency for ^{125}I (relative to efficiency in water = 100) with concentration of materials in aqueous samples with a NaI(Tl) well detector. Sample volumes are 5 mL and bottle diameter is 1.3 cm. From *Malcolm-Lawes and Massey (1980)*; reprinted with permission from Elsevier © 1980.

sample density (e.g., water, bone, and aluminum) for low-energy photons in the energy range 0.010–0.200 MeV for samples with a wide range of counting geometries. Self-absorption can be significant in the solid scintillation analysis of low-energy X- or gamma-ray photons (<400 keV); and it is a function of the thickness and density of the samples (*Lopes et al., 2019; Huy et al., 2013; Elane Streets, 1994*) because of the relatively poor penetrating power of low-energy photons. *Abbas (2006)* and *Carrazana González (2016)* provide analytical formulae for the efficiency calibration of gamma detectors by determining the attenuation of the gamma photons by the source with calculations of the photon path length through the source material. A Monte Carlo GEANT simulation tool, which automatically accounts for sample self-absorption, is described by *Ashrafi et al. (2006)* for the modeling of a NaI(Tl) scintillator detector. In a review of radiometric methods, *Hou and Roos (2008)* emphasize the importance of chemical separation of radionuclides prior to the measurement of X- or gamma-emitting radionuclides to minimize self-absorption.

F. Counting geometry

The counting geometry is the geometric relationship between the sample and detector, including the sample and detector size and shape, the distance between the sample and detector, sample thickness, and angle of orientation of the detector around the sample (e.g., 180 degrees or 2π for a flat sample and planar detector or $>>2\pi$ geometry for a well detector or through-hole detector). The effect of sample geometry on the detection and counting efficiencies for various detector types including the planar, well-type, and through-hole detectors is discussed in [Section III.A](#) of this chapter.

G. Resolution

The resolution of a solid scintillation detector is a measure of the “sharpness” of the X-ray or gamma-ray energy peaks of the pulse height spectra. The sharper or narrower these peaks, the greater the resolution and the ability of the crystal detector to distinguish and measure the photon energy lines of one or more radionuclides in a sample. The resolution is expressed most often as the width of the photon peak at half-maximum peak height. The width of the photopeak in keV at the half-maximum height is expressed in terms of the percentage of the photon energy or peak center and is referred to as % full width at half-maximum (% FWHM). For example, the resolution of the photopeak at the 662 keV gamma energy line of ^{137}Cs illustrated previously in this chapter in [Fig. 9.19](#) is shown to be 3.65%; and it is calculated as follows:

$$\% \text{ FWHM} = \frac{674.1 \text{ keV} - 649.9 \text{ keV}}{662.0 \text{ keV}} \times 100 = 3.65\% \quad (9.35)$$

where 674.1 and 649.9 keV in the numerator are the energy values obtained from the energy axis taken at both sides of the half-maximum peak height (position of the two arrows of [Fig. 9.19](#) and 662 keV in the denominator is the magnitude of the gamma-energy line).

The resolutions of scintillators are energy dependent; and experimental values have been reported by many researchers. Resolutions experimentally measured with a 38×38 mm BGO detector as a function of gamma-ray energy were measured by *Evans (1980)*. When comparing resolutions for photopeaks of different energies, a high % FWHM for a low-energy photon peak could mean a better resolution than a lower % FWHM for a high-energy photon. For example, a 17% FWHM resolution for the 514-keV gamma peak of ^{137}Cs represents an energy resolution of 87 keV (i.e., $0.17 \times 514 \text{ keV}$), whereas a 10% FWHM resolution for the 1275-keV gamma peak of ^{22}Na was calculated by *Evans (1980)*, i.e., an energy resolution

of 127.5 keV. Evans (1980) pointed out that the resolution of the BGO detector is only about half as good as that which can be obtained with equivalent NaI(Tl) crystals. However, the higher efficiency of BGO and the near absence of Compton continua make this detector the choice when a high-resolution detector is not needed.

While energy resolution is an important property in X-ray and gamma-ray photon spectroscopy, other important properties in the selection of desirable characteristics of inorganic crystal scintillators are high density and effective atomic number, high light output (i.e., luminosity), short decay time without afterglow, convenient emission wavelength, mechanical ruggedness, radiation hardness, and low cost (Moses, 2002). Measured energy resolution at 662 keV of numerous scintillators as a function of light output or luminosity is illustrated in Fig. 9.41. All of the ideal properties of a scintillator may not be found with just one scintillator. Often it is a tradeoff between the most desired properties against other desirable ones. For example, the relatively high density and high effective atomic number (Z_{eff}) of BGO ($\rho = 7.13 \text{ g/cm}^3$), GSO ($\rho = 6.71 \text{ g/cm}^3$), and LSO ($\rho = 7.4 \text{ g/cm}^3$) provide these scintillators with a relatively high stopping power; however, they are not as efficient in terms of energy resolution and light output as other scintillators of lower density and lower effective atomic number such as $\text{LaCl}_3\text{:Ce}$ ($\rho = 3.8 \text{ g/cm}^3$) and $\text{LaBr}_3\text{:Ce}$ ($\rho = 5.3 \text{ g/cm}^3$) as depicted in Fig. 9.41.

A scintillation crystal detector can become damaged when the crystal undergoes fracture via thermal or mechanical shock or when it absorbs atmospheric moisture, which can occur with the hygroscopic NaI(Tl) crystals, as well as other hygroscopic crystal detectors, when the

protective cover is damaged. When damage occurs the energy transfer scintillation processes and light transmission of the crystal are impaired and the energy resolution will drop. The photopeaks may become broadened and/or transformed. Modern gamma scintillation analyzers are equipped with a MCA and automatic calibration programs to monitor the integrity of the photopeak resolution with calibrated NIST-traceable gamma-emitting standards.

H. Background

Background includes counts collected by the scintillation detector produced by radiation events arising from sources outside the sample under analysis. The sources of background radiation are cosmic rays, natural radionuclides in the sample tube and neighboring materials (environment), detector contamination, and radioactivity from samples that may be in close proximity to the sample under analysis. The latter source of background should be considered particularly in automatic gamma-counting systems where multiple detectors arrays and multiple sample-changing cassettes are all in close proximity and when high-energy gamma-emitting radionuclides are present in sample tubes.

Background count rates should always be determined for the particular counting region of interest defined by the LL and UL discriminator settings. The background for a particular counting protocol may be determined by using a blank sample, that is, a sample tube or microplate well containing the volume of reagents used without any radioactive sample. This is similar to a reagent blank. When background count rates are significantly high relative to the sample count rates, background counts must be determined and subtracted from the sample counts. Under these circumstances, sample counts and background counts should be collected over a sufficient period of time to get a measure of the sample and background count rates with a low %2S (% 2 sigma standard deviation).

The measurement of background also serves another purpose, that of testing the stability of the instrument detector systems and associated electronics. This fits within a program of IPA, which is dealt with in Chapter 6, Volume 1. The stability of the background count rates serves as an index of the stability of the counting system.

Modern solid scintillation analyzers are equipped with an MCA, which can be programmed to collect the background counts according to pulse height over the entire spectrum of pulse heights for a predetermined time period. The background for any counting region of interest defined by LL and UL discriminator settings is easily obtained from the entire pulse height spectrum. The instrument can be set to sum the pulse heights in those channels for any region of interest.

FIGURE 9.41 Measured energy resolution of several scintillators for 662 keV gamma rays as a function of their light output (expressed as the number of photoelectrons observed with a photomultiplier tube). The solid curve indicates the theoretical lower limit placed by counting statistics. From Moses (2002) and Dorenboos (2002); reprinted with permission from Elsevier © 2002.

V. Automated solid scintillation analyzers

Automated solid scintillation analyzers are referred to here as high-throughput computer-based multiple-detector instruments capable of analyzing simultaneously as many as 10 or 12 samples with automated IPA, multiple-user programming, “walk-away” sample analysis, and “hands-off” data processing of up to 1000 samples with potential links to computer mainframe and local area network (LAN) assay automation and data management. Two types of automated scintillation analyzers will be described in this section: (1) automated gamma analyzers, which utilize up to 10 NaI(Tl) detectors for the simultaneous measurement of gamma- and X-ray-emitting radionuclides in sample tubes, and (2) microplate scintillation analyzers, which utilize 24-, 96-, or 384-well microplates for the solid or liquid scintillation analysis of beta particle- and atomic electron-emitting radionuclides.

A. Automated gamma analysis

An automated gamma analyzer should possess all the components needed to provide a complete unattended analysis of relatively large numbers of samples containing X-ray, gamma-ray, or positron-emitting radionuclides. Among the main components of such a system are (1) a large-capacity sample changer capable of holding and moving large numbers of sample tubes (up to 1000) to and from detectors, (2) multiple detectors for the simultaneous analysis of up to 10 samples when a high sample throughput is required, (3) automatic computer-controlled system with numerous (hundreds) of independent programmable assay protocols, (4) sample number and sample cassette identification via binary code, which can be linked to a LAN data processing and management system through a programmable computer interface, (5) automatic isotope decay correction according to date and time, (6) live gamma spectrum displays, (7) automatic detector normalization and detector cross-talk measurement for multiple-detector instruments, (8) correction for radionuclide interference between two counting regions via automatic spillover calculations, (9) automatic background correction in all counting regions, (10) multiple simultaneous counting regions, either preset for certain radionuclides, such as ^{125}I , ^{57}Co , ^{60}Co , ^{75}Se , ^{51}Cr , ^{131}I , ^{59}Fe , and ^{22}Na , or defined arbitrarily with LL and UL discriminator settings over a wide spectral energy region (e.g., 15–2000 keV), (11) automatic IPA, and (12) special applications software for sample data processing and calculations.

1. Multiple detector design

In an early part of this chapter, a description of the various types of detector geometries was given. Two types of detector geometries for automated gamma counters have been developed. One detector design is the through-hole detector described previously in this chapter (see Fig. 9.6). Another design of automated gamma counters, which provides increased detection efficiencies, is one equipped with as many as 10 well-type inorganic crystal detectors equipped with an automatic sample changer with analysis capacity of up to 1000 samples, such as the PerkinElmer Wizard Automatic Gamma Counter.

Automated gamma counters utilizing a well-type detector geometry are currently the most common commercial detector models utilized, such as the following, among others:

- (i) the PerkinElmer Wizard automatic gamma counters; and a few examples are described by Lodge et al. (2015), Watanabe et al. (2016), Wingelhofer et al. (2016), Chen et al. (2017), Kim et al. (2017), Monteiro et al. (2017, 2018), Sims-Williams et al. (2017), Wang et al. (2017), Dal Maso et al. (2018), Hadj Rabia et al. (2018), Li et al. (2018), Makino et al. (2018), O'Hara et al. (2018a,b), and Okamura et al. (2018),
- (ii) the Hidex AMG automatic gamma counter (Hellberg et al., 2017; Weström et al., 2017; Muuri et al., 2018), or
- (iii) the Hitachi Aloka ARC automatic gamma counter (Yamamoto et al., 2017; Oshima et al., 2017a,b; Zhu et al., 2018a,b).

Automatic gamma counters are commonly used to analyze the activities of positron-emitting radionuclides utilized in PET as evidenced by the numerous citations provided in the previous paragraph. The 0.51 MeV gamma-ray resulting from positron annihilation and the 1.02 MeV gamma-ray line from coincident detection of the two simultaneous 0.51 MeV emissions from positron annihilation are efficiently detected with the well-type NaI(Tl) detector. Lodge et al. (2015) evaluated the performance of a PerkinElmer Wizard automatic well-type gamma counter for the activity analysis of positron emitting radionuclides, which is equipped with NaI(Tl) crystal detector measuring 75 mm in diameter and 80 mm height with a center well measuring 33 mm in diameter and 60 mm deep hole. Radioactive samples are automatically transferred from a sample test-tube rack to the inside of the well detector. The well-type detector design provides improved detection efficiencies over the through-hole detector, as the crystal

FIGURE 9.42 ^{18}F positron annihilation gamma energy spectrum measured with the PerkinElmer 2480 Wizard² automatic gamma counter. With the sample located in a sample tube inside the NaI(Tl) detector well a photopeak corresponding to detection of a single 511 keV positron annihilation gamma-ray photon and a coincidence sum peak at 1.022 keV corresponding to the coincident detection of the two 511 annihilation photons. From Lodge et al. (2015).

detector surrounds the sample with the exception of the sample well opening.

A typical positron annihilation gamma spectrum from a positron emitting radionuclide is illustrated in Fig. 9.42. The spectrum will show a photopeak corresponding to a single 0.511 MeV positron annihilation gamma ray and a smaller coincidence sum peak at 1.022 MeV corresponding to the simultaneous detection of the two 0.511 MeV gamma-ray photons that are emitted in opposite directions following positron annihilation.

The sample volume will affect the counting geometry. In well-type detectors, there is an increased possibility of gamma-ray photon escape without interaction with the detector as the sample volume increases. This is illustrated in Fig. 9.43 where the detection of annihilation gamma-ray photons resulting from positron-emitting radionuclides has a greater possibility of escaping detection through the well opening, as the sample volume increases. This effect of sample volume on detection efficiency will occur with all gamma emitting radionuclides in addition to nuclides that produce annihilation gamma-ray photons from positron emission. It is therefore necessary to determine the effect of sample volume on detection efficiency, which will differ for each detector and radionuclide; and a plot of detection efficiency versus sample volume will provide a measure of sample geometry effects. Lodge et al. (2015) studied sample volume effects on the detection efficiency of positron and gamma-ray emitting radionuclides as a function of window width illustrated in Fig. 9.44. As illustrated in Fig. 9.44, the volume effect is minimal when measuring a positron-emitting radionuclide (e.g., ^{11}C or ^{18}F) in the

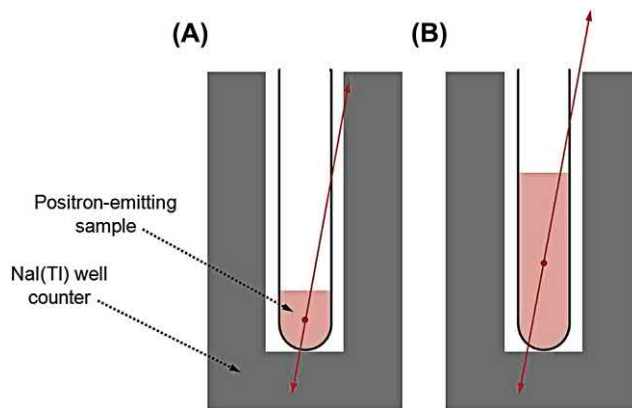

FIGURE 9.43 Sample volume effect. (A) An example pair of annihilation photons contributing to the coincidence sum peak of a positron-emitting radionuclide. (B) As the sample volume increases, there is an increasing likelihood that photons will escape from the hole at the top of the well. Counts lost from the coincidence sum peak due to reduced geometric efficiency become single-photon events. This mechanism tends to increase counts in the 511-keV peak, partially offsetting the loss of counts due to reduced geometric efficiency. The sample volume effect will occur also with gamma-emitting radionuclides. From Lodge et al. (2015).

511 keV photopeak region (409–613 keV) because the escape of one of an annihilation photon will reduce the coincidence sum peak at 1.022 keV; but the same positron annihilation may be registered by the detector in the 511 keV photopeak region. For gamma-emitting radionuclides (e.g., ^{125}I , $^{99\text{m}}\text{Tc}$, and ^{51}Cr), we do not have the benefit of coincident annihilation photons; and an escape of gamma-ray photons from the hole of the detector well should result in a reduction of detection efficiency. The counting of positron emitters in a wide-open counting region or window, which would encompass the 511 keV photopeak and the coincidence 1.022 keV sum peak, shows a more significant effect of sample volume on detection efficiency, as illustrated in Fig. 9.44, due to the escape of annihilation photons from the well opening.

The proximity of the multiple detectors to each other and to samples in the sample changer combined with the penetrating power or range of high-energy gamma radiation emitted by some radionuclides could give rise to possible error from cross-talk. We can define cross-talk as the registration of radiation events by a detector when those events originate from samples other than the sample in the detector.

There are two types of detector cross-talk, namely (1) detector-to-detector cross-talk, which occurs when a detector registers one or more events produced by radiation emanating from a sample located in another adjacent detector, and (2) deck-to-detector cross-talk, which occurs when a detector registers events arising from radiation emitted by samples on the sample changer deck. In multi-detector automatic gamma analysis instrumentation the gamma radiation from one or more samples may be of

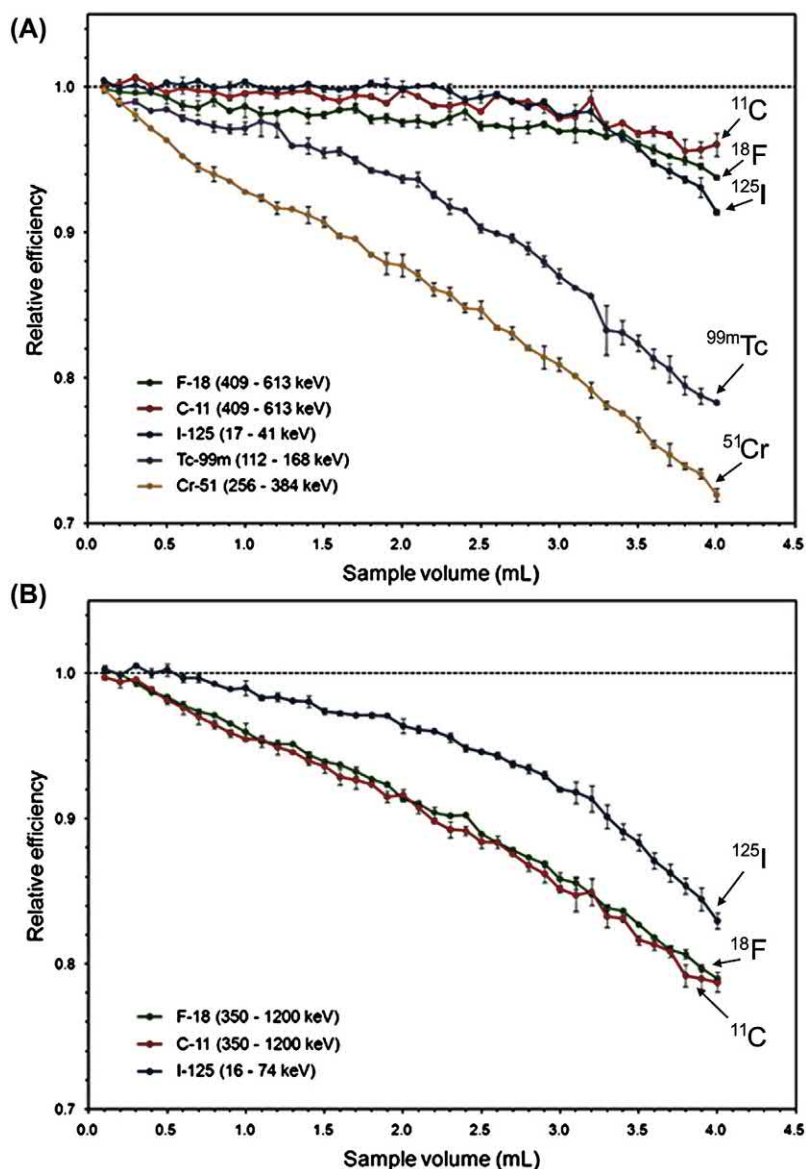

FIGURE 9.44 Relative efficiency as a function of sample volume for five different isotopes: ¹⁸F, ¹¹C, ¹²⁵I, ^{99m}Tc, and ⁵¹Cr with the PerkinElmer 2480 Wizard² automatic gamma counter. Energy windows are indicated in the Figure. (A) Data acquired in a window acquired on the lower photopeak where detection efficiencies for a sample of 4 mL relative to those at 0.1 mL are 0.96, 0.94, 0.91, 0.78, and 0.72 for ¹¹C, ¹⁸F, ¹²⁵I, ^{99m}Tc, and ⁵¹Cr, respectively; and (B) data acquired in a wide window encompassing both the lower photopeak and the coincidence sum peak. From Lodge et al. (2015).

sufficient energy and intensity to reach neighboring detectors and register events in the neighboring detectors.

Detector-to-detector cross-talk can be calculated by determining the count rate (CPM) from a detector containing a blank sample and dividing that count rate by the disintegration rate (DPM) of a sample in an adjacent detector. The ratio is expressed as a percentage. Also, conveyor-to-detector cross-talk could arise from samples that are conveyed by the instrument robotics from the sample deck adjacent to a detector. Conveyor-to-detector cross-talk is also measured with a detector containing a blank sample and dividing that count rate by the

disintegration rate of the closest sample in the sample deck, as described by Lodge et al. (2015). When cross-talk is suspected, the degree of cross-talk should be measured; and sample count rates corrected for cross-talk. Modern automatic gamma analyzers can employ a mathematical matrix calculation to correct for detector cross-talk; and they are equipped with sufficient lead shielding to reduce cross-talk.

Typical detection efficiencies and cross-talk for gamma-emitting radionuclides with a modern automatic gamma counter with a NaI(Tl) detector measuring 50 mm in height and 32 mm in diameter are provided in Table 9.6.

TABLE 9.6 Detection efficiencies, energy resolution, and crosstalk for various gamma-emitting radionuclides with the PerkinElmer 2470 Wizard² automatic gamma counter.^a

Radionuclide	Detection efficiency ^b	Energy resolution	Cross-talk ^c	
			Detector-to-detector	Conveyor-to-detector
¹²⁵ I	78%	<30%	Negligible	Negligible

2. Multiuser automatic gamma activity analysis

Automatic gamma counters are computer based. The entire operation of the gamma analyzer, including the sample changing, counting, single- and multiple-radionuclide spectral analysis, count rate statistical analysis, isotope decay corrections, activity analysis, and data processing, as well as instrument calibration and performance assessment, is controlled and completed by computer. It is necessary only to place the sample tubes in the appropriate sample cassettes and to input the basic information that the computer needs to carry out the automatic hands-off gamma analysis. Some of the major features of a typical automatic gamma analyzer will be outlined briefly here.

The modern automatic gamma analyzer has no toggle switches, buttons, or dials for the operator to set up and carry out an instrumental gamma analysis program. The one and only switch on the instrument is the main power switch, which is kept in the “On” position at all times. The only means of controlling the instrument is via the computer keyboard. Up to 999 user-definable analysis protocols may be available depending on detector model, and a user will select and name or identify one of the analysis protocols and input the necessary information into the instrument computer to define how the instrument will analyze his or her samples. Therefore, an analysis protocol is simply a customized procedure edited by the user that the instrument will implement to count and analyze a particular set of samples. The user will first identify and edit a protocol. The computer keyboard procedure for editing a counting protocol should be user friendly because the instrument should provide on the computer screen the available options for the user on what may be imputed as instructions to the computer. Editing an analysis protocol on the computer screen involves (1) naming the protocol, which helps the user identify that protocol for future

applications and also informs others that the protocol belongs to a particular application or user, (2) defining the count conditions and parameters, which control the counting of samples, and (3) defining the data reduction parameters, which can include assay-specific data calculations, curve fitting, and data printout. Automatic gamma analysis of as many as 1000 samples and the simultaneous counting of 10 samples in 10 well-type NaI(Tl) detectors are possible in commercially available automatic gamma counters, such as the PerkinElmer Wizard gamma counters.

3. Multiple gamma-emitting nuclide analysis

There are two options for measuring multiple gamma-emitting radionuclides in mixtures, namely the solid scintillation crystal detector or the germanium semiconductor detector. The solid inorganic crystal scintillation detectors provide higher detection efficiencies than the semiconductor detector. The higher detection efficiencies of the crystal scintillators require shorter counting times for lower activity samples, but the semiconductor detector yields much improved energy peak resolutions permitting the more facile quantification of complex mixtures particularly when the photopeaks of different nuclides in the mixture are close (L'Annunziata, 1984, 1987; Roig et al., 1999). The differences between the detection efficiencies and resolutions achieved by the crystal scintillators (NaI(Tl) and LaBr₃) and semiconductor (HPGe) detectors were measured by Bender et al. (2015) and illustrated in Fig. 9.45. The differences in energy resolution and detection efficiency between the solid scintillator and semiconductor detector are underscored by Roig et al. (1999), who reported a detection efficiency and photopeak resolution of 22% and 60 keV FWHM at 661.7 keV of ¹³⁷Cs, respectively, for a 3 inch NaI(Tl) detector, whereas the lower 1.7% detection efficiency but much improved

FIGURE 9.45 Comparison of gamma-ray spectra from a nuclear fuel element measured using each detector (NaI(Tl), LaBr₃ and HPGe) which highlights the difference in energy resolution. From *Bender et al. (2015)*; reprinted with permission from Elsevier © 2015.

1.4 keV resolution for the 661.7 keV photopeak of ¹³⁷Cs was obtained with the germanium semiconductor detector. The high detection efficiencies of inorganic crystal scintillation detectors makes these detectors very desirable for the analysis of single radionuclides or, of multiple radionuclides when one of the following conditions can be met: (1) photopeaks of these have energies separated enough to count the areas under the photopeaks of each radionuclide of the mixture, or (2) where corrections for any overlap or spillover of activity from interfering nuclides may be calculated, or (3) the complex spectrum of multiple radionuclides may be mathematically unfolded to provide the intensities of the photopeaks produced by the various radionuclides in the mixture.

Simultaneous analysis of more than one gamma-emitting nuclide in the same sample with the NaI(Tl) scintillation analyzer is common. It is necessary only that the photopeaks of the nuclides be separated enough so that counting regions can be defined to encompass the photopeaks of each nuclide. This will maximize the counts collected for each nuclide in each region, although there can be overlap of counts from the other radionuclide in each counting region. The following sections provide examples of the simplest case of two nuclides in a mixture and a more complicated case of several nuclides in the same sample.

a. Dual-nuclide analysis

The gamma spectrum of two nuclides in the same sample was seen previously in Fig. 9.29 for the case of a mixture of ¹³⁷Cs and ⁶⁵Zn. In this case two counting regions defined

by setting the LL and UL energy or pulse height discriminator settings of A and B (550 and 800 keV) for the ¹³⁷Cs counting region and A' and B' (950 and 1250 keV) for the ⁶⁵Zn counting region, respectively. The counting regions encompass the photopeaks of each radionuclide; however, the region set for counting the lower energy gamma emitter ¹³⁷Cs also contains counts arising from Compton smear of the higher energy nuclide ⁶⁵Zn. This is known as spillover because counts from the high-energy gamma emitter “spill down” into the counting region of the lower-energy gamma emitter. It is necessary, therefore, to calculate the percentage of the counts in the ¹³⁷Cs region that are due to ⁶⁵Zn to correct for the spillover. Often, the photopeaks of both radionuclides of a mixture have counts arising from each nuclide. We would, therefore, also have to correct for spillup, which is the percentage of counts that “spill up” into the counting region of the higher-energy gamma emitter from the lower-energy gamma emitter of the mixture.

The spillover and spillup corrections that must be made can be illustrated easily by using the dual nuclide ¹²⁵I—⁵⁷Co as an example. This is a dual radionuclide tracer used for the common folic acid-vitamin B₁₂ assays in serum samples (Jing et al., 2015; Hampel et al., 2014; Aléisso et al., 2011; Kerkeni et al., 2009; Lim et al., 2008; Lin and Yin, 2009; Maioli et al., 2009). Two counting regions are fixed, namely region A defined by setting the LL-UL discriminators of 15–75 keV for the ¹²⁵I counting region (35-keV photopeak) and region B defined by the LL and UL discriminator settings of 75–165 keV for the ⁵⁷Co counting region (122-keV main photopeak). The spectra of the two

radionuclides overlap. The CPM of ^{125}I in the mixture is obtained from the count rate in region A after subtracting the counts in that region due to spilldown from the higher-energy gamma emitter ^{57}Co . Also, the CPM of ^{57}Co in the mixture is determined from the count rate in region B after subtracting the counts in that region due to the spillup from the lower-energy nuclide ^{125}I .

The spilldown and spillup correction factors are determined by counting the pure samples of each nuclide in each counting region. If regions A and B are the counting regions for the lower and higher-energy nuclides, respectively, we can determine the spilldown and spillup correction factors as follows: First, a pure sample of the higher-energy nuclide ^{57}Co is taken and counted in both regions and the spilldown correction factor calculated as

$$\text{Spilldown} = (\text{CPM region A} / \text{CPM region B})(100) \quad (9.36)$$

The spilldown calculation gives the percentage of counts in the counting region of the lower-energy nuclide generated by the higher-energy radionuclide. Then a pure sample of the lower-energy radionuclide is taken and counted in the two counting regions. From the count rates in these regions the spillup correction factor is calculated as

$$\text{spillup} = (\text{CPM region B} / \text{CPM region A})(100) \quad (9.37)$$

The spillup calculation gives the percentage of counts in the counting region of the higher-energy nuclide generated by the lower-energy nuclide.

Once the percent spilldown and spillup correction factors are determined, the values are imputed into the counting protocol, and the automatic gamma analyzer will make the calculations required for the corrected and final count values for the two radionuclides in the mixture. The following equations form the basis upon which the count rates of the two nuclides in the mixture are calculated:

$$y_1 = x_1 + s_2 x_2 \quad (9.38)$$

$$y_2 = x_2 + s_1 x_1 \quad (9.39)$$

where y_1 and y_2 are the total number of counts from a dual-nuclide mixture in photopeak counting regions 1 and 2 (regions A and B), x_1 and x_2 are the unknown number of counts of nuclides 1 and 2 in their photopeak regions, and s_1 and s_2 are constants, which are the spillover values for nuclides 1 and 2, respectively. Typical values for the spilldown and spillup for the ^{125}I – ^{57}Co dual nuclide with the PerkinElmer Cobra automatic gamma analyzer are 3.00% or 0.03 for the spilldown value (s_2) of nuclide 2 (^{57}Co) into the counting region of ^{125}I and 0.80% or 0.008 for the spillup value (s_1) of nuclide 1 (^{125}I) into the counting region of ^{57}Co . However, the magnitude of spilldown of ^{57}Co into the ^{125}I region is reportedly reduced from the 3.0% to <1.0% when utilizing the preset counting regions utilized by the

PerkinElmer 2480 Wizard² automatic gamma counter (http://www.perkinelmer.com/CMSResources/Images/46-129502SPC_02_WIZARD_2480_Final.pdf). Eqs. (9.38) and (9.39) are solved simultaneously for the two unknown values of x_1 and x_2 , which are the corrected count rate values of nuclides 1 and 2.

The availability of ^{125}I -labeled human serum albumin has renewed interest in using this isotope tracer together with ^{51}Cr -labeled red blood cells to measure simultaneously plasma volume (PV) and red cell volume (RCV), as reported by Gómez Perales (2015). The photopeaks of ^{125}I and ^{51}Cr are at 18 and 320 keV, respectively, and the two NaI(Tl) detector photopeaks overlap significantly. Gómez Perales (2015) describes the count rate determinations of the dual radionuclide tracers by the counting of the two radionuclides in their photopeak windows or gates as previously determined by Wood and Levitt (1965). The method is based on determining the proportions of the two radionuclide counts that appear in each counting window or gate (i.e., gates 1 and 2 with discriminators set to encompass the major photopeaks of each radionuclide) and then solving two equations with two unknowns to resolve the count rates of the two radionuclides as follows:

$$K_1 I + K_2 C = A \quad (\text{gate 1}) \quad (9.40)$$

and

$$K_3 I + K_4 C = B \quad (\text{gate 2}) \quad (9.41)$$

where I = total count (i.e., combined count) of ^{125}I in gates 1 and 2, C = the total count of ^{51}Cr in both gates, A = the observed count in gate 1 and B = the observed count in gate 2, and K_1 and K_2 are the proportions of the activity of ^{125}I and ^{51}Cr in the total observed count A in gate 1, and K_3 and K_4 are the proportions of the activity of ^{125}I and ^{51}Cr in the total observed count B in gate 2. The coefficients K_1 through K_4 are determined by counting samples of pure ^{125}I and pure ^{51}Cr in the two gates as follows:

K_1 = amount of ^{125}I counted in gate 1/amount of ^{125}I counted in gate 1 and gate 2.

K_2 = amount of ^{51}Cr counted in gate 1/amount of ^{51}Cr counted in gate 1 and gate 2.

K_3 = amount of ^{125}I counted in gate 2/amount of ^{125}I counted in gate 1 and gate 2.

K_4 = amount of ^{51}Cr counted in gate 2/amount of ^{51}Cr counted in gate 1 and gate 2.

The two Eqs. (9.40) and (9.41) containing two unknowns are solved for I and C , namely the total counts for ^{125}I and ^{51}Cr in both gates, to give

$$I = (K_4 A - K_2 B) / (K_1 K_4 - K_2 K_3) \quad (9.42)$$

and

$$C = (K_1 B - K_3 A) / (K_1 K_4 - K_2 K_3) \quad (9.43)$$

Other dual-radionuclides combinations that are measured by solid scintillation gamma spectrometry are ^{99}Tc – ^{131}I as renal tubular tracers (Lipowska et al., 2017), ^{125}I – ^{131}I (Vaidyanathan et al., 2018, 2012, 2011; Choi et al., 2014; Zalutsky et al., 2012; Chen et al., 2011; Jia et al., 2011; Medine et al., 2010; Miyamoto et al., 2010; Wilbur et al., 2010; Yeşilagaç et al., 2011), and ^{57}Co – ^{58}Co used in the classical Schilling test to diagnose deficiencies in vitamin B₁₂ absorption (Chen and Chan, 2011; Nay et al., 2011; Malizia et al., 2010; Mazokopakis et al., 2009; Tzellos et al., 2009). The technique of calculating percent spilldown and percent spillup of the overlapping photopeaks is also required in these dual-radionuclide measurements.

b. Spectrum unfolding of multiple radionuclide spectra

The simplest case of the solid scintillation gamma analysis of two nuclides in a mixture is described in the previous section. The solid scintillation analysis of multiple-nuclide mixtures (more than two radionuclides) gives rise to a more complex pulse height spectrum where the counting regions, which are selected to surround the photopeaks of each nuclide of the mixture, will register counts from the nuclide of interest as well as counts from other nuclides spilling up and spilling down into the counting regions. An example of such a case is illustrated in Fig. 9.46, which illustrates the gamma spectrum of a mixture of six radionuclides and six counting regions (regions A through F) selected to encompass the photopeaks of each nuclide. In the fashion of Eqs. (9.38)–(9.41), six equations can be written to describe the counts collected in each of the six counting regions, as illustrated in Fig. 9.46, including the correction factors for the spillup and spilldown of counts from radionuclides in each counting region. The six equations need to be solved simultaneously. To facilitate the analysis of multiple radionuclides of this type, computer software such as PC-GERDA V2.9 can be employed with the automatic gamma analyzer for data processing with corrections for background, radionuclide decay, and spillover. The application of PC-GERDA software for the measurement of regional myocardial blood flow, mechanisms and consequences of vascular remodeling, and coronary vaso-regulation, among other applications by solid scintillation gamma spectrometry of radionuclide mixtures is described in detail in the literature (Stabley et al., 2013; Broisat et al., 2011; Dominguez et al., 2010; Hatada et al., 2006; Kingma et al., 2006; Krause et al., 2004; Riou et al., 2003; Ruiz et al., 2002). Since 2013, the scientific literature ceased to make direct reference to the use of PC-GERDA software for the analysis of multiple radionuclides by solid scintillation gamma-ray spectrometry. This is probably due to the fact that PerkinElmer automatic gamma counters, such as the 2480 Wizard², is equipped with the software for the

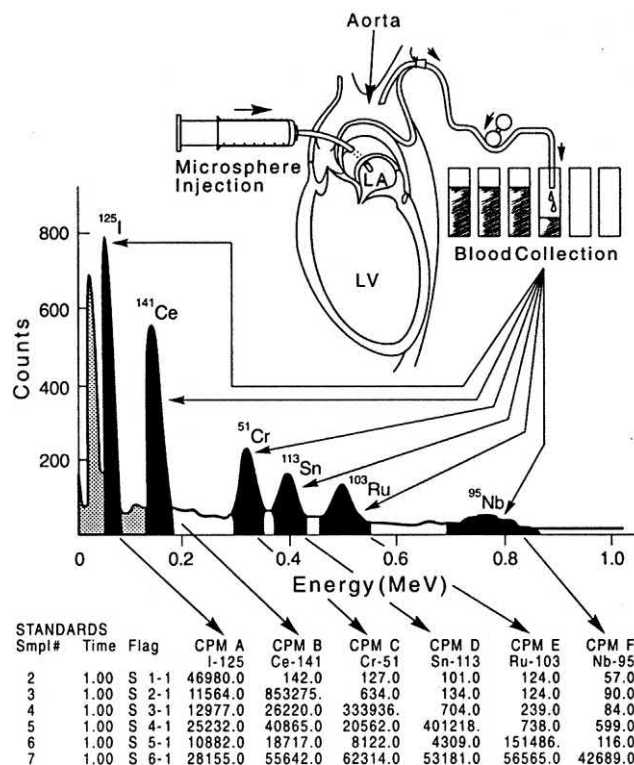

FIGURE 9.46 Six photopeaks from a composite spectrum of ^{125}I , ^{141}Ce , ^{51}Cr , ^{113}Sn , ^{103}Ru , and ^{95}Nb and count rates (CPM) obtained from six counting regions after spillover corrections were applied using PCGERDA software for calculating regional blood flow with radionuclide-labeled microspheres. © 1998–2010 PerkinElmer, Inc. automatic analysis of up to six different radionuclides with automatic spillup and spilldown calculations (http://www.perkinelmer.com/CMSResources/Images/46-129502SPC_02_WIZARD_2480_Final.pdf).

The poor resolution of inorganic crystal scintillation detectors may be overcome with the use of multivariate calibration methods (Roig et al., 1999). Multivariate calibration techniques were discussed in Chapter 6, Volume 1. Among these methods are multivariate regression (MLR), partial least squares regression (PLS), and principal component analysis (PCA), which can be used to determine amounts of radionuclides of interest although other radionuclides are present that affect the experimental signal provided the isotopes are present in both the unknown samples and a calibration set (Coble et al., 2017; Hellesen et al., 2017; Alharbi, 2016; Liu et al., 2016; Dayman et al., 2014; Orton et al., 2011, 2012; Toribo et al., 1995; Martin and Naes, 1989). The advantage is that these methods have proven successful for the analysis of samples with unknown interferences. The MLR and PLS methods were tested by Roig et al. (1999) to determine activities of ^{85}Sr , ^{134}Cs , and $^{110\text{m}}\text{Ag}$ in a mixture, which produced solid scintillation spectra with overlapping photopeaks and Compton smear illustrated in Fig. 9.47. They used the

FIGURE 9.47 Smoothed spectra obtained with a NaI(Tl) solid scintillation detector (PerkinElmer/Packard Auto-Gamma 5530) of single solutions of ^{85}Sr , ^{134}Cs , and $^{110\text{m}}\text{Ag}$ and a sample with the three radionuclides (upper spectrum). Radionuclide activities (when present): 100 Bq of ^{85}Sr ; 1390 Bq of ^{134}Cs ; 1220 Bq of $^{110\text{m}}\text{Ag}$. From Roig et al. (1999); reprinted with permission from Elsevier © 1999.

multivariate calibration, MATLAB (The Mathworks, Inc., Natick, Massachusetts, <https://www.mathworks.com/>) and the PLS-Toolbox for MATLAB written by Wise (1992). They tested the influence of different calibration sets on the prediction of radionuclide activities; and the prediction errors to samples without interferences for the aforementioned mixture were demonstrated to be <4%, which are comparable to errors obtainable with germanium detectors.

Spectrum unfolding methods have proven to be a powerful and practical tool in the measurement of radionuclides with poorly resolved spectra masked with a combination of background, photopeak spillover, and Compton smear. Other spectrum unfolding methods for the solid scintillation analysis of gamma-ray-emitting nuclides are described by Baré et al. (2010), Baré and Tondeur (2011), Mertens et al. (2007), Muravsky et al. (1998), Nguyen et al. (1996), Rahman et al. (2009), Skipper and Hangartner (2002), Sükösd et al. (1995) and Suzuki et al. (1993).

A water-tight housing for a NaI(Tl) detector was designed by van Put et al. (2004), Mertens et al. (2007), Baré et al. (2010), and Baré and Tondeur (2011) for the monitoring of gamma-emitting radionuclides in large bodies of water, such as lakes and oceans, at depths of up to 50 m. Their technique relies on the calculation of response functions of the detector by the Monte Carlo code MNCP4c2 (LANL, 2003) for gamma energies between 15 and 3000 keV; and an applications of the UMG 3.3 package (PTB, 2004) for unfolding the experimental spectra according to the response matrix built by the MNCP code (Baré et al., 2010, and Baré and Tondeur (2011); Mertens

et al., 2007; van Put et al., 2004) simplified the application of the Monte Carlo code by establishing an isotropic source-detector geometry, that is, the source being a large body of water is considered to be an infinite, homogeneous, and constant density medium surrounding the water-tight NaI(Tl) detector and electronic console. Fig. 9.48 illustrates an experimental gamma spectrum obtained by Baré and Tondeur (2011) with 10 hours of count data collection with the NaI(Tl) detector assembly immersed in a 20 m³ tank of simulated sea water containing 1 Bq/L of ^{139}Ce and ^{113}Sn , 12 Bq/L of ^{40}K by addition of KCl, plus 0.10 Bq/L of ^{137}Cs and an unspecified amount of ^{133}Ba . The only visible structures of the gamma spectrum obtained were the main ^{133}Ba peak at 356 keV and the ^{40}K peak at 1460 keV (see upper curve of Fig. 9.48). The unfolded spectrum was obtained by performing 6000 mathematical iterations using the GRAVEL iterative algorithm GRV_MC33 (see lower curve of Fig. 9.48). Baré and Tondeur (2011) demonstrate the power of the spectral unfolding method by a reduction of the minimal detectable activity (MDA) by a factor of 10 for the monitoring of environmental radioactivity in large bodies of water.

For laboratory and field measurements of soil samples Chiozzi et al. (2000a,b) used an EG&G Ortec NaI(Tl) detector and MCA for the measurement of radionuclides of uranium, thorium, and potassium. Samples of 0.65–0.85 kg were measured in polyethylene Marinelli beakers. The analysis was based on solid scintillation gamma spectra of the environmental samples, which provided adequately separated photopeaks for ^{214}Bi (^{238}U series), ^{208}Tl (^{232}Th series), and ^{40}K . Takiue et al. (1999) and

FIGURE 9.48 Top: Spectrum of 0.10 Bq/L of ^{137}Cs together with ^{40}K , ^{139}Cs , ^{133}Ba and ^{113}Sn obtained by a water-tight NaI(Tl) detector immersed in simulated sea water; Bottom: The unfolded spectrum. From Baré and Tondeur (2011); reprinted with permission from Elsevier © 2011.

Fujii et al. (1999, 2000) used the combined spectral information from a NaI(Tl) solid scintillation detector and liquid scintillation analyzer to measure seven beta-, gamma-, and X-ray-emitting nuclides in a mixture. The method is described in detail in Chapter 6, Volume 1.

B. Microplate scintillation analysis

The automated scintillation analyzers with the highest throughput today are the microplate counters, which can analyze all beta particle- and atomic electron-emitting nuclides by liquid or solid scintillation counting as well as carry out nonradioactive luminescence counting. These counters are referred to as microplate scintillation and luminescence counters. In this chapter, we will limit our treatment of this counter to only the solid scintillation counting of radionuclides. The use of these instruments to analyze radionuclides by liquid scintillation and Cherenkov counting are provided in Chapters 6, Volume 1 and Chapter 6, Volume 2, respectively.

1. Solid scintillation counting in microplates

Some commonly used microplate scintillation counters are the TopCount Microplate Scintillation and Luminescence Counter and the MicroBeta Plate Counter, both of which are products of PerkinElmer, Inc., Waltham, MA, USA, and the Hidex Sense Beta Plus Microplate Reader produced by Hidex, Turku, Finland. The TopCount microplate scintillation counter utilizes 2, 6, or 12 PMTs for the simultaneous counting of 2, 6, or 12 samples. The MicroBeta has 1, 2, 6, or 12 PMT detectors. The samples are counted in 24-, 96-, or 384-well microplates, which are stacked in the counter's microplate changing mechanism. The instrument moves the microplates one at a time for the simultaneous counting of up to 12 samples in separate microplate sample wells. Fig. 9.49 illustrates the location of a PMT relative to one of the microplate sample wells of a PerkinElmer TopCount scintillation counter. The highly reflective surface of the microplate well assures reflection of light photons from scintillation events toward the PMT.

FIGURE 9.49 Diagram illustrating the position of a PMT and sample in a microplate well. In TopCount high-throughput automatic scintillation analysis, up to 12 PMTs are positioned simultaneously above 12 sample wells. In SPA aqueous liquid medium is in the sample well, which has a white reflective surface. In solid scintillation analysis the sample is dry and adhered to the surface of a LumaPlate plastic scintillator-coated well. ©1998 PerkinElmer, Inc. Printed with permission.

Although only one PMT per sample is employed, the backgrounds are low due to a patented method of Time-Resolved Liquid Scintillation Counting (TR-LSC), which can distinguish between true scintillation events and background noise (US patent 4,651,006). The theory of TR-LSC for background reduction in TopCount liquid and solid scintillation counting is described in Chapter 6, Volume 1 and in a paper published by PerkinElmer (1991a). In the solid scintillation analysis of beta particle- and atomic electron-emitting nuclides the samples are analyzed in the dry state in the microplate wells as discussed further on in this section.

PerkinElmer MicroBeta Plate Counters are equipped with dual PMTs, which are situated above and below the sample well, with the utilization of microplates with transparent bottoms. The dual PMTs yield higher detection efficiencies with background rejection by coincidence counting. TopCount instruments utilize only one PMT above the sample well and TR-LSC for background rejection.

The 24-, 96-, and 384-well microplates contain wells oriented in a 6×4 , 12×8 , and 24×16 fashion along the length and width of each microplate. The maximum usable well volumes are 1500, 350, and 80 μL for the 24-, 96-, and 384-well microplates, respectively. Up to 40 microplates may be stacked in the counter microplate changing mechanism. If we consider the 384-well microplate, the stacking of 40 microplates in the counter would allow the unattended counting of 15,360 samples. The counter is computer controlled and fully automated for complete hands-off sample analysis.

Solid scintillation counting in microplates involves depositing a sample into the well of a special plastic scintillator microplate (e.g., LumaPlate, FlashPlate, ScintiPlate, and Cytostar-T). The microplate wells contain a scintillator

embedded in clear plastic in one of two possible formats, namely, (1) a clear plastic scintillator is coated as a thin layer along the entire inside wall of a white opaque plastic microplate-well to be used with a microplate counter having only one PMT detector per sample well (e.g., TopCount counters) or (2) the scintillator is embedded into the microplate-well with a transparent bottom to be used with a microplate counter equipped with two PMT detectors per sample well (e.g., MicroBeta counters).

The material to be assayed can be dried and then counted in the microplate scintillation counter. In addition, solid scintillation microplate counting is used for the purpose of the off-line radioassay of high-performance liquid chromatography (HPLC) effluent by fraction collecting into the wells of a scintillation microplate. This is followed by a rapid drying of the collected fractions in the microplate wells and subsequent counting in a microplate scintillation counter. The method is referred to as the combination of HPLC and microplate scintillation counting (MSC) and abbreviated as HPLC-MSC or more simply abbreviated as LC-MSC. The effluent from an HPLC column can be split so that a fraction of the effluent (e.g., 75%) is collected into the wells of a microplate and the remaining HPLC effluent (e.g., 25%) goes on to a mass spectrometer for the structural identification of organic compounds as these are separated off the HPLC column. The combination of HPLC with MSC and mass spectrometry (MS) is abbreviated HPLC-MSC-MS. The radioactivity measured in the various fractions by the microplate counter provides a quantitative measure of the organic compounds in the HPLC effluent (Glaenzel et al., 2018; Gu et al., 2018; Zhuo and Zheng, 2018; Jensen et al., 2017; Dymond et al., 2016; Lacy et al., 2015; Tolonen and Pelkonen, 2015; Koppen et al., 2014; Tong et al., 2012; Barros et al., 2011; Kiffe et al., 2003, 2007; Dear et al., 2006, 2008; Bruin et al., 2006; Zhu et al., 2005a,b; Nedderman et al., 2004).

The basic sequence of combining HPLC with MSC and MS is illustrated in Fig. 9.50. The figure illustrates two possible approaches. One method shown in Fig. 9.50A would be to split the HPLC effluent so that a larger portion of the effluent (e.g., 75%) is directed to a fraction collector for the collection of fractions into the wells of a deep well scintillating microplate; and a smaller remaining portion of the effluent (e.g., 25%) is directed to a mass spectrometer for the analysis of the organic compounds separated on the liquid chromatogram. The on-line spectroscopic analysis of organic compounds in HPLC effluents is described by L'Annunziata and Nellis (2001a,b). The HPLC fractions collected in the wells of the scintillating microplates are vacuum dried; and the radioactivity measured with a microplate counter. A plot of the radioactivity versus the time in minutes for the collection of HPLC fraction will provide an HPLC radioprofile with peaks representing the radioisotope-labeled compounds eluted from the liquid

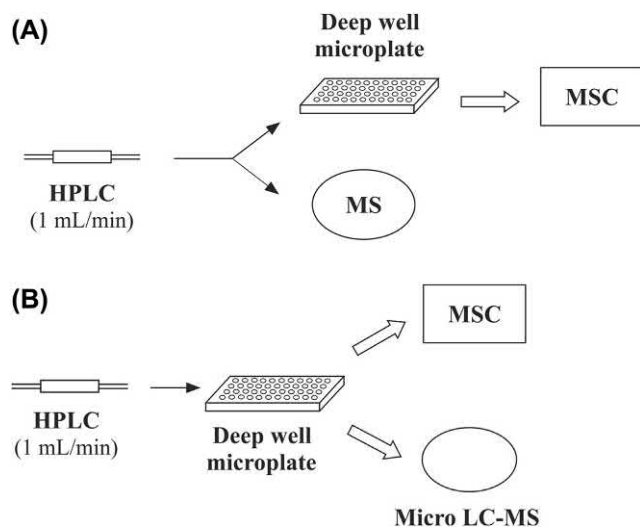

FIGURE 9.50 Setups of the combination HPLC-MSC with mass spectrometry. System A is the setup for simultaneous radioactivity profiling and metabolite identification. The HPLC eluent is split into both MSC and MS. System B is the setup for tandem analysis of metabolite profile by HPLC-MSC and metabolite characterization by micro LC-MS. From *Zhu et al. (2005a)*; reprinted with permission from Elsevier © 2005.

chromatography column, as illustrated in Fig. 9.52. The count rates under each peak will provide a measure of the relative abundance of isotope labeled compound eluted based on the level of radioactivity applied to the column assuming a constant detection efficiency. The mass spectra determined in line with the radioactivity peaks will provide evidence for the identity of the compound eluted from the HPLC column. Another approach is illustrated in Fig. 9.50B where the HPLC effluent is not split; rather, it is collected as fractions into a scintillating microplate and submitted to tandem analysis by MSC and micro liquid chromatography MS (micro LC-MS).

The splitting of the effluent of a liquid chromatography column to allow a fraction of the effluent to go on to a mass spectrometer for organic molecular structure determination and another fraction to go on to be collected into the wells of scintillating microplates is illustrated in Fig. 9.51. From the effluent splitter the fraction going on to the scintillating microplate wells is controlled by a fraction collector, which moves stacked microplates and a syringe plunger in X, Y, and Z directions for the collection of the column effluent fractions into separate microplate wells. Typical fraction collectors are the Collect Pal (Leap Technologies, Inc., Morrisville, NC, USA, <https://www.leaptec.com/>) and the Gilson FC 204 Fraction Collector (Gilson, Inc., Middleton, WI, USA, <http://www.gilson.com/en/default.aspx>). After fraction collection the microplates are dried under vacuum and then counted in a microplate scintillation analyzer. The coupling of liquid chromatography with microplate scintillation counting (LC-MSC) offers an advantage over flow scintillation analysis (FSA) in the detection and measurement of radionuclide-labeled compounds as they are eluted from the chromatography column. The advantage of LC-MSC over FSA is an increased sensitivity because the counting time of the microplate scintillation analyzer can be controlled by the user; whereas the residence time of flow scintillation analyzers is relatively short at the flow rates commonly utilized in liquid chromatography. However, FSA offers the advantage of rapid real-time measurement of radioactivity in the effluent column (see Chapter 10, Volume 2 on Flow Scintillation Analysis). By this technique the count rates (CPM) or even the activities (DPM) of small amounts of ^3H - or ^{14}C -labelled compounds separated by liquid chromatography can be determined. The process of drying the fractions in the wells of the plastic scintillator microplates places the ^3H - or ^{14}C -labelled compounds into intimate contact with the scintillator-embedded plastic

FIGURE 9.51 Typical system configuration for the HPLC radioprofiling with simultaneous mass spectrometry analysis. A photodiode array (PDA) is a UV/Vis detector generally utilized in liquid chromatography systems; and the effluent splitter in this case is shown to direct 25% of the effluent on to the mass spectrometer and the remaining 75% on to the Collect Pal fraction collector. From the fraction collector the samples are dried over night and then counted with a microplate scintillation analyzer, e.g., TopCount. From *Barros et al. (2011)*; reprinted with permission from Elsevier © 2011.

FIGURE 9.52 A radioprofile constructed from data of radioactivity measured in fractions of an HPLC effluent of the carbon-14 labeled drug Selumetinib (most intense peak marked P) and its metabolites in human plasma collected in the wells of scintillating microplates (ScintiPlates) after a single 75-mg oral dose administered to a representative subject. Square brackets indicate matrices in which metabolite was detected (only the radiochromatogram of human plasma extract is illustrated). Values in parentheses indicate mean percentage of dose excreted as each metabolite. *Plasma values indicate percentage chromatogram only. Bold type denotes >10% dose excreted as this metabolite in this matrix or >10% of the radioactivity in the plasma chromatogram. All of the drug metabolites of the numbered peaks were identified; but not illustrated in the figure. From Dymond et al. (2016); reprinted with permission from Elsevier © 2016.

coating of the microplate well. One should keep in mind that the drying process can result in loss of volatile organic compounds; and self-absorption of low-energy beta particles can occur in dried samples. Nevertheless, the LC-MS/SC technique has proven to be a valuable tool in studies involving the chromatographic separation and measurement of radioisotope-labeled organic compounds. A typical liquid radiochromatogram illustrating the radioactivity peaks of ^{14}C -labelled organic compounds eluted from a liquid chromatography column and collected in 96-well scintillating microplates (ScintiPlates) and the identification of eluted ^{14}C -labeled compounds by MS is illustrated in Fig. 9.52. The HPLC postcolumn effluent was split (4:1) with the majority of the flow directed to the fraction collector into the ScintiPlate wells; and the remainder of the flow directed to a mass spectrometer for organic structural analysis (Dymond et al., 2016).

In certain circumstances the solid scintillation counting technique in plastic scintillator microplates can replace conventional liquid scintillation analysis in counting vials when nonvolatile forms of the radionuclides and small

samples need to be analyzed. MSC offers the following advantages: (1) the samples are safer to handle because of their solid nonvolatile state; (2) waste disposal costs are reduced due to the small volumes of the plastic microplates and the solid state of the waste; (3) samples may be recovered from the wells after counting for further studies, if they are stable in the dry state; (4) once in the wells, the sample positions cannot be changed mistakenly by laboratory personnel, which ensures positive sample identification; and (5) sample throughput is increased because as many as 12 samples in wells can be analyzed simultaneously.

The procedure involves simply applying the samples to the wells of a plastic-scintillator microplate (e.g., LumaPlate). The plates are dried in a fume hood overnight, or a heat lamp, hair dryer, or a centrifugal evaporator may be used to facilitate sample drying. Prior to counting, the microplate is sealed with cover film (e.g., TopSeal) to facilitate handling and to prevent contamination of the samples and counter. Börnsen (2000) and PerkinElmer (1996) provide detailed information on

sample handling and performance for solid scintillation counting with the LumaPlate.

The TopCount solid scintillation counting efficiencies (%) reported by Börnsen (2000) for various radionuclide-labeled compounds deposited in separate wells of the 96-well LumaPlate are ^3H (49%), ^{14}C (85%), ^{32}P (87%), ^{51}Cr (24%), and ^{125}I (75%) with backgrounds of only 8–9 CPM. The low backgrounds provide high figures of merit ($\text{FOM} = E^2/B$). The 24-well LumaPlate will provide significantly higher counting efficiencies, for example, ^3H (55%), ^{14}C (95%), ^{32}P (93%), ^{51}Cr (48%), and ^{125}I (83%), but with higher backgrounds of about 19–20 CPM. The FlashPlate is used generally for scintillation proximity assays (SPAs) discussed further on in this chapter. Some examples of the solid scintillation analysis of various radionuclides with the ScintiPlate, LumaPlate, and Cytostar T microplates are found in the following works: ^3H (Omori et al., 2015), ^{14}C (Dymond et al., 2016; Koppen et al., 2014), ^{18}F (Tang et al., 2017), ^{32}P (Crosbie et al., 2013, 2012), ^{51}Cr (Aguilar et al., 2017; Ando et al., 2017; Gravelle et al., 2014), and ^{125}I (Hallinger et al., 2017).

Because the scintillation phenomenon occurs in the solid scintillation detector (wall of the microplate well) separate from the dried sample, there is no chemical quench. However, if the sample residues along the walls of the microplate wells are colored, it is possible to have quenching from the absorption of the scintillation photons from color. The effect of color quenching can be determined with colored agents as described subsequently in Section V.B.2.f of this chapter and in a report by PerkinElmer (1996). A quench correction curve of counting efficiency (E) versus a quench-indicating parameter (QIP) (e.g., transformed spectral index of the sample, tSIS) is prepared with color-quenched radionuclide standards. The quench correction curve is, in turn, used by the instrument to convert count rates (CPM) to activity (DPM) according to $\text{DPM} = \text{CPM}/E$.

The close proximity of the wells and PMTs could contribute to well-to-well cross-talk, which can be defined as pulse events registered by one PMT arising from nuclear radiation originating in a neighboring well. The LumaPlate structural material is opaque to light, which prevents optical well-to-well cross-talk. High-energy beta radiation and low-energy gamma rays could theoretically pass through the walls of one well and produce a scintillation event in the walls of another. Cross-talk expressed as percentage is defined and calculated as described in Section V.A.1 of this chapter. Cross-talk with the TopCount plate counters for the 96-well PicoPlates are reported by Börnsen (2000) to be about 1% or less for radionuclides emitting penetrating radiation such as ^{32}P and ^{125}I ; insignificant for ^{14}C and ^{51}Cr , and undetectable for ^3H .

The plastic scintillator microplates serve as excellent platforms for many SPAs such as immunoassays, receptor

binding assays, enzyme activity, and other bioassays. These techniques carried out with microplate solid scintillation counting are described in the following paragraphs.

2. Scintillation proximity assay

SPA is a technology for the analysis of binding reactions, commonly studied in the medical and biochemical sciences, which circumvents the need to separate bound from free fractions. Glass or plastic solid scintillator microspheres or scintillating microplates are used in this assay together with an isotope-labeled ligand. With the use of modern liquid handling equipment and an automatic scintillation counter for samples in a microplate format, hundreds of samples may be prepared and analyzed in a single day, because traditional processes for the separation of bound and free fractions are not required. This section provides a brief treatment of SPA. Additional sources of general information on SPA are available from PerkinElmer (2018), Wildey et al. (2017), Xia et al. (2016), Sadena and Sadena (2011), Heuvel (2010), Alcamí and Viejo-Borbolla (2009), Glickman et al. (2008), Flaumenhaft (2007), Minor (2006), Schnurr et al. (2007), de Jong et al. (2005), Jones et al. (2003), Park et al. (1997), Cook (1996), and PerkinElmer (1991b, 1997). Additional detailed information and procedures may be obtained from references cited in the following paragraphs.

a. Basic principles

SPA makes use of the weak (low-energy) radiation emitted by certain radionuclides, such as the very low-energy beta-particles emitted by ^3H ($E_{\text{max}} = 18.6 \text{ keV}$) or the weak Auger electrons emitted by ^{125}I ($E_{\text{max}} = 30 \text{ keV}$). The radiations emitted by these radionuclides have very short ranges of travel in water. For example, the maximum range of ^3H beta particles in water is only $\sim 25 \mu\text{m}$ (see Table 1.12 in Chapter 1). The Auger electrons of ^{125}I , which are of slightly higher energy, travel only a few micrometers further in water. Therefore, if these radionuclides are in aqueous solution their radiations will not be detectable unless they are in intimate or very close contact with a scintillating compound. SPA, therefore, makes use of yttrium silicate scintillating glass microspheres, polyvinyltoluene (PVT) scintillator microspheres, or scintillating sample wells of microplates, which emit visible light when the beta particles or Auger electrons from ^3H or ^{125}I are able to penetrate the scintillating glass or plastic. Most of the material in this section will focus on scintillator microspheres; but the principles apply also to scintillating sample wells of microplates. Because of the short ranges of travel of ^3H and ^{125}I radiations in water, their penetration into microsphere scintillators can happen only when the ^3H or ^{125}I nuclides are in intimate or very close contact with the microspheres. If the microsphere scintillators are coated

FIGURE 9.53 Illustration of the principle of scintillation proximity assay (SPA). The scintillation proximity assay is based on the emission of light as a result of energy transfer from the radioactive decay of the radioisotope-labeled ligand (radioligand) to the microsphere that contains a scintillant (SPA bead). The emission of light only proceeds, if the radioisotope-labeled ligand and receptor are in close proximity ($\sim 10\ \mu\text{m}$) illustrated on the left of the Figure. Otherwise the energy of the radioligand is absorbed by the buffer illustrated on the right of the figure. From Wildey *et al.* (2017); reprinted with permission from Elsevier © 2017.

with an antibody or receptor molecule and the ^3H or ^{125}I resides as a label on an antigen or ligand molecule, a binding reaction can occur between the antibody and antigen or receptor and ligand molecules, as illustrated in Fig. 9.53. The close proximity of the ^3H or ^{125}I through the binding reactions enables the beta-particle or Auger-electron radiations to penetrate the microsphere scintillator with concomitant isotropic emission of photons of visible light by the scintillator microspheres. A scintillation counter can detect the photons of light emitted by any aqueous medium (e.g., buffer solution) containing a mixture of (1) microsphere scintillator with surrounding antibody or receptor molecule, (2) free radioisotope-labeled

antigen or ligand molecules, and (3) bound radioisotope-labeled antibody-antigen or bound radioisotope-labeled receptor-ligand molecules on scintillator microspheres. The count rate (CPM) of the photon emissions will serve as a measure of the bound radioisotope-labeled fraction, because radiations emitted from labeled molecules not bound close to the microsphere surface dissipate their energy in the aqueous medium and are not detected.

SPAs are not limited to applications with radionuclides emitting very low-energy particulate radiations, such as ^3H or ^{125}I . However, the use of radionuclides emitting higher-energy beta-particle radiation, such as ^{14}C ($E_{\text{max}} = 155\ \text{keV}$), ^{35}S ($E_{\text{max}} = 167\ \text{keV}$), and ^{33}P ($E_{\text{max}} = 249\ \text{keV}$) is possible (Donnier-Maréchal *et al.*, 2017; Eldeeb *et al.*, 2017; Erdmann *et al.*, 2017; Aas *et al.*, 2011; Chapman *et al.*, 2011; Ojo *et al.*, 2011; Vakalopoulos *et al.*, 2011; Zaghdane *et al.*, 2011; Herdemann *et al.*, 2010; Seimandi *et al.*, 2010; Zhang *et al.*, 2010; Gaster, 2009; Grobler *et al.*, 2009). Because of the relative high energies of the beta particles emitted by ^{14}C , ^{35}S , or ^{33}P and the consequent relative longer lengths of travel of these particles in water (see ^{14}C beta-particle maximum range in water in Table 1.12 of Chapter 1), it is necessary to minimize scintillation proximity bead contact with free radionuclide label in the solution medium. This is accomplished by either (1) letting the scintillation proximity beads settle for several hours or overnight, (2) microplate centrifugation, or (3) suspension (flotation) of the scintillation proximity beads over 7 M cesium chloride.

The suspension or flotation technique noted in the previous paragraph is described by Jeffery *et al.* (2002) and illustrated in Fig. 9.54, which also exemplifies the use of

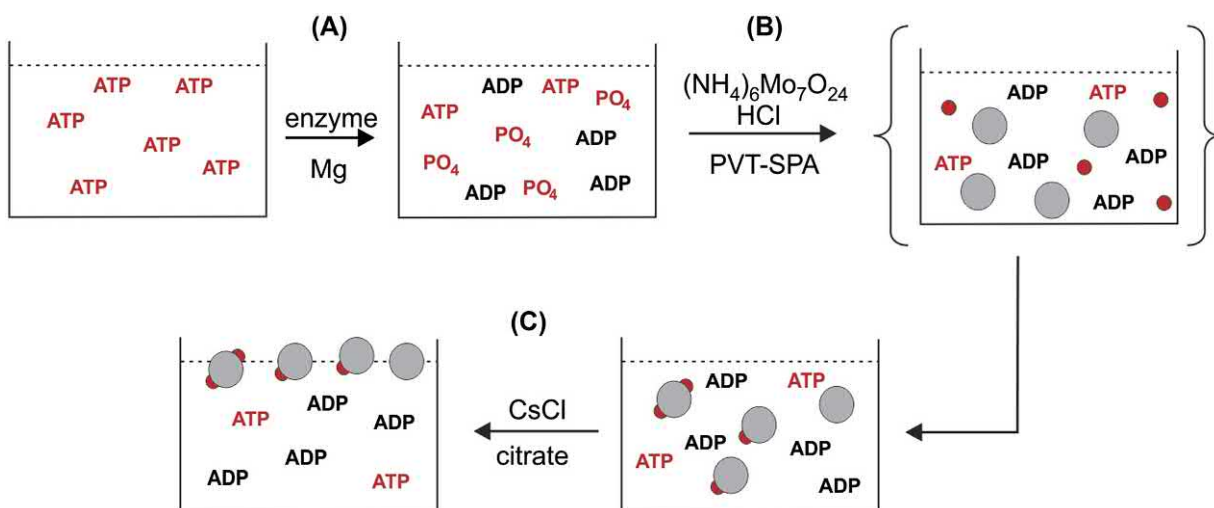

FIGURE 9.54 Schematic representation of the scintillation proximity ATPase assay. (A) The ATPase catalyzes the hydrolysis of ^{33}P -ATP to generate radioactive inorganic phosphate $^{33}\text{P}[\text{PO}_4]^{3-}$. (B) Addition of polyvinyltoluene scintillation proximity beads (PVT-SPA beads, large gray circles) suspended in a solution of ammonium molybdate and HCl. The ^{33}P phosphomolybdate anion ($^{33}\text{PMo}_6\text{O}_{40}^{3-}$, small dark circles or small red circles in colored version of Figure) forms and then absorbs onto the surface of SPA beads (larger gray circles). (C) Addition of CsCl to float the beads prior to radioactivity analysis in a microplate counter. From Jeffery *et al.* (2002); reprinted with permission from Elsevier © 2002.

SPA in the study of enzyme activity. In this example, ATPase catalyses the hydrolysis of ^{33}P -labeled ATP to generate radioactive inorganic phosphate. Scintillation proximity beads suspended in a solution of ammonium molybdate are added. The ammonium molybdate forms an anion with the ^{33}P -phosphate, and the phosphomolybdate anion then absorbs onto the SPA beads. The addition of 3.5 M CsCl solution causes the SPA beads to float to the surface of the suspension separating the beads with the bound ^{33}P -phosphate from the unbound ^{33}P -ATP in the solution. The amount of light emitted by the beads provides a measure of the ^{33}P -phosphate adhered to the SPA beads. The technique was demonstrated as useful for kinetic studies of the enzyme activity.

b. Immunoassay applications

In the case of the binding of a ^3H - or ^{125}I -labeled antigen to an antibody adhered to an SPA bead (see the general illustration in Fig. 9.53), the following interactions adapted from Watson (1996) can be written:

where “Ag*” denotes the radioisotope-labeled antigen, “Ab-SPA bead” represents the antibody adhered to an SPA bead, and “Ag*-Ab-SPA bead” the complex between the radioisotope-labeled antigen and antibody on the SPA bead, which reach equilibrium when mixed together (Step 1). Immunoassays are quantitative analytical methods for measuring the amount of unlabeled antigen “Ag” in a sample based on the competitive binding of the unlabeled antigen and labeled antigen for the antibody. In other words, if we add unlabeled antigen to Eq. (9.44) (Step 2) in the form of either a standard solution or an unknown sample, the amount of labeled antigen bound to the antibody on the SPA bead will be reduced by the formation of unlabeled “Ag-antibody-SPA bead” complex (abbreviated Ag-Ab-SPA bead in Eq. 9.44), and the amount of radioactivity detected by the microsphere will diminish corresponding to the amount of unlabeled antigen added to the system. This is also referred to as competitive binding between the labeled antigen (Ag*) and unlabeled antigen (Ag) for the antibody (Ab). Given a limited concentration of antibody molecules attached to microspheres, adding

unlabeled antigen to the system will reduce the number of labeled antigen molecules associated with the microsphere. Consequently the rate of scintillation photon emission and radioactivity measured by the scintillation detector will be reduced correspondingly. If we compare this reduction in scintillation caused by unlabeled antigens in an experimental unknown sample to the same effects produced by known concentrations of unlabeled antigens used as standards, we can determine the concentration of the antigens in our unknown sample. With the preparation of an appropriate standard curve, the count rate of an unknown sample can be used to determine the amount or concentration of unlabeled antigen or ligand in the sample. An example of such a standard curve is illustrated in Fig. 9.55, which was prepared from a commercial SPA kit, also known as a Scatchard plot, is named after George Scatchard, who carried out many of the pioneering studies of macromolecule-ligand interactions. The ordinate gives the ratio of the radioactivity or quench-corrected count rate of the antibody-labeled antigen complex (B) to the radioactivity or quench-corrected count rate (B_0) of the antibody-

FIGURE 9.55 Standard curves (Scatchard plots) for the scintillation proximity assay (SPA) of cyclic AMP determined with a TopCount microplate scintillation counter and a conventional liquid scintillation counter using a commercially available SPA kit. From PerkinElmer (1991a,b); printed with permission © 1991 PerkinElmer, Inc.

labeled antigen complex in the absence of any unlabeled antigen. In other words, the nomenclature B/B_0 arises from the definitions of B = the antibody-bound radioactivity and B_0 = the antibody-bound radioactivity at zero dose of unlabeled antigen. The amount (e.g., fmol) or concentration (e.g., nM) of unlabeled antigen is plotted on the abscissa. The ratio B/B_0 may also be expressed as a percentage. It is obvious that, at zero dose of unlabeled antigen, $B = B_0$, and therefore, the ratio is unity or 100% when no unlabeled antigen is added to the medium. The ordinate may also be expressed in other units, which define the distribution of the radioisotope label, such as the ratio of the bound to the free fraction. The curve, illustrated in Fig. 9.55, shows the similarity in standard curves obtained with two types of detector systems, namely TopCount or MicroBeta microplate scintillation counters and conventional liquid scintillation counting. Both detector systems may be used for SPA. The microplate scintillation counter is preferred for high-throughput assays because the microplate scintillation counter provides the possibility of assaying up to 12 samples simultaneously, as discussed previously in this chapter.

The standard curve, illustrated in Fig. 9.55, is prepared from a given quantity of microspheres containing adsorbed antibody (20–200 μg), a given activity of ^3H - or ^{125}I -labeled antigen, and various amounts of unlabeled antigen. Adequate buffer, which may contain a low concentration (e.g., 0.1%) of bovine serum albumin (BSA), detergent, and 10%–12% glycerol are also added in a total volume of about 200 μL . The BSA serves as a nonspecific protein which, together with the detergent, helps reduce any nonspecific binding of the isotope-labeled antigen with the microspheres. The glycerol prevents settling of the microspheres, keeping them in suspension. The total sample volume is, therefore, very small and generally does not exceed 400 μL .

The small sample volumes involved in SPA (<400 μL) and the large numbers of samples that must be analyzed by most laboratories make SPAs of samples prepared in microplate formats most favorable. Samples may be prepared in sample microplates equipped with 24-, 96-, and 384-sample-well formats. The plates measure only $12.8 \times 5.6 \times 1.9$ cm (L \times W \times H). Automatic microplate scintillation analyzers are equipped to analyze up to 12 samples in microplates simultaneously. The sample wells are organized in three formats, namely, 24-well plates (6 \times 4 wells), 96-well plates (12 \times 8 wells), and 384-well plates (24 \times 16 wells), which accommodate the simultaneous analysis of up to 6 to 12 samples, respectively, by an equal number of PMTs in a microplate scintillation counter. Some applications of SPA as a tool in radioimmunoassay are reported by Meena et al. (2017), Wildey et al. (2017), Wheelan et al. (2015), Wang et al. (2013), Jackson et al. (2011), Shen et al. (2011) and Zhao et al. (2011).

c. Receptor binding assays

A receptor binding assay provides information on the relative competitiveness of ligands for binding sites on receptor molecules. The scintillation proximity technique with microsphere scintillator beads may be used to implement receptor binding assays. The technique involves mixing microsphere scintillator beads with solubilized or membrane-bound receptors such as membrane protein. The high affinity of the membrane protein for the microspheres is the basis of this assay. Once the receptor molecules are immobilized on the microspheres, a radioisotope-labeled ligand is added. The isotope-labeled ligand then binds to the receptor molecules on the microsphere beads [Scintillator coated microplates (e.g., FlashPlate or ScintiPlate described further on in this section of the chapter) may also be used in lieu of scintillating microspheres (Wildey et al., 2017; de Jong et al., 2005)]. The binding of the isotope-labeled ligand with the receptor molecule brings the isotope-labeled ligand into close proximity to the microsphere scintillator beads, which will excite the scintillator. The scintillation photons emitted from the microspheres can be assayed with the microplate scintillation counter. If, however, we add another competing ligand or drug (generally referred to as an analyte), which is not labeled with radioisotope, it will displace the isotope-labeled ligand on the receptor molecules according to its competitive affinity for the receptor and its concentration. The displacement of isotope-labeled ligand from the receptor into the medium solution and away from the scintillator microspheres will result in a reduction of the measured radioactivity. Different ligands over a range of ligand concentrations can be tested in this fashion against a given receptor. A Scatchard plot can then be drawn for each ligand as illustrated in Fig. 9.56 over the entire range of unlabeled competitive ligand concentrations tested where B = the bound ligand radioactivity and B_0 = the bound ligand radioactivity at zero dose of unlabeled competitive ligand. We can determine from the Scatchard plots which ligands or drugs tested have greater or lesser affinity for the receptor. The SPA Scatchard plots illustrated in Fig. 9.56 from the work of Nose et al. (2009) depict the competitive binding of various agonists estrogen receptor α ligand-binding domain (hER α -LBD), which contains a molecular pocket able to capture a hormone-like chemical to build up its activation conformations. The work of Nose et al. (2009) illustrated in Fig. 9.56 demonstrates that the 17 β -estradiol binds more strongly to the receptor molecule than 4-(1-adamantyl)phenol; and 4-*tert*-octylphenol and 4-*n*-octylphenol, which bind increasingly less strongly to the receptor molecule. In receptor binding assays the term IC_{50} and its value are often used to compare the competitive binding of antagonists for the receptor molecule. The IC_{50} is calculated as the concentration required to inhibit 50% of

FIGURE 9.56 Receptor binding assay using purified human estrogen receptor α ligand-binding domain (hER α -LBD receptor) and [3 H]17 β -estradiol radioligand over a range of four analyte concentrations (M) of 1×10^{-11} to 1×10^{-4} nM of 17 β -estradiol (open circle), 4-(1-adamantyl)phenol (closed circle), 4-tert-octylphenol (open triangle), and 4-n-octylphenol (closed triangle). From Nose et al. (2009); reprinted with permission from Elsevier © 2009.

the labeled ligand binding to its receptor. The relative IC₅₀ values for the four antagonists illustrated in Fig. 9.56 from left to right are 1.40, 82.3, 884 nM (nanomolar), and N.D (not determined, see the broken curve in Fig. 9.56), as reported by Nose et al. (2009).

Temperature can have a significant effect on SPAs. The work of Blair et al. (1995) demonstrates the significant differences in IC₅₀ values obtained over the temperature range 15–27°C. It can be important, therefore, to control assay temperature by using a scintillation counter, which has a temperature control. Reviews on the principles and applications of receptor binding assays is given by Wildey et al. (2017), Cook et al. (2006), Powell and Price-Jones (2006), and de Jong et al. (2005). There are numerous examples of the application of SPA to receptor binding studies in the current literature; and a select few are the

following: Luethi et al. (2018), Flanagan (2016), Meleza et al. (2016), Wang and Ma (2015), Zeng and Xu (2015), Dechavanne et al. (2011), Schepmann et al. (2011), Tawa et al. (2011), Stanley et al. (2010), Nose et al. (2009).

d. Enzyme assays

Enzyme assays can be included among the list of applications of SPA. Enzyme assays can be of two types: (1) the enzyme activity toward a substrate is determined by the hydrolytic action of the enzyme (e.g., protease or nuclease) on an isotope-labeled substrate attached to the SPA microspheres, resulting in the release of radioactivity from the scintillation microspheres; and (2) the enzyme activity toward a substrate is determined by the polymerizing action of the enzyme (e.g., polymerase or transferase) on a donor isotope-labeled substrate in the free medium, which becomes attached to the SPA microspheres, resulting in an increase in radioactivity detection from the scintillation proximity beads.

An illustrative example of a scintillation proximity enzyme assay is that of an ATPase assay reported by Jeffery et al. (2002) illustrated previously in Fig. 9.54. In this case, the enzyme catalyzes a reaction on a substrate, whereby the product of the reaction (33 P-inorganic phosphate) becomes attached to the SPA bead. As enzyme activity increases, an increase in radioactivity is observed from the SPA beads. Consequently enzyme kinetics and the effects of inhibitors on enzyme activity can be easily observed without the need of tedious procedures and separation steps. For example, Fig. 9.57 illustrates the ATPase reaction rates as a function of substrate (ATP) concentration and inhibitor ATP- γ -S concentration as measured with SPA. This serves as only one example of many enzyme activity measurements that can be carried out without the tedious preliminary preparations such as HPLC, electrophoreses, or centrifugation.

FIGURE 9.57 Observed reaction rates (ATPase activity) of HPV6 E1 (a E1 helicase from human papillomavirus) via SPA using [γ - 33 P]ATP substrate. (A) The observed rates (in pM inorganic phosphate, P_i, produced per s) for substrate concentrations ranging from 7.5 to 60 μ M at inhibitor (ATP- γ -S) concentrations of 0 (\bullet), 3.1 μ M (\blacksquare), 6.3 μ M (\blacklozenge), 12.5 μ M (\blacktriangle), 25 μ M ($*$), 50 μ M (\circ), and 100 μ M (\square). (B) The same data points plotted in double reciprocal format. From Jeffery et al. (2002); reprinted with permission from Elsevier © 2002.

FIGURE 9.58 Bead-based scintillation proximity assay for methyltransferase enzyme activity. From Zeng and Xu (2015); reprinted with permission from Elsevier © 2015.

Another example of enzyme assay with scintillating microspheres is described by Zeng and Wu (2015) in the measurement of methyltransferase enzyme activity analysis. The assay is illustrated in Fig. 9.58. The *in vitro* methylation assay catalyzed by the methyltransferase enzyme proceeds with a combination of substrate, methyltransferase, and a universal methyl donor labeled with ^3H (i.e., ^3H -SAM or *S*-adenosyl-*L*-methionine). The methyl group is transferred enzymatically to a nitrogen atom of lysine or arginine side chains of the protein substrate, which produces the ^3H -labelled methylated substrate and the SAH (*S*-adenosyl-homocysteine) substrate. Streptavidin-coated microscopic scintillating beads capture the ^3H -labelled biotinylated substrates subsequent to the methylation reaction. This brings the ^3H radionuclides in close proximity to the scintillation beads sufficient for the beads to absorb β -particles from ^3H decay exciting the scintillator with the emission of light detected by the microplate scintillation counter. Unreacted ^3H -SAM substrate remains in solution too distant from scintillation beads to produce any scintillation photons. This avoids any experimental need to filter off any unreacted substrate.

Numerous enzyme assays using SPA technology with scintillating microspheres can be found in the literature, among which the following are excellent examples: Flanagan (2016), Wang and Ma (2015), Zeng and Xu (2015), Kumar et al. (2014), Stevenson et al. (2013), Ojo et al. (2011), Scott et al. (2011), Sun et al. (2011), Thirstrup et al. (2011), and Zhang et al. (2010, 2011).

f. SPA with scintillating microplates

Microsphere scintillators are not the only means of carrying out SPA. It is also possible to use specially prepared 96- and 384-well polystyrene microplates, which contain plastic scintillator-coated wells to which are bonded the antibody or receptor molecules. An example of such a microplate is known as the FlashPlate. A diagram illustrating a FlashPlate microplate well with a radioisotope-labeled ligand (radioligand) in solution and another radioligand bound to a receptor molecule attached to the surface of the scintillant-coated well is shown in Fig. 9.59. The receptor molecules (capture molecules) are coated on

FIGURE 9.59 Diagram illustrating the principle of FlashPlate technology. The scintillant is embedded in a clear plastic coating on the inner wall of the microplate-well. Radioligand bound to the surface of the assay-well leads to the emission of light. Free radioligand, in solution and not proximal to the scintillant, causes only minor background emission. From Schnurr et al. (2007); reprinted with permission from Elsevier © 2007.

the plastic scintillator in each of the 96 or 384 wells of the microplate. Therefore, no scintillator beads are used. Radionuclide-labeled ligand is added and allowed to incubate with the receptor molecules. Only radionuclide labeled ligand bound to a receptor molecule on the surface of the plastic scintillator is in sufficiently close proximity to the plastic scintillator to produce a scintillation effect in the scintillator and the concomitant emission of light. Radioligand in the solution will be too far away from the capture molecules coated on the well surface and scintillator to produce any significant scintillation effect. The addition of unlabeled competitive binding ligand will reduce the number of radionuclide-labeled compounds on the capture molecules and thereby reduce the count rates detected by the microplate scintillation analyzer. The polystyrene-based scintillator on a microplate format provides the platform for nonseparation assays using low- and moderate-energy beta particle-emitting nuclides, such as ^3H ($E_{\text{max}} = 18.6 \text{ keV}$), ^{14}C ($E_{\text{max}} = 155 \text{ keV}$), ^{35}S ($E_{\text{max}} = 167 \text{ keV}$), ^{33}P ($E_{\text{max}} = 249 \text{ keV}$) and the atomic-electron emitter ^{125}I ($E_{\text{max}} = 30 \text{ keV}$).

An example of the application of the FlashPlate to enzyme assays is provided by Zeng and Xu (2015)

FIGURE 9.60 A FlashPlate-based in vitro scintillation proximity assay for methyltransferase activity. From Zeng and Xu (2015); reprinted with permission from Elsevier © 2015.

according to the illustration provided in Fig. 9.60. The figure illustrates a procedure for in vitro methylation assay with methyltransferase enzyme utilizing a FlashPlate-based SPA. In this case, a Streptavidin FlashPlate is used whereby biotinylated histone peptide or protein substrates are coated onto the wells of the Streptavidin FlashPlate. The methylation reaction is then initiated with the addition of methyltransferase and ^3H -S-adenosyl-L-methionine (^3H -SAM), which is a universal methyl donor labeled with ^3H . The methyl group is transferred enzymatically to a nitrogen atom of lysine or arginine side chains of the protein substrate, which produces the ^3H -labelled methylated substrate and the SAH (S-adenosyl-homocysteine) substrate. The ^3H label on the biotinylated histone peptide binds strongly to the Streptavidin; and the proximity of the ^3H label to the plastic scintillator coated onto the FlashPlate well produces scintillation photons from the beta decay, which are counted by a suitable microplate counter. The radiolabeled ^3H -SAM in solution in the sample well of the FlashPlate remains too distant from the scintillator coating to produce any scintillation events.

There are numerous literature references to the applications of FlashPlates in 96-well or 384-well microplate formats. A few examples will be cited here as applied to specific assays, including

- (i) immunoassays (Witkin et al., 2016; Lauritzen et al., 2014; McNamara et al., 2012; Moore, 2012a,b; Møller et al., 2011; Shen et al., 2011; Xiao et al., 2008; Hertel et al., 2007),
- (ii) receptor binding assays (Song et al., 2018; Flanagan, 2016; Wang and Ma, 2015; Knudsen et al., 2012; Harndahl et al., 2011; Shen et al., 2011; Matsushima et al., 2010; Bednarek et al., 2008), and
- (iii) enzyme assays (Prause et al., 2018; Yan et al., 2017; Pagire et al., 2015; Rutter et al., 2014; Yu et al., 2014; Oka et al., 2013; Dechavanne et al., 2011; Kharel et al., 2011; Thirstrup et al., 2011; Reynisson et al., 2009; Miesel et al., 2007), among other specific assays used in molecular biology studies.

g. Color quench correction

The main advantages of SPA are (1) the circumvention of separation steps usually linked to immunoassays, receptor binding assays, and enzyme activity assays, among other assays carried out in the medical and biochemical sciences; (2) the reduced costs per analysis arising from a reduction in reagent volumes consumed and the waste accumulated; and (3) the consequent high-throughput analysis possible when SPA is linked to automatic liquid handling and microplate sample counting techniques. The first advantage of the SPA technique listed above can give rise to colored samples because purification steps in the assay procedure are avoided. Color in the assayed samples can absorb the visible photons of light emitted by the microsphere scintillation beads or scintillator microplates before this light can reach the photomultipliers. Absorption of the light emissions will cause a reduction of the light intensities reaching the PMTs and consequently a reduction in the pulse heights registered by the scintillation counter. A reduction in count rate is generally the result because many reduced pulse heights fall below the detectable levels set by a LL pulse height discriminator setting. The phenomenon of reduced pulse heights and concomitant reduction in count rate of samples due to color of the sample is known as color quenching. It is important, therefore, that sample assays be corrected for color quench. We should keep in mind that chemical quench does not occur in SPA because this is a solid scintillation technique in which the beta particles from ^3H , ^{14}C , ^{35}S or ^{33}P radionuclides or the Auger electrons from ^{125}I enter into the solid scintillator to cause scintillation where no chemical quenching agents can be found.

The correction of quenched sample count rates (CPM) requires a measurement of the detection efficiency of each sample via a quench correction curve of counting efficiency or relative efficiency versus a suitable QIP such as that provided by an external standard (e.g., tSIE). However, fortunately the SPA technique does not require absolute activity measurements and the count rate of the sample

(CPM) will suffice provided the sample count rates are corrected for color quench. In reports by Hughes et al. (2001), Jones et al. (1997), Neumann et al. (1994), and PerkinElmer (2001, 1997), it is demonstrated that the quench-corrected count rate (QC-CPM) produced by a microplate scintillation counter is simple and provides accurate results for most SPAs. For example, the PerkinElmer TopCount and MicroBeta microplate scintillation counters can count simultaneously up to 12 wells of a microplate and, at the same time, determine the color quench of each sample from the sample pulse height spectrum. The QIP measured is the tSIS determined by the TopCount or spectral quench parameter [SQP(I)] or asymmetric quench parameter [AQP(I)] measured with the MicroBeta. A thorough treatment of QIPs and their use are provided in Chapter 6 of Volume 1. These QIPs are excellent for monitoring the color quench level of samples, because they are not affected by the color of the sample; that is, all color quench correction curves will be identical regardless of the color of the sample. A quench correction curve can be prepared using standard (e.g., ^3H -PVT, ^{125}I -PVT or other isotope) SPA beads according to the procedure described in detail in the references cited earlier in this paragraph. Of course, the standard isotope-labeled beads must contain the same radioisotope that is used for the SPAs. Fig. 9.61 illustrates the constant relationship between count rate and tSIS one can expect regardless of sample color. The count rate (CPM) on the ordinate of this curve can be converted to read percent relative efficiency by placing the highest count

rate (corresponding to the highest tSIS value) at 100% with all other count rates converted to a percentage relative to the highest count rate. In practice, a researcher will determine the average CPM of an unquenched radionuclide-bound microsphere scintillator sample (colorless sample) and then input this value into a counting protocol of the instrument to prepare a quench correction curve. Several quenched standards are prepared by adding the same amount of radionuclide-bound microspheres to sample wells including increasing amounts of color-quenching agent. The instrument will then count each sample (unquenched and quenched) and plot a quench curve of percent counting efficiency versus the QIP [e.g., tSIS, SQP(I), or AQP(I)]. Once the curve is prepared, it is stored in the memory of the microplate scintillation analyzer protocol so that each experimental sample that is counted can be corrected for color quench according to the QIP of the sample. For example, if an experimental sample gave a QIP value corresponding to a relative efficiency of 25% from a standard curve, and the count rate of the sample (CPM)_s was 5250, the instrument would calculate a quench corrected count rate (QC-CPM) as

$$\text{QC-CPM} = (\text{CPM})_s / E = 5250 / 0.25 = 21,000 \quad (9.45)$$

Hughes et al. (2001) demonstrated the application of this color quench correction technique to SPAs.

VI. Detection of neutrons

The neutron-induced nuclear reactions that occur in inorganic scintillator detectors as well as in scintillators of other types (e.g., organic), and scintillators in plastic or glass media depend on the energy of the neutron. Fast neutrons are detected in organic and plastic scintillator converters via proton recoil following elastic scattering (Shan et al., 2016; Meshkian, 2015; Li et al., 2014) or via converter material containing ^{232}Th or ^{238}U (Yamane et al., 1998, 1999), which undergo fast-neutron induced fission yielding fission products detectable with inorganic scintillators. Also, fast neutrons are detected by exploiting neutron capture reactions, such as the $^{35}\text{Cl}(n,p)^{35}\text{S}$ and $^{35}\text{Cl}(n,\alpha)^{32}\text{P}$ reactions with Cl in crystal scintillator (Giaz et al., 2016). Reviews on scintillation detectors for fast neutrons are provided by Ryzhikov et al. (2018, 2017), Giaz et al. (2016), Tarasenko et al. (2013), and Klein and Brooks (2006). Thermal neutrons, on the other hand, are detected on the basis of the high neutron reaction capture cross-sections with particular nuclides, such as ^6Li , ^{10}B , ^{155}Gd , ^{157}Gd , ^{235}U (Finocchiaro et al., 2018; Lo Meo et al., 2017; Köhli et al., 2016; Mendicino et al., 2015; Boatner et al., 2012; Oed, 2004; van Eijk, 2004; van Eijk et al., 2004).

FIGURE 9.61 Count rates versus the quench-indicating parameter tSIS observed with ^{125}I -labeled SPA beads on TopCount microplate scintillation counter with various concentrations of five different colors of dye. Similar curves are obtained with PerkinElmer MicroBeta microplate scintillation counters using the quench-indicating parameter [SQP(I)] or [AQP(I)] (see Hughes et al., 2001). From Neumann et al. (1994), printed with permission; © 1994 PerkinElmer Inc.

A. Inorganic neutron scintillators

Due to their low velocity and neutral charge, thermal neutrons are detected by means of their nuclear reaction with target nuclei. These reactions, first discovered by Enrico Fermi as described in Chapter 1, Volume 1, result in the emission of charged particles (e.g., protons, alpha particles, conversion electrons, or fission fragments) or gamma radiation. The ionization or scintillator excitation produced by these reaction products are the basis for the detection and measurement of thermal neutrons. Commonly used target nuclei for thermal neutron detection are ^3He , ^6Li , ^{10}B , ^{235}U , and ^{157}Gd due to their high thermal-neutron reaction cross-sections. The nuclear reactions of thermal neutrons with commonly used target nuclei for neutron detection are listed in Table 9.7. As described by Oed (2004) all of the reactions listed in Table 9.7, with the exception of that of ^{157}Gd , are fission processes with the two fission fragments ejected in opposite directions. The energies of the fission fragments are listed in Table 9.7.

Thermal neutron detection with ^3He listed in Table 9.7 involves gaseous ionization detectors; and these will not be treated in this chapter. Also, the current shortage of ^3He gas led to rigorous research and development of alternative neutron-capturing materials; and ^6Li and ^{10}B have become the current major nuclides of research for the development of thermal neutron detectors (Finocchiario et al., 2018; Lo Meo et al., 2017; Köhli et al., 2016; Mendicino et al., 2015; Boatner et al., 2012; Ianakiev et al., 2011). The natural abundance of ^6Li and ^{10}B are 7.5% and 19.9%, respectively. Also, natural Gd consists of several isotopes, among which ^{155}Gd (14.8% natural abundance) and ^{157}Gd (15.6% natural abundance) have very high thermal neutron capture cross-sections at low thermal neutron energies (see Fig. 9.62); although Gd detectors have some disadvantages discussed further on in this section. Thus, inorganic Gd crystalline scintillators (Pan et al., 2018b; Zaman et al., 2017; Trtik and Lehmann, 2015; Zhuravleva et al., 2011;

Sidletskiy et al., 2010; Kawamura et al., 2007) as well as Gd-loaded plastic scintillators (Watanabe et al., 2015; Ovechkina et al., 2009) also receive due attention in the development of thermal neutron detector materials.

The reactions abbreviated in Table 9.7 are described in more detail by van Eijk et al. (2004) for the key target nuclei utilized in the scintillation measurement of thermal neutrons, i.e., ^6Li , ^{10}B , ^{155}Gd , and ^{157}Gd according to the following reactions where the natural abundance (%) is given alongside each target isotope, the neutron-capture cross-sections are expressed as σ (b = barns) at a neutron wavelength of 1 Å, and the relevant branching ratios (BRs) are given:

About 80% of the neutron captures in Gd occur in ^{157}Gd and 18% of the neutron captures occur in ^{155}Gd (Reeder, 1994b). As described in Chapter 1, Volume 1, the

TABLE 9.7 Commonly used isotopes for thermal neutron detection, reaction products and their kinetic energies.

	Reaction	Light fragment (l.fr)	Energy (MeV)	Heavy fragment (h.fr.)	Energy (MeV)
	$n (^3\text{He}, p) ^3\text{H}$	p	0.57	^3H	0.19
	$n (^6\text{Li}, \alpha) ^3\text{H}$	^3H	2.74	α	2.05
93%	$n (^{10}\text{B}, \alpha) ^7\text{Li} + \gamma$	α	1.47	^7Li	0.83
7%	$n (^{10}\text{B}, \alpha)$	α	1.77	^7Li	1.01

FIGURE 9.62 Neutron-capture cross-sections of some isotopes important for neutron detectors as a function of neutron energy. The lowest curve shows a typical moderated neutron spectrum of a nuclear reactor (right y-axis). From van Eijk (2004); reprinted with permission from Elsevier © 2004.

neutron-capture cross-sections are a function of the neutron energy. The cross-section (σ) as a function of the neutron energy for the above reactions 9.46–9.49 were plotted by van Eijk (2004), which is illustrated in Fig. 9.62. While ^{157}Gd has the highest neutron-capture cross-section for cold neutrons and the low-energy fraction of thermal neutrons, its neutron-capture cross-section drops rapidly at neutron energies $> \sim 0.050$ eV; and ^6Li and ^{10}B have the highest neutron-capture cross-sections at neutron energies > 1 eV, as illustrated in Fig. 9.62.

The linear absorption coefficients μ_n , which has units of cm^{-1} (see Chapter 1, Volume 1), were calculated by van Eijk (2004) as a function of the neutron-capture cross-sections and the weight fraction of the neutron-sensitive nucleus in various scintillators containing 100% enriched ^6Li , ^{10}B , and natural and depleted Gd. The absorption lengths or inverse of the absorption coefficients, $1/\mu_n$ ($\sim 63\%$ absorption) were plotted by van Eijk et al. (2004) as a function of neutron wavelength, which is illustrated in Fig. 9.63. In the thermal region, the neutron absorption lengths are only of the order of tens of μm for natural Gd ($^{\text{nat}}\text{Gd}$) scintillators, 0.1 mm for ^{10}B scintillators, and 1 mm for ^6Li scintillators. The very short absorption length of thermal neutrons in Gd scintillator compounds was reported by Reeder (1994a,b), who studied thermal neutron scintillation in gadolinium orthosilicate, Gd_2SiO_5 (GSO), and noted that thick GSO crystals are not required, as thermal neutrons will penetrate only the first 11 μm from the surface of the GSO crystal. The small size requirement of this detector for thermal neutrons is an advantage in applications in which detector size is a limiting factor. In addition, GSO is reported to have a light output of about 20% of that of $\text{NaI}(\text{TI})$ and a short decay time constant of

FIGURE 9.63 Absorption lengths of typical inorganic scintillator compounds based on ^6Li , ^{10}B , and $^{\text{nat}}\text{Gd}$ as a function of neutron wavelength. The absorption lengths are positioned into three zones for the ^6Li , ^{10}B , and $^{\text{nat}}\text{Gd}$ compounds; and data for some traditional and new neutron scintillators are shown. Li_6 (without superscript) and $^{\text{dep}}\text{Gd}$ represent natural Li and depleted Gd, respectively. From van Eijk et al. (2004); reprinted with permission from Elsevier © 2004.

60 ns (Table 9.4) suitable for measuring arrival times of neutrons from a pulsed source at high count rates (Ishibashi et al., 1998; Tokanai et al., 2000).

The thermal neutron capture product nuclides ^{156}Gd and ^{158}Gd are themselves stable nuclides; however, the binding energies of the neutron capture processes leave the nuclides in an excited state. Deexcitation of ^{156}Gd and ^{158}Gd results in a release of a cascade of gamma rays (up to 2 MeV), X-rays, and conversion electrons (Takanai et al., 2000). Knitel (1998) noted that the thermal neutron capture reactions of gadolinium yield high probabilities of internal conversion. The internal conversion electrons have short ranges in the scintillator yielding fluorescence close to the point of neutron interaction. The 29-keV conversion electrons, because of their charge, have a range of only about 2 μm in the GSO and, therefore, these do not escape the crystal and produce excitation and luminescence. The 44-keV X-rays produced have a range of about 75 μm in GSO. Reeder (1994b) explains that about half of these escape from the GSO crystal without detection because the thermal neutron capture occurs near the crystal surface. Also, the probability for the production of only γ -rays is $\sim 20\%$ (van Eijk et al., 2004). In addition, the gamma radiation produced has a very high probability of escape from the scintillation detector (i.e., essentially all of the gamma radiation escapes as reported by Knitel (1998) and van Eijk et al. (2004)). The gamma radiation escape would be due again to the fact that the thermal neutron capture occurs near the crystal surface, the small size of the detector, and the greater penetrating power of the gamma radiation. Knitel (1998) provides an excellent example of the relevance of high probability for internal conversion. He provides the example of ^{113}Cd , which has a very high thermal neutron capture, but a relatively low probability of internal conversion, only 4% that of ^{155}Gd and ^{157}Gd .

For the detection of 6 Å cold neutrons, Tokanai et al. (2000) characterized a 0.5 mm-thick GSO:Ce scintillator activated with a Ce concentration on 0.5 mol % coupled to a PMT. They obtained a pulse height spectra with clear 31 and 81 keV peaks corresponding to conversion electrons or X-ray singles peaks and their coincidence doubles peaks, respectively. A position resolution of 1.3 mm FWHM of a two-dimensional neutron image was measured. Tokanai et al. (2000) concluded that with a GSO scintillator as thin as 20 μm, more than 90% of 80 keV gamma rays and 44 keV X-rays, induced by neutron absorption by Gd, would escape the GSO scintillator, and the main component of the pulse height spectrum would be the 31 keV X-ray conversion electron peak. This is ideal for the reduction of background from gamma- and X radiation and, in addition, the spatial resolution would be improved because the range of 31 keV conversion electrons in GSO is only 2 μm. The neutron position resolution in such a detector system would be limited only by the light imaging system.

While thermal neutron detectors based on natural gadolinium have specific applications, van Eijk et al. (2004) point out that Gd scintillators are less attractive because of several factors including the small amount of energy deposited in the Gd detector, the ~80% limit on its detection efficiency (i.e. ~20% is lost as undetected gamma radiation), and the absence of the possibility of neutron-gamma discrimination, among other factors. Thus, research and development are focused on scintillator compounds with ⁶Li as the target nucleus as well as some compounds containing ¹⁰B target nuclei (Mahl et al., 2018; Giaz et al., 2016; Celentano et al., 2015; Ianakiev et al., 2015; Lee et al., 2013). An advantage of ⁶Li and ¹⁰B over Gd, as target nuclei in scintillation detectors for the detection of neutrons, is that the reaction products are relatively heavy nuclei, which obviously have very short ranges in the scintillator detectors with total energy absorption. The energies of the product nuclei are of the order

of magnitude of a few MeV (see Eqs. 9.46–9.49); and their ranges in a scintillator generally are ≤40 μm (van Eijk et al., 2004).

Thermal neutron scintillators along with their properties and limitations are listed in Table 9.8. Compounds are synthesized with enriched ⁶Li at 95 atom % or higher to enhance thermal neutron capture. The column of mean free path (mm) of Table 9.8 is also referred to as the neutron absorption length (mm); and these values are calculated at a neutron wavelength of 1.8 Å. The mean free path is calculated as the inverse of the absorption coefficient, which is a function of the neutron energy or wavelength. The term α/β ratio in the last column of Table 9.8 refers to the ratio of the number of photons per MeV produced by the heavy charged particles (e.g., ³H and ⁴He product nuclides from thermal neutron capture by ⁶Li) and the number of photons produced by electrons from gamma-ray interactions via photoelectric, Compton, and pair-production interactions. A high α/β ratio is preferred to facilitate discrimination between neutron radiation and background gamma.

Research and development in thermal neutron scintillators include the following, among other detector designs:

- (i) ⁶Li-glass scintillator (Ianakiev et al., 2015; Rich et al., 2015; Fukabori et al., 2011a), ⁶Li-loaded plastic scintillator (Balmer et al., 2015),
- (ii) ⁶Li metal foil sandwiched together with scintillator and light pipe (Ianakiev et al., 2011, 2015),
- (iii) ⁶Li-enriched crystal scintillators, such as, Cs₂LiYCl₆:Ce (Qin et al., 2018; Giaz et al., 2016),
- (iv) LiAlO₂ (Pejchal et al., 2011), ⁶LiCaAlF₆ (Iwanowska et al., 2011), LiSrAlF₆ (Yanagida et al., 2011),
- (v) mixed-alkali rare-earth double phosphate [e.g., CsLi₂Lu(PO₄)₂] scintillator (Neal et al., 2007),
- (vi) the measurement of ultracold neutrons (UCNs) with ⁶Li-glass scintillator (Jamieson and Rebenitsch, 2015; Ban et al., 2009), and

TABLE 9.8 Properties of state-of-the-art thermal neutron scintillators.

Host material	Dopant	Density (g/cm ³)	Mean free path at thermal energy (mm)	Decay time(s) (ns)	Limitations
⁶ Li glass	Ce	2.5	0.52	75	Poor light output; low α/β ratio
LiI	Eu	4.1	0.54	1400	Gamma sensitize; hygroscopic
LiF/ZnS	Ag	2.6	0.8	>1000	Poor efficiency; slow
LiBaF ₃	Ce,K,Rb	5.3	7.9	1/34/2100	Long mean free path; UV window needed; intrinsic radioactivity
Cs ₂ LiYBr ₆	Ce	4.1	3.7	89/2500	Large mean free path; hygroscopic; neutrons absorbed in Cl and Cs

FIGURE 9.64 Lithium foil sandwich detector concept. The ^6Li sheets are shown in red, the PVD scintillator film is shown in blue, and the polymethyl methacrylate (PMMA) light-guide strips and fishtail light guide are shown in yellow. The electronic version of this text will display the color coding of the elements of the sandwiched neutron detector. From *Ianakiev et al. (2011)*; reprinted with permission from Elsevier © 2011.

- (vii) the suppression of gamma-radiation background with the design of a portable double photodiode coincident readout system using a 96% enriched $^6\text{Li}(\text{Eu})$ neutron detector (*Yang et al., 2011*).

The use of thin ^6Li foil sandwiched between scintillator and strips of light guide is an interesting neutron detector design reported by *Ianakiev et al. (2011)* to reduce interference from gamma radiation. The detector design is illustrated in *Fig. 9.64*. The thermal neutrons are captured by the ^6Li metal foil, the charged particles produced (primarily Triton) are detected by a physical vapor deposition (PVD) scintillator, and the light guide sandwiched with the scintillator transfers the light photons from the scintillator to PMT tubes on either side of the sandwiched detector. Gamma energy discrimination is improved by low-energy deposition in the thin scintillator film.

With the objective of designing a detector with properties similar to ^3He tubes embedded in a High Density Polyethylene (HDPE) moderator, *Ianakiev et al. (2015)* designed a ^6Li glass scintillator as a thermal neutron detector due to the attractive properties of ^6Li glass scintillator, which include excellent light output with a single peak neutron response (~ 7000 photons/neutron), very good thermal neutron macroscopic cross-section (15 cm^{-1}), fast light decay time ($\sim 70\text{ ns}$), and the flexibility of glass to be fabricated into any desirable shape or size. The only drawback of using ^6Li glass scintillator is its gamma sensitivity, which *Ianakiev et al. (2015)* were able to reduce by embedding small ^6Li glass scintillator particles attached to a glass support structure embedded in an organic light-guide medium consisting of a mineral oil, which matches the indices of refraction and minimizes the scintillation light output at 396 nm. They demonstrate with various neutron and gamma-ray sources very good separations of neutron and gamma distributions (see *Fig. 9.65*) with normalized plateau characteristics similar to ^3He detectors.

Another sandwich detector design was reported by *Ban et al. (2009)* for the detection of ultra-cold neutrons (UCNs), which is illustrated in *Fig. 9.66*. The detector consists of a ^6Li -depleted glass scintillator sandwiched together with a ^6Li -enriched glass scintillator. Both scintillators are of $100\text{ }\mu\text{m}$ thickness. The principle of the UCN detection design is depicted in *Fig. 9.66*. A UCN crosses the ^6Li -depleted scintillator and then reaches the ^6Li -enriched scintillator. A neutron capture occurs close to the entrance surface of the ^6Li -enriched glass scintillator,

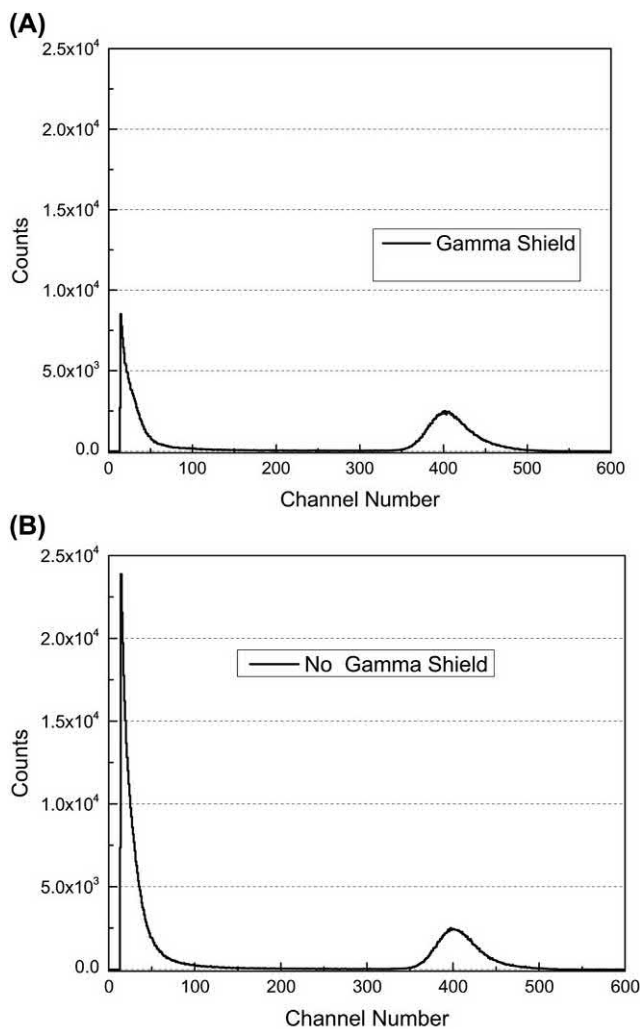

FIGURE 9.65 ^{252}Cf pulse height spectra: (A) with lead gamma shield and (B) without lead shield. The spectra are normalized to the neutron peak to show the difference in the gamma pulse-height distribution. From *Ianakiev et al. (2015)*; reprinted with permission from Elsevier © 2015.

the escaping Triton, which has a range of $37\text{ }\mu\text{m}$ deposits its energy in the upper scintillator; whereas, the alpha particle deposits its energy in the first $6\text{ }\mu\text{m}$ of the lower scintillator. The differences in the ^6Li densities of the depleted and enriched scintillators are 6.5×10^{17} and $2.2 \times 10^{22}\text{ cm}^{-3}$, respectively. Thus, the UCN absorption length, based on the ^6Li neutron capture reaction for UCN velocities ranging from 3 to 10 m/s, are determined to vary

FIGURE 9.66 Scheme of an Ultra-Cold Neutron (UCN) detector. From Ban et al. (2009); reprinted with permission from Elsevier © 2009.

between 2.4×10^4 and $7.7 \times 10^4 \mu\text{m}$ for the ^6Li -depleted scintillator and between 0.6 and $2.2 \mu\text{m}$ for the ^6Li -enriched scintillator (Ban et al., 2009). Thus, the upper ^6Li -depleted scintillator is practically transparent to the UCN; whereas, all UCN are stopped in the lower ^6Li -enriched scintillator. The events occurring at the edge or interface between the two scintillators lead to full energy deposition and a greater discrimination between the UCN and gamma background contribution (Ban et al., 2009). The two sides of this type of detector are very similar to the microscopic level, as both sides consist of cerium-doped lithium glass, one side depleted in ^6Li and the other side enriched in ^6Li . It is important therefore to determine which side of the glass should face toward the UCN source. Jamieson and Rebenitsch (2015) report a method of determining, which side of the glass is enriched with ^6Li with the use of a Si surface barrier detector, which sees an excess of events of α and Triton energies of neutron capture when the enriched side is facing the Si surface barrier detector and the detector is exposed to an AmBe and ^{252}Cf neutron sources.

A coincidence photodiode (PD) detector design with a 96% enriched $^6\text{LiI(Eu)}$ neutron detector as a portable handheld neutron-sensitive device capable of discriminating against background gamma radiation was reported by Yang et al. (2011). The detector utilizes a coincident readout by two PDs attached to two sides of a $^6\text{LiI(Eu)}$ crystal scintillator. The output signal is accepted only when both PDs register a coincident output signal; and the probability for a gamma-ray to generate a significant pulse in the active volumes of both PDs simultaneously is very low. Yang et al. (2011) demonstrated the method to effectively suppress gamma-radiation background in the neutron counting window to natural background levels. A gamma-radiation background of 0.034 CPS is reported with three ^{137}Cs sources having a total activity of $128.1 \mu\text{Ci}$ in contact with the detector. Such low gamma-ray

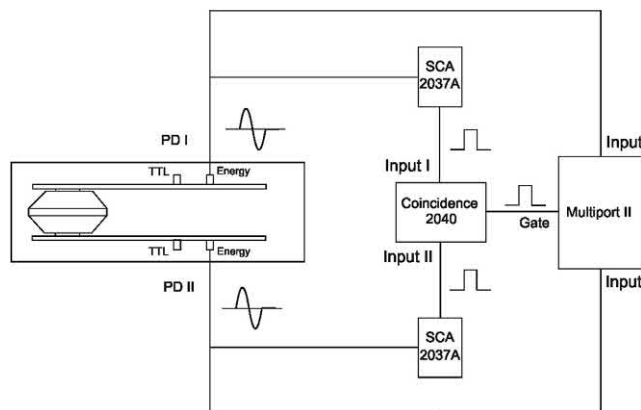

FIGURE 9.67 Coincidence electronics schematic of a portable handheld neutron detector. From Yang et al. (2011); reprinted with permission from Elsevier © 2011.

backgrounds would be equivalent to a probability of $1.69 \times 10^{-6}\%$ for a 662 keV gamma-ray from the ^{137}Cs impinging on the detector to create a false coincident event. Pulse-shape discrimination could be used to discriminate against gamma-radiation; however, that would increase the size and weight of the hand-held device. To avoid this Yang et al. (2011) modified the conventional detector design by placing two PDs on either side of a $^6\text{LiI(Eu)}$ neutron scintillator and combined this with a coincidence circuit, illustrated in Fig. 9.67, that would accept relevant neutron events in the scintillator. The high intrinsic thermal neutron detection efficiency of 99.83% together with the coincidence circuitry provide the hand-held detector with high gamma-discrimination capability, which is needed generally in scenarios involving the inspection of special nuclear materials.

The detector and its associated electronics, as described by Yang et al. (2011), is very compact, as it is all housed within an aluminum enclosure measuring externally only $89 \times 36 \times 30 \text{ mm}$. The detector consists of a $^6\text{LiI(Eu)}$ crystal of 1 in. (2.5 cm) diag. by 3 mm thick coupled with a light guide on each side with two PDs on both sides of the crystal, which are labeled in the schematic of Fig. 9.67 as PD I and PD II. The PDs have a compact $10 \times 10 \text{ mm}$ active area with a 0.3 mm depletion layer thickness. The readout circuit has a built-in preamplifier and shaping amplifier. The outputs are one analog energy signal and one TTL (transistor–transistor logic) timing signal. The energy signal has a bipolar shape with 3 μs shaping time. The TTL is generated at the zero crossing point of the bipolar energy pulse, which is fed from the front end electronics to an SCA (2037A) and an input on the Multiport II multichannel analyzer (Canberra MCA). The gate on the MCA is only open when the coincidence output is active, which ensures that only the coincident outputs of both PDs are registered in the MCA.

From Fig. 9.62, illustrated previously in this chapter, it can be seen that the neutron capture cross-section of the ^{10}B target nucleus is much greater than that of ^6Li throughout the cold, thermal and epithermal neutron energy regions. We would expect, therefore, that replacing ^6Li with ^{10}B in scintillator compounds would improve neutron detection efficiency. However, ^{10}B scintillator compounds as neutron converters result in decreased light yields when compared to ^6Li scintillator compounds, which is due to the reduced nuclear reaction energy of ^{10}B and to the degradation in the transparency of the ^{10}B compounds (Kojima et al., 2004). The Q value of the $n(^6\text{Li}, \alpha)^3\text{H}$ reaction is 4.78 MeV; whereas, the Q value of the $n(^{10}\text{B}, \alpha)^7\text{Li}$ is only 2.79 MeV. Research into the development of efficient ^{10}B scintillators is ongoing (Mahl et al., 2018; Pan et al., 2018; Yin et al., 2018; Celentano et al., 2015). Kojima et al. (2004) indicate that the reduced light yields can be overcome somewhat by placing the scintillator (e.g., ZnS:Ag) and ^{10}B compound (e.g., $^{10}\text{B}_2\text{O}_3$) as close as possible so that the scintillator can receive efficiently the energy of the α - and ^7Li -particle. Also increasing the transparency of the scintillator is important. Ishii et al. (2005) studied Ce-doped oxide glass containing B and Li. The light output of the $\text{B}_2\text{O}_3\text{--Li}_2\text{O:CeO}_2$ glass by neutron irradiation was 9.2% of Li-glass; however, the low density, high neutron absorption and short decay time (30–45 ns) provide this glass scintillator with the properties useful to neutron detection. Fujimoto et al. (2011) have synthesized Ce-doped $\text{Ba}_3(\text{BO}_3)_2$ crystals as neutron scintillators, which exhibit short decay times (~ 36 ns); however, light yield is still a limiting property, which can be increased with improvements in crystalline quality.

B. Solid organic neutron scintillators

Organic scintillators are rich in protons and thus effective moderators of fast neutrons. Proton recoil resulting from elastic scattering of fast neutrons in solid organic scintillators can result in the transfer of most if not all of the neutron energy to protons depending on the scintillator dimensions. A fast neutron of a few MeV can lose 90% of its energy via collisions with protons during the first 10 ns in the scintillator (Fisher et al., 2011). As described in Chapter 1, Volume 1, the maximum energy, that may be transferred by a fast neutron to a recoil proton via a head-on collision, would be equivalent to the neutron energy. The recoil protons, which are charged particles, can then deposit their energy in the organic scintillator; and the scintillation photon intensities measured with a PMT or PD. Pulse shape discrimination (PSD), which is discussed further on in this chapter, may be used to discriminate between pulse events produced by the recoil protons and those produced by electrons, which result from background gamma-ray photon interactions in the organic scintillator.

Various forms of organic scintillators serve as fast neutron detectors including:

- (i) organic crystalline materials such as stilbene or *p*-terphenyl (Becchetti et al., 2018; Carman et al., 2018; Grodzicka-Kobylka et al., 2018; Bourne et al., 2016; Sardet et al., 2015; Yanagida et al., 2015; Tarasenko et al., 2013; Robinson et al., 2011; Mertens et al., 2010; Hull et al., 2009; Budakovsky et al., 2007),
- (ii) plastic scintillators available commercially from suppliers or prepared in the laboratory, such as polystyrene-based plastic containing primary and secondary fluors (e.g., 1% PPO and 0.1% POPOP, among others (Roy et al., 2018; Yu et al., 2017; Hartman et al., 2015; Lawrence et al., 2014a,b; Stevanato et al., 2011; Ovechkina et al., 2009), and
- (iii) plastic scintillators doped with target nuclei having high neutron capture cross-sections, such as ^6Li , ^{10}B , or $^{155,157}\text{Gd}$ (Dumazert et al., 2018, 2016; Mahl et al., 2018; Balmer et al., 2015; Pawelczak et al., 2014; Zaitseva et al., 2013). This type of plastic neutron detector offers the possibility of capture-gated neutron detection for discrimination against undesirable background events.

Stilbene crystal slabs may be solution-grown up to 10 cm in thickness, as illustrated in Fig. 9.68; and organic polycrystalline detectors of diameters up to 25 cm can be made by pressing crystalline powder of *p*-terphenyl doped with diphenylbutadiene molecules or stilbene crystals from

FIGURE 9.68 A deuterated stilbene- d_{12} crystal grown in the shape of a hexagon. The initial seed is still seen through the optically transparent material that does not show any visible defects. The crystal mass is 38 g with a height of 35 mm. The crystal bottom has prints of the square marks lined on the platform for the growth rate measurements. From Carman et al. (2018); reprinted with permission from Elsevier © 2018.

a melt (Carman et al., 2018; Zaitseva et al., 2015; Budakovsky et al., 2007). Currently the most well-investigated organic crystal scintillator for the measurement of fast neutrons, in a n/γ mixed field with good n/γ PSD, is stilbene (Hull et al., 2009). The crystalline stilbene may be prepared at proton natural abundance or deuterated to facilitate PSD (Carman et al., 2018). The stilbene scintillators may be manufactured as single crystals grown from a melt or from stilbene crystalline powder and polymerized in a compound transparent to scintillation photons (Budakovsky et al., 2007; Robinson et al., 2011).

The response of stilbene scintillator as a single crystal measuring 30 mm in diameter \times 30 mm in length to fast neutrons from a ^{239}Pu –Be source was compared to that of stilbene scintillators prepared from stilbene crystalline powder by Budakovsky et al. (2007). Three scintillators measuring 25 mm diameter \times 20 mm length were prepared with stilbene powder having three different stilbene powder particle-size dimensions $L < 0.5$ mm, $L = 1 \dots 2$ mm, and $L > 2.5$ mm. The three stilbene crystalline powder fractions were immersed into a glue compound that yielded a silicone scintillator matrix transparent to scintillation photons. The response of the various stilbene scintillators to fast neutrons from a ^{239}Pu –Be source is illustrated in Fig. 9.69.

FIGURE 9.69 Recoil proton spectra of ^{139}Pu –Be source of fast neutrons for a reference stilbene scintillator consisting of a single crystal (curve 1) and for the composite scintillators prepared on the base of stilbene crystalline powder in silicone matrix. The fractions of stilbene powder are $L < 0.5$ mm (curve 2), $L = 1 \dots 2$ mm (curve 3), and $L > 2.5$ mm (curve 4). The relative efficiencies for the detection of the fast neutrons are 0.12, 0.83, and 0.78 for the composite scintillators yielding curves 2, 3, and 4, respectively, compared to the reference scintillator consisting of a single crystal (curve 1). From Budakovsky et al. (2007); reprinted with permission from Elsevier © 2007.

Budakovsky et al. (2007) used pulse-shape n/γ discrimination to obtain the proton-recoil spectra from the ^{239}Pu –Be neutrons net of the accompanying gamma radiation. The recoil proton pulse height spectra cover a broad range of energies, as the neutrons can undergo numerous scatterings in the organic crystal yielding proton recoil energies varying between zero and the neutron energy. The stilbene reference detector consisting of a single crystal yields the highest neutron detection efficiency and higher light yield than the composite stilbene neutron detectors prepared from crystal powders. The composite scintillator made from very fine-meshed stilbene crystalline powder (<0.5 mm) yields the lowest neutron detection efficiency. This may be due to proton scattering that can occur close to the surface of the small crystalline powder resulting in the emission of the recoil proton after depositing only a fraction of its energy in the crystal. The range of a 2 MeV recoil proton in the stilbene is only ~ 0.07 mm (Budakovsky et al., 2007); however, the elastic scattering of fast neutrons in the small crystal powder (<0.5 mm) at depths of <0.07 mm can result in the emission and loss of the recoil proton from the scintillator.

The current limited supply of ^3He has sparked a concerted research effort to find suitable alternatives for neutron detectors; and the performance of these new detectors is sometimes compared to that of ^3He . Robinson et al. (2011) used a Monte Carlo N-Particle (MCNP) radiation transport code to simulate the performance of stilbene crystals of various dimensions as fast neutron detectors compared to that of a ^3He detector embedded in a moderator, which is commonly used as a radiation portal monitor. The intrinsic detection efficiency of each of the neutron detectors, which is defined as the number of neutrons counted per neutron incident on the detector surface, was used to evaluate detector performance. The simulated response of stilbene crystal detectors, based on perfect discrimination between neutron and gamma radiation events, relative to that of the moderated ^3He detector system is illustrated in Fig. 9.70. All detectors were attributed the same counting geometry and same solid angle so that the collection efficiency (neutrons incident on the detector per emitted neutron) were the same for all detectors). As seen from Fig. 9.70, optimum neutron detection is a function of stilbene crystal thickness; and the efficiency of the moderated ^3He detector system is that of the horizontal line. To achieve equivalent intrinsic efficiency to the moderated ^3He system, while maintaining the same detector area, require stilbene thicknesses in excess of 2 cm, given contemporary pulse-shape discrimination thresholds (Robinson et al., 2011).

Organic scintillators including plastic scintillators loaded with target nuclei having high thermal neutron capture cross-sections (e.g., ^{10}B or ^6Li) can serve as excellent detectors of fast neutrons via the principle known

FIGURE 9.70 Simulated intrinsic efficiencies of stilbene crystal detectors as a function of thickness for several PSD thresholds (labeled by neutron energy) and that of a moderated ^3He detector system. From Robinson et al. (2011); reprinted with permission from Elsevier © 2011.

as **capture-gated neutron detection**. The organic scintillator has a high density of protons, which can moderate efficiently the energy of the fast neutrons, as described in Chapter 1, Volume 1. The principle of capture-gated neutron detection is illustrated in Fig. 9.71. As described by Fisher et al. (2011), a fast neutron enters the organic scintillator; and elastic scattering causes a proton recoil with approximately half (on average) of the neutron energy, producing scintillation light. The neutron then scatters off another proton producing a second recoil proton (see Fig. 9.71); and the neutron continues to scatter until it leaves the detector volume or is captured generally at thermal energies by a target nucleus, such as ^6Li or ^{10}B , which have a high thermal neutron capture cross-section. The major portion of the detected scintillation light will come from the recoil protons; and a neutron of a few MeV energy will lose 90% of its energy in the organic scintillator via neutron scattering with proton nuclei during the first 10 ns in the scintillator (Fisher et al., 2011). The thermalized neutron will diffuse in the scintillator until it is captured by a nucleus particularly that of an isotope that was introduced into the crystal during its manufacture, because of its high thermal neutron capture cross-section, such as ^6Li or ^{10}B . The time to capture of the fast neutron from the time of its entry into the scintillator is ~ 100 ns depending on the size and geometry of the scintillator and the isotope and its concentration introduced into the scintillator as a capture target nucleus. The delayed-coincidence signature (i.e., the fast proton recoil scintillation at ~ 10 ns and the delayed capture scintillator at ~ 100 ns) indicates that the fast neutron dissipated essentially all of its energy within the scintillator, which provides

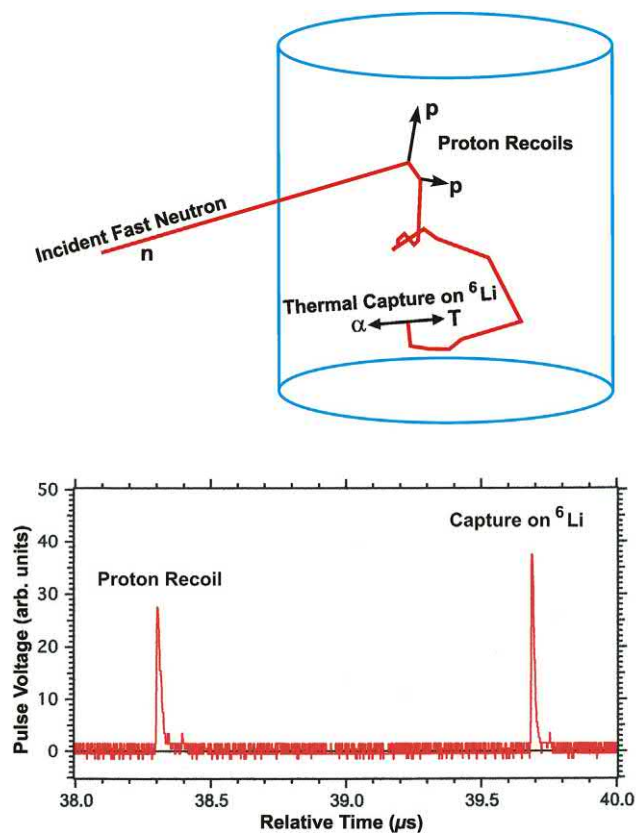

FIGURE 9.71 (Upper) An illustration of the principle of capture-gated detection. A fast neutron impinges on the detector. It rapidly gives up its energy primarily with protons. The thermalized neutron diffuses in the medium until it is captured by a nucleus with a high capture cross-section. (Lower) Plot of the PMT pulse of the detector response to a fast neutron within a scintillator following fast neutron scatter with proton recoil and neutron capture on ^6Li . Time difference between the two events is ~ 1.4 μs . From Fisher et al. (2011); reprinted with permission from Elsevier © 2011.

a method for the rejection of uncorrelated background events together with PSD (Fisher et al., 2011; Wilhelm et al., 2017).

Britvich et al. (2005) recommends ^{10}B isotope in natural boron as a target isotope in molded polystyrene scintillators in lieu of ^6Li target nuclei. The ^{10}B has a natural abundance of 19.9%, which can be suitable for fast neutron measurements in plastic scintillators; and it avoids the expensive procedures of its enrichment. Boron-10 also has a higher neutron-capture cross-section than ^6Li (see Fig. 9.62); although ^6Li is often used as a target nucleus at very high isotope enrichments exceeding 95%. Quarenta et al. (2011) report the synthesis and testing of boron-doped polysiloxane scintillators with boron concentrations ranging from 4 wt.% up to 8 wt.% with excellent sensitivity to fast and thermal neutrons measurement. Holm et al. (2014) designed a capture-gated neutron spectrometer with boron loaded plastic scintillator with 5% weight with excellent

neutron and gamma photon discrimination with one out of 10^5 photons misclassified. The capture-gated neutron detection in ^{10}B -doped scintillator is illustrated in Fig. 9.72. With a ^{10}B -loaded liquid rather than a solid scintillator, Hunt et al. (2016) provide an excellent example of a detailed analysis of PSD in capture-gated neutron spectrometry. Fig. 9.72 illustrates two possibilities for the interaction of incident neutrons in the ^{10}B -doped

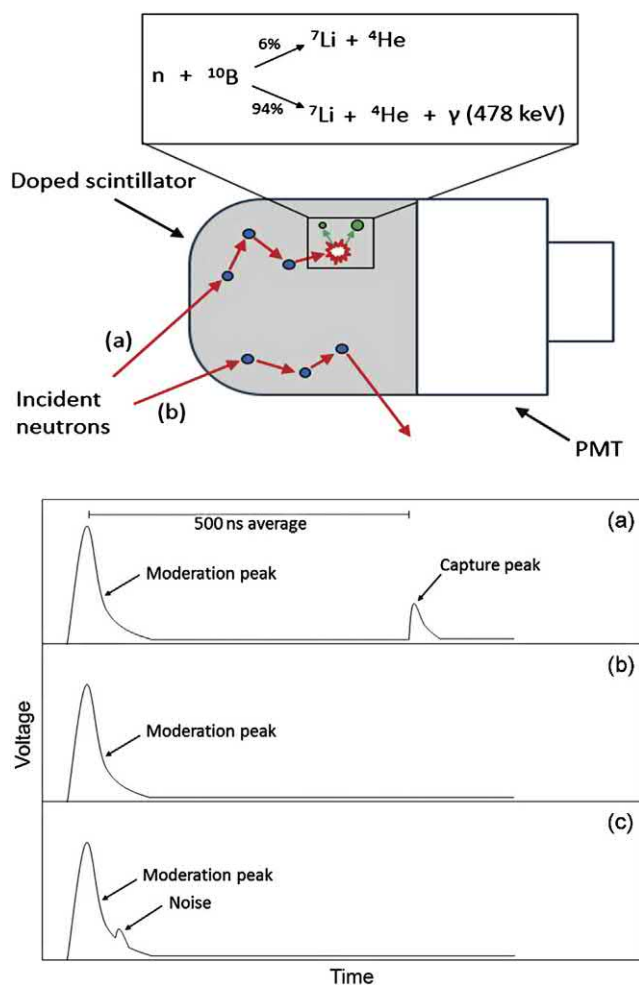

FIGURE 9.72 Upper Panel: Neutron-induced events in a ^{10}B doped liquid scintillator. (a) Full energy deposition of fast neutron energy, giving rise to the waveform shown below plot (a). (b) Partial energy deposition of fast neutron energy, giving rise to the waveform shown below in plot (b). Lower Panel: Schematic waveforms of a ^{10}B -doped liquid scintillator. (a) From full energy deposition of an incident fast neutron. The first peak is caused by the moderation of the fast neutron and carries the information about the incident energy, while the second peak is caused by the moderated neutron undergoing a $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction. The mean time between moderation pulse and capture pulse is 500 ns. (b) From an incident γ -ray or partial energy deposition of an incident fast neutron, i.e., no $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction has occurred. (c) Noise on the tail of a moderation peak. scintillation. In the interaction (a) illustrated, the incident neutron interacts with protons resulting in proton recoil and neutron attenuation and finally capture by ^{10}B at the thermal neutron energy state. The neutron capture by ^{10}B results in the production of an α -particle and ^7Li and the concomitant emission of a gamma-ray photon from the ^7Li nuclide. The moderation of the neutron via proton recoil produces a moderation peak; and the α -particle produces the capture peak, illustrated in the lower panel of Fig. 9.72. Partial moderation of a neutron via neutron scatter and proton recoil with the eventual escape of the neutron from the scintillator depicted in the interaction of the incident neutron (b) does not result in neutron capture within the scintillator and thus only a moderation waveform is produced, illustrated in the waveform (b). Hunt et al. (2016) explain that noise can produce a second pulse in the tail of a neutron scattering peak as illustrated in the waveform (c) illustrated in Fig. 9.72. With the double-peak signature, illustrated in waveform (a) of Fig. 9.72, full energy deposition of the neutron occurs; and the incident neutron energy can be estimated from the pulse height of the first moderation peak. Hunt et al. (2016) use PSD to identify fast neutrons from thermal neutrons as well as γ -ray photons and noise.

The isotopes ^{155}Gd and ^{157}Gd occur with natural abundances of 15% and 16%, respectively; and ^{157}Gd has the highest thermal-neutron capture cross-section among all isotopes commonly used as target nuclei for thermal neutron energies $< 0.05 \text{ eV}$ (see Fig. 9.62). Ovechkina et al. (2009) synthesized and tested a Gd-loaded polystyrene scintillator. The plastic scintillator was prepared from liquid styrene mixed with concentrations of 1% 2,5-diphenyloxazole (PPO) as primary fluor and 0.1% 4-bis(5-phenyl-2-oxazole) abbreviated POPOP as secondary fluor; and gadolinium isopropoxide, $\text{Gd}[\text{OCH}(\text{CH}_3)_2]_3$, was added as the neutron-sensitive dopant in concentrations up to 6.4%. Polymerization of the mixture was accomplished at $125\text{--}140^\circ\text{C}$ in an argon atmosphere into plastic scintillator having a 14 mm diameter and up to 13 mm thickness. A 13 mm thick scintillator containing 0.5% gadolinium by weight detected 46% of incident thermal neutrons.

A unique approach to the design of a large-volume Gd-loaded plastic scintillator is described by Pawelczak et al. (2011). The addition of Gd into large-volume plastic scintillators can cause opacity and significantly reduce the light attenuation length. Thus, Pawelczak et al. (2011) devised a capture-gated Gd-loaded plastic scintillator, NSTAR (Neutron Sandwich Transmuter/Activation- γ Radiator), consisting of Gd foil sandwiched between layers of plastic scintillator (Saint Gobain BC-408) as illustrated in Fig. 9.73. Separating physically the Gd target nuclei from the scintillator avoids the opacity problem associated with the target nuclei loaded directly in the scintillator and permits the manufacture of large volume detectors. The

FIGURE 9.73 Schematic view of an NSTAR capture-gated Gd-loaded neutron prototype detector. From Pawelczak et al. (2011); reprinted with permission from Elsevier © 2011.

detector consisted of $12 \times 20 \times (50 \text{ or } 100) \text{ cm}^3$ stacks of plastic scintillator slabs alternating with thin Gd converter films viewed by fast photomultipliers. The principle of the capture-gated measurement of fast neutrons in the NSTAR, as described by Pawelczak et al. (2011), is as follows: Fast neutrons are rapidly moderated in the plastic scintillator where they produce a “prompt” scintillation light output signal. The thermalized neutrons diffuse slowly through the detector until captured by the nuclei in the second detector component (i.e., Gd-loaded film, See Fig. 9.73), the $n_{\text{th}}-\gamma$ converter, which gives rise to a delayed output signal. The $^{\text{nat}}\text{Gd}$ film, which contains natural gadolinium isotopes, in particular, ^{155}Gd and ^{157}Gd at 16% and 15% natural abundance respectively, having very high thermal-neutron capture cross-sections, emit a cascade of two to three gamma rays (see Eqs. 9.48 and 9.49) following the neutron capture process corresponding to neutron binding energies of 8.46 MeV (^{155}Gd) and 7.87 MeV (^{157}Gd), which are detected with the plastic scintillator component of NSTAR via Compton scattering and are absorbed with an increasing efficiency with active detector volume to yield a delayed photopeak at $\sim 8 \text{ MeV}$ to signal the total absorption of capture γ -rays (Pawelczak et al., 2011).

C. Neutron detectors with scintillating and optical fibers

Fiber-optic arrays can be used as detectors of nuclear radiation including the detection and measurement of neutrons. There are two types of basic detector arrangements when using scintillating fibers for the detection of nuclear radiation including neutron measurements. These are (i) a scintillating fiber (i.e., one that contains fluor molecules) absorbs energy of the impinging nuclear radiation and the scintillation photons propagate along the fiber to a photodetector and (ii) a scintillation detector (e.g., plastic or inorganic scintillator) is coupled to an optical fiber, which propagates the scintillation photons on to a photodetector. These are described in the following sections.

1. Scintillating fibers arrays

Plastic scintillating fibers are reported to provide better photon yields, longer light attenuation, shorter decay times, and longer nuclear reaction and radiation lengths than glass fiber (Leutz, 1995). As reported by Leutz (1995), the plastic fibers are manufactured with a scintillating plastic core several micrometers up to a few millimeters in diameter, and the cores are surrounded by a cladding layer ($\leq 5 \mu\text{m}$) of lower refractive index than the scintillating core (see Fig. 9.74). The scintillating core may consist of polystyrene (PS) plastic polymer and the cladding of polymethyl methacrylate (PMMA). When the cladding is of lower refractive index than the scintillating core (i.e., $n_g < n_c$) the fiber traps a fraction t of the scintillating light, as illustrated in Fig. 9.74 according to the equation

$$t = 1 - (n_2 / n_1) \quad (9.50)$$

where n_2 and n_1 are the index of refraction of the cladding material and that of the scintillating core, respectively. Any untrapped light is absorbed by an extramural absorber (EMA), if the fiber is coated with a black layer. As explained by Leutz (1995), even in the absence of an EMA the untrapped light escapes at an angle, which prevents it from being trapped again by a neighboring fiber; and it becomes lost after about 50 mm of fiber length. Therefore, the untrapped light will not contribute to appreciable cross-talk between neighboring scintillating fibers.

The fiber diameter and type of scintillator used in the plastic core material govern the spatial resolution because proper selection of scintillating fluor in the core minimizes cross-talk between neighboring fibers. Leutz (1995) points out that the ionizing nuclear radiation will first cause excitation of the polystyrene. Because the polystyrene fluorescence yield is poor, an aromatic scintillator must be included in the polystyrene core polymer. Both primary and secondary scintillators have been used, such as *p*-terphenyl (PTP) and POPOP, respectively; however, POPOP has an overlapping absorption and emission spectrum. A single scintillator concentration of $>0.015 \text{ M}$ fraction of 1-phenyl-3-mesityl-2-pyrazoline (PMP) as a one-component fluor in the polystyrene scintillating plastic core can be used as it has a large Stokes shift, that is, practically no overlap of its absorption and emission spectra. Leutz (1995) indicates that cross-talk between scintillating fibers is avoided by using only one fluor component, which displays a large Stokes shift in the polystyrene core, such as PMP (Güsten and Mirsky, 1991). This is explained by the fact that light emitted by the first fluor (dopant) can escape from fibers of small diameter, excite the wavelength shifter (second fluor or dopant) in neighboring fibers, and cause undesirable cross-talk when the absorption and emission spectra of the two dopants overlap.

FIGURE 9.74 Schematic diagram of the optical propagation in the plastic scintillating fiber. From *Ikhlef et al. (2000)*; reprinted with permission from Elsevier ©2000.

Barbagallo et al. (2011) used an array of scintillating fibers in the design of a thermal-neutron detector suitable for measurements in the decommissioning of storage and radioactive waste or the mapping of flux in the out-of-core regions of fission reactors. The detector designed by Barbagallo et al. (2011) is illustrated in Fig. 9.75, which operates on the following principle:

- a thermal neutron impinges on a layer of ${}^6\text{LiF}$ enriched to 96% in ${}^6\text{Li}$;
- the thermal neutron is captured by the ${}^6\text{Li}$ triggering the reaction ${}^6\text{Li}(n,t){}^4\text{He}$;
- the triton and the α -particle are emitted back to back; and each hit the scintillator in opposite directions;
- the scintillation photons produced by the triton or α -particle propagate along a scintillating fiber (9 cm in length) to be detected by a corresponding SiPM at each end of the scintillating fiber bundle.

The neutron converter consisted of a $3\text{ }\mu\text{m}$ thick and 10 mm diameter film of ${}^6\text{LiF}$ deposited by evaporation on a

glass substrate. The converter was assembled in contact with the middle point of a bundle of nine plastic scintillating fibers (0.3 mm in diameter). The bundle (9 cm long) is arranged flat onto the converter; and at each end the bundle of 3×3 fibers is squeezed into a square array with dimensions of $0.9 \times 0.9\text{ mm}$, which fits comfortably with optical grease onto the sensitive area of $1 \times 1\text{ mm}$ of each SiPM. This experimental arrangement enabled left-right coincidence counting to suppress spurious counts, which could arise from SiPM dark noise and cross-talk between adjacent SiPMs.

Gamma background radiation was determined with a detector insensitive to neutrons, i.e., without the ${}^6\text{Li}$ neutron converter; and the difference of the pulse events of the two detectors would yield the spectra due the neutron flux as measured by the alpha-particle and tritium reaction products of neutron capture, as illustrated in Fig. 9.76. The gamma-ray rejection is good, as the gamma-ray efficiency is reported to be 10^{-4} ; and the neutron/gamma rate was

FIGURE 9.75 Sketch of the operating principle of the thermal neutron detector, based on neutron capture by ${}^6\text{Li}$ and detection of either the alpha-particle or tritium produced by means of a scintillating fiber bundle and two SiPM photosensors. From *Barbagallo et al. (2011)*; reprinted with permission from Elsevier © 2011.

FIGURE 9.76 Difference between two spectra produced by detectors with and without ${}^6\text{LiF}$ neutron converter. Two bumps in the spectrum are due to the detection of α -particles (lower channels, 500–1000) and tritium (higher amplitude channels, 1000–3000). The pulse amplitudes due to tritium appear at the higher channels since the lighter and more energetic tritium on the average produces more light in the scintillation fibers. From *Barbagallo et al. (2011)*; reprinted with permission from Elsevier © 2011.

$\sim 2\%$. [Barbagallo et al. \(2011\)](#) propose to improve the detector by depositing the ^6LiF neutron converter directly onto the scintillating fiber bundle and sandwiching or stacking two or more bundles.

A thermal neutron detector with a spatial resolution of ~ 1 micron is proposed by [Song et al. \(2016\)](#). They utilized a Monte Carlo toolkit Geant4 to design a detector assembly composed of cerium-doped lithium glass scintillator microfibers of $1\text{ }\mu\text{m}$ diameter. The location of neutron absorption is reconstructed from the charged particle products (α -particle and tritium) of neutron capture on ^6Li , as described by [Eq. \(9.46\)](#) earlier in this chapter. The detector design includes surrounding each scintillating fiber with air-filled glass capillaries with the same diameter of the fiber to suppress cross-talk of scintillation light from fiber to fiber and thereby improve on spatial resolution, as illustrated in [Fig. 9.77](#). The front end of the detector is coated with a thin optical reflector to maximize the light collection efficiency at the output end. The scintillation light produced by neutron absorption is magnified and recorded by an intensified CCD camera (ICCD) illustrated in [Fig. 9.77](#).

Scintillating fiber arrays are applied to various applications including:

- (i) the real-time measurement of gross beta radiation in drinking water ([Lv et al., 2018](#)),
- (ii) the coupling of scintillating fiber arrays to silicon photodiode (Si-PD) or SiPM photo sensors as hodoscope detectors in beam monitoring where their fast response and insensitivity to magnetic fields make them ideal particle trackers where timing information is required ([Damyanova and Bravar, 2017](#); [Blasco et al., 2015](#)), and
- (iii) the construction of trackers associated with the LHCb detector of the Large Hadron Collider (LHC) ([Kirm on behalf of the LHCb collaboration, 2017](#); [Tobin on behalf of the LHCb Upgrade Scintillating Fiber Tracker group, 2016](#); [Leverington et al., 2013](#)).

The basic principle of the scintillating fiber (SciFi) particle tracker designed for the LHCb detector located at the LHC is illustrated in [Fig. 9.78](#). As described by Kirm on behalf of the LHCb collaboration (2017), the SciFi detector consists of scintillating fiber mats having a length of 5 m and a width of 0.53 m consisting of layers of honeycomb and carbo fiber—reinforced polymer (CFRP) glued to both sides of the scintillating fiber mats to provide rigidity to the module. The plastic scintillating fibers are 0.25 mm in diameter. An epoxy glue loaded with 25% TiO_2 reflective material minimized optical cross-talk between adjacent fibers while at the same time established the fibers as a composite unit. [Fig. 9.78](#) illustrates how a charged particle traveling through the honeycomb of scintillating fibers

FIGURE 9.77 (A) The schematic layout (not to scale) of the neutron detector system. (B) Both hexagonal and square microfiber assemblies are viewed in the neutron beam direction. From [Song et al. \(2016\)](#); reprinted with permission from Elsevier © 2016.

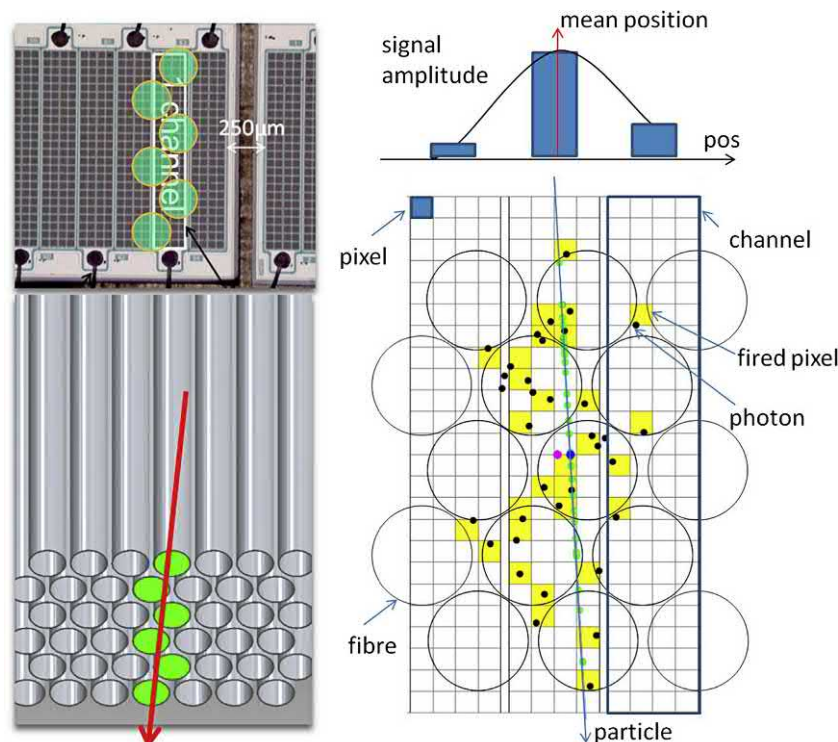

FIGURE 9.78 A sketch of the basic principle of the SciFi (scintillating fiber) tracker. A charge particle passing through the fiber produces scintillation light which travels to the end and is detected in a SiPM array. The black dots indicate photons arriving at the SiPM, the yellow squares indicate the pixels that fire. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this chapter). From *Kirn on behalf of the LHCb collaboration* (2017); reprinted with permission from Elsevier © 2017.

initiates excitation and scintillation with emissions of photons captured by the SiPM pixel array, which provide a signal amplitude corresponding the energy absorbed by the scintillating fibers.

2. Optical fiber—neutron detector arrays

Plastic or quartz optical fiber of lengths extending to several meters may be coupled to a scintillation detector with or without neutron converter, in lieu of the scintillating fibers described in the previous paragraphs. Arrangements with optical fiber may include a small (~ 1.0 mm dia.) organic or inorganic scintillator surrounded with a neutron converter (e.g., ${}^6\text{LiF}$ enriched to $> 95\%$ ${}^6\text{Li}$) coupled to a desirable length of plastic or quartz optical fiber. The measurement of gamma background is possible with the use of the scintillator detector without the neutron converter. Such detector arrangements are illustrated in Fig. 9.79.

To improve the detection of photons emitted by the scintillator a short section (~ 1 cm) of wavelength shifting fiber (WSF) may be coupled between the scintillator and optical fiber. The WSF absorbs the scintillation photons and then emits photons at a longer wavelength, which may be more efficiently detected by the photomultiplier. A neutron detector arrangement with WSF and optical fiber is illustrated in Fig. 9.80. The measurement principle of this optical fiber—neutron detector arrangement, as described

by Yagi et al. (2011) is as follows: (1) A converter material, such as ${}^6\text{LiF}$, generates charged particles by reacting with neutrons; (2) scintillation light is emitted from a scintillator, such as ZnS(Ag) , after the charged particles have collided with it; (3) the scintillation light is absorbed by the WSF; and the WSF then emits light with a longer wavelength than the original light; and (4) the light inside the WSF is then transmitted to the tip of the optical fiber; and finally travels through the optical fiber until it reaches the PMT.

Commonly utilized converter materials for thermal neutrons, which emit fission fragments upon thermal neutron capture, discussed previously, are enriched ${}^6\text{Li}$ and ${}^{10}\text{B}$. Also fissile ${}^{235}\text{U}$ and ${}^{239}\text{Pu}$, which undergo nuclear fission yielding fission fragments, may also be utilized as converter isotopes. On the other hand, common converter materials for fast neutrons are the fissionable radionuclides ${}^{232}\text{Th}$ (Haas et al., 2011) and ${}^{238}\text{U}$, which undergo fission upon reaction with fast neutrons (> 1 MeV). With neutron converter materials in mind, a detector was developed at Nagoya University (Mori et al., 1994), which consists of an optical fiber with its tip covered with a mixture of a neutron converter and ZnS(Ag) scintillator. Along these lines, Yamane et al. (1998, 1999) designed and tested small detectors for thermal and fast neutron flux measurements in a research reactor. They chose ${}^6\text{Li}$ as converter for the analysis of thermal neutron flux and ${}^{232}\text{Th}$ as converter for fast neutron flux measurements. The scintillator selected was ZnS(Ag) , which was mixed with a converter and glued with

FIGURE 9.79 Cross-section of the fiber-optic (A) neutron sensor and (B) gamma sensor. The detector arrangement utilizes ^6LiF and BCF-20 (Saint Gobain) organic scintillator. A thin cladding surrounding the plastic optical fiber is depicted as a lighter color or hue between the plastic optical fiber and black jacket. FIGURE 9.80 Transmission mechanism of an optical fiber detector with a WSF and surrounding ^6LiF neutron converter and ZnS(Ag) scintillator. The WSF and its surrounding neutron converter and scintillator are ~ 1 cm in length. The optical fiber is only 1 mm in diameter; and its length is measured in meters. An optical grease connects the WSF and optical fiber. Charged particle tracks in the scintillator are illustrated with broken arrows; and the scintillation light in the scintillator and WSF is depicted with solid arrows. From Yagi *et al.* (2011); reprinted with permission from Elsevier © 2011.

epoxy to the tip of glass optical fiber (2 mm diameter quartz). Glass optical fiber was selected because it is more resistant to radiation damage than plastic fiber. A 0.5 mm thick aluminum cap covers the neutron detector tip, which both serves to protect the scintillator and converter material and reflect light toward the optical fiber. A schematic view of the detector and measurement layout is provided in Fig. 9.81. The electric signals from the PMT are sent

through a preamplifier and amplifier (AMP), and MCA for pulse height measurements. An SCA and multichannel scalar were also applied to the measurements.

The advantages of this type of detector for neutron flux measurements demonstrated by Yamane *et al.* (1999) are the following: (i) The detector is slim (2 mm dia.) and capable of fitting into narrow measurement positions such as between reactor fuel plates. (ii) Due to the small size of the detector, it has reduced spatial dependence of the neutron flux providing good flux measurement resolution. (iii) Small changes or fluctuations in the neutron flux at certain known positions in the reactor core, such as dips caused by spacers, can be measured. (iv) The neutron current or gradient of the flux can be measured. (v) A neutron flux mapping can be made over large distances of the reactor core in a short period of time. This is a major advantage as conventional measurements of the axial flux profile of a reactor core using cobalt wire activation measurements may take several hours, while the use of a glass fiber detector would take only a few minutes for the same measurement. Yagi *et al.* (2011) increased the sensitivity of such a small neutron detector by using a WSF between the ^6LiF neutron converter/ ZnS(Ag) scintillator and the optical fiber. The sensitivity of the detector for thermal neutrons increased significantly with the WSF. They utilized the detector with a WSF of up to 20 cm in length attached to the optical fiber for the measurement of reaction rate distributions in a reactor core.

Jang *et al.* (2011) underscore the advantages of optical fiber in the detection and transmission of scintillation light signals, among which are long-distance signal transmission, real-time measurement, and no disturbances from

FIGURE 9.81 Schematic view of (A) the quartz fiber tip and the measurement arrangement, and (B) layout of the measurement of neutron flux in a research reactor. From Yamane *et al.* (1999); reprinted with permission from Elsevier © 1999.

temperature, pressure, and electromagnetic waves. As gamma-radiation background is often present in the measurement of neutron radiation, they devised an integrated fiber-optic neutron-, gamma-, and Cherenkov sensors using a cable containing three fiber optic sensors, which are described as follows: (1) thermal neutrons were measured with the ^6LiF converter coated onto organic scintillator at the tip of a 0.5 mm diameter optical fiber, as illustrated in Fig. 9.79, (2) the gamma-ray background was measured with organic scintillator without the neutron converter at the tip of an optical fiber, as illustrated in Fig. 9.79 and (3) background from high-energy particles, which produce Cherenkov radiation, was determined with a fiber optic cable containing neither an organic scintillator detector nor neutron converter. The three fiber optic sensors housed in a

light tight jacket as an integrated fiber optic sensor are illustrated in Fig. 9.82.

Large area neutron-sensitive scintillators for neutron diffractometers and reflectometers were designed by McKnight *et al.* (2008) and Nakamura *et al.* (2009). These contain $\text{ZnS}/^6\text{LiF}$ as the scintillator and neutron converter material, which surround numerous WSFs, which can lead to specific PMTs. The detector designed by Nakamura *et al.* (2009) measured 32 mm long and 70 mm wide. It exhibited a spatial resolution of 0.5 mm, a detection efficiency of 35% for 1 Å neutrons, and a gamma sensitivity of less than 10^{-7} .

A common application of the coupling of scintillation detectors with optical fiber is the coupling of scintillators sensitive to neutrons with a wide variety of wavelength

FIGURE 9.82 Structure of the integrated fiber optic sensors. From Jang et al. (2011); reprinted with permission from Elsevier © 2011.

shifting optical fiber arrays such as the following: (i) the use of 0.5 cm thick wafers of Europium-activated lithium calcium aluminum fluoride (LiCAF) crystals mated to SiPMs to measure neutron flux (Ford et al., 2018), (ii) ZnS/⁶LiF scintillating layers with embedded WSF with SiPM readout (Mosset et al., 2014), (iii) a scintillating screen composed of ZnS/⁶LiF coupled to WSFs of 100 μm diameter oriented in the x- and y-directions with 34 × 34 μm pixel size output yielding sub 100 μm spatial resolution (Nakamura et al., 2014a), (iv) large area (256 × 256 mm²) neutron-sensitive ZnS/¹⁰B₂O₃ screens coupled to cross-arranged (x- and y-directions) WSF arrays for application in a neutron diffractometer (Kawasaki et al., 2014), and (v) a two-dimensional high-spatial-resolution scintillating-based neutron detector consisting of a ZnS/¹⁰B₂O₃ scintillating screen coupled to wavelength-shifting fibers oriented in x- and y-directions to provide a position-sensitive neutron detector (Nakamura et al., 2015).

A schematic view of the high-spatial-resolution neutron detector designed by Nakamura et al. (2015) is illustrated in Fig. 9.83. The neutron-sensitive spatial resolution detector covers a detection area of 320 × 320 mm consisting of ZnS/¹⁰B₂O₃ scintillator screens, which are placed on both sides of 1 mm diameter wavelength shifting (WLS) fibers. The WLS fibers are situated at a 2.5 mm pitch in the x and y directions; and the crossed WLS fibers are in direct contact (cross-talk) with each other. Overall, the detector contains 256 WLS fibers comprised of 128 fibers in two layers oriented in the x and y directions. As noted by Nakamura et al. (2015), a neutron incident on the scintillator screen is absorbed and captured by the nuclear reaction ¹⁰B(n,α)⁷Li; and the secondary α-particle and ⁷Li ion deposit energy in the ZnS scintillator. The ZnS phosphor has a peak photon emission at 450 nm with ~100,000 photons emitted per neutron absorbed. About one-half of the photons escape the screen and enter the WSFs, which reemits the light at a longer wavelength of 500 nm. The light propagates along the affected fibers to the PMTs at the end of each fiber. The PMTs and detector electronics are

operated in the photon counting method to ensure a high detection efficiency. The photoelectrons (p.e.) detected at each fiber are counted for 2 μs when a trigger signal opens a gate; and a scintillation event from a fiber is recorded as a neutron event when the total number of photoelectrons exceeds a threshold level. The position of the incident neutron is calculated based on an MPC (Model Predictive Control) method, which utilizes algorithms similar to those implemented with Anger cameras.

VII. Scintillation in plastic media

Plastic scintillators may be considered as solid solutions of one or more organic scintillation fluors (fluorescent dopants) in translucent plastic. The solid plastic medium plays a role similar to that of the liquid solvent in liquid scintillation counting (Chapter 6, Volume 1). Many types of plastic scintillators are in use today mainly for the measurement of low penetrating radiation, such as particulate radiation, X-rays, and low-energy gamma rays. Plastic scintillators have also become popular for the measurement of neutrons via neutron-induced nuclear reactions in the plastic media, as described in the previous paragraphs. Two main types of plastic scintillator designs exist: (1) the integral plastic scintillators, which are constructed of one whole piece of plastic polymer containing scintillator varying in size from microspheres of 100–1000 μm in diameter to large detectors measuring a meter or more in diameter, and (2) fiber-optic arrays of plastic scintillator consisting of as many as several thousand plastic scintillating fibers each 25–60 μm in diameter as individual light pipes bundled together into only a few mm diameter.

A. The scintillation process in plastic

Plastic scintillators are classified into binary, ternary, or even higher order scintillator solutions. A binary scintillator consists of two molecular species, namely the solvent *X* (plastic or organic liquid) and the solute *Y* (organic fluor or dopant). The solvent (plastic) medium, which is the bulk material, absorbs the major part of the energy dissipated by incident radiation (see Brookes, 1979). This absorbed energy, that is, excitation energy of the solvent molecules, is then transferred to the solute molecules, which is represented as follows:

where *X*^{*} and *Y*^{*} represent excited states of solvent *X* and solute *Y*, respectively. Decay of *Y*^{*} from its excited state to the ground state results in fluorescence or the emission of visible light.

The addition of a wavelength shifter or secondary solute, *Z*, to the medium constitutes a ternary system. In such a system, the energy transfer process is extended to a third

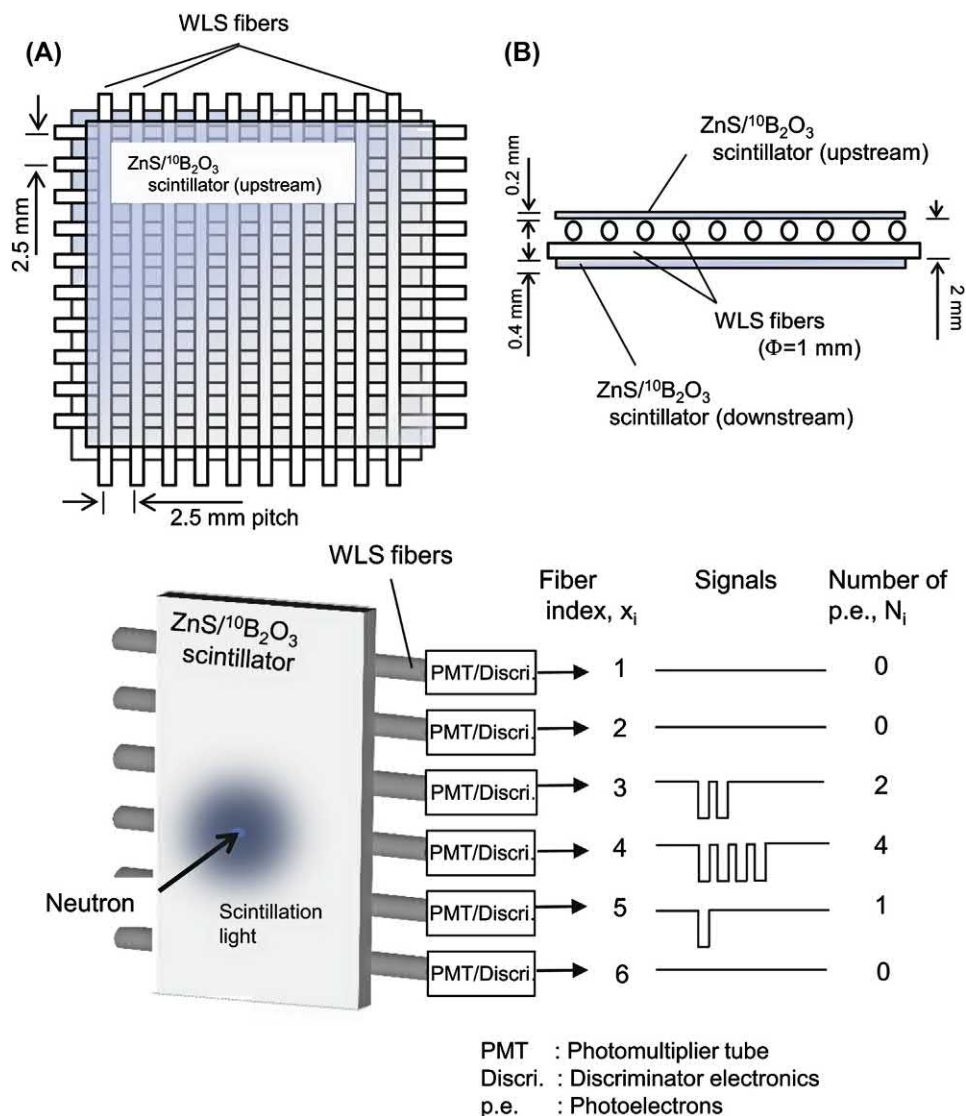

FIGURE 9.83 Upper Panel: Schematic views of the neutron-detecting head: (A) top view and (B) side view. Only 10 fiber channels for each direction are shown. Lower Panel: Schematic diagram of the scintillator and wavelength-shifting (WLS) fiber detector (only the WLS-fibers array in the x direction is presented for simplicity). In this case, the incident position of the neutron is calculated as $\sim 3.9 (= (3 \times 2 + 4 \times 4 + 5 \times 1) / (2 + 4 + 1))$ with the MPC method. From Nakamura et al. (2015); reprinted with permission from Elsevier © 2015.

molecular species, namely the secondary solute. In other words, the excited primary solute Y^* transfers its energy of excitation both radiatively and nonradiatively to the secondary solute, Z , as follows:

Decay of Z^* occurs with the emission of visible radiation of longer wavelength than that emitted by Y^* . Secondary solutes are used primarily to provide fluorescent radiation with a maximum emission wavelength that may be better matched to the sensitivity of the PMT or PD. A unitary scintillator is one that consists of a single pure molecular species such as the organic crystalline phosphor (e.g., anthracene). Unitary scintillators, described previously in this chapter, are not discussed here, because plastic scintillators consist of only the binary or higher order scintillators.

Polystyrene-based plastic scintillators have become popular, as polystyrene (PS) is easily drawn into fibers used in scintillator fiber-optic arrays. In a study of polystyrene-based scintillators, Bross (1990) reviews the scintillation process and its efficiency. As explained by Bross (1990), solutions of polystyrene with an efficient fluorescent dopant can give a 100% quantum yield, which is defined as the probability that an excited state in the polymer leads to an emission of a photon by the dopant (fluor). The primary dopant referred to as Y in Eqs. (9.51) and (9.52), which couples directly to the primary scintillation of the solvent, is of higher concentration ($\sim 1\%$). The secondary dopant (Z of Eq. 9.52), which is added to the polystyrene polymer in low concentration ($\sim 0.01\%$), shifts the mean fluorescent wavelength of the primary dopant from the deep blue 350–390 nm further into the red.

Bross (1990) underscores the ideal conditions for fluorescence in polystyrene scintillators. These are (1) a wavelength shifter with emission and absorption spectra that do not overlap, such as exhibited by compounds that undergo intramolecular proton transfer (IPT compounds) upon excitation; (2) a primary dopant, with an absorption spectrum that overlaps the fluorescence emission distribution of polystyrene; and (3) a fluorescence spectrum of the primary dopant with emission peaks longer than 500 nm, which obviates the need for a secondary dopant. The primary dopants 3-hydroxyflavone (3HF), 2-(2-hydroxyphenyl)-benzothiazole (HBT), *p*-terphenyl (PTP), and 1-phenyl-3-mesityl-2-pyrazoline (PMP), among others, have been tested as favorable dopants in polystyrene and poly(vinyltoluene) polymers (Rahmanifard et al., 2018; Güsten and Mirsky, 1991; Bross, 1990; Destruel et al., 1989; Zorn et al., 1988). Reviews on the development, composition, and applications of plastic scintillators and dopants utilized in plastic polymers are provided by Rahmanifard et al. (2018) and (L'Annunziata, 1987).

B. Applications of plastic scintillators

The applications of plastic scintillator in the detection and measurement of radionuclides are numerous. Many applications are treated in this book, including the use of plastic scintillator beads for the measurement of beta, beta-gamma, and alpha-emitting radionuclides (see Chapter 6, Volume 1), high sample-throughput scintillation analysis with plastic scintillator microplates (see Section V.B of this chapter), and the use of plastic scintillators loaded with a neutron converter as capture-gated neutron detectors (Section VI.B of this chapter).

Plastic scintillators are useful in the detection of fast neutrons through collisions of the neutrons with protons in the scintillator. Plastic scintillators are appropriate because of the relatively high hydrocarbon polymer proton (hydrogen) content of plastics. Inorganic scintillator detectors described earlier in this chapter contain no protons (hydrogen atoms) in their molecular structures.

The collisions of fast neutrons with protons in plastic scintillators result in transfer of energy to the proton with recoil of the proton (see Fig. 1.78, Chapter 1) with

subsequent conversion of the proton recoil energy to light in the scintillator. The light is then subsequently converted to an electric pulse by a photomultiplier in intimate contact with the plastic scintillator, as illustrated in Fig. 9.84.

VIII. n/γ pulse shape discrimination

Often it is necessary to measure neutron radiation in fields of high gamma-ray intensity. Effective discrimination between neutron and gamma radiation is possible with certain inorganic and organic scintillators that display significant differences in their scintillation pulse shapes analyzed by their decay time. Many scintillators display significantly different pulse shapes produced by two groups of particles, namely, (i) heavy charged particles (i.e., p, d, t, or α), which are products of neutron interactions with scintillators (e.g., neutron scattering or capture reactions) and (ii) electrons, which are products of γ -ray interactions with scintillators (e.g., Compton electrons). For example, under gamma irradiation $\text{LiBaF}_3\text{:Ce}$ yields a very fast (~ 1 ns) light output due to core-valence (CV) transitions or luminescence followed by an additional light output with a short lifetime of about 35 ns arising from Ce^{3+} excitation. Both of these light outputs arising from gamma interactions are considered fast, and both of these fast components are absent under neutron irradiation. Both neutron and gamma irradiation produce light output with a relatively long component with a lifetime of about 2.5 μs due to self-trapped-excitation (STE) luminescence. The n/γ radiation can be discriminated, therefore, on the basis of the presence or absence of the short (ns) lifetime components in the scintillation pulse events.

Reeder and Bowyer (2001, 2002) used a data acquisition system consisting of a multi-input charge-to-digital converter (QDC). The scintillator is coupled to a PMT, and the signal from the PMT is set to two separate inputs to the QDC. Each input is gated to record the amount of charge in two portions of the pulse. A “short” gate of about 30 ns records the fast components due to the CV and Ce^{3+} fluorescence arising from gamma interactions, and the “total” gate of about 1.6 μs records both the short and long components due to STE excitations as a consequence of both gamma and neutron interactions. A two-dimensional

FIGURE 9.84 Schematic of a neutron path in a plastic scintillation neutron detector illustrating a recoil proton track and the emitted scintillation light within the scintillator. The symbols θ and α represent the angles of light emission and recoil proton track, respectively. From De et al. (1963); reprinted with permission © IEEE.

FIGURE 9.85 Two-dimensional array of pulse heights from “short” to pulse heights from “total” gate for ^{252}Cf at 11.55 cm from crystal. Data were obtained with a Cd shield around the scintillator and a 1.27-cm thick Pb absorber between the source and scintillator. Outlined regions define events attributed to neutrons or to gammas. From Reeder and Bower (2002), reprinted with permission from Elsevier © 2002.

array of the “short” signal versus the “total” signal demonstrates the discrimination of n/ γ events, as is illustrated in Fig. 9.85. This technique of n/ γ discrimination is referred to as the charge-comparison technique, because a fractional charge collected (e.g., a fast signal) is compared to the total charge collected being a slow or long signal.

Kaschuck and Esposito (2005) describe the performance of a n/ γ digital pulse shape discrimination (DPSD) system by means of a commercial 12-bit 200 MSample/s transient recorder card with three organic scintillators, namely, stilbene, NE 213, and anthracene, as analog electronic pulse-shape discrimination (PSD) modules, which do not allow data processing and are limited in count rate capability (up to ~ 200 kHz). They used the charge-comparison method to obtain the simultaneous n/ γ discrimination and pulse height analysis with the organic scintillators demonstrated to perform with count rates in excess of 1 MHz (Esposito et al., 2010; Kaschuck and Esposito, 2005). The charge comparison method to discriminate between the n and γ events, as described by Kaschuck and Esposito (2005) is the following:

If two equal amplitude n- and γ -pulses are considered, the neutron pulse has a larger slow component (see Fig. 9.86). Each pulse is integrated numerically for two different time intervals (Δt_F and Δt_S) corresponding to the fast and slow components. The value of the ratio $R = Q_S/Q_F$ (Q_F and Q_S

FIGURE 9.86 Neutron and γ -ray pulses recorded with 12-bit 200 MSamples/s transient recorder card; time intervals for charge comparison method analysis are shown. From Kaschuck and Esposito (2005); reprinted with permission from Elsevier © 2005.

are the charges in the two intervals Δt_F and Δt_S) provides the indication whether a n- or a γ -event has taken place. Two integrating systems were selected $\Delta t_1 = 25$ ns and $\Delta t_2 = 120$ ns; and the integration was performed starting at the time at the peak value of each pulse. After the end of the data processing, both the pulse height spectra for neutron and γ -rays as well as the total spectrum are provided simultaneously.

By recording events from neutron and γ -ray radionuclide sources Kaschuck and Esposito (2005) plotted the two-dimensional intensity distributions Q_F versus Q_S for stilbene scintillator illustrated in Fig. 9.87 using the DPSD data processing software. An Am—Be source was used with the source shielded in ~ 15 cm-thick polyethylene shielding and the n/ γ separations at different electron energies are illustrated in Fig. 9.87B.

Jhingan et al. (2008) describe how the charge comparison technique for n/ γ discrimination, which has been implemented over the past 2 decades, can be implemented electronically in more than one fashion. The conventional method is to compare the fractional or slow charge in the tail (see Fig. 9.86 above) with the full or total charge of the PMT anode pulse fed to a charge integrating analog digital converter (ADC) or charge digital converter (QDC). Jhingan et al. (2008) devised an alternative electronic method of comparing the shaped-dynode pulse, fed to a peak-sensing ADC, with the fractional slow charge integrated in the QDC, which reduces the number of gate and delay generators employed in the conventional method.

Watanabe et al. (2002) report a unique application of plastic scintillator sandwiched together with pure lucite plastic to separate high-energy neutron and gamma radiation. The detector consists of 10 layers of plastic scintillator plates alternately sandwiched between 10 Lucite plastic plates. The Lucite plastic plates are pure, that is, they do not

FIGURE 9.87 Stilbene (HV = -1400 V) and Am-Be source: (A) Two-dimensional intensity distribution in Q_f - Q_s space. The color scheme of intensities can be observed with the electronic version of the figure. (B) n/γ separation profiles at various electron energies (neutron peaks are on the left) obtained with 12-bit 200 MSamples/s sampling. From Kaschuck and Esposito (2005); reprinted with permission from Elsevier © 2005.

contain scintillator and consequently act as Cherenkov radiators. The plates measure $100 \times 103 \times 3.7$ mm (width \times length \times thickness). When sandwiched together and coupled to two photomultipliers at two ends they form a n/γ

γ discriminator, referred to as a scintillator-Lucite sandwich detector (SLSD). The principle behind the SLSD is that high-energy gamma radiation will form e^+ and e^- in the detector, which will result in the emission of scintillation light in the plastic scintillator sheets and Cherenkov photons in the pure Lucite sheets; while the neutron radiation will not produce any light in the pure Lucite, but will produce scintillation in the plastic scintillator through proton and carbon recoil from $n-p$ and $n-C$ collisions. Effective n/γ separation is demonstrated in the energy region of 20 MeV to 12 GeV with a neutron detection efficiency of 7%–10% and a γ -misclassification probability of $<10^{-2}$.

Yanagida et al. (2015) studied the neutron-gamma discrimination capabilities of the pure solid-state organic scintillators, anthracene, stilbene, and p-terphenyl. They demonstrate the differences between the scintillation decay time profiles of each scintillator under neutron and gamma-ray excitation, illustrated in Fig. 9.88; and the discrimination achieved between neutron and gamma-ray events when plotting the events against the slow to fast components of the scintillation decay time profiles of each scintillator, as illustrated in Fig. 9.89. Anthracene produced the best n/γ discrimination as measured by the figure of merit (FOM) defined as

$$\text{FOM} = \frac{S}{\text{FWHM}_{\text{neutron}} + \text{FWHM}_{\text{gamma}}} \quad (9.53)$$

where S is the distance between the neutron and gamma-ray peaks and $\text{FWHM}_{\text{neutron}}$ and $\text{FWHM}_{\text{gamma}}$ are the full width at half maximum of the neutron and gamma-ray peaks, respectively. The FOMs calculated by Yanagida et al. (2015) were 1.53, 1.10, and 1.26 for anthracene, stilbene, and p-terphenyl, respectively.

Pulse shape n/γ discrimination is not limited to solid organic scintillators; but it is also carried out efficiently with liquid scintillators as described in Chapter 6, Volume 1. Jhingan et al. (2008) used two detectors, a plastic scintillator to provide a start signal and a second liquid scintillator detector at a 30-cm distance to establish time-of-

FIGURE 9.88 Scintillation decay time profiles under neutron and gamma-ray excitation of anthracene (left), stilbene (center), and p-terphenyl (right) by event selection. From Yanagida et al. (2015); reprinted with permission from Elsevier © 2015.

FIGURE 9.89 Histograms of neutron and gamma-ray events of anthracene (left), stilbene (center), and p-terphenyl (right), plotted on the ratio of slow/fast components. The fast/slow integrated time windows of anthracene, stilbene, and p-terphenyl were 20–40/40–150 ns, 20–40/40–150 ns, and 20–30/30–150 ns, respectively. From Yanagida et al. (2015); reprinted with permission from Elsevier © 2015.

flight (TOF) discrimination in addition to PSD. TOF measurements for n/γ discrimination are described in Chapter 6, Volume 1 and Chapter 6, Volume 2. Effective n/γ PSD has been demonstrated with several new inorganic and organic scintillators including ^6Li –boron–phosphorus glass scintillator and ^6Li -loaded plastic scintillators (Katagiri et al., 2004), $\text{Cs}_2\text{LiYCl}_6\text{:Ce}^{3+}$ (Bessiere et al., 2005), 9,10-diphenylanthracene (van Loef et al., 2011), and Ce:L-iCaAlF_6 (Yamazaki et al., 2011) and well as ^6Li -containing organic scintillators (Bertrand et al., 2015; Zaitseva et al., 2013). Liao and Yang (2015) describe a frequency gradient analysis (FGA), as a new method of neutron-gamma discrimination developed by Liu et al. (2010). The FGA method, as described by Liao and Yang (2015), exploits the difference between the Fourier transforms of the neutron and gamma pulse.

Reviews of recent developments and state of the art of neutron/gamma PSD in plastic scintillator is provided by Zaitseva et al. (2018), Bertrand et al. (2015) and Liao and Yang (2015).

IX. Bonner sphere neutron spectrometry

The methods by which one determines the energy spectra of neutron radiation have an interesting similarity to that by which we determine gamma-ray energy spectra. Both neutrons and gamma-ray photons are neutral particles. Therefore, their energies can only be determined indirectly by the energies that they transfer to charged particles. Neutron energies are measured by the energies they transfer to recoil protons via n–p scattering; and gamma-ray energies are measured by the transfer of gamma-ray energy to atomic electrons via Compton scatter or the photoelectric effect. Unfortunately, neutron spectra are not characterized with a specific photopeak or Compton edge; rather, there is a broad proton-recoil pulse height distribution due to the large range of neutron scatter angles and proton recoil energies that result.

Various techniques may be used to measure the energy of neutrons; and these are reviewed by Thomas (2010) including (i) time-of-flight, (ii) nuclear reaction methods [i.e., $^3\text{He}(\text{n,p})^3\text{H}$] where the neutron energy is shared between the proton and Triton products, and the neutron energy measured by the sum of the proton and Triton energies, (iii) hydrogen-filled proton-recoil spectrometers, and (iv) Bonner sphere spectrometers (BSSs). Most of these methods are beyond the scope of this chapter; however, BSSs may utilize a solid crystal scintillator; and these will be discussed here. For other methods, the reader is referred to reviews on neutron spectrometry by Thomas (2010, 2004), Brooks and Klein (2002) and Klein et al. (2002).

The Bonner sphere neutron spectrometer was first designed by Richard L. Bramblett, Ronald I. Ewing, and Tom W. Bonner (Bramblett et al., 1960) at Rice University with a $^6\text{LiI}(\text{Eu})$ scintillator mounted on a polystyrene light pipe as coupling to a PMT. The detector is named after Tom W. Bonner (1910–61), who is known for his work on the development of instrumentation and methods for studies of neutron and nuclear physics. The Bonner sphere has developed into a popular instrument to measure neutron fields up to energies of ~ 10 MeV in various environments including the nuclear industry (Roberts et al., 2017), boron neutron capture therapy (BNCT) and accelerators associated with hadron therapy in nuclear medicine (Masuda et al., 2017; Tamaki et al., 2017, 2015; Bedogni et al., 2012), nuclear reactor beam port measurements (Mazrou et al., 2016; Vega-Carrillo et al., 2014), around a linear accelerators (Lagares et al., 2016; Mohammadi et al., 2015; Benites-Rengifo et al., 2014; Barquero et al., 2005), around HEP accelerators (Mares et al., 2017; Agosteo et al., 2012), cosmic-ray shower neutrons (Lee and Sheu, 2017; Vega-Carrillo and Manzanares-Acuña, 2004), neutron spectra associated with cyclotrons for the production of PET radionuclides (Benavente et al., 2015; Vega-Carrillo, 2001), and neutron field measurements associated with a nuclear fusion reactor (Hu et al., 2018) among other applications.

The first BSS consisted of a small 4 mm diameter \times 4 mm thick $^6\text{LiI}(\text{Eu})$ scintillation crystal containing 96.1% ^6Li and many modern BSS still utilize the small $^6\text{LiI}(\text{Eu})$ detector (Bedogni et al., 2010, 2018; Lacerda et al., 2017; Vega-Carrillo et al., 2014; Mirzajani et al., 2013; Ortiz-Rodríguez et al., 2013; Agosteo et al., 2012; Marek and Viererbl, 2011, 2008; Kim et al., 2010; Howell et al., 2009), Mazrou et al. (2008), and Burgett et al. (2008); although other thermal neutron detectors, such as ^3He based on the thermal neutron capture reaction $^3\text{He}(n,p)^3\text{H}$ are used (Masuda et al., 2017; Roberts et al., 2017; Lagares et al., 2016; Mazrou et al., 2016; Tamaki et al., 2015; Bedogni et al., 2014a, 2012; Rühm et al., 2014; Birattari et al., 2010; Méndez-Villafañe et al., 2010; Pioch et al., 2010) and passive detectors, such as ^{197}Au or ^{55}Mn activation foil material (Ueda et al., 2015; Domingo et al., 2010; Burgett et al., 2008; Fernandez et al., 2007), as well as spectrometers utilizing dysprosium activation foils based on the reaction $^{164}\text{Dy}(n,\gamma)^{165}\text{Dy}$ (Bedogni et al., 2013, 2014b; 2015; Gómez-Ros et al., 2012).

The spectrometer is calibrated with various polyethylene spherical moderators of differing diameters to provide an isotropic response to neutrons. The moderator spheres are manufactured to dimensions measured to the exact inch or half-inch. The units used to define Bonner sphere moderator dimensions since the onset was in inches and the dimension in inches in this particular case has remained popular, although centimeters are used by some

just as well. A schematic of the apparatus is illustrated in Fig. 9.90. Approximately 10–12 polyethylene moderator spheres of different diameter are used to calibrate the spectrometer. The sphere dimensions are precisely defined and may range from 2 to 18 inches in diameter. Each sphere, of course, has a hole to accommodate the detector, which is situated at the center of the sphere.

Each polyethylene moderator sphere of various diameters are constructed with a cylindrical hole drilled at the bottom leading to the center of the sphere to accommodate either a $^6\text{LiI}(\text{Eu})$ or ^3He thermal neutron detector. Fast neutrons are thermalized according to the size or diameter of the polyethylene sphere, as described by Reginatto (2009), and illustrated in Fig. 9.91. Neutrons that are thermalized within the polyethylene sphere and captured by the ^6Li according to the reaction $^6\text{Li}(n,\alpha)^3\text{H}$ produce a scintillation event within the $\text{LiI}(\text{Eu})$ crystal scintillation detector and a pulse event in the PMT.

Each polyethylene sphere with its thermal neutron detector combination has a different energy response to neutrons; and as the size of the moderator is increased, the peak of the response function shifts to a higher energy. Measurements of thermal neutrons without a sphere (bare detector) are also made. In addition to measuring thermal neutrons without a polyethylene sphere, i.e., the “bare detector”, measurements may be made with the thermal neutron detector covered with cadmium, which is referred to as the “Cd-covered bare detector” (Reginatto, 2009). The

multiple n–p scatterings that occur in the polyethylene sphere result in neutron thermalization before they hit the detector as illustrated in Fig. 9.91. Reginatto (2009) underscores that a BSS with a wide range of polyethylene spheres of various diameters is suitable for measurements of neutron energies in the range from thermal to ~ 20 MeV; and for measurements of higher neutron energies, it is necessary to use an extended-range Bonner sphere spectrometer (ERBSS) which includes, in addition to the standard sphere of a BSS, a few modified spheres with shells of high-Z metals embedded in them. Modified polyethylene spheres with concentric shells of Cu, Pb, and W provide response to neutrons energies >100 MeV (Lee and Sheu, 2017, 2015; Mares et al., 2017; Wang et al., 2015a,b; Esposito et al., 2010; Howell et al., 2010, 2009; Reginatto, 2009; Wiegel et al., 2009; Burgett et al., 2008).

The size and shape of the $^6\text{LiI}(\text{Eu})$ crystal and its high ^6Li enrichment is chosen to provide good gamma-ray discrimination and high efficiency for thermal neutrons, respectively. Approximately 80% of the thermal neutrons are absorbed in the surface 1.0 mm of the $^6\text{LiI}(\text{Eu})$ crystal, while gamma- and fast neutron interactions would be proportional to the volume of the detector. The small 4×4 mm detector provides a large surface to volume ratio to reduce detector response to fast neutrons and gamma rays. Also, the small dimensions of the $^6\text{LiI}(\text{Eu})$ detector permit the use of small polyethylene spheres (e.g., 50–60 mm in diameter) for the detection of low-energy neutrons. Either the $^6\text{LiI}(\text{Eu})$ crystal or the SP9 spherical ^3He proportional counter of 32 mm diameter operated at 2 atm pressure (Centronic Ltd., UK) can be used as thermal neutron sensors. The ^3He proportional counter is sensitive to thermal neutrons reacting according to the $^3\text{He}(\text{n,p})^3\text{H}$ reaction; and the $^6\text{Li}(\text{Eu})$ scintillator is also sensitive to thermal neutrons according to the reaction $^6\text{Li}(\text{n},\alpha)^3\text{H}$. The detector has superior neutron fluence response and gamma-ray discrimination. The use of pressurized ^3He detectors, which are highly sensitive to thermal neutrons, has been used commonly in the past; however, Bedogni et al. (2018) reports that due to the supply restrictions and high cost of ^3He , the scientific community is leaning toward cheaper detectors with acceptable sensitivity. With this in mind Bedogni et al. (2018) tested a Large $^6\text{LiI}(\text{Eu})$ Bonner Sphere Spectrometer (LL-BSS) measuring 11×3 mm, which is significantly larger than the standard 4×4 mm $^6\text{LiI}(\text{Eu})$ detector. Its sensitivity is lower than the 32 mm diameter pressurized (200 kPa) SP9 spherical ^3He detector; however, the large $^6\text{LiI}(\text{Eu})$ detector responds 50% better than the smaller 05NH1 pressurized (8 kPa) cylindrical (10×9 mm) ^3He detector.

The spherical spectrometer is calibrated as a function of sphere diameter and neutron energy over a broad range of neutron energies (e.g., $10^{-7} - >1000$ MeV). The response

of small moderator spheres will show an increase, peak out, and then decreases rapidly as the neutron energy is increased. This is what would be expected, because when the moderator is small low energy neutrons will have a good probability of reaching the detector; but as the neutron energy increases, small moderators become increasingly less efficient in thermalizing neutrons. The response of larger spheres is low for the low-energy neutrons, then increases according to neutron energy, reaches a maximum, and finally decreases at very high neutron energies. The low response of large-sphere moderators to low-energy neutrons is due to the capture of the thermalized neutrons by hydrogen of the polyethylene moderator. The path-length of travel of neutrons after thermalization is longer in the larger spheres, which increases their probability of capture before reaching the $^6\text{LiI}(\text{Eu})$ or ^3He detector. The high-energy neutrons, therefore, have increased chances of becoming thermalized in the larger polyethylene spheres and yet reach the detector. At very high neutron energies (>10 MeV) probabilities for thermalization in the larger polyethylene spheres diminishes and the response drops.

A key to the BSS is its calibration in terms of its response as a function of neutron energy. Bedogni et al. (2018) defines the response function of a given sphere as the counts in the central detector, per unit incident neutron fluence, when the sphere is uniformly irradiated. The response functions for different sphere sizes over a wide range of neutron energies are calculated; and Monte Carlo methods are used (Bedogni et al., 2018; Ghal-Eh et al., 2017; Lacerda et al., 2017; Rühm et al., 2014; Mirzajani et al., 2013; Mazrou et al., 2010; Howell et al., 2009; Vega-Carillo et al., 2008, 2009). The plot of Fig. 9.92 illustrates that the peak of the response function varies according to neutron energy and sphere size, and the response peak moves to higher energies as the sphere size increases. In a review by Thomas and Alevra (2002) they describe the sphere readings according to the following:

$$M_i = \int R_i(E)\phi(E)dE \quad (9.54)$$

where M_i is the reading for sphere i , $R_i(E)$ is the response function of sphere i exposed to a neutron field with spectral fluence $\phi(E)$. Good numerical methods are available that provide approximations to $R_i(E)$ supported with measurements from monoenergetic neutron sources. From measurements taken by the Bonner sphere set in an unknown neutron field, the extraction of $\phi(E)$ from the above calibration data permits the unfolding of the energy spectrum. As elucidated by Thomas and Alevra (2002) and Thomas (2010), neutron spectra is represented as an array where ϕ_j is the neutron fluence in group j extending over the energy range of E_j to E_{j+1} and a measured reading is given by

FIGURE 9.92 The calculated response functions of a $^6\text{LiI}(\text{Eu})$ BSS with the bare detector and with polyethylene spheres ranging in diameter from 3 inches to 15 inches. From Mirzajani et al. (2013); reprinted with permission from Elsevier © 2013.

$$M_i = \sum_{j=1}^n R_{ij} \phi_j \quad (9.55)$$

where R_{ij} represents the response function $R_i(E)$ averaged over group j . Eq. (9.54) provides a set of m linear equations, one for each sphere; and if $m \geq n$, the equations can be solved by least squares (Zaidins et al., 1978) to provide values of the spectral fluence ϕ_j . However, since the number of spheres is usually small ($m \approx 10$), the solution provides a poor representation of the neutron spectrum (Thomas and Alevra, 2002), and additional a priori information combined with spectral unfolding techniques are used. Many spectral unfolding codes have been developed; and the methods are reviewed by Roberts et al., (2017), Mazrou et al. (2016), Bedogni et al. (2014c), Thomas (2010) and Matzke (2002).

With the use of additional measurements with a “bare detector” (i.e., no polyethylene moderator sphere) and moderator spheres containing shells of high- Z metals providing ERBSS, a response function over a broader range of neutron energies can be obtained.

Chiles et al. (1990) developed a combined neutron and gamma-ray spectrometer using a cerium-activated ^6Li glass scintillator coupled to a Bicorn BC501 liquid scintillator, which can discriminate between thermal neutrons, high-energy neutrons, and gamma radiation. The ^6Li glass scintillator is sensitive to the thermal neutrons and emits light with a time constant of ~ 60 ns, while light emitted in the liquid scintillator by proton recoil from fast neutrons is emitted with a decay constant of ~ 30 ns, and the time constant for scintillations occurring from gamma-scattered Compton electrons is only ~ 3.7 ns. The three different

light decay constants make possible the electronic discrimination of pulses arising from the three different radiations. This type of detector was fabricated to facilitate neutron monitoring and surveillance in nuclear facilities and weapons storage, where a possibility of fission excursion exists.

Astronauts living and working in orbital space are exposed to various type of radiation including neutrons, protons, gamma radiation, heavier charged particles, etc. A unique neutron spectrometer capable of measuring the neutron spectrum in mixed neutron-gamma and neutron-proton radiation fields was developed by Taniguchi et al. (2001). The spectrometer utilizes a pair of ^6Li and ^7Li glass scintillators in a spherical polyethylene multi-moderator spectrometer similar to the Bonner sphere. A schematic view of the spectrometer is provided in Fig. 9.93. The spectrometer is designed to discriminate neutron from other particles, such as protons, which are dominate components of space radiation, by subtracting the light outputs of ^7Li glass scintillator from light produced by ^6Li glass scintillator. NE912 and NE913 glass-scintillator detectors are employed, which measure 2.54 cm long \times 2.54 cm diameter. The NE912 glass scintillator is doped with 7.7 wt% of 95% ^6Li -enriched lithium, whereas the NE913 glass scintillator contains 8.3 wt% of 99.99% ^7Li -enriched lithium. The ^6Li has a high sensitivity to thermal neutrons through the $^6\text{Li}(n,\alpha)^3\text{H}$ reaction discussed earlier in this chapter, and the ^7Li has a low sensitivity to neutrons. The scintillators are coupled to photomultipliers and the output pulse events are amplified and analyzed by a multichannel pulse height analyzer. Taniguchi et al. (2001) calculated the response functions to neutrons for the various polyethylene

FIGURE 9.93 Schematic view of the multi-moderator spectrometer with a pair of ^6Li and ^7Li glass scintillators. From Taniguchi et al. (2001); reprinted with permission from Elsevier © 2001.

moderator thicknesses and neutron energies (0.25–22 MeV). The detector demonstrated clear separation of neutron from gamma-ray events, when the neutron to gamma-ray flux was >0.3 , and neutron from proton events could be clearly discriminated.

X. Lucas cell

The Lucas cell is a popular instrument and among the most sensitive for the measurement of radon from various parts of the environment including soil gas (Sethy et al., 2014a; Cosma et al., 2013; Künze et al., 2012, 2013; Al-Hilal and Al-Ali, 2010; Mujahid and Hussain, 2010; Prasad et al., 2008), water with adequate water bubbling techniques (Shivakumara et al., 2014; Khan et al., 2009; Cosma et al., 2008; Singh et al., 2008; Machaj and Bartak, 2004), and in the general indoor environment of buildings and homes (Cosma et al., 2013; Frutos Vázquez et al., 2011; Hassan et al., 2011; Maharana et al., 2010; Al-Masri and Shwiekani, 2008; Prasad et al., 2008; Quindos Poncela et al., 2005; Abbady et al., 2004).

The Lucas cell is a solid scintillation chamber designed for the specific purpose of measuring the alpha-particle emissions of environmental levels of ^{222}Rn . It was first designed by Lucas (1957) at the Argonne National Laboratory, Lemont, Illinois; and the basic components of the cell have not changed since. A typical Lucas cell is illustrated in Fig. 9.94. The cell consists of a vessel of ~ 100 mL volume or larger and made of Kovar metal with a narrow brass collar at the top as the only orifice and a clear silica window at the flat bottom (face). The inner wall of the cell is coated with a thin layer (~ 20 – 50 mg/cm^2) of

FIGURE 9.94 Schematic diagram of a Lucas cell. From Eappen et al. (2008); reprinted with permission from Elsevier © 2008.

ZnS(Ag) scintillator. The inner surface of the flat window at the face of the Lucas cell is not coated with scintillator; it is covered with a transparent coat of tin oxide to maintain electrical conductivity and prevent any accumulation of radon or its daughters on the window. Environmental ^{222}Rn is first collected by a variety of methods, which may include grab sampling of soil gas into a large 120 mL gas tight syringe, as described by Cosma et al. (2013), Künze et al. (2012, 2013) with injection into an evacuated Lucas cell (Sethy et al., 2014b) or air sampling pump (El-Abnoudy and Hassan, 2016) including the continuous sampling of air into collection chambers (Chu et al., 2016) for the measurement of time dependence on radon

concentration (Tommasino, 2005) or bubbling the radon in water samples into evacuated Lucas cells (Shivakumara et al., 2014). To measure radon activity, the clear window of the Lucas cell is placed in contact with the face of a conventional PMT. The alpha particles of radon and its daughters in the Lucas cell interact with the scintillator; and the scintillation photons from these interactions are detected by the PMT and counted.

Radon (^{222}Rn) is the dominant source of human exposure to ionizing radiation worldwide (Tommasino, 2005). It is a colorless and odorless noble gas. Radon-222 is produced as a product of radium (^{226}Ra) in the uranium-238 decay series described in Chapter 1, Volume 1. Radon occurs in soil gas and groundwater from which it can seep into dwellings through building foundations and household bath and kitchen water. Added to the hazard are the four immediate radioactive decay products of radon-222, which achieve secular equilibrium with radon-222, illustrated in Fig. 9.95. Tommisino (2005) underscores that the alpha-particle emissions from the decay products exhibit a high linear energy transfer to human tissue. Continued exposure to excessive levels can impart damage to the human lungs increasing cancer risk, which is the underlying motivation for the analysis, monitoring, and remediation of radon in our environment.

Semkow et al. (1994) have determined the detection efficiency of the Lucas cell for ^{222}Rn and the three alpha particle emissions from ^{222}Rn and its daughters ^{218}Po and ^{214}Po . Cosma et al. (2013) reports a detection efficiency of 2.2 counts sec^{-1} to 1 Bq of radon activity. This corresponds to 2.2 counts for three alpha-particle emissions or a detection efficiency of $2.2/3.0 = 0.73$ when the ^{222}Rn and its daughter nuclides are in secular equilibrium within the Lucas cell. Shivakumara et al. (2014) also reported a detection efficiency of 0.74. Tommasino (2005) reports the efficiency of the Lucas cell to vary between 70% and 80%. It is necessary to allow at least 3 hours for the ^{222}Rn and its short-lived decay products ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po to reach secular equilibrium with the longer-lived ^{222}Rn before counting with the Lucas cell (El-Abnoudy and

FIGURE 9.95 Radium-226 subseries illustrating the radon-222 short-lived decay products (shaded area) that achieve secular equilibrium with the radon-222.

FIGURE 9.96 Ingrowth of daughter nuclides ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po with newly isolated ^{222}Rn plotted as I/I_{Rn} , which is the ratio of the radionuclide intensity to that of the parent ^{222}Rn , against time in minutes. The activities of ^{214}Bi and ^{214}Po are equal, as noted by Robley D. Evans, due to the very short 163.5 μs half-life of ^{214}Po . The radionuclide symbols are added by the writer. From El-Abnoudy and Hassan (2016); reprinted with permission from Elsevier © 2016.

Hassan, 2016; Shivakumara et al., 2014; Künze et al., 2012). The ingrowth of the short-lived daughter nuclides with the ^{222}Rn immediately after radon sampling is illustrated in Fig. 9.96, based on the ingrowth equations provided by Robley D. Evans (1907–95) in his classic paper on radon daughters (Evans, 1969).

The Lucas cell can also be used for the measurement of ^{226}Ra in water via the measurement of its emanating ^{222}Rn daughter after secular equilibrium is reached. The detailed procedure is provided by Peters et al. (1993) and Shivakumara et al. (2014). In brief, the principle of the method described by Peters et al. (1993) entails the concentration and separation of the radium-226 in water by coprecipitation with barium sulfate. The concentrated sample is redissolved and sealed in a purged flask (bubbler). After 21 days to allow for ingrowth of the radon-222 daughter, the gaseous ^{222}Rn is transferred to a Lucas cell using helium as a carrier gas and then counted as described. The detection limit is reported to be about 0.05 pCi per sample when counted for 1000 minutes, depending on the individual background of the Lucas cell used.

To improve the detection efficiency for a large volume Lucas cell and reduce background counts, Sakamoto and Takahara (2001) designed a scintillation cell with an inside diameter of 7.5 cm and a length of 30 cm constructed of a vinyl chloride tube with acrylic resin windows at each end. Condensing lenses were also placed at each end of the tube to aid in the detection of scintillation light by PMTs placed at each end. The inside wall of the tube was coated with $\text{ZnS}(\text{Ag})$ scintillator adhered onto aluminum sheet. The two PMTs provided for coincidence counting to reduce background. Pulse height analysis provides a spectrum of the alpha peaks, whereby proper selection of a counting window with discriminator settings would further facilitate

background reduction. The average counting efficiency for radon and its progenies was reported to be 0.55 with a background count rate of 0.015 cps. The lower limit of detection (LLD) for a 2-h counting time was less than 10 Bq/m³. [Quindos-Ponceta et al. \(2003\)](#) devised a modified Lucas cell whereby the inside walls of the cell were lined with ZnS(Ag) coated Mylar; and devised a removable transparent bottom to the cell. These modifications enabled the opening and removal of used ZnS(Ag) coated Mylar and its replacement with new ZnS(Ag) coated Mylar whenever contamination or background buildup would occur. This reduces the cost of recoating the inside surfaces of the cell with new scintillator; and the cell is rendered reusable at any time.

[Eappen et al. \(2007\)](#) used the Lucas cell for the on-line measurement of thoron (²²⁰Rn) by modifying the method used to measure radon (²²²Rn). In radon analysis, the α -counting with the Lucas cell is performed after a delay period varying from a few hours to a few days; however, in the thoron measurements the α -counting was initiated immediately after sampling due to the short half-life of thoron (55.6 seconds). [Eappen et al. \(2008\)](#) further developed the technique to permit the simultaneous analysis of radon and thoron with the Lucas cell. The method utilizes two arbitrary counting intervals from zero time with respect to the sampling and the formulation of simultaneous linear equations with two unknown variables, the radon and thoron activities in the Lucas cell.

XI. PHOSWICH detectors

A phoswich detector consists of two or more scintillation detectors optically coupled as a phosphor sandwich, from which the scintillation light output is viewed by a single PMT. This unique detector arrangement is designated as a PHOSWICH, which is the acronym for PHOSphor sandWICH. Research is directed to the development of phoswich detectors as practical instruments for the simultaneous measurement and discrimination of alpha, beta, gamma, and neutron radiation.

The principle behind phoswich detectors is the different properties of the interaction between scintillators and different types of radiation. In particular, scintillators will differ in their propensity to interact or absorb radiation depending on the type and even the energy of the radiation as well as display differing light output decay times with concomitant different pulse shapes. Consequently placing multiple scintillators of different types layered on top of each other as a sandwich detector and coupling the combined scintillators to one photomultiplier (e.g., PMT) will constitute a detector capable of measuring simultaneously several types of radiation.

The selection of the scintillators, their dimensions, and their arrangement as a sandwich will depend on the types

of radiation to be analyzed. For example, a phoswich detector designed to measure alpha/beta/gamma and neutron radiation will consist of scintillators sandwiched in a fashion so that the alpha particles are first absorbed by a thin scintillator sensitive to alpha particles, followed by a second scintillator that may be thicker but capable of absorbing the more penetrating beta particles, and another scintillator sensitive to the more penetrating gamma radiation and finally a fourth scintillator for the measurement of neutron radiation. Also, the scintillators that constitute the sandwich are carefully selected taking into account their differing scintillation light decay times, which can further facilitate pulse shape analysis for radiation discrimination.

A. Simultaneous counting of α -, β -, and γ -rays or α -, $\beta(\gamma)$ -rays, and neutrons

There is a need for detectors that can measure simultaneously radiations of several types particularly in the different processes and nuclear safety management required in the nuclear fuel cycle. Much research and development had gone initially into the development of phoswich detectors for the simultaneous measurement and discrimination of α -, β -, and γ -rays [Usuda \(1992\)](#); [Usuda and Abe \(1994\)](#); and [Usuda et al. \(1994a,b\)](#). An example of such a phoswich detector is the coupled three-detector array of ZnS(Ag), NE102A, and BGO scintillators designed by [Usuda et al. \(1994a\)](#) for the simultaneous counting of α , β , and γ rays. The phoswich consisted of a thin (10 mg/cm²) ZnS(Ag) scintillator sandwiched with a thicker (5 mm) NE102 plastic scintillator, which was sandwiched with a third 5 mm thick BGO scintillator. The α particles penetrate only the ZnS(Ag) scintillator, while the β particles and γ rays continue on to interact with the NE102A plastic scintillator, where β and soft γ interactions occur, and finally the hard γ rays continue on to interact with the BGO scintillator. This phoswich detector was tested for the discrimination of radiation types from a mixture of several sources such as ²⁴⁴Cm for α particles, ⁹⁰Sr(⁹⁰Y) for β particles, ²⁴¹Am for soft γ rays as well as α particles, and ¹³⁷Cs and ⁶⁰Co for β and γ counting. [Usuda et al. \(1994a,b\)](#) demonstrated that ZnS(Ag) is insensitive to β and γ rays with a pulse rise time the slowest among the scintillators, and the NE102A plastic scintillator has the highest sensitivity to β particles (low-Z scintillator), the fastest pulse rise time among the scintillators used, and a relatively narrow peak width (FWHM). The third scintillator, BGO, has a rise time intermediate between those of ZnS(Ag) and NE102A and a high sensitivity to γ rays (high Z and density). The BGO may be replaced with an NaI(Tl) scintillator for the third phoswich for radiation monitoring purposes, as the latter provides lower backgrounds in this triple-phoswich detector.

Usuda (1995) noted that, in the radiation monitoring of high burn-up spent fuels, significant neutron emission must be considered in addition to other forms of radiation. He devised a modification of the triple-phoswich detector previously described to include a ${}^6\text{Li}$ glass scintillator (NS8), which has a high reaction cross-section for thermal neutrons. A triple-phoswich detector assembly consisting of ZnS(Ag), NE102A plastic, and ${}^6\text{Li}$ glass scintillators permits the simultaneous counting of α , $\beta(\gamma)$ rays and thermal neutrons. The ${}^6\text{Li}$ glass scintillator used was cerium-activated 7.5% lithium silicate glass containing 95.6% enriched ${}^6\text{Li}$ (NS8 Nikon scintillator). The detector was further developed by Usuda et al. (1997, 1998a,b) and Yasuda et al. (2001) with the careful selection of scintillator detectors according to their pulse decay rise times, light outputs, and emission wavelengths with the employment of optical filters to further enhance the discrimination of pulse events from each scintillator according to pulse shape analysis. The phoswich detectors were developed to measure simultaneously α -, $\beta(\gamma)$ -rays, and fast neutrons (n_f) and thermal neutrons (n_{th}). A typical arrangement of a phoswich detector with these capabilities is illustrated in Fig. 9.97. Alpha particles are fully absorbed by the thin (10 mg/cm²) ZnS(Ag) scintillator. Beta particles of low

FIGURE 9.97 Arrangement of a ZnS(Ag)/anthracene/NS8 phoswich for simultaneous counting of α -, $\beta(\gamma)$ -rays and neutrons. From Usuda et al. (1997); reprinted with permission from Elsevier © 1997.

FIGURE 9.98 Pulse shape spectra of α , β particles (including γ rays), thermal and fission neutrons observed with ZnS(Ag)/anthracene/NS8 phoswich. From Usuda et al. (1998a); reprinted with permission from Elsevier © 1998.

energy (<20 keV) interact slightly with the ZnS(Ag), but the higher-energy beta particles continue on to be fully absorbed by the 10 mm thick anthracene scintillator. The fast neutrons interact with the anthracene via proton recoil while the thermal neutrons undergo neutron capture in the 5 mm thick NS8 ${}^6\text{Li}$ glass scintillator enriched in ${}^6\text{Li}$ to 95.6%. The phoswiches are protected from ambient light with Al-coated Mylar film (0.25 mg/cm²). The phoswiches can also be placed into radioactive solutions if protected with Au-coated Mylar film (0.9 mg/cm²). The output signals from the PMT have specific rise times and pulse heights that are analyzed by PSD. The rise-time distributions of α -, $\beta(\gamma)$ -rays, n_f and n_{th} from ${}^{244}\text{Cm}$, ${}^{137}\text{Cs}$, ${}^{252}\text{Cf}$ and ${}^{252}\text{Cf} + {}^{244}\text{Cm}$ reported by Usuda et al. (1997, 1998a,b) with the ZnS(Ag)/anthracene/NS8 phoswich are illustrated in Fig. 9.98. The acronym FOM in the figure refers to crystal figure of merit. The FOMs are separated into different categories, to reflect the ability of the scintillator to discriminate pulse events from different radiation sources. For example, Usuda et al. (1997) classified FOMs into $\beta(\gamma)/\alpha$, $\beta(\gamma)/n_f$, n_f/n_{th} , and n_f/α . Yasuda et al. (2001) used a more simple dual detector phoswich of ZnS(Ag)/ ${}^6\text{Li}$ glass or ZnS(Ag)/anthracene and a three-dimensional analysis of pulse event number, height, and rise time to fully separate β/γ , n_f , and α events.

Researchers at the University of Missouri—Columbia designed a triple crystal phoswich detector for the simultaneous analysis of alpha-, beta-, and gamma radiation (Childress and Miller, 2002; White and Miller, 1999), and they have evaluated each crystal for mischaracterizations of beta- and gamma radiation. Their detector design consisted of a sandwich of the following three detectors provided in the order of radiation penetration: (1) a 10 mg/cm² thick (0.002445 cm) ZnS:Ag for the detection of alpha particles, (2) a 0.254 cm thick $\text{CaF}_2\text{:Eu}$ crystal for the detection of beta particles and some low-energy gamma radiation, and

(3) a 2.54 cm thick NaI:Tl crystal for the measurement of gamma radiation. They used MCNP (Monte Carlo N-particle) simulation analysis (Briesmeister, 2000) capable of simulating electron, photon, and neutron interactions in detectors of simple geometry including spheres, cylinders, planes, cones, and ellipsoids. The application of Monte Carlo computer simulations to model interactions in detectors has been demonstrated to yield low errors (<5%) when compared to collected data (Bronson and Wang, 1996; Kamboj and Kahn, 1996; Ródenas et al., 2000). Analysis by Childress and Miller (2002) demonstrates that the most probable beta-particle energy loss in the first scintillator ZnS:Ag is around 20 keV due to the short path length that electrons can traverse in ZnS:Ag. The Monte Carlo code showed that the ZnS:Ag attenuation of gamma rays was restricted to gamma photons below 50 keV. The CaF₂:Eu preferentially interacts with beta particles. The Monte Carlo simulations found that the phoswich design has minimum inherent energy limits of 250 keV E_{\max} for beta particles and 50 keV for gamma rays. The 2.54 cm thick NaI:Tl crystal yielded intrinsic gamma efficiency ranges from a maximum of 80% for 100 keV to 26% for 2 MeV photons. Mischaracterization of gamma events in the CaF₂:Eu crystal can be calculated and corrected.

Yamamoto and Ishibashi (2015) developed a three-layer phoswich as an alpha-beta-gamma imaging detector, which may be used remotely for the imaging and analysis of radiation at sites of nuclear power plant accidents such as the Fukushima Daiichi accident. In such situations nuclear fission products abound with emissions of beta and gamma radiation and some nuclear fuels contain plutonium giving rise to alpha particle emissions. The imaging detector was comprised of a three-layer phoswich coupled to a positive photomultiplier tube (PSPMT) illustrated in Fig. 9.99. The face of the detector consisted of a thin plastic scintillator with a very short decay time of ~ 5 ns for the measurement and imaging of alpha particle sources. The second layer of the detector was made of thin Gd₂SiO₃ (GSO) scintillator with 1.5 mol % Ce with a decay time of 35 ns for the

FIGURE 9.99 Schematic drawing of alpha-beta-gamma imaging detector. From Yamamoto and Ishibashi (2015); reprinted with permission from Elsevier © 2015.

detector of mostly beta particles. The third layer consisted of a thin layer of GSO scintillator with a high concentration of Ce (0.4 mol %), which yielded a decay time of 70 ns. With PSD, the images produced by the alpha, beta, and gamma radiations were separated on the basis of the Anger Principle utilizing 8×8 anode signals from the PSPMT with resolutions of 1.25 mm FWHM for alpha and beta particles and 2 mm FWHM for gamma photons. The pulse shape spectra from alpha and beta particle and gamma photons are illustrated in Fig. 9.100. The peak to the right of the figure is from the first layer of plastic scintillator of the phoswich arising from mainly the alpha-particles of ²⁴¹Am, the middle peak is due mainly to the beta-particle radiation of ⁹⁰Sr/⁹⁰Y; and the peak to the left is due to gamma photons from ¹³⁷Cs.

B. Remote glass-fiber-coupled phoswiches

Studies by Yasuda et al. (2000a) found that a YAP scintillator (YAlO₃:Ce) has a fast rise time and sharp peak (small FWHM) with only 10 mg/cm² thickness in a

FIGURE 9.100 Pulse shape spectra for alpha and beta particles and gamma photons in the three-layer phoswich detector. The peak to the right is from the first layer of thin plastic scintillator mainly due to alpha particles from ²⁴¹Am. The middle peak is from the second layer of GSO scintillator with 1.5 mol % Ce due to mainly ⁹⁰Sr/⁹⁰Y; and the peak to the left is from the third layer of GSO scintillator with 0.4 mol % Ce mainly from ¹³⁷Cs gamma photons. phoswich detector coupled to a 5 mm thick YAG ($\text{Y}_3\text{Al}_5\text{O}_{12}:\text{Ce}$) scintillator, which was sufficient to accept high count rates and clearly distinguish alpha particles from beta and gamma rays. A new type of phoswich detector was developed by coupling a ZnS(Ag)/NE102A phoswich to the PMT via a quartz optical fiber. A NE172 wavelength shifter was positioned between the phoswich and the optical fiber for optimum scintillation light transmission via the optical fiber and readout by the PMT. The light from the phoswich detector is transmitted through the optical fiber for remote pulse shape analysis and discrimination of alpha and beta(gamma) rays (Yasuda et al., 2000b). This phoswich detector can be used to measure radioactivity in liquids as a dip-type inline monitor or to measure radioactivity in narrow or isolated spaces such as glove boxes or hot cells.

C. Low-level counters

Phoswich detectors are also employed in low-level counting of radionuclides in the environment in the presence of interfering γ radiation. For example, Wang et al. (1994) utilized a double $\text{CaF}_2(\text{Eu})$ -NaI(Tl) phoswich central (β, γ) detector in an anticoincidence low-background detector assembly for the measurement of β -emitting $^{89}\text{Sr} + ^{90}\text{Sr}(^{90}\text{Y})$ activities in waste effluent of nuclear power plants in the presence of γ -emitting radionuclides. The window of the $\text{CaF}_2(\text{Eu})$ crystal used in the phoswich assembly was coated with aluminized Mylar; and the crystal was very thin (0.0635 mm) compared with the coupled NaI(Tl) detector (6.36 cm thick). This allowed the low-atomic-number $\text{CaF}_2(\text{Eu})$ to perform as an effective β detector with negligible interaction of γ radiation. A separate detector guard consisting of a surrounding NaI(Tl) crystal operated in anticoincidence mode to reduce backgrounds in a high-background laboratory from 5880 ± 229 cps without shielding to 1.0 ± 0.1 cpm with shielding and anticoincidence counting. An MDA for ^{90}Sr of 20 pCi/L is reported.

Rajabi Moghadam et al. (2015) developed a combination of a fast and slow scintillator for the simultaneous spectroscopy of alpha particles and gamma photons for the analysis of environmental solid samples. They chose a BC400 plastic scintillator with 2.4 ns decay time sandwiched with a CsI(Tl) scintillator with a fast decay time of 0.68 μs . The stark differences in time responses of the sandwiched scintillators, pulses arising from only one decay are easily discriminated against those obtained with both decay components by means of pulse shape analysis. A 50 μ BC400 scintillator was demonstrated sufficient to completely stop and absorb the entire energy of 5485.56 keV alpha particles; and 2.5 cm thick CsI(Tl) was sufficient to capture the energy of 100 keV gamma photons, which demonstrated the suitability of this detector for

gamma-ray photons. The Minimum Detectable Activity (MDA) of 62.37 ± 5 mBq for alpha particles and 372.08 ± 10 mBq for gamma-rays is reported. The higher MDA for gamma photons is due to higher backgrounds from the thicker CsI(Tl) detector.

D. Simultaneous counting of n/ γ /p fields

Neutron spectrometers that can adequately discriminate between neutrons and charged particles and measure equivalent doses to the human body are needed in space exploration and inside large human spacecraft such as the International Space Station. In these environments high-energy charged particles in space produce high-energy neutrons by their interaction with the spacecraft structural materials. With this objective in mind, Takada et al. (2002) developed a phoswich detector for neutron spectrometry in a mixed field of neutrons and charged particles. They coupled two organic scintillators of different light-output decay times, which could measure high-energy neutrons up to 130 MeV.

The phoswich neutron detector consists of a 133 mm diameter by 133 mm long NE213 organic liquid scintillator surrounded by a 15 mm thick NE115 plastic scintillator. A glass cell encapsulates the liquid scintillator to protect the optically coupled NE115 plastic scintillator. The phoswich is coupled to a single PMT via a light guide. The NE213 scintillator was selected by Takada et al. (2002) for the measurement of high-energy neutrons because of its ability to discriminate between gamma rays and neutrons. The light-output decay times of this scintillator are 3.7 ns for gamma-ray induced scintillation and 30 ns for neutron-induced scintillation. The surrounding NE115 scintillator provides for charged-particle detection because it has a much longer 225 ns decay time.

The light decay time constants between the two scintillators employed in this phoswich detector was used to discriminate pulses of the three different particle species (n/ γ /p). Fig. 9.101 illustrates how the light output signals are produced in the scintillators via interactions of the three particle species, and how PSD of the light output are used to characterize the signals from the detector. In brief, the Compton electron scattered by a gamma ray dissipates its energy only in the NE213 scintillator, and its signal displays a fast component of 3.7 ns (Fig. 9.101A). The neutron is detected via proton recoil, illustrated in Fig. 9.101B, that occurs only in the NE213 scintillator; and it has a slower decay time of 30 ns compared to the gamma-ray. The proton dissipates its energy in both scintillators (NE115 + NE213), and its signal is much longer as it becomes the sum of the fast and slow components with a decay time of 225 ns for the slow component.

The three particles were detected by Takada et al. (2002) using PSD based on the standard Computer

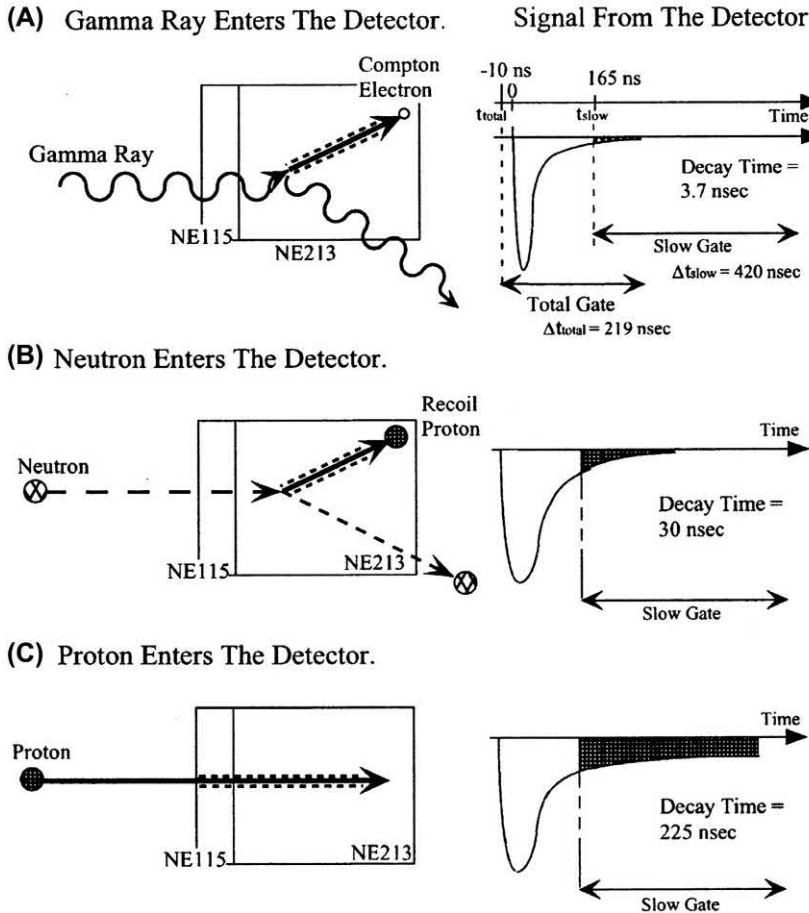

FIGURE 9.101 Schematic models of signals produced by the NE115/NE213 phoswich detector. (A), (B), and (C) are the cases of a gamma ray, neutron, or proton entering into the detector, respectively. The top-right sketch is the time relation between the pulse from the detector and the gate inputs to two ADCs. Two light outputs (total and slow components) are obtained by integrating the gate signal with the time intervals. From [Takada et al. \(2002\)](#); reprinted with permission from Elsevier © 2002.

Automated Measurement and Control (CAMAC) charge-integration ADCs (Lecroy 2249w, Lecroy Corp., Chestnut Ridge, NY). Analog-to-digital converters (ADCs) can be of two kinds, namely, an ADC that measures either charge or voltage and produces a digital number proportional to the magnitude of the input signal. [Takada et al. \(2002\)](#) developed energy-response functions of the phoswich detector to photons, neutrons, and protons. From the response functions, the energy spectra of the gamma photons, neutrons, and protons could be obtained through spectrum unfolding. Research in this direction was reported previously by [Takada et al. \(2001a,b\)](#).

Bismuth- and lithium-load transparent plastic (polyvinyltoluene, PVT) scintillators were fabricated and tested by [Cherepy et al. \(2015\)](#) for gamma photon and neutron discrimination. A phoswich detector consisting of bismuth-loaded PVT plastic coated with $\text{ZnS}(^6\text{Li})$ paint provided simultaneous gamma and neutron measurements via PSD with an FOM of 3.8 together with gamma spectroscopy with energy resolution of 15% at 662 keV. The FOM is a measure of the separation of the gamma-ray and neutron peaks, which is measured by the

difference between the centroid of the two peaks divided by the sum of the FWHM of each peak described further on in this section and defined by [Eq. \(9.53\)](#) earlier in this chapter.

A portable phoswich detector was designed by [Hartman and Barzilov \(2017\)](#) capable of differentiating fast and thermal neutrons and gamma photons. The phoswich consisted of ^6Li -loaded glass (5 cm dia. and 1 mm thick disc) enriched with $1.58 \times 10^{22} \text{ } ^6\text{Li atoms/cm}^3$ and EJ-299-33A plastic scintillators coupled to a single PMT. The ^6Li -glass scintillator has a high sensitivity to thermal and epithermal neutrons while it exhibits a low sensitivity to fast neutrons. A key factor in the design of the phoswich is the difference in the decay times of the two scintillators. The thermal neutron decay time in the ^6Li -glass is $\sim 60 \text{ ns}$; whereas, the plastic scintillator has a scintillation time constant of 4 ns for gamma photons and $\sim 30 \text{ ns}$ for neutrons via proton recoil, which enabled excellent discrimination between neutrons and gamma photons. It was designed as a highly portable handheld instrument measuring $9 \times 25 \times 17 \text{ cm}$ with a liquid crystal display touchscreen and a WiFi module for wireless communication.

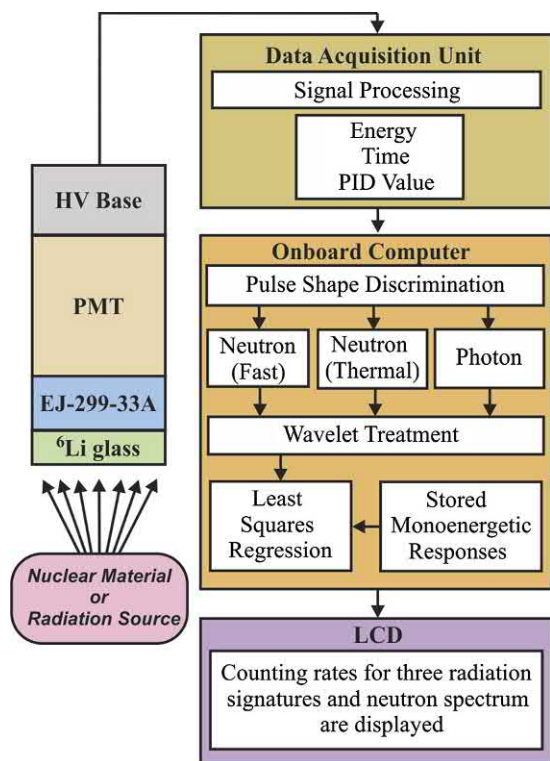

FIGURE 9.102 Scheme of operation of the handheld portable phoswich detector for neutron-gamma discrimination. From Hartman and Barzilov (2017).

In brief, the portable neutron-gamma phoswich detector of Hartman and Barzilov (2017) processes a gamma-neutron source as follows: The PMT anode signals created by scintillation photons go on to a data acquisition (DAQ) chip (See Fig. 9.102) which processes the data assigning an energy, time, and PID value to each signal. The PID value is the ratio of the integral under the tail of a signal (slow component) to the integral of the front part of the pulse (fast component), as illustrated in Fig. 9.103. The

FIGURE 9.103 Digitized PMT neutron and gamma photon signal waveforms for the EJ-299-33A plastic scintillator. From Hartman and Barzilov (2017).

PID values go on to a computer chip within the handheld device for PSD identifying the signals separate categories for fast neutrons, thermal neutrons, or gamma photons. The segregated waveforms then undergo a wavelet treatment plotting the shape of the response with data smoothing, which facilitates spectral unfolding and least squares regression for the decomposition of a polyenergetic neutron detector response as the sum of monoenergetic neutron responses. The slower scintillation decay time of the ^6Li -glass scintillator provided a measurement of the thermal neutron count rate. Hartman and Barzilov (2017) measured an FOM of 1.3 for the separate gamma photons and neutrons by the plastic scintillator, as illustrated in Fig. 9.104. The FOM is calculated as the difference between the centroid of the two peaks divided by the sum of the FWHM of the two peaks.

FIGURE 9.104 Neutron/gamma photon figure of merit. From Hartman and Barzilov (2017).

Huang et al. (2018) developed a gamma and neutron phoswich detector as a spectroscopic personal radiation detector (SPRD) in the form of a pocket-sized device for applications in homeland security related applications. The phoswich consists of a $\Phi 25 \times 25$ mm NaI(Tl) for gamma photon detection and a $\Phi 25 \times 3$ mm LiI(Eu) crystal for neutron detection. Pulse shape and pulse amplitude discrimination were used to separate gamma photon and neutron radiation. Energy resolutions for 661.6 keV gamma photons in NaI(Tl) and thermal neutrons in LiI(Eu) were measured as $7.0 \pm 0.2\%$ and $11.2 \pm 0.2\%$ respectively at a selected PSD threshold; and an FOM for gamma-neutron separation as a function of the PSD metric was measured as 4.4 ± 0.2 .

E. Neutron spectrometry

In the measurement of neutron energy by the recoil-proton method, undesired events in the scintillator are those where the recoil proton does not deposit all of its energy in the

scintillator, but rather escapes via scatter out of the scintillator. To eliminate those protons that deposit only part of their energy in the scintillator and thereby optimize energy resolution, Watanabe et al. (2008) devised a phoswich detector consisting of a plastic scintillator (NE 102A) with a fast decay constant (24 ns) surrounding a NaI(Tl) scintillator with a slow decay constant (230 ns). The large difference in decay constants of the two scintillators permits the use of PSD to discriminate between a pulse event that occurs in only one scintillator from an event that occurs in both scintillators. The principle of discrimination between recoil protons produced by a proton radiator (e.g., polyethylene) in the path of a neutron beam is illustrated in Fig. 9.105. The phoswich detector illustrated in the left-hand portion of Fig. 9.105 has a trapezoid body of NaI(Tl) inorganic crystal scintillator 362.5 mm in length surrounded with a NE102A plastic scintillator of 10 mm thickness with the exception of the detector face where the particles are incident. The length of the detector is sufficient to fully stop 400-MeV incident protons. Scintillation light

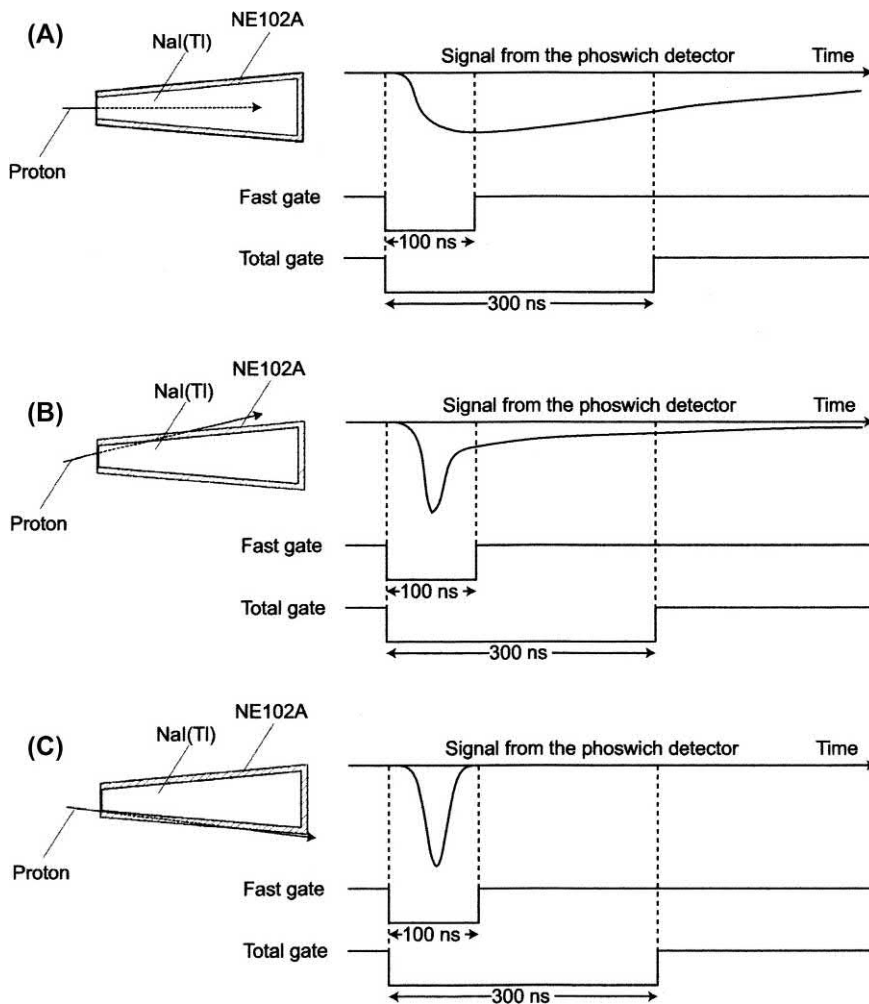

FIGURE 9.105 Schematic description of the principle of discriminating recoil protons with the phoswich detector: (A) recoil-proton deposits its energy in the NaI(Tl) crystal; (B) recoil-proton deposits its energy in both scintillators; and (C) recoil proton deposits its energy in the plastic scintillator. From Watanabe et al. (2008); reprinted with permission from Elsevier © 2008.

from the phoswich detector is transmitted onto a single PMT via a light guide at the rear end of the detector, which is not illustrated. [Watanabe et al. \(2008\)](#) took advantage of the fast decay time of the plastic scintillator (a few ns) and the slow decay time of the NaI(Tl) scintillator (230 ns) and utilized two different gate-charge integrations, illustrated schematically in [Fig. 9.105](#), to discriminate between proton events occurring only in the NaI(Tl) scintillator against events occurring in both scintillators. [Fig. 9.105A](#) illustrates the case where a proton deposits all of its energy in the NaI(Tl) scintillator whereby the output signal has a relatively small fraction in the fast component compared to the total scintillation light. On the other hand, when a recoil proton passes through both the NaI(Tl) and plastic scintillators, the resultant output signal has a larger fast component, as illustrated in [Fig. 9.105B](#). When a recoil proton losses energy only in the plastic scintillator, the output signal consists only of a fast component, as illustrated in [Fig. 9.105C](#). [Watanabe et al. \(2008\)](#) set charge integration to be made over time durations defined by the fast gate and the total gate, as illustrated in [Fig. 9.105](#). The fast gate was set to encompass the scintillation peak of the fast scintillator (100 ns); and the total gate covers a large portion of the long tail of the NaI(Tl) scintillator output signal.

The phoswich detector was calibrated for proton deposited energy by establishing the relationship between the deposited energy and the ADC channel for the NaI(Tl) scintillator. The calibration procedure, which made use of the Particle and Heavy Ion Transport code System (PHITS) described by [Iwase et al. \(2002\)](#), is elaborated by [Watanabe et al. \(2008\)](#) as follows: The energy deposited by the recoil proton was first calculated by PHITS, at the peak position generated by the H(n,p) reaction for an incident neutron energy. Then the calculated deposition energy was related

to the ADC channel of the full-energy peak in the response function that was measured for the same incident neutron energy. The calibration demonstrated a linear dependence of the ADC channel on the deposition energy over the proton-recoil deposited energy range of 40–400 MeV. Examples of phoswich detector response functions for incident neutron energies of 195–205 and 245–255 MeV are illustrated in [Fig. 9.106](#).

F. Simultaneous beta- and gamma spectroscopy

[Farsoni and Hamby \(2005\)](#) carried out initial studies on the β -particle energy depositions at different depths of a triple-layer phoswich detector consisting of BC-400/CaF₂:Eu/BC-444 scintillators with decay constants of 2.4, 940, and 264 ns, respectively. The scintillators had thicknesses sufficient to completely stop 0.1 MeV electrons in the first layer, 1.0 MeV electrons in the second layer, and 2.5 MeV electrons in the third layer. Using Monte Carlo N-Particle (MCNP) analysis, it was demonstrated that the traditional rise time measurement technique could not provide appropriate and accurate PSD with this type of phoswich detector. These results guided future work by [Farsoni and Hamby \(2007\)](#) into the development of a triple-layer phoswich detector capable of the simultaneous discrimination and spectroscopy of beta- and gamma-ray particles. The phoswich detector contained three scintillators layered as illustrated in [Fig. 9.107](#). The first layer after the aluminized Mylar window is a thin plastic scintillator (BC-400) with very fast light decay characteristics (2.4 ns); and the second layer is an inorganic crystal scintillator (CaF₂:Eu), which displays a very slow light decay signal (900 ns). The effective atomic numbers (Z_{eff}) are low for the first two scintillators; and thus both layers are appropriate for β -

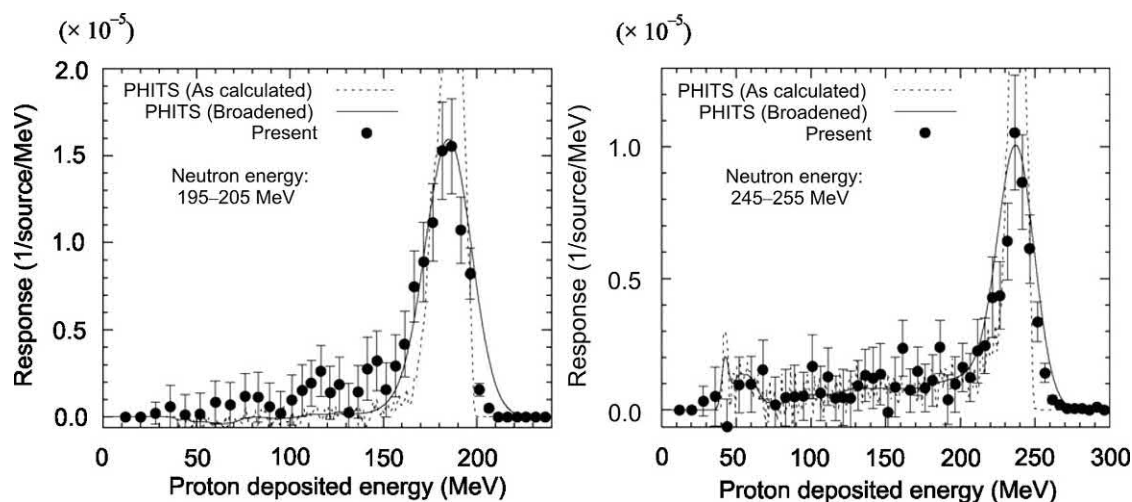

FIGURE 9.106 Experimental response functions of the phoswich detector with the calculation by PHITS. From [Watanabe et al. \(2008\)](#); reprinted with permission from Elsevier © 2008.

FIGURE 9.107 Schematic diagram of a triple-layer phoswich detector for the simultaneous discrimination and spectroscopy of β -particles and γ -rays. Layers of the detector are separated for clarity; but the real design has no spaces. From Farsoni and Hamby (2007); reprinted with permission from Elsevier © 2007.

particle detection with a thickness sufficient to stop electrons with energies up to 3.2 MeV. Beta particles are accepted, if they deposit energy in one or both of these two scintillators. The third scintillator of the phoswich is layered under or after a 6.36 mm thick quartz optical window. It consists of the inorganic crystalline scintillator NaI(Tl), which displays moderately slow scintillation light decay characteristics (230 ns). This last scintillator is intended to measure only γ -rays. The combined thickness of the previous two scintillators and the quartz optical window prevents the incursion of electrons (i.e., β -particles) with energies ≤ 6.7 MeV. Thus, any commonly

encountered β -particles cannot reach the NaI(Tl) scintillator.

Simultaneous beta/gamma spectroscopy was demonstrated with the phoswich detector devised by Farsoni and Hamby (2007); and an example of typical spectra obtained for ^{14}C and ^{137}Cs sources are illustrated in Fig. 9.108. The system utilizes a customized digital pulse processor and characterization logarithm. The MCNP software package was used to establish response characteristics of the phoswich detector to electrons and photons. When a mixed beta/gamma field is analyzed, the detector generates pulses from which the type of radiation and its energy can be distinguished. The energy maximum (E_{max}) of the ^{14}C β -particles of 156 keV illustrated in Fig. 9.108 corresponds to the theoretical value; and the γ -ray spectrum of ^{137}Cs at 662 keV has an energy resolution of $\sim 6.7\%$ (Farsoni and Hamby, 2007).

A phoswich detector composed of two detectors consisting of an inorganic scintillator (calcium chlorborate) together with a scintillating plastic was devised by Arsaev and Kladov (2007) for beta spectrometry. The phoswich detector was able to discriminate backgrounds by a factor of 9.3 lower than that of a single detector based on plastic scintillator and pulse heights were linearly proportional to the beta-particle energy.

The measurement of radioactive xenon in the atmosphere is one of several methods that are used to monitor nuclear weapons testing. Farsoni et al. (2013) underscore that the measurement of the four xenon radioisotopes listed in Table 9.9 together with their relative concentration ratios in the atmosphere will enable the International Monitoring

FIGURE 9.108 Simultaneous beta and gamma-ray energy deposition spectra from ^{14}C and ^{137}Cs obtained with a triple-layer phoswich detector. From Farsoni and Hamby (2007); reprinted with permission from Elsevier © 2007.

System (IMS) to monitor nuclear weapon testing worldwide. Research is directed toward improving a highly efficient and sensitive method of measuring the xenon radioisotopes by beta-gamma coincidence, which involves measuring simultaneously the beta-particles or conversion electrons and the gamma-rays or X-rays emitted by the xenon radioisotopes.

For the simultaneous beta-gamma analysis, small amounts of xenon must be extracted from large volumes of air; and to circumvent the use of separate monitoring stations and separate detectors to analyze low-levels of beta and gamma emissions from radioisotopes of xenon, the development of a single phoswich detector for this purpose has been researched (Yongchun et al., 2017; Farsoni et al., 2013; Warburton et al., 2011; Hennig et al., 2009; de la Fuente et al., 2008; de Celis et al., 2007; Henning et al., 2007; Ely et al., 2005; Ringbom et al., 2003; McIntyre et al., 2001). A phoswich detector composed of ZnS(Ag), $\text{CaF}_2(\text{Eu})$, and NaI(Tl) scintillators was coupled to a single PMT for $\alpha/\beta/\gamma$ recognition and a fast electronic card for PSD analysis (de la Fuente et al., 2008). The phoswich detector could be operated in coincidence mode to identify a composed signal produced by the simultaneous detection of α/β particles and X-ray/ γ particles. The coincidence detection technique can enable the monitoring of low levels of gaseous fission products produced by underground nuclear explosions. Warburton et al. (2011) reviews phoswich detector designs, which employ a BC404 plastic scintillator to detect the beta-particles and a CsI(Tl) or NaI(Tl) scintillator to detect the gamma photons in coincidence with the beta-particles, referred to as “PhosWatch”, which can achieve radioxenon detection limits required for nuclear explosion monitoring. They also research the application of an atomic layer deposition of Al_2O_3 as a coating to prevent the “memory effect” arising from the diffusion of Xe into the BC404 scintillator. Yongchun et al. (2017) research the

absorption-desorption behavior of xenon gases on BC-404 scintillator, as the phoswich detector is required with sufficient sensitivity for its utilization in verifying the Comprehensive Nuclear Test Ban (CTBT) treaty with the measurement of radioxenon.

Farsoni et al. (2013) designed a unique phoswich for the beta-gamma coincidence measurement of xenon radioisotopes applicable to the monitoring of nuclear weapons testing. The phoswich is designed with three scintillation layers illustrated in Fig. 9.109. The beta-gamma coincidence events from radioxenon are identified when a coincidence energy absorption is measured in the first BC-400

FIGURE 9.109 Schematic diagram of the three-layered phoswich detector for beta-gamma coincidence measurements of atmospheric radioxenon. From Farsoni et al. (2013); reprinted with permission from Elsevier © 2013.

plastic scintillator and the second CsI(Tl) crystal scintillator. A BGO scintillator layer surrounds the CsI(Tl) crystal to identify and reject Compton scattering events in the gamma photon detection layer. When a gamma photon triggers both the CsI(Tl) and BGO layers, the event is rejected, which provides a Compton suppression capability to reduce the Compton continuum in the gamma photon energy spectrum measurements. A 1 μm aluminum coating on the face of the BC-400 scintillator blocks the diffusion of Xe into the scintillator. The decay times of the BC-400 and CsI(Tl) scintillators are 2.4 and ~ 1000 ns, which facilitates the beta-gamma PSD. The detection system implements an online real-time digital processing firmware implemented in a Field-Programmable Gate Array (FPGA) device as well as a PC-based digital pulse processing algorithm. By means of the FPGA algorithm structure the system is triggered, pulse shapes are discriminated, Compton events are rejected, beta-gamma coincidence events are identified, the beta and gamma energies are measured, and the energy histograms are updated. An example of the real-time beta-gamma coincidence analysis and discrimination of beta and gamma events for ^{135}Xe and ^{133}Xe is provided by Figs. 9.110 and 9.111. The beta-spectrum of ^{135}Xe in Fig. 9.110 extends slightly beyond the 850 keV E_{max} of the beta-particle emissions due to the coincident detection of conversions electrons at 45 keV.

G. Other phoswich detectors

Phoswich detectors are under development for a wide range of applications not mentioned previously in this chapter among which include the detection and measurement of heavy ions in the region of $Z \gg 10$ (Carbone et al., 2018; Muralithar et al., 2013), for the discrimination and measurement of neutrons, photons, and protons in the showers of cosmic radiation (Kole et al., 2015; Lawrence et al., 2014a,b; Takada et al., 2010) and in high-energy nuclear reaction experiments (Cherepy et al., 2015; Nácher et al., 2015; Tengblad et al., 2013), the measurement of fast (1–10 MeV) solar neutrons in the inner heliosphere (McKibben et al., 2005), and for X- and low-energy γ -ray astronomy at high altitudes (Mazumdar et al., 2010).

There is a current impetus in research on the development of phoswich detectors for the coincident measurement of annihilation radiation in PET as a tool in the medical field as an advanced imaging technique for cancer diagnosis and research (Kobayashi et al., 2017a,b; Olaya Dávila et al., 2017; Shimazoe et al., 2017; Yamamoto et al., 2016, 2014). As described by Olaya Dávila et al. (2017), an image produced by a PET is based on the external coincidence detection of two 0.511 MeV gamma-ray photons emitted at opposite directions from their point of origin; and the validation of an annihilation event requires a coincidence

FIGURE 9.110 Gamma (top) and beta (bottom) energy spectra from ^{135}Xe collected in real-time using the “MCA” mode of the Field-Programmable Gate Array device of the phoswich detector of atmospheric radioxenon. From Farsoni et al. (2013); reprinted with permission from Elsevier © 2013.

FIGURE 9.111 Gamma (top) and beta (bottom) energy spectra from ^{133}Xe collected in real-time using the “MCA” mode of the Field-Programmable Gate Array device of the phoswich detector of atmospheric radio-xenon. From Farsoni et al. (2013); reprinted with permission from Elsevier © 2013.

measurement in the order of 12 ns of difference between the opposite detectors in a PET system, as illustrated in Fig. 9.112. Coincident events are registered and an image constructed according to the points of origin of the positron-negatron annihilations. Research is underway to improve the spatial resolution of the images produced in PET by utilizing phoswich detectors. High-resolution PET can be achieved by the determination of the depth-of-interaction (DOI), which improves the spatial resolution in peripheral areas of the field of view by reducing the parallax error for the 511 keV annihilation gamma photons (Shimazoe et al., 2017). Depth-of-interaction measurements can be achieved with phoswich detectors, which have

different decay times and PSD for scintillation crystal identification in the PET electronics (Kobayashi et al., 2017a,b; Olaya Dávila et al., 2017; Shimazoe et al., 2017; Yamamoto et al., 2016).

H. Analytical expressions

The analytical expressions for the total and full energy peak efficiencies of phoswich detectors are provided by Abbas (2010), Abbas and Noureddeen (2011), and Yalcin et al. (2009). These expressions involve accurate analytical calculations of the path length, that the photon traverses in the active volume of the detector and the geometrical solid

FIGURE 9.112 Schematic drawing of a phoswich detector arrangement in a PET instrument. A positron emitted by the Na-22 undergoes annihilation emitting two 511 keV gamma photons in opposite directions, which are detected at opposite ends in a 12 ns coincidence window. The ^{22}Na of 2.6 y half-life is used only for research into PET experimental design. Very short-lived positron emitters are utilized in nuclear medicine imaging such as ^{11}C , ^{13}N , ^{15}O or ^{18}F , among others. The detectors consist of two sandwiched Ce-doped $\text{Li}_{1.8}\text{Gd}_{0.2}\text{SiO}_5$ (LGSO) scintillators with different Ce concentrations yielding scintillating crystals with fast and slow pulse decay times. The scintillators are coupled to highly sensitive silicon photomultipliers. From Yamamoto et al. (2016); reprinted with permission from Elsevier © 2016.

angle subtended by the source to the detector at the point of entrance. Monte Carlo and experimental methods are described by these researchers.

XII. Neutrino interactions

As discussed in Chapter 1, Volume 1, the neutrino is an elusive particle of zero charge and very low mass. The detection and measurement of neutrinos is traditionally carried out with very large masses of liquid scintillators (see Chapter 6, Volume 1), which can provide tons of target material.

Solid scintillators including inorganic crystal scintillators have yet been found to be as useful compared to liquid scintillators, for the detection and measurement of neutrinos because of the large mass of target material needed and the difficulty of fabricating inorganic scintillator crystals to very large size and mass. Nevertheless, a large 500 kg CsI(Tl) detector is under development for the detection and measurement of nuclear reactor antineutrinos near the core of the Kuo-sheng Nuclear Power Station in Taiwan. Nuclear power reactors are an abundant source of electron antineutrinos ($\bar{\nu}_e$) in the low-energy (MeV) range. The work is a collaboration mainly between China and other countries, referred to as the TEXONO Collaboration, which is described in detail by Wong (2015), Zhu et al. (2006), Liu et al. (2002), Lai et al. (2001), Li et al. (2001) and Wong and Li (1999, 2000). More than one detector may be utilized inside an inner target volume; and one of the detectors is an array of CsI(Tl) crystal scintillators illustrated in

FIGURE 9.113 Schematic of the CsI(Tl) target configuration. From Wong (2015), and Zhu et al. (2006); reprinted with permission from Elsevier © 2006.

Fig. 9.113. The detector, consists of about 187 kg of CsI(Tl) crystals (Unique Crystals, Beijing) arranged in a 17×15 matrix with each crystal module weighing ~ 2 kg. The individual CsI(Tl) crystal modules are hexagonal in shape with a length of 40 cm and side measuring 2 cm. PMTs are situated at both ends of each module for scintillation light readout; whereby, the sum of the two PMT signals ($Q_{\text{tot}} = Q_1 + Q_2$) can provide the energy of the event and the difference of the two signals can serve as a measure of the longitudinal position of the event. The PMT signals are received by amplifiers and shapers, and then digitized by a Flash Analog Digital Converter (FADC). Pulse shape analysis is possible to discriminate between pulse events produced by heavy charged particles, such as alpha particles, and those produced by electrons from γ events in the crystal.

The compact and massive CsI(Tl) detector enables sufficient shielding to be built around it including an outer plastic scintillator cosmic-ray veto, 15 cm of lead and 5 cm of steel to shield against ambient background radioactivity, 25 cm of boron-loaded polyethylene to absorb cosmic-ray induced neutrons, and a dry-nitrogen outer atmosphere sealed in plastic to prevent radon gas from diffusing into the target region. Wong (2015) and Liu et al. (2001) describe advantages of the CsI(Tl) detector when compared to the conventional liquid scintillation detector, in addition to its compactness described above. These are the following:

- (1) a large γ -ray photon attenuation of the crystal detector due to its high Z nuclei and density, particularly in the low energy range below 500 keV. For example, the attenuation length for a 100 keV γ ray is only 0.12 cm in the CsI(Tl) detector; whereas, in a liquid scintillator it would be 6.7 cm. Thus, at this low γ -ray energy, 10 cm of CsI(Tl) detector would have the same attenuation power as 5.6 m of liquid scintillator.
- (2) a characteristic detector response, that is, the energy resolution of the CsI(Tl) detector is better than a typical liquid or plastic scintillator; and the low-energy γ -ray photons in the crystal scintillator would be fully stopped.

The major event that would be measured in the CsI(Tl) detector are neutrino–electron scattering, which is described in Chapter 1, Volume 1, Section X.G and Chapter 6, Volume 1, Section XII.B. The electron antineutrinos originating from the decay of reactor fission products interact with electrons in the CsI(Tl) detector via the elastic scattering reaction

due to charged current (CC) and neutral (NC) weak current interactions (Deniz, 2012). The scattered electron can receive any kinetic energy from the neutrino less than or

equal to the kinetic energy of the neutrino (Kraus, 2006). Experimentally, the recoil energies of the electrons from the neutrino interactions can be measured in the scintillator; and experimental searches for the neutrino magnetic moment will focus on the reduction in the threshold for the recoil electron energy (Li et al., 2001).

Other electron antineutrino interactions that can occur with the CsI(Tl) detector are inverse beta decay with ^{133}Cs and ^{127}I . Inverse beta decay is discussed in detail in Chapter 1, Volume 1, which is described by the following:

$$\bar{\nu}_e + p^+ \rightarrow n + \beta^+ \quad (9.57)$$

Inverse beta decay results in a reduction in atomic number of the isotope be it ^{133}Cs or ^{127}I according to the following:

$$\bar{\nu}_e + (A, Z) \rightarrow (A, Z - 1)^* + \beta^+ \quad (9.58)$$

The positron yields a prompt signature with the emission of 511 keV annihilation photons. Characteristic gamma lines from the daughter nuclides are additional signatures. Li et al. (2001) note that with CsI(Tl) as the active target, the gamma lines with M1 transitions would be 81 and 160 keV for ^{133}Cs and 58, 202, and 418 keV for ^{127}I . These would be observed in the pulse height spectra from the CsI(Tl) detector.

Bressi et al. (2001) and Antonini et al. (2001) proposed the use of Yb-doped $\text{Y}_3\text{Al}_5\text{O}_{12}$ (YAG:Yb) scintillator for the detection of low-energy neutrinos. Subsequent research support the potential of Yb-doped YAG as well as other Yb-doped crystal scintillators for neutrino measurements (Yoshida et al., 2018; Zhu et al., 2018a,b; Chékir-Mzali et al., 2016; Nikl et al., 2013; Ferhi et al., 2012; Ricci et al., 2011; Belogurov et al., 2003, 2004; Chipaux et al., 2002). The electron neutrino reacts with the ^{176}Yb as follows:

$$\nu_e + ^{176}\text{Yb} \rightarrow ^{176}\text{Lu}^* + e^- \quad (Q = 301 \text{ keV}) \quad (9.59)$$

$$^{176}\text{Lu}^* \rightarrow ^{176}\text{Lu} + \gamma \quad (E_\gamma = 72 \text{ keV}) \quad (9.60)$$

The asterisk in Eqs. (9.59) and (9.60) denote an excited state of ^{176}Lu . The signature for this neutrino event is a prompt electron and delayed gamma signal, and to provide discrimination against background noise, a delayed coincidence within 50 ns is required as well as high light yield. The charge transfer luminescence of Yb^{3+} has a great potential to be used for fast scintillator applications. Scintillators having fast response can be a strong tool for applications requiring detections with a high count rate (Yoshida et al., 2018). Also, Zhu et al. (2018a,b) notes that the charge-transfer luminescence of Yb^{3+} in Yb-doped YAG crystals can have a decay time of <4 ns; and that such an ultrafast scintillation property of the Yb:YAG crystal has attracted broad attention in many research areas including

applications in solar neutrino detection. The neutrino reaction with ^{176}Yb differs from that of reactions described by Eqs. (9.57) and (9.58), as the neutrino reacts with a neutron resulting in an increase in atomic number, as described in Chapter 1, Volume 1 according to the following:

$$\nu_e + n \rightarrow p^+ + e^- \quad (9.61)$$

$$\nu_e + (A, Z) \rightarrow (A, Z + 1) + e^- \quad (9.62)$$

Tests on YAG:Tb crystals with as much as 15% Yb have been conducted by Bressi et al. (2001) and Antonini et al. (2001). They demonstrated a fluorescence time of approximately 10 ns and a light yield of 8000 photons/MeV, which would be suitable for neutrino detection.

Other potential inorganic scintillators for the detection and measurement of neutrinos are the Indium-based crystal scintillators (Lasserre, 2013; Hsiao and Chang, 2011; Borisevich et al., 2005). Inverse beta decay with ^{115}In was first proposed by Raghaven (1976) for the detection and measurement of neutrinos. The inverse beta decay in nuclei of ^{115}In would occur in indium-based crystal scintillators as follows:

$$\nu_e + ^{115}_{49}\text{In} \rightarrow ^{115}_{50}\text{Sn}^* + e^- \quad (9.63)$$

The superscript asterisk in Eq. (9.63) denotes an excited state of ^{115}Sn , which decays to the ground state with a lifetime of 4.76 μs and emits two γ -ray photons of 116 and 497 keV. This provides a triple-coincidence signal, namely the emitted electron together with the two γ -ray photons (Fukuda et al., 2010).

XIII. Double beta ($\beta\beta$) decay measurements

The discovery, principles, and current research on double beta decay are reviewed in Chapter 1, Volume 1. A treatment of the liquid scintillation techniques and semiconductor detectors employed in the search for neutrinoless double beta decay is provided in Chapters 6 and 4, Volume 1. Only a brief treatment of the methods applied in the use of solid inorganic crystal scintillators to the measurement of double beta decay and the search for neutrinoless double beta decay will be given here.

Double beta decay was predicted by Nobel Laureate Maria Goeppert-Mayer (1935) at Johns Hopkins University. The first observation of double beta decay was made by Steven R. Elliott, Alan A. Hahn, and Michael K. Moe at the University of California, Irvine in 1987. They measured double beta decay in a sample of ^{82}Se enriched from its natural abundance of 8.7% to an isotope abundance of 97% to provide more source material for the double beta decay as well as reduce contamination from other sources (Elliott

et al., 1986, 1987; Moe, 1986; Moe and Rosen, 1989). The decay scheme is written as follows:

where the parent nucleus decays to a daughter nucleus of the same mass number A , but with an increase in atomic number Z by two. In general, the double beta decay process is expressed in terms of the nuclear atomic and mass numbers as

Thus, in accord with the beta decay scheme, within the nucleus of the parent nuclide, two neutrons decay to two protons with the simultaneous emission of two beta particles and two antineutrinos. This type of beta decay is abbreviated as $2\nu\beta\beta$ or $2\nu2\beta$ to signify the simultaneous emission of two neutrinos and two beta particles.

Double beta decay is a rare event manifested by very long half-lives from 10^{18} to 10^{24} years. Because of the rarity of the event, the measurement of double beta decay is extremely difficult requiring a large mass of nuclide often achieved with highly enriched radionuclide sources and the use of instrumentation with the capability of extreme suppression or vetoing of background radiation. The National Nuclear Data Center of the Brookhaven National Laboratory currently lists 12 nuclides that are known to undergo double beta decay, and for which decay data are well documented; these are in order of increasing atomic order $^{48}_{20}\text{Ca}$, $^{76}_{32}\text{Ge}$, $^{82}_{34}\text{Se}$, $^{96}_{40}\text{Zr}$, $^{100}_{42}\text{Mo}$, $^{116}_{48}\text{Cd}$, $^{128}_{52}\text{Te}$, $^{130}_{52}\text{Te}$, $^{136}_{54}\text{Xe}$, $^{130}_{56}\text{Ba}$, $^{150}_{60}\text{Nd}$, and $^{238}_{92}\text{U}$ (NNDC-BNL, 2018). As discussed in Chapter 1, Volume 1, beta decay is not confined to negatron emission. Other modes of beta decay also exist, which include positron emission and EC decay processes. Research is underway with inorganic crystalline scintillation detectors including low-temperature scintillating bolometers for the measurement of $\beta^+\beta^+$, β^+/EC , and double EC (i.e., ECEC) decay processes (Barabash, 2015; Kang et al., 2013; Krutyak et al., 2013; Belli et al., 2008, 2009; Kim et al., 2007; Danevich et al., 2003).

There is much research underway in numerous laboratories around the world directed toward the potential application of solid inorganic crystal scintillation detectors among other detection methods (see also Chapter 4, Volume 1 and Chapter 6, Volume 1) for the detection and measurement of neutrinoless double beta decay, and only a few of the reports on this work are cited here. Among these are research projects into the measurement of double beta decay of the following nuclides with crystal scintillation detectors including:

- (i) ^{106}Cd and ^{116}Cd with CdWO_4 crystal scintillator (Sisti et al., 2016; Belli et al., 2010; Bardelli et al., 2006; Danevich et al., 2003, 2005a, 2006),

- (ii) ^{48}Ca with CaF_2 and CaWO_4 crystal scintillators (Iida et al., 2016; Sisti et al., 2016; Maneschg, 2015; Umehara et al., 2015; Yoshida et al., 2005, 2009; Ogawa et al., 2003, 2004),
- (iii) ^{64}Zn , ^{180}W and ^{186}W with ZnWO_4 crystal scintillator (Danevich et al., 2014; Krutyak et al., 2013; Belli et al., 2008, 2009),
- (iv) ^{100}Mo with CaMoO_4 crystal scintillator (Jiang et al., 2018; Pan et al., 2018a; Park et al., 2016; Sisti et al., 2016; Maneschg, 2015; Kang et al., 2013; Annenkov et al., 2008),
- (v) ^{150}Nd with yttrium–aluminum garnet doped with neodymium, abbreviated as YAG:Nd (Danevich et al., 2005b),
- (vi) ^{82}Se and ^{100}Mo with ZnSe and ZnMoO_4 crystals (Maneschg, 2015), and
- (vii) ^{160}Gd with $\text{Gd}_2\text{SiO}_5(\text{GSO}):\text{Ce}$ scintillating crystals (Kobayashi et al., 2012).

Beyond the Standard Model there exists the possibility that the neutrino could be its own antiparticle, referred to as a Majorana neutrino. According to this theory, if the neutrino possesses a rest mass (now estimated to have a mass upper limit of $2.3 \text{ eV}/c^2$) and is its own antiparticle, a neutrino emitted in one beta decay could be reabsorbed in the second beta decay resulting in a double beta decay in which no neutrinos are emitted. i.e., a neutrinoless double beta decay often abbreviated as $0\nu\beta\beta$ or $0\nu2\beta$ (See Chapter 1, Volume 1 for a more detailed treatment). Current investigation into the search for neutrinoless double beta decay is important, because it would affirm the mass of the neutrino, as only a particle with a definite rest mass can oscillate from one form into another. The Nobel Prize in Physics 2015 was awarded jointly to Takaaki Kajita and Arthur B. McDonald for the discovery of neutrino oscillations, which provides evidence that neutrinos have mass. The current search and measurement of neutrinoless double beta decay would allow the measurement of the effective neutrino mass and define the absolute neutrino mass scale as described by Maneschg (2015).

In the $2\nu\beta\beta$ process, the two beta particles that are emitted simultaneously share the total decay energy, $Q_{\beta\beta}$, with the two neutrinos. Thus, the decay energy is shared between four particles, namely, the two neutrinos and two beta particles. In the $0\nu\beta\beta$ process, the two beta particles emitted share the entire decay energy, as there would be no neutrinos emitted with which to share the decay energy. The general beta-particle energy spectra for $2\nu\beta\beta$ and $0\nu\beta\beta$ decay are illustrated in Fig. 9.114. The two beta-particle spectra are very distinct. In the $2\nu\beta\beta$ decay process, the numbers of beta particles (N) vary over a wide range of energy plotted as the sum of the two beta-particle energies divided by the decay energy, i.e., $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta}$. The beta-particle energy spectrum for the $2\nu\beta\beta$ decay would

FIGURE 9.114 Beta-particle energy spectra for (A) two-neutrino double-beta decay ($2\nu\beta\beta$), and (B) neutrinoless double-beta decay ($0\nu\beta\beta$). In the $2\nu\beta\beta$ decay process, the sum of the two beta particle energies divided by the decay energy, $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta}$, displays a continuous spectrum and the maximum will never reach 1.0; whereas, the spectrum for $0\nu\beta\beta$ would display a single line at $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta} = 1$. From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.

encompass the continuous energy range with a spectral shape similar to that of the single beta-particle emission, because they share the decay energy with neutrinos. From Fig. 9.114 it can be seen, that the endpoint of the continuous beta-particle spectrum of the $2\nu\beta\beta$ decay does not reach the value of 1.0. This is due to the fact that the two beta particles emitted in the $2\nu\beta\beta$ decay process must share decay energy with two neutrinos, and thus the sum of the two beta particle energies can never equal the decay energy, $Q_{\beta\beta}$. However, the beta-particle energy spectrum for the $0\nu\beta\beta$ decay, where neutrinos do not escape with any of the decay energy, would display a single energy line for the sum of the two beta particle energies, and this line would occur at $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta} = 1$. Current research is underway in the search for the sum of the two beta particles to equal the decay energy, $Q_{\beta\beta}$, or where $\sum(E_{\beta_1} + E_{\beta_2})/Q_{\beta\beta} = 1$, which would confirm $0\nu\beta\beta$ decay.

An example may be taken from the case of double beta decay of ^{116}Cd , where $2\nu\beta\beta$ decay has been measured with $^{116}\text{CdWO}_4$ crystal scintillator; and the $0\nu\beta\beta$ decay is yet to be confirmed (Sisti et al., 2016; Arnaboldi et al., 2010; Gironi et al., 2009; Bardelli et al., 2006; Danevich et al., 2003, 2005a,b, 2006). The $2\nu\beta\beta$ decay of ^{116}Cd can be written as

where the mass number remains constant at 116; and the atomic number increases from 48 to 50. The beta decay scheme of ^{116}Cd ; and the simulated response functions of a $^{116}\text{CdWO}_4$ crystal scintillator in $2\nu\beta\beta$ and $0\nu\beta\beta$ decay of

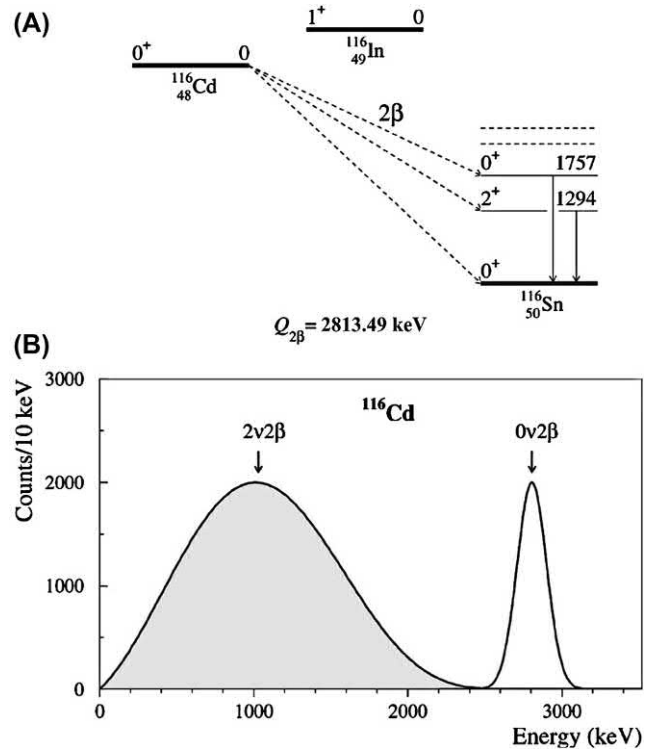

FIGURE 9.115 (A) The scheme of ^{116}Cd – ^{116}In – ^{116}Sn triplet and (B) Simulated response functions of the $^{116}\text{CdWO}_4$ crystal scintillators to the 2ν and 0ν modes of the 2β decay of ^{116}Cd . From Danevich et al. (2003); reprinted with permission from Elsevier © 2003.

the ^{116}Cd are illustrated in Fig. 9.115. The double beta decay energy ($Q_{\beta\beta}$) of the ^{116}Cd of 2813.49 keV, given in Fig. 9.115, is calculated by the difference in parent and daughter nuclide atomic mass units ignoring the negligible difference in the binding energies of the electrons of the two nuclides (see Eq. (1.247) of Chapter 1, Volume 1) or

$$\begin{aligned} Q_{\beta\beta} &= (M_{^{116}\text{Cd}} - M_{^{116}\text{Sn}})c^2 \\ &= (115.90476323\text{u} - 115.90174282\text{u})(931494 \text{ keV/u}) \\ &= 2813.49 \text{ keV} \end{aligned} \quad (9.67)$$

where $M_{^{116}\text{Cd}}$ and $M_{^{116}\text{Sn}}$ are the atomic masses of the parent and daughter nuclides ^{116}Cd and ^{116}Sn , respectively, in atomic mass units; and where $1\text{u} = 931.494 \text{ MeV}/c^2$ (see Eqs. (1.10) and (1.11) of Chapter 1, Volume 1). Atomic Mass Units are available from IOP Science of which the latest table was published in 2017 (Chinese Physics C 41, No. 3 (2017) 030003, <http://iopscience.iop.org/article/10.1088/1674-1137/41/3/030003>).

The ^{116}Cd decays by double beta ($\beta\beta$) directly to ^{116}Sn , as illustrated in Fig. 9.115A. There is no transition of ^{116}Cd via a single beta decay to ^{116}In because the mass and thus energy level of the ^{116}In is higher than the ^{116}Cd ; and this

transition is thus forbidden. The simulated response functions of a ^{116}Cd -enriched CdWO_4 crystal scintillator is illustrated in Fig. 9.115B. The $2\nu\beta\beta$ decay would produce a broad peak covering a wide range of energies, as this peak represents a broad spectrum of energies that the two β -particles share with two neutrinos (i.e., four particles share the 2813.49 keV decay energy, two β -particles and two neutrinos); whereas, the neutrinoless double beta decay ($0\nu\beta\beta$) would be manifested as a single peak at 2813.49 keV, as illustrated in Fig. 9.115B, because two β -particles would be emitted simultaneously without neutrino emission; and the sum of their energies would be equivalent to the decay energy.

To take the example of ^{116}Cd further, the calculated $\beta\beta$ decay energy and simulated $^{116}\text{CdWO}_4$ crystal scintillator response, discussed in the previous paragraph, was put to experiment by Danevich et al. (2006, 2005a, 2003). These researchers utilized four cadmium tungstate $^{116}\text{CdWO}_4$ scintillators enriched to 83% ^{116}Cd providing a total mass of 330 g of detector material. The $^{116}\text{CdWO}_4$ detector was surrounded with an active shield consisting of 15 CdWO_4 crystals of large volume providing a mass of 20.6 kg. An additional outer active shield was made of plastic scintillator measuring $40 \times 40 \times 95$ cm providing a complete 4π active shield of the main $^{116}\text{CdWO}_4$ detector. Additional outer passive shielding with high purity copper, lead, and polyethylene layers were utilized. For each event in the $^{116}\text{CdWO}_4$ detector, signal amplification, arrival time and pulse shape were recorded. With the combined active and passive shielding and pulse shape analysis, the background count rate in the energy region 2.5–3.2 MeV was reduced to 0.037(10) counts/(yr·kg·keV), which was the lowest background achieved with crystal scintillators. Low backgrounds in the 2.5–3.2 MeV energy region was important because the calculated $Q_{\beta\beta}$ is 2.813 MeV (see Eq. 9.67). The measured spectra from the $^{116}\text{CdWO}_4$ detector are illustrated in Fig. 9.116, among which is the clearly defined energy spectrum from the $2\nu\beta\beta$ decay of ^{116}Cd (curve a).

The $0\nu\beta\beta$ decay peak is not observed from the experimental data illustrated in Fig. 9.116; however, the $2\nu\beta\beta$ decay peak (curve a) is clearly defined; and Danevich et al. (2003, 2005a) illustrate the experimentally determined value of the double-beta decay energy $Q_{\beta\beta} = 2808 \pm 43$ keV (see Inset of Fig. 9.116). The experimentally determined double-beta decay energy is very close to the theoretically computed value ($Q_{\beta\beta} = 2813.49$ keV) as computed above in Eq. (9.67); and calculated with QCalc (2018), which is the on-line computer and data base of the National Nuclear Data Center, Brookhaven National Laboratory (<https://www.nndc.bnl.gov/qcalc/>).

From the inset of Fig. 9.116, we can see from the experimental spectrum that the peak corresponding to $0\nu\beta\beta$ decay should be measured unequivocally at $Q_{\beta\beta}$, which is

FIGURE 9.116 Spectra of $\gamma(\beta)$ events measured with $^{116}\text{CdWO}_4$ detector during 12,649 hours. Also shown are the most important model components: (A) the $2\nu\beta\beta$ spectrum of ^{116}Cd ; (B) external γ background caused by radioactive contamination of the PMTs; ^{40}K contamination of the (C) nonenriched and (D) enriched CdWO_4 scintillators. Solid line represents the fit of the data in the 860–2700 keV energy interval. (Inset) The $2\nu\beta\beta$ decay Kurie plot and its fit. From Danevich et al. (2003, 2005a); reprinted with permission from Elsevier © 2005.

also where the tail of the $2\nu\beta\beta$ spectrum will appear. Thus, a sufficient number of counts from $0\nu\beta\beta$ decay must be measured over very long periods of measurement. This is an extremely challenging task that requires low backgrounds and large masses of double-beta decaying nuclide. In view of the difficulty in meeting the challenge of measuring $0\nu\beta\beta$ decay, Orío (2016) underscores the following criteria: “In order to have chances of observing the $0\nu\beta\beta$ peak, it is mandatory to have a consistent detector mass (at least of the order of 100 – 1000 kg) to maximize the number of $\beta\beta$ emitters, and a very low background in the region of interest (ROI) to minimize the spurious events. Another fundamental requirement to fulfill is a good energy resolution, to discriminate the $0\nu\beta\beta$ peak from the right tail of the $2\nu\beta\beta$ distribution. The difficulty in observing the $0\nu\beta\beta$ peak can be appreciated by the inset of Fig. 9.117.”

Examples of the application of inorganic crystal scintillators as well as other detector types utilized in the search for $0\nu\beta\beta$ decay are listed in Table 9.10. The table also lists the eight principle nuclide candidates to the measurement of $0\nu\beta\beta$, the Q value for the double beta decay ($Q_{\beta\beta}$), the natural abundance of the nuclide of interest, the world production of the elements with natural isotope abundance of the nuclide of interest, and the acronym for the research project or collaboration, detector type, and fiducial $\beta\beta$ mass. Enrichment of the nuclide of interest whenever possible is obviously an advantage. Also, the greater the fiducial mass of the $\beta\beta$ nuclide, the greater will be the potential for the measurement of $0\nu\beta\beta$ decay.

FIGURE 9.117 $2\nu\beta\beta$ and $0\nu\beta\beta$ two electrons sum energy spectra. $2\nu\beta\beta$ is a continuum between 0 and $Q_{\beta\beta}$, while $0\nu\beta\beta$ is a peak centered at $Q_{\beta\beta}$. In the inset is shown that a good energy resolution is needed to disentangle the two spectra. The y-axis scale and the $0\nu\beta\beta$ relative peak height are arbitrary. From *Orio (2016)*.

Inorganic crystal scintillators offer, in certain circumstances, advantages over other detector types or they may be the only alternative for the measurement of $\beta\beta$ decay on the basis of the following:

- With inorganic crystal scintillators several nuclides of interest that undergo $\beta\beta$ decay can be incorporated directly into the molecular structure of crystal scintillators, and often at an atom-percent enrichment. In other words, the source = the detector. Examples are (1) the measurement of ^{116}Cd decay with $^{116}\text{CdWO}_4$ crystal enriched in ^{116}Cd to 83% (*Sisti et al., 2016; Belli et al., 2010; Bardelli et al., 2006; Danevich et al., 2003, 2005a, 2006*); (2) the measurement of ^{106}Cd decay with $^{106}\text{CdWO}_4$ crystal scintillator enriched in ^{106}Cd to 66.4% (*Belli et al., 2010*); (3) the search for double beta decay processes in ^{64}Zn with ZnWO_4 crystal scintillator at the ^{64}Zn natural abundance of 48.6% (*Danevich et al., 2014; Krutyak et al., 2013; Belli et al., 2008, 2009*); (4) the development of CaMoO_4 crystal scintillators for double beta decay measurements of ^{100}Mo (*Jiang et al., 2018; Pan et al., 2018; Park et al., 2016; Sisti et al., 2016; Maneschg, 2015; Kang et al., 2013; Annenkov et al., 2008*); (5) the development of yttrium–aluminum garnet doped with Nd (YAG:Nd) scintillator to measure double beta decay of ^{150}Nd (*Danevich et al., 2005b*); (6) the use of $^{48}\text{CaWO}_4$ to measure ^{48}Ca double beta decay (*Zdesenko et al., 2005*); (7) The search for double beta decay processes in ^{64}Zn , ^{70}Zn , ^{180}W and ^{186}W with ZnWO_4 crystal scintillators (*Belli et al., 2009*) and ZnMoO_4 (*Maneschg, 2015*); and (8) The measurement of ^{48}Ca $2\nu\beta\beta$ decay and the search for $0\nu\beta\beta$ decay with $^{48}\text{CaF}_2$ crystal

scintillator at a 2% enrichment of ^{48}Ca (*Suzuki, 2010; Ogawa et al., 2003, 2004; Yoshida et al., 2005, 2009*).

- Measurements of radionuclide decay where source = detector with inorganic crystal scintillators can provide the potential for a large mass of source and target material in a small or minimal volume of detector. For example, one of the largest projects ongoing in the search of $0\nu\beta\beta$ decay with a crystal scintillator is the CANDLES (CALcium fluoride for the study of Neutrinos and Dark matter by Low Energy Spectrometer) system utilizing $^{48}\text{CaF}_2$ crystal scintillator in Osaka, Japan. A 305 kg prototype detector is undergoing experimentation (*Iida et al., 2016; Umehara et al., 2015*). The project will increase the target mass to 3.4 tons and eventually 30 tons with 2% enrichment (*Suzuki, 2010*).

Bonvicini et al. (2014) lists advantages and disadvantages of certain scintillation detectors over other detector types in the search for $0\nu\beta\beta$ decay. In brief, these advantages are listed as follows:

1. Ge diode detectors and bolometers have excellent energy resolutions; and they offer solutions for background reduction. However, Ge diodes and bolometers are limited in the achievable mass increase, which is due to cost in the case of Ge diode detectors and technical issues in the case of bolometers.
2. Large-scale organic scintillation detectors have no apparent limitation in terms of mass scalability in low background environment; however, these detectors yield poor energy resolution.
3. Xenon liquid- or gas-based time projection chambers must make a trade off between source mass and energy resolution; although they provide powerful background reduction concepts.
4. The ideal is to include, in one single instrumental setup, all of the critical factors for the measurement of $0\nu\beta\beta$, namely (i) high energy resolution, (ii) powerful background reduction methods, and (iii) source mass scalability. Large arrays of inorganic scintillators may achieve this end.
5. Inorganic scintillating crystals offer the following advantages: (i) They can be grown with a high level of purity with the source isotope within the crystal structure often at a high isotopic enrichment. The high purity achievable with inorganic crystal scintillators can yield excellent scintillation properties needed for a high energy resolution. (ii) Several $0\nu\beta\beta$ candidate nuclei are contained in a wide range of inorganic scintillators, which can provide flexibility on the choice of scintillation detector. (iii) Quenching factors (i.e., differences in light yield for an α -particle or nuclear recoil compared to that of an β -particle or γ -photon) and PSD remove all alpha background from the energy region around

Left: A side view of an array of 108 $^{40}\text{Ca}^{100}\text{MoO}_4$ crystal scintillators, Right: Front view of 19 stacked scintillator detectors where a silicon drift detector as photodetector is coupled to each circular surface of each detector. The calcium can be deleted in the isotope ^{48}Ca and enriched in ^{100}Mo . The CaMoO_4 scintillator has a very high molybdenum content of 48% in mass. From [Bonvicini et al. \(2014\)](#).

$Q_{\beta\beta}$, which are powerful tools for background reduction. (iv) Large arrays of inorganic scintillators can be assembled without much technical complications in a relatively low-cost experimental setup. For example, inorganic scintillation crystals are easily shaped as separate units and stacked together to form a large detector with an optimum mass of $\beta\beta$ source nuclide, as illustrated in [Fig. 9.118](#).

General reviews on the methods used for the measurement of double beta decay and the search for neutrinoless double beta decay are available from [Henning \(2016\)](#), [Maneschg \(2015\)](#) and [Ejiri \(2010\)](#).

XIV. Scintillating bolometers

A scintillating bolometer consists of a crystal scintillator connected to a thermistor, which will measure the temperature increase in the scintillator caused by energy absorbed from the incident radiation, and connected to a second bolometer (e.g., thin film of $\sim 100\ \mu\text{m}$ of Ge), which will measure the energy of the scintillation photon by the increase in temperature caused by the absorbed light. Scintillating bolometers are used to discriminate and measure nuclear particles; and they are promising tools in the search for neutrinoless double beta ($0\nu\beta\beta$) decay and for Weakly Interacting Massive Particles (WIMPs) of Dark Matter.

A. Operating principle

The operating principle of a scintillating bolometer is illustrated in [Fig. 9.119](#). Current scintillating bolometers

FIGURE 9.119 Operating principle of a scintillating bolometer. The energy of an incident particle is absorbed by the scintillating crystal. The release of energy inside the scintillating crystal follows two channels: light production and thermal excitation. The heat produced in the process is read out by temperature sensors (e.g., thermistors) attached to the crystal scintillator and to the light detector. The energy absorbed by the scintillator and the light intensity are converted into heat. From [Gironi \(2010\)](#); reprinted with permission from Elsevier © 2010.

may be referred to as containing dual bolometers because they contain the crystal scintillating bolometer, which absorbs most of the energy of the incident particle with that energy measured as heat increase, while in turn, a second optical bolometer absorbs emitted scintillation light, which is also measured by the temperature increase produced by the absorbed light.

The possibility of the simultaneous measurement of the heat and light signals as a new tool for particle identification was proposed by [González-Mestres and Perret-Gallix \(1988\)](#). The very different scintillation yield of different particles (e.g., β/γ particles, α particles, and recoiling nuclei) could be used to identify the type of particle, whereas the heat signal would serve as a measure of the deposited energy with high resolution ([Ortigoza et al., 2011](#)). The β/γ particles are grouped together here because γ photons produce Compton electrons in the crystal scintillator and these electrons deposit their energy like β particles. The work of [Alessandrello et al. \(1992\)](#) demonstrated the first simultaneous detection of scintillation light and heat signals at low temperature (20 mK) with a $\text{CaF}(\text{Eu})$ scintillating bolometer. The light intensity was measured with a Si PD. [Bobin et al. \(1997\)](#) advanced the technology further with the simultaneous measurement of heat and light with a $\text{CaF}_2(\text{Eu})$ target bolometer optically coupled to a second infrared bolometer for the measurement of the scintillation light intensity. [Alessandrello et al. \(1998\)](#) demonstrated the strong suppression of background with the scintillating bolometer, and thus the potential of the scintillating bolometer for the measurement of double beta ($\beta\beta$) decay.

A schematic diagram of a current scintillating dual bolometer (i.e., scintillating crystal bolometer with optical

FIGURE 9.120 Schematic view of a dual bolometer configuration. The ^{55}Fe source, is not a necessary component. It is included here as an inner ^{55}Fe X-ray source placed opposite the Ge optical bolometer to calibrate the energy absorbed on the optical detector. From *Ortigoza et al. (2013, 2011)*; reprinted with permission from Elsevier © 2011.

bolometer) is illustrated in Fig. 9.120. The principle of operation is described in detail by several researchers (Artusa et al., 2014a,b; Arnaboldi et al., 2011a,b; Ortigoza et al., 2011; Cebrián et al., 2005; Coron et al., 2004, 2008, 2009). In brief, the principle of operation, in accord with the schematic illustrated in Fig. 9.120, is as follows: A scintillating crystal (e.g., ~ 50 g BGO) is located within a reflecting cavity of Ag-coated Cu. The crystal scintillator is connected to a Neutron Transmutation Doped Ge (NTD-Ge) thermistor, which measures the heat signal from the scintillator resulting from the absorption of an incident particle. A second bolometer, the optical detector, consists of a thin (~ 100 μm) Ge disk, which is connected to a second NTD-Ge thermistor, receives the heat signal following the absorption of scintillation light from the crystal scintillator. The dual bolometers (i.e., scintillating crystal and optical detector) are thermally linked to a mixing chamber of a dilution refrigerator at 20 mK. A plastic optical fiber permits the periodic feeding of light pulses ($\lambda = 820$ nm) to the bolometers to monitor bolometer stability and correction for gain drifts. An inner ^{55}Fe X-ray source may be placed on the back side of the Ge optical bolometer to calibrate the absorbed energy. When an incident particle deposits its energy in the scintillation crystal, the major portion of that energy will be converted to heat; and the remaining energy is emitted as scintillation light, which is likewise converted to heat in the optical detector. The heat signals from the scintillator crystal and Ge optical sensors are received by their respective NTD-Ge thermistors.

The energy-absorbing scintillator and Ge-optical detector must be coupled to a constant temperature source by means of a thermal link. As described by Arnaboldi et al. (2011a,b), the temperature variation induced by an energy

release (E) in the absorber is inversely proportional to the heat capacitance (C) of the bolometer, which is written as

$$\Delta T = \frac{E}{C} \quad (9.68)$$

The accumulated heat flows to the heat sink through the thermal link; and the absorber returns to the base temperature with a time constant $\tau = C/G$, where G is the thermal conductance of the link:

$$\Delta T(t) = \frac{E}{C} e^{-t/\tau} \quad (9.69)$$

To obtain a measurable temperature rise, the heat capacity of the absorber must be very small. Thus, bolometers must be operated at cryogenic temperatures of the order of 10–100 mK (Arnaboldi et al., 2011a,b).

The pulse amplitude of the signal from the scintillator bolometer is registered as a Heat Signal, and the pulse amplitude from the optical bolometer is registered as a Light Signal, as illustrated in Fig. 9.121. The intensities of the light signals or scintillation yields (i.e., light outputs) will differ in accord with the type of particle absorbed in the scintillator at a given energy. The light/heat amplitude ratios of the following orders of magnitude for a CaWO_4 crystal scintillator have been measured: 1, 2.5, and 10 for neutron-induced nuclear recoil events, α events, and β/γ events, respectively (Cébrian et al., 2003, 2005); and different scintillation yields by the different particle events in the scintillator serve as the basis for the discrimination of particles, as discussed in the subsequent paragraphs.

FIGURE 9.121 Signal due to the energy released (2615 keV) by a γ -ray in a CdWO_4 crystal scintillator (solid line) and light detected simultaneously by the Ge light detector faced toward the CdWO_4 crystal (dashed line). From *Gironi et al. (2009)*; reprinted with permission from Elsevier © 2009.

B. Search for neutrinoless double beta ($0\nu\beta\beta$) decay

The theory of neutrinoless double beta ($0\nu\beta\beta$) decay is discussed in detail in Chapter 1, Volume 1 and techniques used in the search for $0\nu\beta\beta$ decay are provided in Chapters 4 and 6 of Volume 1, and previously in [Section XIII](#) of this chapter. Scintillating bolometers promise to be an important tool in the detection of $0\nu\beta\beta$ decay.

Double beta ($\beta\beta$) decay with the simultaneous emission of two neutrinos, abbreviated $2\nu\beta\beta$ decay, exhibits a continuous beta spectrum as illustrated in Fig. 1.59 of Chapter 1, Volume 1 and [Figs. 9.114, 9.115 and 9.117](#) of this chapter. The continuous $2\nu\beta\beta$ decay has been demonstrated in liquid scintillation measurements to present a significant background interference in the observation of the peak, which would be due to $0\nu\beta\beta$ decay (see Fig. 6.112 of Chapter 6, Volume 1). However, [Gironi \(2010\)](#) underscores that with the excellent resolutions provided by scintillating bolometers the continuous spectrum of $2\nu\beta\beta$ would seldom present a significant source of background. Research efforts are underway in several countries to develop the scintillating bolometer for the ongoing worldwide search for $0\nu\beta\beta$ decay ([Arnaboldi et al., 2010, 2011a,b; Barinova et al., 2010; Gironi, 2010; Gironi et al., 2009; Pirro et al., 2006](#)).

[Artusa et al. \(2014a,b\)](#) provide a detailed description of the varying light and heat yields of particles in scintillating bolometers, which forms the basis for particle discrimination; and the following is a brief explanation based on their account: The ratio of light and heat signals from the scintillating bolometer is a function of particle mass and charge. The thermal response of a bolometer will not vary to a high degree with particle type ($\sim 7\%$ with TeO crystals and $\sim 10\%–20\%$ for scintillating crystals); however, the light yield from the scintillator (i.e., fraction of particle energy emitted as photons of light) will differ significantly with ionization energy density. Thus, the light emission produced by β -particles and γ -photons will be similar; whereas, the light emission induced by α -particles and neutrons will differ from that produced by the β - or γ -particles. Thus, in the search for $0\nu\beta\beta$ with scintillating crystals containing a double beta decaying nuclide, the energy deposited by the two β -particles from the double beta decay can be identified from an α signal; and only beta-particles and gamma photons contribute to background events.

The varying scintillation yields of particle-events of different types, namely neutron recoil events, α events, and β/γ events in the scintillating bolometer crystal absorber permits the discrimination of these particle events, and consequently a means of significantly reducing background. The β/γ events are classified together, because γ -rays interact with scintillator by the production of Compton

electrons, which interact with scintillator similar to β -particles. Obviously then γ -ray and β -particle interactions are indistinguishable; and any γ -ray interference as background must be eliminated in the search for $0\nu\beta\beta$ decay. Background reduction or elimination is carried out mainly by means of the discrimination of particles according to their different scintillation yields or light outputs. The pulse amplitude of the Ge optical bolometer (Light Signal) measured in coincidence with the pulse amplitude of the scintillator bolometer (Heat Signal) are plotted against each other (Light Pulse Amplitude vs. Heat Pulse Amplitude) to provide a scatter plot whereby α events and nuclear recoil events can be discriminated against β/γ events, as illustrated in [Fig. 9.122](#). Further discrimination of background α events from β/γ events is achievable through PSD of the heat signals ([Arnaboldi et al., 2011a,b](#)).

One of the major sources of interfering background in the search for $0\nu\beta\beta$ decay is γ -rays because events due to γ -rays are indistinguishable from β -particle events. However, [Pirro et al. \(2006\)](#) and [Arnaboldi et al. \(2011a,b\)](#) point out that the highest interfering γ line is the 2615 keV line of ^{208}Tl with the exception of the extremely rare high-energy γ -rays from ^{214}Bi ; and that the problem of interfering γ -ray backgrounds would be avoided by confining the search for $0\nu\beta\beta$ decay to nuclides with $\beta\beta$ decay energies ($Q_{\beta\beta}$) above 2615 keV. Nuclides with double beta decay energies above the 2615 keV line are listed in [Table 9.11](#).

FIGURE 9.122 Light versus heat signals plot obtained at Orsay under ^{252}Cf neutron source irradiation. The inset shows a detail of the low-energy region. From [Cebrián et al. \(2003\)](#); reprinted with permission from Elsevier © 2003.

Pirro et al. (2006) demonstrate that by confining the search for $0\nu\beta\beta$ decay to nuclides that have decay energies above the 2615 keV γ -line of ^{208}Tl will altogether eliminate background events. They demonstrate that, in a 417 hours live-time background measurement with a CdWO_4 bolometer, the background above 2615 keV drops to zero using the optical detector to discriminate the background α events. The discrimination of α - and γ -events is illustrated by the scatter plot of Fig. 9.123; and an arrow in Fig. 9.123 points out the location in the scatter plot where the search for $0\nu\beta\beta$ decay events (abbreviated $0\nu\text{-DBD}$ in Fig. 9.123) of ^{116}Cd should concentrate ($Q_{\beta\beta} = 2805$ keV). This is also in the region where no background events from either α - or γ -events are observed. The small size of the Ge optical detector (≤ 1 mm thickness) does not permit the detector calibration with external sources; and thus, a ^{55}Fe calibration X-ray source can be placed on the back side of the optical detector, as illustrated

previously in Fig. 9.120 (Gironi et al., 2009; Ortigoza et al., 2011).

Crystal and scintillating bolometers are currently under development in the search for $0\nu\beta\beta$ decay with the isotopes ^{82}Se , ^{100}Mo , ^{116}Cd , and ^{130}Te in the following crystal chemical formula: Zn^{82}Se (Dafinei et al., 2017; Artusa et al., 2016; Gironi, 2016; Orto, 2016; Beeman et al., 2015; Dafinei, 2014; Tenconi et al., 2014), $\text{Zn}^{100}\text{MoO}_4$ (Armengaud et al., 2017; Poda, 2016; Chernyak et al., 2015, 2013; Tenconi, 2015; Barabash et al., 2014; Shlegel et al., 2014; Beeman et al., 2012a, 2012b), $\text{Li}_2^{100}\text{MoO}_4$ (Buşe et al., 2018; Chen et al., 2018; Armengaud et al., 2017; Velázquez et al., 2017; Bekker et al., 2016), $^{116}\text{CdWO}_4$ (Barabash et al., 2016; Arnaboldi et al., 2010; Gironi et al., 2009), and $^{130}\text{TeO}_2$ (Casali, 2017; Artusa et al., 2015a,b; 2014a,b; Gironi, 2013; Beeman et al., 2012c).

Artusa et al. (2014a) reviewed the strategy and potential for future scintillating bolometers in light of the properties of very promising scintillating crystals containing ^{82}Se , ^{116}Cd , ^{100}Mo , and ^{130}Te $\beta\beta$ candidate isotopes. For comparative purposes, Table 9.12 lists the total number of the $\beta\beta$ isotopes in towers of individual bolometers comprising 988 crystals of a given dimension. The rarity of a $0\nu\beta\beta$ event requires a detector with large numbers of $\beta\beta$ candidate isotope and thus a large number of scintillating bolometers to provide an adequate mass of source material to permit the detection and measurement of the $0\nu\beta\beta$ decay. Thus numerous (up to ~ 1000) single bolometers must be coupled into towers that are enclosed within the cryostat and radiation shielded barriers of the detector. Artusa et al. (2015a,b, 2014a,b) describe the CUORE (Cryogenic Underground Observatory for Rare Events) towers that will encompass 988 bolometers containing either $^{130}\text{TeO}_2$ or

FIGURE 9.123 Scatter plot of light versus heat obtained in a 417 hours live-time background measurement. The energy scale of the light detector is normalized to the one of the CdWO_4 . The points in the 0–300 keV (heat) region are due to pileup. The α -induced background is clearly discriminated. From Pirro et al. (2006); reprinted with permission from Elsevier © 2006.

TABLE 9.12 Characteristics of different $\beta\beta$ candidates in the search for $0\nu\beta\beta$ with scintillation crystal bolometers. Listed are the $\beta\beta$ candidate isotope, crystal containing the isotope, the total mass of 988 crystal arrays in individual bolometers with crystals measuring $5 \times 5 \times 5 \text{ cm}^3$, the total number of $\beta\beta$ candidates ($N_{\beta\beta}$), the number of decays in 5 years ($N_{0\nu\beta\beta}$) for the most and least favorable values of $F_N^{0\nu}$, the nuclear Figure of merit^b, for $|m_{ee}| = 50 \text{ meV}$ and $|m_{ee}| = 10 \text{ meV}$ with a 90% isotope enrichment in the $\beta\beta$ emitting isotope.^a

^bThe nuclear figure of merit is a variable in the following relation: $1/T_{1/2}^{0\nu} = (|m_{ee}|^2/m_e^2)F_N^{0\nu}$ where $T_{1/2}^{0\nu}$ is the $0\nu\beta\beta$ decay half-life, $|m_{ee}|$ is the effective Majorana neutrino mass, and m_e is the electron mass.

Zn^{82}Se crystals. The CUORE detector has 19 towers with each tower containing 13 floors with 4 bolometer modules on each floor. An example of a single bolometer containing a 0.51 kg $^{116}\text{CdWO}_4$ scintillating crystal is illustrated in Fig. 9.124; that of a tower of 30 single scintillating bolometers each with its individual crystal and light detector

is illustrated in Fig. 9.125. Gironi (2016) reports that the tower illustrated in Fig. 9.125 for the LUCIFER (Low-background Underground Cryogenic Installation For Elusive Rates) project would contain 30 bolometers each with 430 g crystals of Zn^{82}Se at a 96.5% isotope enrichment providing $\sim 5 \times 10^{25}$ ^{82}Se nuclei.

FIGURE 9.124 A single scintillating bolometer with a $^{116}\text{CdWO}_4$ crystal. It is held together with four L-shaped Teflon pieces (PTFE) fixed to two cylindrical Cu frames. The frames are held together with two Cu columns (not visible from the chosen perspective). The crystal is surrounded by a 43 mm reflecting sheet. The light detector (Ge LD) consists of a 1 mm thick pure Ge crystal absorber. The surface of the Ge LD facing the crystal is darkened with a 600 Å layer of SiO_2 to increase light absorption. A resistor of $\sim 300 \text{ k}\Omega$ is attached to each absorber and acts as a heater to stabilize the gain of the bolometer. From Arnaboldi et al. (2010); reprinted with permission from Elsevier © 2010.

FIGURE 9.125 Five towers of Zn^{82}Se crystal bolometers for the LUCIFER project in the search for $0\nu\beta\beta$ decay. Each tower contains six floors of scintillating bolometers. Each bolometer contains a single Zn^{82}Se crystal and its individual Ge light detector. The 30 crystals each weighing 0.43 kg of Zn^{82}Se at a ^{82}Se isotope enrichment to 96.5% yielding a total of $\sim 5 \times 10^{25}$ $\beta\beta$ ^{82}Se nuclei. C. Search for weakly interacting massive particles

There is a concerted effort worldwide to determine the nature of dark matter in the universe of which a component is considered to be a neutral WIMP. Galactic halo WIMPs could be detected by their weak interaction with nuclei in scintillating bolometers with the production of low-energy recoils. The nuclear recoil (NR) energies from WIMP interactions would be of the order of tens of keV at low event rates, i.e., below tenths of events per kilogram per day (Cebrián et al., 2003). The ability to detect the NR events would depend on the elimination of interfering background due to β/γ events. Numerous laboratories are researching the use of scintillating bolometers as a promising tool for the detection of the NR events from WIMP interactions due to the excellent resolutions and discrimination power against β/γ events (Angloher et al., 2016a,b, 2014, 2005; Eitel, 2015; Armengaud, 2012, 2013; Beeman et al., 2013; Coron et al., 2013, 2004, 2008, 2009; Ortigoza et al., 2013, 2011; Schmidt et al., 2013; Arnaboldi et al., 2011a,b; Cebrián et al., 2003, 2005). Among these research efforts are (i) The Rare Objects Search with Bolometers Underground (ROSEBUD) Collaboration, which is a joint effort between the Institut d'Astrophysique Spatiale (IAS, Orsay, France) and the University of Zaragoza (UZ, Zaragoza, Spain). This project is underway in an ultralow-level radioactivity environment in the Canfranc Underground Laboratory (2450 m.w.e) in northeastern Spain, (ii) the Cryogenic Rare Event Search with Superconducting Thermometers (CRESST) Collaboration including universities in Germany, the United Kingdom and Italy at the Gran Sasso underground laboratory in Italy, (iii) the Expérience pour Detector Les WIMPs En Site Souterrain (EDELWEISS) project at the Modane Underground Laboratory in France, and (iv) The European Underground Rare Event Calorimeter Array (EURECA), which will combine researchers on the CRESST and EDELWEISS experiments at the Modane Underground Laboratory.

The discrimination of β/γ events from NR events with the scintillating bolometer is based on the higher light output for a given energy that a β/γ event produces compared to that of a heavy charged particle, such as a NR produced by neutrons or WIMPs. The evaluation of the ability of a scintillating bolometer to discriminate nuclear recoils from β/γ events is based on the “quenching factor” of the event. The “quenching factor” is defined as the reduction factor for the light output of a NR event relative to an electron/photon event of the same energy (Angloher et al., 2005). Quenching factors in the range of 10 to 8.2 were measured by Angloher et al. (2005) for recoil energies in the energy range of 10–150 keV with a bolometer equipped with a CaWO_4 crystal detector. A quenching factor of 10 was measured by Cebrián et al. (2003, 2005)

for nuclear recoils. The ratio of 1:10 for the weak light output from NR events to the stronger light output from β/γ events offers the foundation for the discrimination of β/γ background events from NR events.

By exposing a 50 g undoped sapphire (Al_2O_3) crystal in a scintillating bolometer equipped with a Ge optical bolometer (i.e., light detector) to sources of ^{241}Am , ^{57}Co , and ^{252}Cf , Ortigoza et al. (2013) demonstrated the excellent discrimination among NR events from the ^{252}Cf source and the electron/gamma events in the 100 keV energy range of interest, which would be the energy range for the observation of WIMP recoil events. An example is the scatter plot of the light pulse amplitude measured by the Ge bolometer light detector against the energy in keV deposited as heat in the scintillating bolometer illustrated in Fig. 9.126. The energy scale is calibrated with the γ -lines of ^{241}Am and ^{57}Co sources. Dark matter search experiments with scintillating crystal bolometers, as noted in previous sections, utilize the differences in light intensity produced by β/γ events in the scintillating bolometer and that produced by NR events. Ortigoza et al. (2013) measured the ratios of the scintillating signals (i.e., light signals or light intensities) produced by β/γ events to those produced by NR events, expressed as β/γ :NR ratios, in BGO and Al_2O_3 scintillating bolometers. β/γ :NR ratios in the energy region between 0–100 keV were of the order of magnitude of 8 and 17 for the BGO and Al_2O_3 scintillating bolometers, respectively. The magnitude of these ratios provide good discrimination from β/γ background events from WIMP NR events in the low-energy region where WIMP recoil events would be detected.

FIGURE 9.126 Light versus heat scatter plot obtained with a Al_2O_3 scintillating bolometer when irradiated with neutrons from a ^{252}Cf source and photons from ^{241}Am and ^{57}Co . The heat channel was calibrated in energy with the gamma lines of the ^{241}Am and ^{57}Co . From Ortigoza et al. (2013); reprinted with permission from Elsevier © 2013.

Michael F. L'Annunziata

Michael F. L'Annunziata, Ph.D. is the Founding Editor and co-author of the *Handbook of Radioactivity Analysis* now in its Fourth Edition. His graduate thesis research at the University of Arizona, Tucson, AZ, USA in the 1960s, financed by the then U.S. Atomic Energy Commission, dealt with the analysis of ^{89}Sr and ^{90}Sr in the event of nuclear fallout. During 1970–71, he worked in the chemical industry (Amchem Products, Inc., Ambler, PA, USA) as ^{14}C -tracer chemist. Michael was then appointed Professor at the Postgraduate College, Chapingo, Mexico (1972–75) and Senior Research Scientist and graduate thesis advisor at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico City during (1975–77). Michael served as Scientific Officer in the

Department of Research and Isotopes and Department of Technical Co-operation of the International Atomic Energy Agency (IAEA) in Vienna, Austria during 1977–91 and Head of IAEA Fellowships and Training during 1987–91. Michael F. L'Annunziata was first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as the chemical pathway and origin of the various inositol phosphate stereoisomers in soils (Ph.D. dissertation, 1970, <https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum=>) and in 1975 (*SSSA Journal* 39(2), 377–379), and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–736, <https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733>). From 1977 to 2007, he served as IAEA Expert in peaceful applications of nuclear energy in over 50 countries of the world in Europe, Asia, Africa, Latin America and the Middle East. His book entitled “Radioactivity: Introduction and History”, First Edition, published by Elsevier, was on the Best Sellers List in Physics (*LibraryJournal Academic Newswire* in 2008); and his much expanded Second Edition entitled “Radioactivity: Introduction and History, From the Quantum to Quarks” published by Elsevier in 2016 (<https://www.sciencedirect.com/book/9780444634894/radioactivity>) was awarded an Honorary Mention in the 2017 PROSE AWARDS in the category of Chemistry & Physics.

 Bib Bang and, 196–197

- CMB radiation (*Continued*)
 discovery of, 196
 precise spectrum of, 196–197
- Cobalt-57
 liquid Xe pulse height spectrum, 750f
 sum-peak activity analysis, 936
- Cobalt-60
 modified sum-peak analysis, 940f
 sum-peak activity analysis, 936, 937f
- Cold neutrons
 crystal scintillators for, 965
- Collective model, nuclear, 44–46
 quadrupole moments in, 45
 rotational spectra in, 46f
- Color charge
 as quantum number, 30
- Comprehensive Nuclear Test-Ban-Treaty (CTBT) verification, 272
- Compton, Arthur H., 170
- Compton edge, 932–933
 calculation of, 170–171
- Compton effect
 mechanism, 169
 partial attenuation coefficients for, 175f
- Compton efficiency tracing, 693–694
- Compton electron energy
 calculation of, 171
- Compton scatter
 equation for, 170
- Compton scatter photon
 energy of, 171
 equation for, 170
- Computer tomography, 263
- Continuous air monitoring
 with PIPS detectors, 455, 456f
- Copper-64
 branching beta decay, 90f
 liquid scintillation analysis, 623t
- Cosmic radiation
 classification and properties, 188
 classification of, 186–187
 composition of, 188–189
 definition, 186–187
 discovery of, 186–187
 dose from, 188
 of galactic origin, 188t, 189
 primary, 189f
- Cosmic radiation air showers, 186–187
 classification of, 186–187
- Cosmic radiation, primary
 acceleration in space, 191
 all-particle spectrum of, 191, 191f
 definition, 188
 nuclei fluxes in, 189f
 origin of, 196
 proton energies of, 189–190
 proton relativistic masses, 190
 proton relativistic speeds, 190
 protons and He nuclei in, 189
- Cosmic radiation, secondary
 definition, 188
 positrons and antiprotons in., 189
 showers of, 192f
- Cosmic radiation showers
 mechanisms of formation, 191–192
 muon detection and measurement in, 194
 muon fluxes in, 193
 muon lifetime measurement, 194
 muon losses in rock, 195f
 origin of, 191
 particle fluxes in, 191–192
 underground, 194–195
- Cosmic-ray muon flux
 relativistic measurements of, 55
- Cosmogenic nuclides, 22
 in atmosphere, 23t
- Coster–Kronig transition, 110
- Counting efficiency, 248
- CR-39
 alpha-energy measurements, 331–332
 alpha measurements from fusion, 332
 alpha-particle measurements, 329
²⁵²Cf fission fragment tracks, 363f
 fission fragment detection, 335
 IR absorption bands, 321t
 neutron dosimetry with, 390
 as nuclear track detector, 318
 proton and light nuclei detection, 325
 proton energy measurements, 326f, 327
 proton measurements, 326
 proton spatial distribution measurements, 328
 proton track measurements, 320f
 track detector applications, 319, 321f
- CR-39-DAP series
 energy threshold track detector, 323
 potential applications, 323
- Critical mass, 184–185
- Crookes, William, 900
- Cross section, reaction
 definition, 65–66
 unit of measure of, 66–67
- CUORE Collaboration
 progress in, 1011–1012
- Curie, definition of, 218
- Curie, Marie, 4
- Curie, Pierre, 4
- Curium
 creation of, 14–15
- Curium-243, 244
 alpha spectrometry of, 506
 deconvolution models, 518
- Cyclotron
 applications of, 14
 invention of, 13–14
 medical application of, 15
 principle of, 13–14
 worldwide numbers of, 15
- D**
- Dead time
 of detectors, 503
- de Broglie, Louis Victor, 7
- Decay chains
 natural, 22–23
- Decay constant, radionuclide, 208
- Decay energy
 of alpha emitters, 68
- Delayed neutron activation analysis, 285
- Delta rays
 definition, 205
- Deuterons
 ranges in liquids and solids, 74
- Diffused junction detectors, 505–506
- DiMF techniques
 neutron radioactivity measurements with, 142f
- Dirac, Paul A.M., 10
- Disequilibrium, radioactive, 186
- Displacement law
 radioisotope, 6f
- Dosimetry, 273–276
- Double beta decay
 current research in, 93
 description of, 92
 discovery of, 93, 709, 1002–1003
 known nuclides involved, 92
 liquid scintillation measurement, 709–716
 measurements, 1002–1008
 nucleon transformations in, 92
 observations of, 483
 radionuclides decaying by, 709, 710t
 spectrum for, 1004f
- Double beta decay, neutrinoless, 94–95
 theory of, 94–95, 483
- Drift-tube neutron detector, 283–284
- Dynode photomultiplier, 913
- E**
- EC decay rates
 chemical and pressure effects on, 89–90
- Efficiency tracing LSA
 percent recoveries, 616t
- Einstein, Albert, 16
 mass-energy conversion, 20
- Elastic scattering
 definition of, 126
- Electret detectors, 253–254
- Electromagnetic radiation
 classification of, 147
 particle-wave duality of, 146–148
 spectrum, 148f
- Electron antineutrino measurements
 via inverse beta decay, 1002
- Electron beams
 industrial applications, 157
 relativistic wavelength measurements of, 59
- Electron capture
 decay energy calculations, 88
 description of, 86–88
 neutrino emission in, 89
 n/p/ imbalance and, 86
 nucleon transformations in, 86
 positron emission and, 86–87
 principles of, 86–87
 quark transformation in, 16
- Electron ranges
 differences due to charge, 103t
- Electrons
 discovery of, 3–4
 range calculations, 100–101, 101t
 ranges in air, 102t

Electron spectroscopy
 with PIPS and silicon drift detectors,
 453–454
 Electron volt, definition, 20
 Electron volt-joule
 conversion of, 20
 Elementary particle
 definition of, 15
 Elster, Julius, 900
 Energy resolution, 248
 Energy total, definition, 20
 Environmental radioisotopes, 862, 863f
 Environmental radionuclides
 extraction chromatography of, 850–851
 from nuclear devices and industry, 852,
 854t–855t
 SIMS analysis, 871
 Enzyme assays, 959–960
 Etching condition, 359–360
 European TEPC, 275
 Europium-152
 sum-peak activity analysis, 936
 Europium-157
 gamma spectrum, 922
 EuTEPC, 275
 Exclusion Principle, 9, 18, 30
 Exotic isotopes, 134–135
 Extractive magnetic nanoparticles
 in alpha LS spectrometry, 725–726, 727t

F

Fast neutron detection
 with plastic scintillators, 980
 stilbene scintillators for, 969
 Fast neutron detectors, 282–285
 Fast neutrons
 solid scintillation detection, 962
 Fermi Beta Decay, 10–11
 Fermi, Enrico, 10–11
 Feynman diagrams, 29
 Field programmable gate array, 930–932
 Fissile isotopes
 definition of, 120
 Fissionable isotopes
 definition of, 121
 Fission chambers, 254–255, 280
 Fission, nuclear, 33–34
 binding energy and, 33
 discovery of, 12
 neutrons emitted in, 12
 Fission rate measurements
 with muscovite mica, 312–313
 Fission, spontaneous, 33–34
 Fission track dating, 381–387
 absolute approach, 381–383
 age equation, 381–382
 of ancient man, 385
 anthropology, 385–386
 archeology, 385–386
 continental drift, 385
 LA-ICP-MS approach, 384–385
 neutron fluence, 382–383
 ocean-bottom spreading, 385
 principle, 381

prominent age standards, 384t
 Tectonic up-lift rate, 386–387
²³⁸U spontaneous decay constant, 382
 Zeta approach, 383–384
 Fission, U-235
 energy released from, 35
 liquid-drop model for, 39
 Fission, U-236
 energy released from, 33
 Fission vs Fusion
 energy yields, 35
 Flerovium-289, 47
 Fluorescence
 definition of, 507
 Fluorine-18, 279
 automated gamma analysis, 945f
 gamma spectrum, 944f
 liquid scintillation analysis, 622
 LSA pulse height spectrum, 622f
 Fluors, liquid, 805–806
 Force, electromagnetic, 29f
 Force, strong
 pion exchange in, 28–29
 Frisch grid detector, 504
 Frisch grid ion chambers, 251–252
 Fukushima accident samples
 ICP-MS analysis, 877
 Full-energy peak efficiency, 934
 Full width at half-maximum (FWHM), 248
 Fusion
 deuterium-deuterium, 123
 deuterium-tritium, 123
 Fusion, D-D
 energy released from, 34
 Fusion, D-T
 efficiency of, 35
 energy released from, 34
 Fusion, nuclear
 binding energy and, 34–35
 Fusion power reactor
 advantages of, 37–38
 schematic and function of, 36–37
 Fusion reactors
 energy liberated in, 123
 Fusion, thermonuclear
 as power source, 35

G

Gadolinium-155
 thermal neutron capture with, 963
 Gadolinium-157
 thermal neutron detection with, 963
 Gallium-67
 liquid scintillation analysis, 623
 LSA pulse height spectra, 591
 Gallium-68
 liquid scintillation analysis, 623t
 Gamma analysis
 automated, 943–951
 Gamma camera, 263
 Gamma-camera imaging
 with PIN photodiodes, 921
 Gamma radiation
 discovery of, 4
 industrial applications, 157
 origin of, 147
 properties, 148
 Gamma-ray attenuation, 176
 half-value thickness, 176, 178
 K-edge, 179–180
 linear attenuation coefficient, 176
 mass attenuation coefficient, 1–243, 178,
 178t
 Gamma rays
 discovery of, 4
 Gamma-ray spectra
 backscatter peaks in, 932–933
 doubles peak in, 932
 escape peaks in, 933
 interpretation of, 932
 Gamow, George, 39
 Gas avalanche photomultiplier, 264f
 Gas electron multiplier, 261f–262f
 glass, 267f–268f
 neutron detection with, 265–266
 neutron measurements with, 265
 two dimensional, 262f, 263
 Gas electron multiplier (GEM), 260
 Gas ionization chamber, ionization regions
 of, 247f
 Gas ionization detectors, 246–247
 active shielding of, 268–269
 characteristics of, 504–505
 design of, 246
 field strength of, 246–247
 filling gas, 246
 ionization energy of, 505
 localization with, 249
 low-level counting techniques with,
 268–270
 operating characteristics of, 248–249
 Gas proportional counter
 position-sensitive WELL detector,
 245–306
 4π pressurized, 258
 Gas proportional scintillation counter, 257,
 258f
 Ge and Si bolometers
 alpha energy resolution with, 511
 Ge and Si detectors
 atomic number effects, 412–413
 charge carrier lifetimes, 414
 energy gap effects, 412–414
 properties, 411t, 412f
 purity/resistivity effects, 413–414
 n-type Ge detector, 417f
 Ge detectors
 absolute efficiency curves, 446f
 active background reduction, 444–445
 background and background reduction,
 431–445
 background in absence of source, 432
 background in presence of source, 431
 background reduction, 443–445
 backscatter and Compton edge, 417f
 efficiency, 427
 efficiency calculations, 429–431
 efficiency stability, 431

- Ge detectors (*Continued*)
 energy resolution, 423–427
 escape peaks, 423
 experimental efficiency curve, 429, 430f
 FWHM calculation, 423
 gamma-ray interaction cross sections, 413f
 gamma spectra, background lines in, 433t–439t
 geometrical efficiency factor, 427
 intrinsic efficiency and transmission, 427–428
 passive background reduction, 443–444
 peak summation, 419
 relative efficiency, 428–429
 spectrum analysis for $E_\gamma < 1022$ keV, 416–418
 spectrum analysis for $E_\gamma > 1022$ keV, 418–419
 standard characteristics, 423–431
 transmission curves, 427f
 transuranic characteristic signals, 415t–416t
 true coincidence correction (simple case), 420–421
 true coincidence GammaVision software correction, 422–423
 true coincidence Genie 2000 software correction, 422
 true coincidence software correction, 421–422
 true coincidence software correction (Monte Carlo methods), 422
 true coincidence summing, 419–423
 typical gamma-spectra analysis, 414
- Ge detectors, background
 from cosmic rays, 432
 "delayed" γ rays, 432
 from man-made isotopes, 432
 from natural isotopes, 432
 neutron-induced "prompt" γ rays, 432
 "prompt" continuous background, 432
- Ge detectors, background reduction
 Compton suppression spectrometer, 444–445
 construction materials and cryostat design, 444
 cosmic veto shield, 445
 from venting, 444
- Ge detectors, choice of,
 BEGe detector, 447–448
 general criteria, 445–448
 "relative efficiency" limitations, 446
 size of HPGe detector, 445
 well-type, 446
- Ge detectors, high-purity
 merits and limitations, 414
 transuranic characteristic signals, 414
- Ge detectors, resolution
 delta noise, 424
 Doppler broadening, 426
 electronic noise contribution, 423–425
 Flicker noise, 424
 Gaussian peak shape, 426–427
 intrinsic FWHM, 424f
 noise vs. shaping time, 425f
 peak-to-Compton ratio, 427
 radiation damage, 426
 recoil broadening, 426
 recoil energy shift, 426
 step noise, 424
 temperature effects, 425–426
 vibration and radio frequency noise, 425
- GeGi spectrometer
 Compton image by, 482f
- Geiger discharge region, 277
- Geiger, Hans, 7, 900
- Geiger–Müller counters, 246, 276–279
 applications, 277
 counting plateau of, 277
 filling gas of, 276
 GM counter monitoring of, 278
 GM tube, 248
 Monte Carlo simulation methods and, 277
 neutron detection with, 282
 quench gas for, 277
 quenching in, 276–277
 radiation monitoring with, 278
- Geiger–Nuttall law, 70, 496–498
- Geiger–Nuttall plot, 499f
- Geitel, Hans, 900
- Gell-Mann, Murray, 15–16, 29
- GERDA Collaboration
 HPGe detector design, 484–486
 in $0\nu\beta\beta$ search, 484
- Gerlach, Walter, 18
- Giesel, Friedrich Oskar, 900
- Glasses
 fission fragment measurements, 335
- Glass GEM (G-GEM), 266
- Glow discharge mass spectrometry, 863
 applications, 868–869
 depth profiling with, 869
 environmental radioisotope analysis, 869
 isotopic analysis with, 869
 principle of ionization in, 868–869
 trace and bulk analysis with, 868–869
- Gluons
 color charge of, 30
 evidence for, 15–16
 interactions with quarks, 30
 prediction of, 15
- Goeppert-Mayer, Maria, 9, 1002–1003
 nuclear shells and, 41
- Graphite
 as neutron moderator, 120
- Gridded ionization chamber
 alpha spectrometry and, 501
 principle of, 504f
- Gridded ionization chambers
 characteristics of, 505
- Gridded ionization detectors
 alpha spectra from, 520
- H**
- Hadron, definition of, 28
- Hadronization, 15–16
- Hadrontherapy, 262
- Hahn, Otto, 12, 39
- Half-life
 branching decays and, 217
 decay calculations, 208, 210
 decay chains and, 217
 definition, 206
 general decay equations, 211–212
 for mixture of radionuclides, 209
 no equilibrium, 216–217
 of radionuclide mixtures, 209–210
 secular equilibrium and, 212–213
 transient equilibrium and, 214–215
- Half-life determinations
 of short-lived nuclides, 211
- Half-life measurements
 of long-lived nuclides, 210–211
- Half-life
 discovery of, 206–207
- Heavy ion measurements, 346–347
- Heavy water
 as neutron moderator, 120
- Heisenberg, Werner, 9
- Helium-3
 neutron detection and, 279–280
 neutron detectors with, 280
 thermal neutron detection with, 963
- Hess, Victor, 187–188
- High-resolution alpha spectrometry, 506
- Hofstadter, Robert, 15
- HPGe detectors
 in GERDA Collaboration, 483, 486f
 in Majorana Collaboration, 483, 484f–485f
 in $0\nu\beta\beta$ search, 483
- HPGe detectors, multisegmented
 imaging with, 481–482
- HPGe detectors, segmented
 applications, 482
 GeGi imaging spectrometer, 482
 imaging with, 482
- HPGe detectors, X-Y segmented
 applications, 483
- Hybrid photomultiplier, 914–915
- I**
- IC electrons
 liquid scintillation counting, 618
- IECF devices
 applications, 125–126
 as neutron sources, 124
 as portable proton and neutron sources, 125
- Indium-111
 liquid scintillation analysis, 623
- Indium-115
 inverse beta decay in, 78–79
 inverse beta decay measurements with, 1002
- Inductively coupled mass spectrometry
 Chernobyl and Fukushima samples and, 877
 hyphenated systems with, 875
 isobaric interferences and, 877
 isotope ratios and, 875–876
 laser ablation and, 875
 nebulization with, 874
 nuclear waste analysis, 876–877
 principle and instrumentation, 872–877
 radioecology studies and, 876
 radionuclide application with, 875–877

- sample introduction with, 874–875
 - Inductively coupled plasma mass spectrometry, 863
 - Inelastic scattering
 - definition of, 127
 - Internal conversion, 106–107
 - electron energies in, 106

Liquid scintillation counting (*Continued*)

AQP(I) quench parameter, 594–595
 aqueous sample preparation, 851–853
 of aqueous samples, 812–813
 background measurements, 623–624
 background reduction, 767–769
 of biological samples, 830–837
 of biological tissue, 833–834
 of blood, 819
 of buffers, 812t
 chemical + color quench correction, 609, 610f, 611
 chemical quench in, 584, 843
 chemiluminescence in, 831–832
 of chromatographic eluents, 852t
 cocktail components, 804–808
 cocktail equivalents, 809t–810t
 cocktails for, 808
 cocktail waste and, 858–859
 color quench in, 585, 843, 846
 combustion methods, 825–826
 complex spectral analysis, 644–658
 CO₂ trapping in, 827–829
 counting efficiency and, 585–586, 841
 of electrophoresis gels, 821–822
 elution methods, 838
 environmental sample preparation, 849–853, 850t
 ESCR and, 848–849
 ESCR quench parameter, 596–597
 ESP quench parameter, 599–600
 of fatty tissue, 835–836
 of feces, 818–819, 836
 of filter material, 829t
 of filters and membranes, 837–840
 G# quench parameter, 604–605
 of ³H and ¹⁴C, 624f
 with Hitachi Aloka LSC, 848–849
 H# quench parameter, 597–599
 of IC electron emissions, 618
 interferences in, 623–630
 ionization quenching in, 585
 IS quench correction, 588–589
 IS-SCR quench correction, 590–591
 of liver, 815–818
 of liver and kidney, 834–835
 of low ionic strength buffers, 808–811
 low-level tritium, 852t
 luminescence in, 625–628
 in microplate format, 721–723
 of multiple radionuclides, 624–625
 of muscle, 815
 of plant material, 819–821
 of plant matter, 819–820
 of plasma and serum, 833
 plastic scintillating microspheres in, 742–743
 plastic scintillators in, 741
 of protein, 830–831
 quench correction curve in, 843–849
 quench correction in, 588–617
 quench curve errors in, 846–848, 847t

quench curve preparation, 608–609, 844–846
 quench curve use, 609, 846, 848
 quench curve with selectable MCA, 848–849
 quench effects in, 584–588, 586f–587f, 624
 quench measurement, 843–844
 quench standard preparation, 606–609, 845–846
 radionuclide identification, 594f
 sample combustion for, 820–821, 824, 826t
 sample dissolution in, 808–813
 sample oxidation and solubilization, 822–826
 sample preparation for, 815–822
 sample solubilization and combustion, 836–837
 sample solubilization in, 813–822, 823t, 826t
 sample solubilizers for, 817t–818t
 sample stability monitoring, 840–841
 SCR quench correction, 589–590
 with selectable MCA, 850f
 SIS quench parameter, 591–593
 solubilization methods, 825
 solvents, 804–805
 SQP(E) quench parameter, 600–601
 SQP(I) quench parameter, 593–594
 static in, 628–629
 swipe assays in, 841–843
 tissue and gel solubilizers, 809t–810t
 of tissue homogenates, 836
 tSIE quench parameter, 601–604
 of urine, 830–831
 wall effect in, 629–630
 of whole blood, 831–833
 of whole tissue, 815, 818
 Liquid scintillation fluors
 particle interactions in, 579–580
 Liquid scintillators
 anionic surfactants in, 807
 cationic surfactants in, 807–808
 concentrations of, 805–806
 nonionic surfactants in, 806–807
 surfactants in, 806–808
 Lithium-6
 thermal neutron detection with, 963
 Long counter, 284–285
 Long-range alpha detectors, 289–292, 290f, 291t
 Lorentz, Hendrik A., 52
 Lorentz transformations, 52
 Lower limits of detection
 background and count time, 767f
 determination of, 766
 LR-115
 alpha-particle measurements, 329
 LSC cocktails
 regulatory information on, 857–858
 Lucas cell
 principal of, 987–989
 radon-222 LLDs with, 989

LUCIFER Project
 progress in, 1011–1012
 Cluster radioactivity
 detection and measurement, 49

M

Magic numbers
 alpha decay and, 45f
 beta decay and, 44f
 nuclear stability and, 42–43
 nucleon shells and, 42–43
 of radioactivity clusters, 50t
 Magnetic moment, 18
 Majorana Collaboration
 HPGe detector design, 484
 in 0νββ search, 484
 Majorana particles, 483
 Majorano neutrino, 94–95, 146, 710
 properties, 1003
 Manganese-54
 liquid scintillation analysis, 623
 Mass-energy
 conversion, 20
 Mass number, 17–18
 Mass spectrometric methods
 categorization of, 863–864
 dynamical range of, 865
 figures of merit of, 864–866
 mass resolution of, 865
 precision of, 865
 sensitivity of, 865
 Mass spectrometry
 applications, 861–862
 of beta- and alpha-emitters, 862
 criteria for application of, 862
 detection limits of, 862
 isobaric selectivity in, 863–864, 866–868, 873, 878–879, 881–884
 Mass thickness
 alpha particle ranges in, 75, 75t, 102t
 beta particle ranges in, 102t
 Mather, John C., 196–197
 Matter-wave duality
 discovery of, 7
 McMillan, Edwin M., 14–15, 210
 MEDIPIX, 914
 Meitner, Lise, 12, 39
 3M Empore Rad Disks, for radium alpha spectrometry, 551
 Mesons
 quark color charge in, 30
 quark composition of, 28–29
 Microchannel plate photomultiplier
 advantages of, 917
 principle of, 915–917, 916f
 Micromegas counter, 268
 Micromegas detector, 262, 266–267
 Microplate scintillation analysis
 enzyme assays with, 959
 receptor binding assays with, 958–959
 Microplate scintillation counters
 advantages and disadvantages, 722–723

T

TDCR analyzers
 portable, 692–693
 validation of, 693t
 TDCR counters
 performance assessment, 761t–762t
 TDCR efficiency calculation
 efficiency calculations, 686–688
 experimental conditions, 686–688
 free-parameter model, 686
 history of, 682
 instrumentation, 684f
 ionization quench function, 686
 laboratories worldwide using, 683t
 with plastic microspheres, 693
 principles, 682–686
 radionuclide standardization, 682–693, 691t–692t
 summary of method, 688–689
 Technetium-99
 APD beta spectrum, 923f
 TDCR standardization, 690t
 Technetium-99 LS analysis
 extractive scintillating resins, 748
 Technetium-99m
 automated gamma analysis, 945f
 Tektite
 fission track registration, 317
 TEXONO Collaboration, 1001
 Thallium-204
 LSA efficiency tracing, 614f
 Thermal ionization mass spectrometry, 863
 applications, 867–868
 high-sensitivity measurements with, 867–868
 isotope ratio determination with, 867
 principle of surface ionization, 866–868
 Thermal neutron detection
 isotopes for, 963t
 Thermal neutron detectors
 scintillating fiber arrays in, 973
 Thermal neutron scintillators, 965–966
 properties of, 965t
 Thermonuclear reactor
 development of, 35–36
 Thick gas electron multiplier (THGEM), 262–263, 274
 Thomson, George, 58–59
 Thomson, J.J., 3–4
 Thomson, Joseph, 58–59
 Thorium-204
 nanoparticle fluor efficiency, 745t
 Thorium-228, 230, 232
 PERALS spectrum of, 521f
 Thorium-229
 TDCR standardization, 690t
 Thorium-230/232
 TIMS measurements, 867
 Thorium-232
 decay chain, 442t
 as neutron converter, 962
 Thorium-228, alpha spectrum, 525f
 Thorium decay chain, 22–23
 Time dilation
 cosmic-ray measurements with, 54–55
 Time-of-flight RIMS
 limits of detection, 881
 Time-of-flight spectrometry
 neutron/gamma discrimination, 706–707
 Tin-113
 liquid scintillation analysis, 618f, 623
 liquid scintillation spectrum, 619f
 Tin-126
 TIMS measurement of, 867–868
 Tin-119m
 decay scheme, 150f
 Tissue equivalent proportional counter (TEPC), 246, 273, 274f–275f
 Tokamak, 35–36
 Total/absolute efficiency, 935–936
 Townsend avalanche, 255
 Track detector calibration
 with mono-energetic proton beam, 327–328
 Transient equilibrium, 214–216
 Transition-edge sensor
 alpha energy resolution, 511
 Tritium
 analysis in liquid effluent, 747
 liquid scintillation analysis, 612f, 765t

Tritium (*Continued*)

- LSA sample preparation, 822
- LSC cocktails for, 852t
- LSC pulse height spectra, 586f
- LSC quench correction, 592t, 599f, 601f–604f
- LSC quench curves, 609f
- nanoparticle fluor efficiency, 745t
- PSm detection efficiencies, 744t
- sample optimization for LSA, 769t
- scintillation proximity analysis of, 955–956
- TDCR standardization, 690t
- Tritium + Carbon-14
 - LSC pulse height spectra, 591f
- Tritium in air, 271–272

U

- U-235 decay chain, 22–23, 25f
- U-238 decay chain, 22–23, 25f
- U-235 fission
 - energies released in, 120t
 - fission fragments in, 118
 - neutron energies in, 118
 - Q values calculation of, 118
- U-236 fission, 33
- Ultra-cold neutrons, crystal scintillators for, 966–967, 967f
- Uncertainty Principle, 9, 30–31
- Uranium-233
 - extraction and analysis, 726f
 - LSC pulse height spectra, 587f
 - SSNTD analysis, 337
- Uranium-234/238
 - simulated alpha spectra of, 495
 - TIMS measurements, 867
- Uranium-235
 - decay chain, 441t
 - fission-fragment track analysis, 312–313
 - SSNTD analysis, 337
- Uranium-235/238
 - TIMS measurements, 867
- Uranium-236
 - GDMS analysis, 869
 - RIMS analysis, 882–883
- Uranium-236, 238
 - alpha analysis software, 520
- Uranium-238
 - air luminescence counting, 755
 - decay chain, 440t
 - as neutron converter, 962
 - production of Th-232 neutron capture, 120
 - SSNTD analysis, 337
- Uranium alloy fuels
 - GDMS analysis, 868–869
- Uranium and plutonium in hot particles

- SSNTD measurements, 391
- Uranium and plutonium oxides
 - GDMS analysis, 869
- Uranium and thorium
 - ion exchange separation of, 541
 - TEVA resin processing, 546
- Uranium concentrations
 - from quartz track detectors, 316
- Uranium in groundwater
 - extractive scintillating resins, 748
- Uranium, natural
 - alpha spectra of, 512f
- Uranium, plutonium and thorium
 - gridded ionization spectrum of, 520f
- Uranium-234/238 ratios
 - ICP-MS determination, 875–876
- Uranium-235/236 ratios
 - ICP-MS determination, 875–876
- Uranium-235/238 ratios
 - GDMS analysis, 869
 - ICP-MS determination, 875–876
- Uranium-236/238 ratios
 - ICP-MS determination, 876

V

- Vacuum silicon photomultiplier, 915
- Vanadium-49
 - liquid scintillation counting, 619
- Vavilov, Sergei I., 160
- Villard, Paul, 4f

W

- Waste materials
 - incineration of, 857
- W⁺ boson
 - in charged current interactions, 144f
- W[−] boson
 - role in negatron emission, 17f
- Weak interaction, 10–11, 17f
- Weakly interacting massive particles
 - search for, 1013
- WELL detector
 - position-sensitive gas PC, 245–306
- Whitlockite
 - ²⁴⁴Pu fission tracks in, 315–316
 - track etching conditions, 315
- Wilson, Robert, 196
- Wu, Youxun, 170

X

- Xenon-133
 - beta- and gamma spectra of, 1000f

- PHOSWICH measurements of, 998–999
- Xenon-135
 - PHOSWICH measurements of, 998–999
- Xenon radionuclides
 - PHOSWICH measurements of, 997–998
- X-radiation
 - from beta-particle emitters, 158–159
 - as bremsstrahlung, 151, 153–154
 - characteristic of absorbers, 159
 - characteristic of beta-emitter, 159
 - following Auger electron emission, 152
 - following internal conversion, 153
 - following internal conversion, 151–152
 - following K-capture, 151–152
 - as line spectra, 151–153
 - origin, 147
 - origins and properties, 151
 - radiation induced, 152–153
- X-ray detector
 - position-sensitive, 264
- X-ray emission
 - from atomic electrons, 109f
- X-ray fluorescence detectors, 262
- X-ray spectrometry, 256–257

Y

- Ytterbium-176
 - electron neutrino reaction with, 1002
- Yttrium-88
 - liquid scintillation analysis, 623
- Yttrium-90
 - decay scheme for, 173f
 - LSA efficiency tracing, 614f
 - LSA pulse height spectrum, 629f
- Yukawa, Hideki, 28–29

Z

- Z⁰ boson
 - in neutral current interactions, 144–145
- Zeeman Effect, 146
- Zinc-65
 - decay scheme of, 87
 - gamma spectrum of, 929f
 - liquid scintillation analysis, 623
 - sum-peak activity analysis, 936
- Zinn, Walter, 12
- Zircon
 - track detector applications, 314
 - track etching, 314
- Zirconium alloys
 - GDMS analysis, 868–869
- Zweig, George, 15, 29

HANDBOOK OF RADIOACTIVITY ANALYSIS

VOLUME ONE

FOURTH EDITION

RADIATION PHYSICS AND DETECTORS

EDITED BY

MICHAEL F. L'ANNUNZIATA

The updated and further expanded **fourth edition** of the *Handbook of Radioactivity Analysis* is an authoritative reference providing the principles, practical techniques, and procedures for the accurate measurement of radioactivity—everything from the very low levels encountered in the environment to higher levels measured in radioisotope research, clinical laboratories, biological sciences, radionuclide standardization, nuclear medicine, nuclear power, and fuel cycle facilities and in the implementation of nuclear forensic analysis and nuclear safeguards. It includes sample preparation techniques for all types of matrices, including those found in the environment such as soil, water, air, plant matter, and animal tissue and surface swipes.

Volume 1: Radiation Physics and Detectors provides a detailed discussion of our current understanding of the atomic nucleus, nuclear stability and decay, nuclear radiation, and the interaction of radiation with matter as the foundational principles for our selection of the best methods for radionuclide detection and measurement. This volume also provides the current methods of detection and measurement of all types of nuclear decay and radiation.

Key Features

- Spans two volumes, *Radiation Physics and Detectors* and *Radioanalytical Applications*
- Includes a much-expanded treatment of calculations required in the measurement of radionuclide decay, energy of decay, nuclear reactions, radiation attenuation, nuclear recoil, cosmic radiation, and synchrotron radiation
- Includes the latest advances in liquid and solid scintillation analysis, alpha- and gamma spectrometry, mass spectrometric analysis, gas ionization and nuclear track analysis, and neutron detection and measurement
- Covers high-sample-throughput microplate techniques and multi-detector assay methods

Michael F. L'Annunziata, Oceanside, CA, USA

Michael F. L'Annunziata earned his undergraduate BSc degree in Chemistry in 1965 from St. Edward's University and MSc and PhD degrees in 1967 and 1970, respectively, at the University of Arizona. His graduate thesis research in the 1960s was carried out under a research contract with the then US Atomic Energy Commission (US AEC). The research work dealt with the analysis of radionuclides and chemical remediation of the environment in the event of possible nuclear war and fission product fallout. His main research interests have been focused on the development of chemical and instrumental methods for the detection and measurement of radioactive nuclides and the utilization of radionuclides as tracers in biological research. L'Annunziata was formerly Head of Fellowships and Training at the International Atomic Energy Agency (IAEA) in Vienna, Austria; and he has served as a representative for the IAEA in fact-finding, planning, and implementation assignments on peaceful applications of nuclear energy for development in over 50 countries of the world from 1976 to 2007. He is the author and editor of several books, including *Radioactivity; Introduction and History, From the Quantum to Quarks* published by Elsevier in 2016, which received an Honorable Mention in the 2017 PROSE Awards and the *Handbook of Radioactivity Analysis* now in its fourth edition.
