Pavel P. Povinec

Prof. RNDr. **Pavel Povinec**, DrSc, obtained his PhD degree in physics from the Comenius University in Bratislava in 1974. He worked at the Department of Nuclear Physics of the Faculty of Mathematics and Physics of the Comenius University as Associated Professor (1978) and Professor of physics (1984), also as Head of the Department (1981−92), focusing on developments of radiometric methods for analysis of radionuclides at very low levels with wide applications in nuclear (rare nuclear decays), environmental (radionuclides as tracers, radiocarbon dating), and space (radionuclides in lunar samples and meteorites) physics. From 1993 to 2005, he worked at the IAEA's Marine Environment Laboratories in Monaco as Head of the Radiometrics Laboratory responsible for the development of radiometric (including underground laboratory) and mass spectrometry methods (ICP-MS, AMS) for marine radioactivity studies. He has led several international projects on assessment of dumping of radioactive wastes, on impacts of nuclear weapons test sites, on worldwide marine radioactivity studies (WOMARS), on submarine groundwater discharge studies, on the development of global marine radioactivity databases (GLOMARD/MARIS), etc. After his return to the Comenius University, he established at the Faculty of Mathematics, Physics and Informatics the Centre for Nuclear and Accelerator Technologies (CENTA) focusing on the development of IBA and AMS methods and their wide applications in nuclear, material, environmental, and biomedical sciences. He supervised 26 PhD students, published over 20 books and book chapters and over 700 referred papers with over 13,000 citations, organized over 20 international conferences, and delivered over 50 invited talks.

Mats Eriksson

Associate Professor **Mats Eriksson** received his PhD in radiation physics from the Lund University (Sweden) in 2002 and became a docent in radiation physics at Linköping University in 2011. He has worked at Risoe National Laboratory in Roskilde, Denmark (1998−2003), at the Institute for Transuranic Elements, EC-JRC, in Karlsruhe, Germany (2003−05), at the IAEA's Environmental Laboratories in Monaco (2005−12), and presently he chairs his time between the Linköping University and the Swedish Radiation Safety Authority (SSM) in Stockholm. His research interests have been on environmental radioactivity and radioanalytical methods, specifically on investigations of contaminated marine environment after accidents involving nuclear weapons, as well as on radioactive particles to study the behavior of actinides in natural conditions. A wide range of analytical techniques has been applied in these studies, including traditional radiometric methods (gamma- and alpha-spectrometry), mass spectrometric techniques (ICP-MS, AMS, SIMS) and synchrotron light-based techniques (μ-XRF, μ-XANES) with the aim to study physical and chemical properties of the contamination.

Jan Scholten

Dr. **Jan Christoph Scholten** received his PhD from the University of Heidelberg (Germany) in 1988. From 2005 to 2011, he worked at the IAEA's Environment Laboratory in Monaco, and he is now a senior research scientist at the Institute of Geosciences, Kiel University (Germany). His research interests focus on the application of natural radionuclides in marine process studies. For age dating of carbonate-poor sediments from high latitudes, he applied the thorium-230 excess method. Later, he concentrated his work on the distribution and behavior of thorium and protactinium in seawater of the Arctic, North Atlantic, and Southeast Atlantic Oceans, and in the Arabian Sea. The application of thorium-230 to calibrate the particle flux intercepted by sediment traps was one of his most recognized studies. In recent years, he has focused his research on submarine groundwater discharge and how radium isotopes and radon can be used for the detection and quantification of this process in different coastal settings.

Maria Betti

Dr. **Maria Betti** obtained her PhD in chemistry from the University of Pisa in 1984 with a specialization in environmental, instrumental and radiochemistry. From 1985 to 1991, she served at the Italian National Research Council and at the Department of Chemistry and Industrial Chemistry of the University of Pisa, where she has continued to lecture until 2012. She has research experience at different research laboratories in Europe and in the United States. As of March 1, 1991, she joined the European Commission as Head of the Analytical Chemistry Sector at the Institute for Transuranium Elements (DG Joint Research Centre, JRC) in Karlsruhe. In March 2008, she was appointed as Director of the IAEA Marine Environment Laboratories in Monaco, as seconded in the interest of the service from the European Commission. As of October 1, 2012, she rejoined the EC as Director of the Institute for Environment and Sustainability (IES) at the DG JRC, located in Ispra. As of April 16, 2015, she is Director of the EC Joint Research Centre, former Institute for Transuranium Elements, and since July 2016 Directorate G for Nuclear Safety and Security and Director of the JRC Karlsruhe site owning responsibility of the nuclear license of the site. Maria Betti is author of about 200 peer-reviewed publications in international journals with high impact of factors in the field of analytical chemistry, radiochemistry, environmental and instrumental chemistry, and nuclear safeguards. In 2012, she was the international winner of the "Prix Monte-Carlo Femme de l'Année" for the establishment after the RIO+20 summit of the International Centre on Ocean Acidification at the IAEA office in the Principality of Monaco. From 2004 to 2008, she chaired the JRC Women and Science Network. In November 2016, Maria Betti has been honored with the magnificent distinction by the Ordre de Saint Charles (Principality of Monaco).

I. Introduction

Photons of visible radiation are produced when a charged particle travels through a transparent medium at a speed greater than the speed of light in that medium. The medium may be any liquid or solid provided it is transparent. These photons are referred to as Cherenkov radiation in honor of the Russian physicist Pavel A. Čerenkov for his basic research and discovery of the properties of this unique radiation (see Čerenkov, 1934a, 1937d). The process, that gives rise to Cherenkov photons, is referred to as the Cherenkov effect. In the scientific literature, four variations of the contemporary spelling or naming of Čerenkov radiation can be found, namely, (1) *Čerenkov radiation* after the Russian, which is the spelling used by Pavel Čerenkov in most of his original papers (Čerenkov, 1934a,b, 1936, 1937a–d, 1938a–c); (2) *Vavilov–Čerenkov radiation*, in honor also of Sergei Ivanovich Vavilov (1891–1951), who was the doctoral research advisor to Pavel Čerenkov during the pioneering discoveries of Cerenkov radiation; (3) *Cherenkov radiation*, which provides the English pronunciation from the Russian Č. This is also the spelling used by Cherenkov (1986) in his last publication; and it is the spelling adopted by the Nobel Foundation (http://nobelprize.org/index.html); and (4) *Cerenkov radiation*, which is the anglicized version. All four versions of the spelling are found in the current scientific literature. Throughout this chapter, the writer will adopt the spelling *Cherenkov*, for the following reasons: (1) it conforms with that used by Pavel Cherenkov in his last paper (Cherenkov, 1986) entitled "At the Threshold of Discovery", that appeared in the journal *Nuclear Instruments and Methods in Physics Research*, (2) it is the spelling adopted by *Chemical Abstracts*, (3) it is the spelling adopted by the Nobel Foundation, and (4) it is the spelling adopted most often by authors of papers in the journal *Nuclear Instruments and Methods in Physics Research*.

The Cherenkov effect and the resulting radiation produced by a charged particle traveling in a transparent medium at a velocity exceeding the speed of light in that medium were predicted theoretically as early as 1888 by Heaviside (1888, 1889, 1892, 1899, 1912a,b), but long forgotten until the radiation was discovered finally by Cherenkov (see Čerenkov, 1934a,b) and interpreted by Frank and Tamm (1937). Heaviside's early prediction was based on a traveling point charge; as the electron was discovered by J.J. Thompson years later in 1897. Govorkov (2005) reviewed the historical significance of Heaviside's prediction, namely, that Heaviside first predicted theoretically that a point charge (*e.g.*, electron) would produce a conical wavefront if it were to travel at a speed greater than the speed of light in a medium. Heaviside's prediction was before Einstein's theory of relativity, which holds that matter cannot travel faster than light in a vacuum; however, matter can travel faster than light in a medium. In the time of Heaviside, even outer space was not considered to be a vacuum but to consist of an "ether", and therefore, according to Heaviside, the conical wavefront would be produced in the "ether" as well as any other medium, provided the point charge travels at a speed exceeding that of light in that medium. In the words of Govorkov (2005),

> *"A genius, Heaviside was half a century in advance of his time in his calculations and predictions, but unfortunately he was not understood by his contemporaries. His works were forgotten, and scientists had to start from the beginning, this time from experiment"* [i.e., *the experiments and discovery by Cherenkov (see Čerenkov, 1934a,b, 1936, 1937a–d, 1938a–c)*].

The German physicist, Sommerfeld (1904), also predicted a radiation wavefront that would be produced by an electron traveling at a speed exceeding the speed of light in a medium. Sommerfeld's prediction was with no apparent knowledge of the previous theories of Heaviside. Electrons, as well as other charged particles, with sufficient energy can indeed travel faster than light in media where light travels at speeds less than its speed in a vacuum. The speed of light in a transparent medium is defined by the index of refraction, n, of the medium where $n = c/v$ and c is the velocity of light in a vacuum and v the velocity of light in the medium. Heaviside (1912a) had even calculated the geometry and angle of emission of the electromagnetic wavefront relative to the axis of travel of the charged particle. Also, Afanasiev et al. (1999) explain that the early theoretical predictions of Heaviside, namely, that a conical radiation wavefront would arise when the point charge velocity exceeds the light velocity in a medium, had been forgotten by the scientific community until 1974 when they were revived by Tyapkin (1974) and Kaiser (1974).

Cherenkov radiation was observed by Marie Curie in 1910. She observed in a dark room a pale blue light from concentrated radium solutions as related in a biography by her daughter Curie (1941). The radiation was researched by Lucien Mallet (1926, 1928, 1929). He found that the light would be emitted by a variety of transparent bodies when exposed to radioactive sources; however, the unique origin and anisotropic properties of the radiation were yet to be discovered. It was not until the extensive work of Cherenkov (see Čerenkov, 1934–38) and the theoretical interpretations of Frank and Tamm (1937), who shared the 1958 Nobel Prize in Physics with Cherenkov, was the origin and properties of Cherenkov radiation finally understood. Comprehensive treatments on the theory, properties, and history of Cherenkov radiation are available from Frank (1960), Jelley (1958, 1961), Ritson (1961) and in a book by the writer (L'Annunziata, 2016). A concise overview will be provided in this chapter.

Cherenkov radiation consists of a continuous spectrum of wavelengths extending from the ultraviolet region into the visible part of the spectrum peaking at about 420 nm (see Kulcsar et al., 1982; Claus et al., 1987). Only a negligible amount of photon emissions is found in the infrared or microwave regions.

Cherenkov photon emission is the result of local polarization along the path of travel of the charged particle with the emission of electromagnetic radiation when the polarized molecules return to their original states (Gruhn and Ogle, 1980). This has been described by Marshall (1952) as the electromagnetic "shock" wave that is analogous to the acoustical shock wave or sonic boom created by supersonic aircraft. The Cherenkov radiation is propagated as a conical wave front, that is, the radiation is emitted as a cone in the direction of particle travel, as illustrated in Fig. 6.1. The figure illustrates the effect of a high-energy proton traveling through a transparent medium at a speed greater than the speed of light in the medium; and similar effects are produced by other high-energy charged particles, such as electrons and beta-particles when their energy is sufficient to provide them with speeds exceeding that of light in transparent media.

Cherenkov radiation, when produced at significant levels, can be employed for the efficient measurement of radioactivity. This was first demonstrated by Belcher (1953), who used a liquid-nitrogen cooled single photomultiplier to measure Cherenkov radiation intensity in terms of count rates per mCi of various radionuclides in aqueous solution. However, it was not until dual photomultiplier liquid scintillation analyzers became available commercially and in widespread use in the early 1960s, did practical research into Cherenkov counting for the measurement of radioactivity begin. Although the production of Cherenkov radiation does not involve the scintillation phenomenon, a conventional liquid scintillation counter can detect and count Cherenkov photons emitted from a given sample in a standard counting vial. Certain radionuclides may be counted in water or other suitable transparent medium without the use of scintillation fluor or any other chemical reagents. They may even be counted in the dry state, albeit at a diminished counting efficiency, where the glass or plastic vial wall containing the sample acts as the transparent medium for the production of Cherenkov photons.

Cherenkov counting of radionuclides in an aqueous medium (*i.e.*, without scintillation cocktail) leaves the sample in an unadulterated state that maintains the sample suitable for any other chemical tests deemed necessary in a given research study. This technique is popular for the assay of relatively high-energy β-particle-emitting nuclides. The threshold β-particle energy for the production of Cherenkov radiation is discussed subsequently in this chapter. The ease of sample preparation, low cost (no need for fluors and fluor solvents), and the automated counting available with a liquid scintillation analyzer are among the principal reasons for the widespread use of this counting method. The Cherenkov effect is also an important tool in nuclear particle physics including the detection, measurement, and discrimination of muons, pions, kaons, and protons, among others. Even neutrinos, which carry no charge and cannot produce the Cherenkov effect, are detected indirectly by the Cherenkov effect produced through neutrino-electron elastic scattering (ES) interactions, and charged current (CC) and neutral current (NC) reactions with detector nuclei. The principles of the Cherenkov effect and its application to the detection and measurement of radionuclides and nuclear particles will be discussed in this chapter.

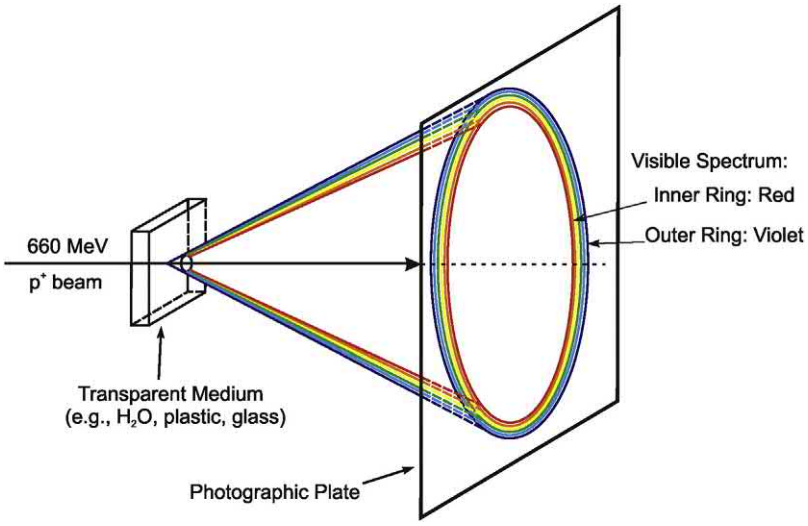

FIGURE 6.1 Diagram of the Cherenkov radiation cone and an experimental arrangement for obtaining photographs of the cone section in the plane of a photographic plate placed perpendicular to the path of high-speed (660 MeV) protons in an accelerator beam. Color of the cone and ring, which is observable in electronic format was added by the writer according to the depiction provided by Govorkov (2005). *From Cherenkov's Nobel Lecture (1958), printed with permission © 1958 The Nobel Foundation.*

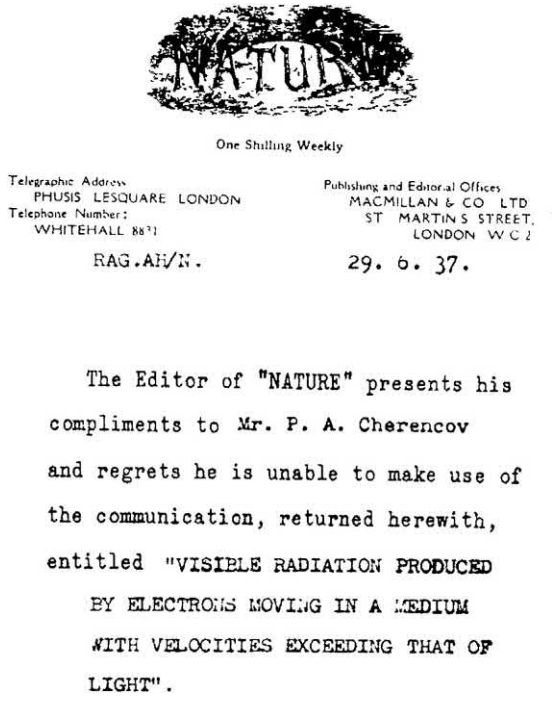

II. Discovery of Cherenkov radiation

In 1933 Sergei I. Vavilov was Head of the USSR State Optical Institute and Head of the Academy of Science Physics Department in Leningrad (now Saint Petersburg, Russia) and since 1934 was named the P.N. Lebedev Institute of Physics of the Russian Academy of Sciences. He organized teams of young scientists to carry out research in neutron physics and luminescence. Sergei Vavilov was then one of the world's leading scientists in the field of luminescence. At that time, Vavilov believed the glow of blue light emitted by highly radioactive solutions was due to luminescence. Vavilov had a doctoral student whose name was Pavel Alekseyevich Cherenkov. For his doctoral research, Vavilov proposed that Pavel Cherenkov work on the topic of "*The luminescence of uranyl salt solutions under the influence of hard gamma radiation*". High-energy gamma radiation would induce the production of a weak blue light from solutions of uranium salts, and it was thought, that this might be due to the occurrence of luminescence. Vavilov and Cherenkov started the research to investigate what they thought was luminescence. Sophisticated photomultiplier detectors were not available in 1933; however, Vavilov had developed a visual method of measuring low light intensities very close to the thresholds of human vision. To observe and measure the intensities of this weak light, Cherenkov had to adapt his eyes by remaining in a dark room for an hour or more before taking any measurements.

Cherenkov found that the weak light was emitted not only from the uranium salt in sulfuric acid solution when irradiated with strong gamma rays, but that there was a background glow from the solvent itself, that is, when sulfuric acid solution without the uranium solute was irradiated with the hard gamma-rays. Bolotovski et al. (2004) give an account that Vavilov asked Cherenkov to investigate other solvents that were highly purified to see if these also emitted light when irradiated. Cherenkov determined that 16 different pure solvents produced about the same intensity of blue light when these were irradiated with the hard gamma radiation. Various attempts to quench the effect were unsuccessful, which provided evidence that the phenomenon was not fluorescence. What was occurring was obvious to them at this point. This was not fluorescence, but that the light emission was a new phenomenon of origin yet unknown to mankind. They had discovered a new radiation, which they reported in two papers back-to-back in the 1934 Proceedings of the USSR Academy of Sciences (Čerenkov, 1934a,b; Vavilov, 1934). In his paper, Vavilov (1934) provided a preliminary theory on the origin of the radiation. He proposed that Compton electrons produced by the hard gamma radiation would yield a type of Bremsstrahlung radiation. He was correct in the conclusion that the mysterious light was being produced by the Compton electrons; however, the mysterious light was not the result of Bremsstrahlung. It was yet of unknown origin. It would not be until a few years later (1935–38) with more research by Čerenkov (1936, 1937a–d, 1938a–c) and theoretical calculations by Frank and Tamm (1937), would it be understood finally that the new radiation was produced by charged particles when these particles had sufficient energy to travel at a speed in excess of the speed of light in the transparent medium. The new radiation soon became known as "Vavilov–Cherenkov radiation". Pavel Cherenkov, Il'ja Frank, and Igor Tamm shared the Nobel Prize in Physics in 1958 "for the discovery and interpretation of the Cherenkov Effect". Sergei Vavilov would have shared in the prize had he not passed away several years before. Very interesting accounts of the life and works of Pavel Cherenkov are provided in papers by Govorkov (2005), Belousov (2006), and by his daughter Cherenkova (2008). A very detailed treatment of the life and pioneering experiments of Pavel A. Cherenkov and the works of Il'ja M. Frank and Igor Y. Tamm is provided in a previous book by the writer (L'Annunziata, 2016).

III. Theory and properties of Cherenkov radiation

Some of the unique properties of the radiation discovered by Čerenkov (1936, 1937a–d, 1938a–c) were (1) the radiation was produced by charged particles, (2) the intensity of the radiation was a function of the particle energy and the properties of the solution (*i.e.*, its index of refraction), (3) the light was polarized and the emission of the light was asymmetric, that is, it was emitted only in the direction of travel of the charged particles, (4) the radiation was emitted at specific angles to the direction of travel of the charged particles and the angle of emission was a function of the particle velocity (*i.e.*, particle energy) and the index of refraction of the medium. Frank and Tamm (1937) analyzed Cherenkov's findings and concluded, as described subsequently, that this phenomenon could only occur if the charged particle traveled in the transparent medium at a speed in excess of the speed of light in that medium. Cherenkov wrote up his findings in a paper submitted to the journal *Nature*, which was rejected by the journal in a letter dated 19 June 1937, illustrated in Fig. 6.2, as there was an atmosphere of distrust among some of the scientific community concerning this new theory. After consulting with Vavilov on the rejection by *Nature*, Cherenkov transferred the paper without any changes to a new envelope addressed to *Physical Review* published by the American Physical Society; and the paper was published in the next issue of *Physical Review* (see Čerenkov, 1937d).

The Editor of "NATURE" presents his compliments to Mr. P. A. Cherencov and regrets he is unable to make use of the communication, returned herewith, entitled "VISIBLE RADIATION PRODUCED BY ELECTRONS MOVING IN A MEDIUM WITH VELOCITIES EXCEEDING THAT OF LIGHT".

FIGURE 6.2 Letter to Pavel Cherenkov from the editors of the journal *Nature* rejecting his historic findings for publication. *From Cherenkov (1986), reprinted with permission from Elsevier © 1986.*

A. Interpretation by Il'ja M. Frank and Igor Y. Tamm

Once it was understood that Vavilov and Cherenkov had discovered a new and previously unknown phenomenon, Il'ja Frank and Igor Tamm of the Theoretical Physics Division of the P.N. Lebedev Institute of Physics in Moscow took notice and went to work on the interpretation of this new phenomenon. Their findings were published in a joint paper entitled "*Coherent Visible Radiation of Fast Electrons Passing through Matter*" (Frank and Tamm, 1937). They explained the Cherenkov effect is caused by a charged particle traveling in a medium at a speed in excess of the speed of light in that medium. It was known from Einstein's theory of relativity that matter could not travel in excess of the speed of light in a vacuum ($c = 2.99 \times 10^8$ m/s); however, in a gas, liquid, or solid medium, the velocity of light will be less than its velocity in a vacuum and, an elementary charged particle with sufficient energy could travel in such media at speeds exceeding that of light. The charged particle in passing through the electron clouds of a medium would create an electromagnetic shock wave analogous to that of a "sonic boom" created by a jet airplane or projectile traveling in the atmosphere at a speed exceeding that of sound. In the words of Frank and Tamm (1937):

> *We shall consider an electron moving with constant velocity v along [an] axis through a medium characterized by its index of refraction n. The field of the electron may be considered as the result of superposition of spherical waves of retarded potential, which are being continually emitted by the moving electron and are propagated with the velocity* (c/n) *[See Fig. 6.3]. It is easy to see that all these consecutive waves emitted will be in phase along the directions making the angle* θ *with the axis of motion [of the particle], if only v, n, and* θ *do satisfy the condition*

$$\cos\theta = \frac{1}{\beta n} \tag{6.1}$$

> *where* $\beta = v/c$. *Thus there will be a radiation emitted in the direction* θ, *whereas the interference of waves will prevent radiation in any other direction.*

The term β of Eq. (6.1) is the relative phase velocity of the charged particle, that is, the velocity of the particle, v, divided by the speed of light in a vacuum, c. Frank and Tamm (1937) demonstrated that the above condition described by Eq. (6.1) can be fulfilled only if

$$\beta n > 1 \tag{6.2}$$

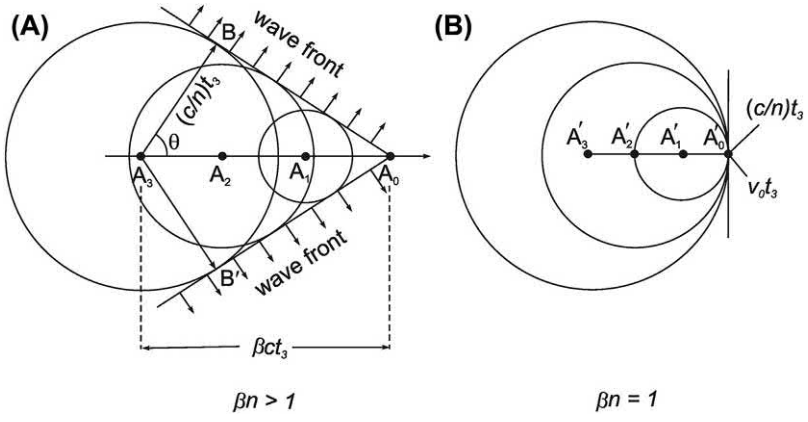

FIGURE 6.3 A Huygens construction of the spherical waves of retarded potential produced by a charged particle traveling along an axis in a refractive medium from points A_3 to A_0 at two velocities, namely (A) $\beta n > 1$ and (B) $\beta n = 1$. *Adapted from Nobel Lecture of Il'ja Frank (1958). Printed with permission © 1958 The Nobel Foundation.*

that is, the product of the relative phase velocity of the particle (β) and the index of refraction of the medium (n), must be greater than unity.

In his Nobel Lecture, Frank (1958) derived Eq. (6.1) from the distance of travel of the spherical wave front relative to the distance traveled by the electron as seen in Fig. 6.3. In the words of Frank (1958) in his Nobel Lecture with the writer's words in brackets:

> *We have to consider each point of the particle trajectory as a source of waves. In this case, the wave phase is determined by the instant of passage of the particle through a given point. Let us assume that at moment* $t = -t_3$ *the emitter was at point* A_3*, at moment* $t = -t_2$ *at point* A_2*, at moment* $t = -t_1$ *at* A_1*, and, finally, at the moment of observation* $t = 0$ *at* A_0 *[see Fig. 6.3].*
>
> *The velocity of the waves is equal to the phase velocity of light* c/n *… The surfaces of the rays are simply spheres whose radii for points* A_3*,* A_2*,* A_1*, and* A_0 *are* $(c/n)t_3$*,* $(c/n)t_2$*,* $(c/n)t_1$*, and 0, respectively [see Fig. 6.3A]. The envelope of these spheres evidently represents a cone of circular cross-section with the apex at* A_0*. Its generatrices in the plane of the drawing are* A_0B *and* A_0B'*.*
>
> *According to the Huygens' principle, the directions of the rays are defined by the radius vectors drawn from some center of the waves to the point of tangency with the envelope. For example, [in Fig. 6.3] it is* A_3B *and* A_3B' *coinciding with the generatrices of the wave normal cone.*
>
> *From Fig. 6.3 it is not difficult to determine the magnitude of the threshold velocity. When the velocity diminishes, the distances between points* A *decrease. The threshold case arises when point* A*, occupies the position* A_0' *on the surface of the sphere [This case is depicted separately in Fig. 6.3B.) At lower velocities, one of the spheres lies completely within the other and they do not have a common envelope. In the threshold case* $[\beta n = 1]$*, they have only a common point of tangency,* A_0'*. Thus, evidently* $(c/n)t_3 = v_0t_3$*, i.e.,* $v_0 = c/n$*. The cone of wave normals is compressed in the direction of velocity v, and the wave cone transforms into a plane perpendicular to the axis of motion at point* A_0' *[Fig. 6.3B].*

From Fig, 6.3a the equation defining the angle θ as a function of the particle phase velocity β and index of refraction n, that is, $\cos\theta = 1/\beta n$, is derived from the distances of travel of the wavefront with respect to that traveled by the charged particle. The velocity v of travel of the wavefront in a particular medium is a function of the index of refraction n of the medium, since by definition $n = c/v$. The distance traveled by the wavefront from A_3 to B of Fig. 6.3A is the product of velocity and time t or $A_3B = vt_3$, and the distance traveled by the charged particle in the same time span from A_3 to A_0 is the product of the particle velocity in the medium v_p and time t_3 or $A_3A_0 = v_pt_3$, which may be written as $A_3A_0 = (v_p/c)ct_3$. Since the particle phase velocity β is defined as v_p/c, the distance A_3A_0 traveled by the charged particle becomes $A_3A_0 = \beta ct_3$. The angle of emission θ of the Cherenkov radiation with respect to the direction of travel of the charged particle is defined as

$$\cos\theta = \frac{A_3B}{A_3A_0} = \frac{(c/n)t_3}{\beta ct_3} = \frac{1}{\beta n} \tag{6.3}$$

Thus, the Cherenkov photons are anisotropic, that is, the photons are not emitted in all directions; rather, the photons are conical, *i.e.*, they are emitted as a cone at an angle θ. The angle of emission is a function of the phase velocity (β) of the particle and the index of refraction (n) of the medium within which the particle is traveling. If the particle is assigned a maximum velocity, where β approaches unity, there will be a maximum angle of emission θ of the Cherenkov photons, and the angle would be a function of the index of refraction of the medium or

$$\cos\theta_{\max} = \frac{1}{n} \quad \text{when} \quad \beta = 1 \tag{6.4}$$

For example, if an electron traveling in water is assigned a maximum velocity, where $\beta = 1$, and the index of refraction of water $n = 1.333$ at the sodium line (589.0 nm) at 20°C (Haynes, 2011), the maximum angle of emission of Cherenkov photons in water would be calculated according to Eq. (6.4) as

$$\theta_{\max} = \cos^{-1}\frac{1}{1.333} = 41.4^0 \tag{6.5}$$

Frank and Tamm (1937) calculated the total energy, W, radiated by an electron via the Cherenkov effect through a cylindrical region of medium of length, l, where the axis of the cylinder coincided with the line of motion of the electron. Under the assumption that β is constant over a short length, dl, of the electron track, they derived the equation

$$W = \frac{e^2\, l}{c^2}\int_{\beta n>1}\omega d\omega\left(1 - \frac{1}{\beta^2 n^2}\right) \tag{6.6}$$

where ω is the frequency of the Cherenkov radiation. The lower limit of the integral, $\beta n > 1$, is the threshold condition for the production of Cherenkov photons in any medium. Frank and Tamm (1937) established the equation to be valid provided that l should be large in comparison with the wave length λ of the Cherenkov radiation emitted. Čerenkov (1938c) took Eq. (6.6) of Frank and Tamm and evaluated the energy, W, radiated by an electron taking under consideration that the magnitude of β will vary greatly over the entire path length of the electron. Čerenkov stated (1938c) the following:

> *In reality, the motion of an electron in the medium involves a considerable change in velocity and, accordingly, magnitude* β *will vary greatly in different sections of the path of the electron. Hence on the assumption that a but*

relatively small region of the spectrum is examined, within which β may be considered as constant, formula 6.6 with reference to the true motion of the electron should be written as follows:

$$W = \frac{e^2}{c^2}\int \omega d\omega \int_{\beta n>1}\left(1-\frac{1}{\beta^2 n^2}\right)dl \tag{6.7}$$

where β depends on l.

Frank and Tamm (1937) thus calculated the rate of radiated energy per path length of travel, *dW/dl*, to be of the order of only several kilovolts per centimeter. Thus, the electron energy loss via the emission of Cherenkov radiation would be a negligible quantity of energy in comparison to the energy lost by the electron by other mechanisms, such as ionization. Čerenkov (1938c) confirmed this through calculations and experimentation and concluded that the radiation expended by β-particles from Ra(B + C) (*i.e.*, ^{214}Pb + ^{214}Bi) via the emission of Cherenkov radiation amounts to a value of the order of only 0.1% of the total energy of the β-particles.

From Eq. (6.6) Frank and Tamm (1937) deduced the following equation for the number of photons, *N*, emitted by an electron within the limits of a given spectral region confined by the wavelengths λ_1 and λ_2 for a constant β, that is, for a short length of the electron track where the phase velocity of the electron remains relatively constant to be

$$N = 2\pi\alpha\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\left(1-\frac{1}{\beta^2 n^2}\right) \tag{6.8}$$

where α is the fine structure constant ($\alpha \approx 1/137$). From Eq. (6.8), Frank and Tamm (1937) calculated that a 500 keV electron, which would correspond to $\beta^2 = 0.75$, traveling in water, where $n = 1.33$, would produce approximately 10 photons per 0.1 cm within the visible region between $\lambda_1 = 4000$ Å and $\lambda_2 = 6000$ Å as follows:

$$N = 2(3.14)(1/137)\left(\frac{1}{4\times10^{-5}\text{cm}}-\frac{1}{6\times10^{-5}\text{cm}}\right)\left(1-\frac{1}{(0.75)(1.33)^2}\right) \tag{6.9}$$

$$= 101 \text{ photons/cm} = 10 \text{ photons/0.1 cm}.$$

The above approximation by Frank and Tamm was confirmed with more precise calculations by Belcher (1953), who calculated the integral number of Cherenkov photons produced by an electron as a function of its varying phase velocity over the entire effective range of travel of the electron in water ($n = 1.33$) and Perspex plastic medium ($n = 1.50$). The effective range of travel of the electron is that of its highest energy or highest phase velocity ($\beta = \beta_{max}$) to a lower energy as a result of reduced velocity in the medium corresponding to the threshold phase velocity or $\beta = 1/n$ at which point Cherenkov photons are not produced. The calculations of Belcher are treated in more detail further on in this chapter.

B. Quantum mechanical interpretation

The theory of Cherenkov radiation explained by Frank and Tamm is based on classical electrodynamics, and successfully explains the main characteristics of radiation in terms of its spectral properties (i.e., its coherence and anisotropy). However, Cherenkov radiation is attributed to the radiation produced by a uniformly moving charged particle in a medium, and consequently it appears that the theory allows for a violation of the laws of conservation (Kobzev, 2010, 2014). Intuitively, we know that any violation is not possible. However, within the framework of classical electrodynamics, it could appear as such. Therefore, for a rigorous treatment of the Cherenkov phenomenon, it is necessary to reach for the tools of quantum theory, although some controversy cannot be avoided (Ginzburg, 1977; Skobel'tsyn 1977). Such a rigorous treatment delves deep into quantum electrodynamics (Jauch and Watson, 1948a, 1948b, 1949; Feynman, 1950; Ivanov et al., 2016). Through the following basic principles of the quantum approach, an explanation of the Cherenkov effect is provided (Supek, 1990; Ginzburg, 1996, 2005; Afanasiev et al., 2006; Wang, 2015). In the quantum mechanical approach, the motion of a "free charged particle (electron)" can be expressed by that of a plane wave $\boldsymbol{u}$:

$$u = e^{-i\mathrm{kr}} \tag{6.10}$$

where $\boldsymbol{u}$ is characterized by wave vector $\mathbf{k}$ and position $\mathbf{r}$. Formally, on the basis of the matrix elements for a charged particle (electron) transition from state $\mathbf{k}$ to state $\mathbf{k}'$, we can write

$$\int e^{-i\mathrm{qr}} u_{\mathrm{k}} u_{\mathrm{k}'} d\tau \tag{6.11}$$

where $\boldsymbol{d\tau}$ is the space increment and $\mathbf{q}$ is the photon wave vector. This is equivalent to the following equation:

$$\int e^{i(-\mathrm{k}+\mathrm{q}+\mathrm{k}')\mathrm{r}} d\tau \tag{6.12}$$

from which it can be concluded that the electron emits photons through the conservation of the total wave vectors or momentum $\mathbf{k} = \mathbf{q} + \mathbf{k}'$. The conservation of momentum imposes that the matrix element should be different from zero and that the electron will produce photons without constant motion. This conclusion is incorrect, because in the matrix elements, the Dirac function for the transition probability $\boldsymbol{\delta(E_0 - E_1)}$ should be taken into account, due to the law of the conservation of energy (Jauch and Watson, 1948; 1948a; Feynman, 1950; Supek, 1990). The Dirac function $\boldsymbol{\delta(E - E' - \hbar\omega)}$ is different from zero only in

the case when energy conservation is fulfilled, where $\boldsymbol{E_0}$ is the initial energy of an electron, and $\boldsymbol{E_1} = \boldsymbol{E'} + \hbar\boldsymbol{\omega}$ is the sum of the energies of the electron $\boldsymbol{E'}$ and photon $\hbar\boldsymbol{\omega}$ (Supek, 1990). The energy $\boldsymbol{E}$ of a relativistic particle (i.e., electron) is written as

$$E = c\sqrt{m_0^2c^2 + p^2}, \tag{6.13}$$

an expression of Eq. (1.373) derived in Chapter 1, Volume 1, namely,

$$E^2 = \left(m_0c^2\right)^2 + (pc)^2 \tag{6.14}$$

which is the relativistic energy−momentum relation where m_0 is the particle rest mass (i.e., intrinsic mass), p is the particle momentum, and c is the speed of light in a vacuum (see Eqs. (1.371) to (1.373) of Chapter 1, Volume 1, Section XI.A. "Dual Nature Wave and Particle"). The change in particle energy can be obtained by differentiation of Eq. (6.13) $\boldsymbol{dE/dp}$

$$\frac{dE}{dp} = \frac{2cp}{2\sqrt{m^2c^2 + p^2}} \tag{6.15}$$

By changing of $\boldsymbol{dE}$ and dp with ΔE and Δp gives

$$\Delta E = \frac{cp\Delta p}{\sqrt{m^2c^2 + p^2}} \tag{6.16}$$

The energy of a photon (ε) is the product of the speed of light and its momentum Π, as derived in Chapter 1, Volume 1 (see Eq. 1.375)

$$\varepsilon = c\Pi \tag{6.17}$$

The photon momentum should be equal to the change in electron momentum (ε) or

$$\varepsilon = c\Delta p \tag{6.18}$$

The division of Eqs. (6.16) and (6.18) provides a comparison of the energy and momentum changes of the electron and photon, or

$$\frac{\Delta E}{\varepsilon} = \frac{p}{\sqrt{m^2c^2 + p^2}} < 1 \tag{6.19}$$

As the relation $\Delta E/\varepsilon < 1$, the relation $\Delta E = \varepsilon$ cannot be fulfilled without the addition of energy to the electron, if the photon carries off part of the momentum. On the contrary, if the electron loses energy to photon energy, then it should disperse part of the momentum. The conservation law for the electron and photon momentum is written, according to the previously described Eq. (6.16), as

$$\Delta p = \frac{\sqrt{p^2 + m^2c^2}}{cp}\Delta E \tag{6.20}$$

and

$$\Pi = \frac{\Delta E}{c} \tag{6.21}$$

Dividing Eqs. (6.20) and (6.21) provides a comparison of the particle and photon momentum as

$$\frac{\Delta p}{\Pi} = \frac{\sqrt{p^2 + m_0^2c^2}}{p} > 1 \tag{6.22}$$

Thus, the spontaneous electron production of photons is possible only in the case of electron retardation in other particles or when the particle velocity $v > c/n$ (Supek, 1990), where n is the refractive index of the medium through which the particle travels. In other words, when the speed of the electron is greater than the speed of light in a medium, Cherenkov radiation will occur. In this fashion, on the basis of the quantum mechanical approach, Ginzburg (1940, 1996, 2005) developed the theory of Cherenkov radiation. He used Eq. (6.13) to express the particle energy as

$$E_{0,1} = c\sqrt{m^2c^2 + p_{0,1}^2} \tag{6.23}$$

and its momentum as

$$p_{0,1} = \frac{m_0v_{0,1}}{\sqrt{1 - \left(v_{0,1}^2/c^2\right)}} \tag{6.24}$$

where the term $m_0\Big/\sqrt{1 - (v^2/c^2)}$ is the expression for the relativistic mass of a particle as derived in Chapter 1, Volume 1, Section VII.E. "Energy and Mass in Relativity" (see also Eqs. (6.32) and (6.34) further on in this chapter). The terms $E_{0,1}$ and $p_{0,1}$ are the energy and momentum of a charged particle of rest mass m_0 before (0) and after (1), the emission of a photon of energy $\hbar\boldsymbol{\omega}$, and momentum $\hbar\mathbf{k} = (\hbar\boldsymbol{\omega}/\boldsymbol{c})$ $(\mathbf{k}/\mathrm{k})$, where $k = \omega/c$. Eqs. (6.22) and (6.23) have no solution with $\boldsymbol{\omega} > 0$ at $v < c$, whereby radiation is impossible. Let us assume that a charged particle with rest mass m_0 and momentum p_0 is moving in a medium with refractive index n. After propagation, it emits a photon with momentum p_1. The radiated photon is emitted at an angle θ_0 with the direction of propagation governed by the conservation of momentum, which requires (Wang, 2015)

$$p^2 = p_0^2 + p_1^2 - 2p_0p_1\cos\theta_0 \tag{6.25}$$

The energy conservation relation and solution for $\cos\theta_0$ gives (Ginzburg, 1996, 2005)

$$\cos\theta_0 = \frac{c}{n(\omega)v_0}\left[1 + \frac{\hbar\omega(n^2 - 1)}{2m_0c^2}\sqrt{1 - (v_0^2/c^2)}\right] \tag{6.26}$$

In the case when

$$\frac{\hbar\omega}{m_0c^2} << 1 \tag{6.27}$$

Eq. (6.24) becomes

$$\cos\theta = \frac{1}{\beta n(\omega)} \tag{6.28}$$

where β is the relative phase velocity of the particle, that is, the velocity of the particle in a medium divided by the speed of light in a vacuum (v/c) and n is the index of refraction of the medium. Eq. (6.26) is the threshold condition for the production of Cherenkov photons in a transparent medium of refractive index n, where n is a function of wavelength $\omega = 2\pi c/\lambda$. This is natural because condition (6.26) becomes classical in the case when $\mathrm{h} \to 0$. This means that the classical limit corresponds to the neglect of recoil (a change in the particle momentum p_0) due to "photon emission in a medium" with momentum $\hbar\mathbf{k}$, as noted by Ginzburg (1996). According to Ginzburg (1996), the conservation laws may be formulated in the classical domain under the condition that the relationship between the emitted electromagnetic energy and radiation momentum be taken into account. An explanation of the Cherenkov radiation mechanism in the context of energy and momentum conservation laws is not trivial and sometimes provokes controversy, which can be seen from the recent papers of Kobzev (Kobzev, 2010, 2014) and also from the discussions of Ginzburg and Skobel'tsyn (Ginzburg, 1977; Skobel'tsyn 1977).

Kobzev stipulates that "the Vavilov-Cherenkov radiation microscopic mechanism does not contradict with the basic laws" (see Kobzev, 2010, 2014). The radiation arises from the interaction of the moving charge with bound charges that are spaced fairly far away from its trajectory. The Cherenkov radiation mechanism bears a slowing down character, but it differs fundamentally from bremsstrahlung, primarily because the Vavilov–Cherenkov radiation onset results from a two-stage process. First, the moving particle polarizes the medium; and then, the already polarized atoms radiate coherently, provided that the particle velocity exceeds the phase speed of light in the medium (as illustrated in Fig. 6.4). If the particle velocity is less than the phase speed of light in the medium, the polarized atoms return energy to the outgoing particle. In this case, "radiation is not observed" (Kobzev, 2010).

Even nowadays we encounter the misconception that Cherenkov radiation is in some way associated with ionization. In terms of energy loss, the ionization process dominates over Cherenkov radiation, but a very small part of ionization energy appears as light, so that Cherenkov radiation in the optical part of the spectrum is dominant. Some substances, such as scintillators, will produce light from the ionization process. However, this cannot be seen as Cherenkov radiation. Namely, light emitted in association with the ionization process will appear at a time, after the original ionizing event, determined by the specific lifetimes of the atomic energy states responsible for the emission. For this light, coherence between the wavelets from the different portions of the track, the characteristic cone, and the velocity threshold do not exist. As a consequence, such light is emitted isotropically. This is in contrast to Cherenkov radiation, which is characterized by threshold, coherence, and anisotropic properties. On the other hand, a consideration of the energy exchange between the particle and a single individual atom involved in the Cherenkov process shows a very small energy transfer. Jelley (1961) showed that the energy exchange is only 8×10^{-13} eV for blue light. This is far below the energy required for excitation as well as ionization.

C. Threshold condition

As discussed in the previous section, the threshold condition for the production of Cherenkov radiation in a transparent medium is given by

$$\beta n = 1 \tag{6.29}$$

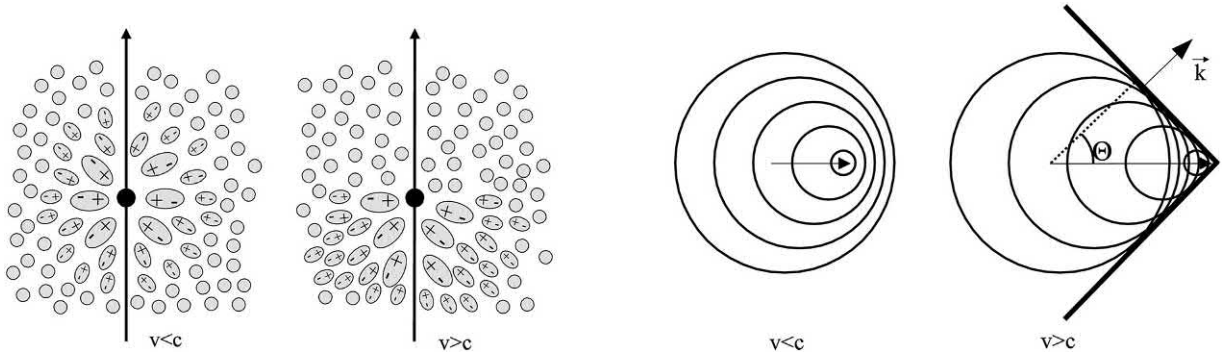

FIGURE 6.4 Left: Illustration of the polarization of the medium induced by the crossing of a relativistic particle. Right: Construction of Cherenkov wavefront. *From de Naurois and Mazin (2015), reprinted with permission © 2015 Elsevier Masson SAS. All rights reserved.*

where β is the relative phase velocity of the particle, that is, the velocity of the particle divided by the speed of light in a vacuum, and n is the refractive index of the medium (*i.e.*, the ratio of the velocity of light in a vacuum to its velocity in the medium). Only charged particles that possess

$$\beta > 1/\mathrm{n} \tag{6.30}$$

produce Cherenkov photons in transparent media (Frank and Tamm, 1937). The value of β of the charged particle is dependent on its kinetic energy, which is obtained from the equation describing the total energy of the particle. As described in Chapter 1 of Volume 1 of this book (see Eqs. 1.269 to 1.271 of Chapter 1, Volume 1), the total energy (E_{tot}) of a particle is the sum of its kinetic (E_K) and rest energies (m_0c^2) or

$$E_{tot} = E_K + m_0c^2 = \gamma m_0c^2 \tag{6.31}$$

and

$$E_K = \gamma m_0c^2 - m_0c^2 \tag{6.32}$$

where

$$\gamma = \frac{1}{\sqrt{1-(u^2/c^2)}} \text{ and } u^2/c^2 = \beta^2 \tag{6.33}$$

u is the particle speed and $u < c$. (The particle speed is often represented with the symbol v or u.) If m_0 is the particle rest mass, then the particle relativistic mass, m_r, which is the speed-dependent mass of the particle, would be defined as

$$m_r = \frac{m_0}{\sqrt{1-(u^2/c^2)}} = \frac{m_0}{\sqrt{1-\beta^2}} \tag{6.34}$$

Thus, for a particle traveling at relativistic speed, Eq. (6.32) can be expressed as

$$E_K = m_0c^2\left[\frac{1}{(1-\beta^2)^{1/2}} - 1\right] \tag{6.35}$$

where m_0 is the particle rest mass in grams, c is the velocity of light in a vacuum (equal to 2.99×10^{10} cm/s), and E_K is the kinetic energy in erg (where 1.602×10^{-12} ergs = 1 eV). Eq. (6.35) can be solved for β to give the expression for the phase velocity of the particle as a function of its energy or

$$\beta = \left[1 - \left(\frac{1}{(E_K/m_0c^2)+1}\right)^2\right]^{1/2} \tag{6.36}$$

The value of the rest energy for an electron is $m_0c^2 = (9.11 \times 10^{-28}\ \mathrm{g})\ (2.99 \times 10^{10}\ \mathrm{cm/s})^2 = 8.14 \times 10^{-7}$ ergs. The energy in ergs may be converted to electron volts as follows: $(8.14 \times 10^{-7}\ \mathrm{ergs})/(1.602 \times 10^{-12}\ \mathrm{ergs/eV}) = 511$ keV. Substituting the value of 511 keV for m_0c^2 in Eq. (6.36) and solving for β gives

$$\beta = \left[1 - \left(\frac{1}{(E_K/511\ \mathrm{keV})+1}\right)^2\right]^{1/2} \tag{6.37}$$

Thus, the value of β, where electrons or beta particles are concerned, is dependent upon the electron or beta-particle energy, E_K, in keV according to Eq. (6.37).

D. Threshold energies

As noted above, the particle phase velocity, β, is a critical factor in the production of Cherenkov photons in a medium of given index of refraction, n, that is, Cherenkov radiation will occur only when $\beta > 1/n$. Consequently the particle energy, upon which the particle phase velocity is dependent, is a critical factor. Thus, a minimum or threshold energy of the particle must be reached when traveling in a medium of given index of refraction before Cherenkov photons will be produced. If we apply the threshold value of β for the production of Cherenkov photons from Eq. (6.29), *i.e.*, $\beta = 1/n$, to Eq. (6.37), we will obtain the threshold energy that electrons or beta-particles must possess for the production of Cherenkov radiation as a function of the index of refraction of the medium as

$$E_{\mathrm{th}} = 511\ \mathrm{keV}\left[\left(1 - \frac{1}{n^2}\right)^{-1/2} - 1\right] \tag{6.38}$$

When water is the transparent medium, where $n = 1.333$ (at 20°C at the sodium line, *i.e.*, 589.0 nm), the threshold energy for the production of Cherenkov photons by electrons or beta-particles is calculated according to Eq. (6.38) to be 262 keV (or 0.262 MeV) as follows:

$$E_{\mathrm{th}} = 511\ \mathrm{keV}\left[\left(1 - \frac{1}{n^2}\right)^{-1/2} - 1\right]$$

$$= 511\ \mathrm{keV}\left[\frac{1}{\sqrt{1 - \frac{1}{(1.333)^2}}} - 1\right]$$

$$= 262\ \mathrm{keV}$$

Thus, only electrons or beta-particles that possess energy in excess of 262 keV or 0.262 MeV produce Cherenkov photons in water.

We can write Eq. (6.38) in general terms for the calculation of the threshold energy of charged particles of any mass as follows

$$E_{\mathrm{th}} = m_0c^2\left[\left(1 - \frac{1}{n^2}\right)^{-1/2} - 1\right] \tag{6.39}$$

where m_0 is the particle rest mass and c is the velocity of light in a vacuum (2.99×10^{10} cm/s).

As described in Eq. (6.39), the threshold energy for the Cherenkov effect (*i.e.*, Cherenkov photon production) will vary according to the particle rest mass and index of refraction of the medium. The energy required for the production of Cherenkov photons, E_{th}, increases with particle mass, and it will be lower for media of higher index of refraction. For example, according to Eq. (6.39), electrons or beta-particles traveling through polyethylene plastic of refractive index $n = 1.52$, will have the following calculated threshold energy of 167 keV or 0.167 MeV, which is considerably lower than the threshold energy of 262 keV or 0.262 MeV for the production of Cherenkov photons in water:

$$E_{th} = m_0c^2\left[\left(1-\frac{1}{n^2}\right)^{-1/2}-1\right]$$

$$= \left(9.10938\times10^{-28}g\right)\left(2.99792\times10^{10}\text{cm/sec}\right)^2$$

$$\left[\frac{1}{\sqrt{1-\frac{1}{(1.52)^2}}}-1\right]$$

$$= 8.18707\times10^{-7}\text{ergs}\left[\frac{1}{\sqrt{0.5671745}}-1\right]$$

$$= \left(\frac{8.18707\times10^{-7}\text{ergs}}{1.602\times10^{-12}\text{ergs/eV}}\right)\left[\frac{1}{0.753109}-1\right]$$

$$= \left(0.5110\times10^{6}\text{eV}\right)(0.3278)$$

$$= 0.167\text{ MeV or }167\text{ keV}$$

Thus, the use of plastic, which has a higher index of refraction than water, as a counting medium through which β particles must travel, will reduce the threshold energy for the production of Cherenkov photons and increase the detection efficiency of radionuclides measured by Cherenkov counting (L'Annunziata and Passo, 2002).

Table 6.1 lists the calculated threshold energies of particles of differing mass in media of differing index of refraction calculated according to Eq. (6.39). A medium within which Cherenkov photons are produced is referred to as a *Cherenkov Radiator*.

Data in Table 6.1 illustrate that the threshold energy for a particular particle decreases in media of increasing index of refraction. Also, the threshold energy required for the production of Cherenkov photons in any particular medium increases proportionally with the mass of the particle. Thus, by the selection of a medium of given index of refraction, it is possible to discriminate between particles of different energies or mass, which is discussed further on in this chapter. Beta-emitting radionuclides of high E_{max} (e.g., ^{90}Y with $E_{max} = 2280$ keV) can be analyzed efficiently with a Cherenkov radiator of low index of refraction (e.g., aerogel with n = 1.05 listed in Table 6.1), which has a high beta-particle or electron threshold energy thereby discriminating against background radiation from low-energy beta-particles and Compton electrons resulting from gamma-radiation background. The application of aerogel Cherenkov radiators for the detection of high-energy beta-emitting radionuclides is discussed further on in this chapter. Fig. 6.5 provides an excellent illustration of the relation between Cherenkov threshold energy for beta-particles or electrons and index of refraction of the Cherenkov radiator with data points calculated according to Eq. (6.38) or (6.39) (Yoo et al., 2013). The highest threshold energy (~1160 keV) illustrated in the graph of Fig. 6.5 is

that of an aerogel radiator with index of refraction n = ~ 1.05. The expanded section of the graph provides data points determined experimentally by Yoo et al. (2013) with liquid radiators of differing index of refraction. Yoo et al. (2013) report the development of a fiber optic Cherenkov radiation sensor that is coupled to the Cherenkov radiator for the detection and measurement of beta-particles.

E. Photon spatial asymmetry

An important property of Cherenkov radiation is its asymmetry, that is, the directional emission of the Cherenkov photons. Cherenkov radiation is not emitted in all directions. When Čerenkov (1936) discovered the asymmetric properties of this radiation, he knew he had discovered a type of radiation yet unknown. Frank and Tamm (1937) explained the spatial asymmetry of the radiation as a result of the charged particle traveling in a medium at a velocity exceeding the velocity of light in the medium. Frank and Tamm (1937) theorized that when the phase velocity of the charged particle, β, exceeded the reciprocal of the index of refraction, n, of the medium, that is, $\beta > 1/n$, Cherenkov photons are emitted as a cone at an angle, θ, to the direction of the charged particle as depicted in Figs. 6.1, 6.6 and 6.7. According to the theory of Frank and Tamm (1937), the angle, θ, of photon emission would be defined by the relationship

$$\cos\theta = \frac{1}{\beta n} \tag{6.40}$$

which was derived earlier in this chapter.

Čerenkov (1937b) tested the theory of Frank and Tamm (1937) using gamma rays directed at a vessel of water to create high-energy electrons in the water via the Compton effect. He then measured the angles of emission of the photons relative to the direction of the incident gamma radiation. Cherenkov found a broad range of photon emission angles in water with a maximum around 30 degrees. The

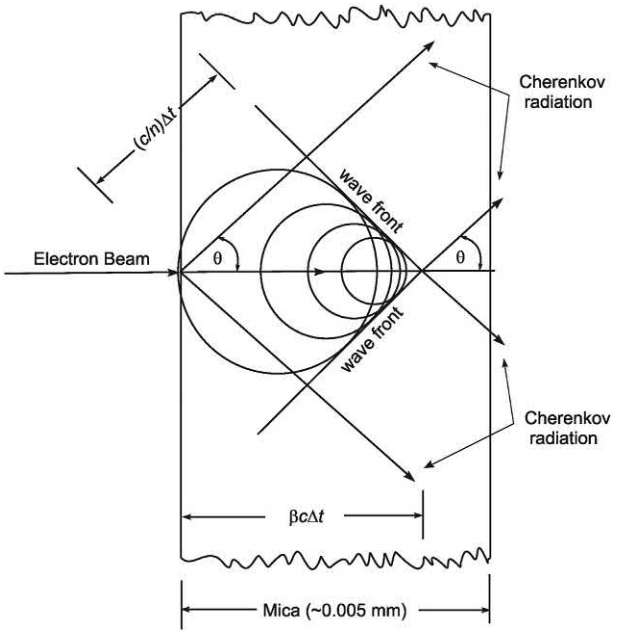

FIGURE 6.6 A thin section of mica used by Collins and Reiling (1938) and Wyckoff and Henderson (1943) as the transparent medium for the production of Cherenkov photons by a beam of high-energy electrons of uniform energy. The thin section of Cherenkov radiator would assure minimal loss of electron energy in traversing the mica. *From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.*

maximum angle of emission would depend on the phase velocity of the Compton electron, β, and thus on the energy of the electron. Although Cherenkov definitely was able to demonstrate the spatial asymmetry of the newly discovered photons, the Compton electrons unfortunately are not unidirectional and can display wide angles of deflection relative to the direction of the gamma rays that created them. Consequently, Cherenkov's results were not precise enough to demonstrate irrefutably Frank and Tamm's theory that cos $\theta = 1/\beta n$. It was not until monoenergetic electrons were used by researchers, such as Collins and Reiling (1938) and Wyckoff and Henderson (1943), could the angle of photon emission, θ, be accurately measured. They directed electrons of uniform energy into thin sections of transparent media such as mica, glass, cellophane, and water. A thin section of Cherenkov radiator assured insignificant loss of electron energy in traversing the medium.

According to the theory of Frank and Tamm (1937) the angle, θ, illustrated in Fig. 6.6, is defined by the equation

$$\cos\theta = \frac{\text{distance of travel of radiation front in the medium}}{\text{distance of travel of charged particle in the medium}} \tag{6.41}$$

or

$$\cos\theta = \frac{(\text{speed of light in the medium})(\Delta t)}{(\text{speed of particle in the medium})(\Delta t)} \tag{6.42}$$

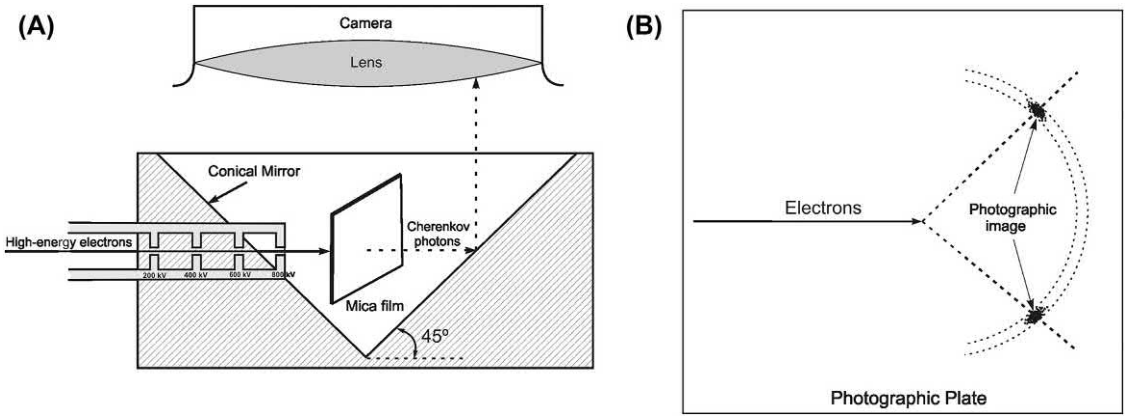

FIGURE 6.7 Basic experimental arrangement used by Collins and Reiling (1938) and Wyckoff and Henderson (1943) to demonstrate the relation cos $\theta = 1/\beta n$. In (A) an electron gun provides electrons of uniform energy by accelerating electrons across potentials varying from 200 to 800 kV. Wyckoff and Henderson (1943) produced electrons with energies over the range of 240−815 keV and Collins and Reiling (1938) accelerated electrons up to 2000 keV. The electrons in (A) traverse the mica film and produce cones of Cherenkov radiation. The Cherenkov photons are produced only in the direction of the electrons, and the photons are reflected off the conical mirror toward the camera. The photographic plate in (B) provides two spots produced by the Cherenkov radiation cone reflected in two dimensions from which the angle θ can be calculated. *From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.*

where Δt is a time interval. Using the notation provided in Figs. 6.3 and 6.6, we can then write

$$\cos\theta = \frac{(c/n)t}{\beta ct} \tag{6.43}$$

The term $(c/n)t$ represents the distance of travel of the radiation wavefront measured by the product of the velocity of the light in the medium (c/n) and time (t), while the term βct measures the distance of particle travel according to $\beta ct = (v/c)ct = vt$ where v is the velocity of the particle in the medium, c the speed of light in a vacuum, and t is time. From Eq. (6.43) we obtain the expression

$$\cos\theta = \frac{1}{\beta n} \tag{6.44}$$

when $\beta = 1/n$, which is the threshold condition for the production of Cherenkov photons (Eq. 6.44), the charged particle possesses a threshold energy where Cherenkov radiation is yet to be produced, that is, cos $\theta = 1$ and $\theta = 0$. When $\beta > 1/n$, the charged particle possesses sufficient energy and velocity to produce Cherenkov photons, which are emitted in the exact forward direction of the charged particle at an angle θ, as defined according to Eq. (6.44).

As the particle energy, E, of Eq. (6.36) increases to relativistic speeds, the value of β approaches unity and cos θ approaches $1/n$ of Eq. (6.44). Thus, the maximum angle of emission of a Cherenkov photon produced by a charged particle in any transparent medium would occur when the charged particle possesses a high energy to the point where the value of β of Eq. (6.36) approaches unity or

$$\cos\theta = \frac{1}{n}, \text{ when } \beta \text{ approaches } 1 \tag{6.45}$$

If we consider the case of mica as the transparent medium with index of refraction $n = 1.59$, such as that tested by Collins and Reiling (1938) and Wyckoff and Henderson (1943), the maximum possible angle of emission of Cherenkov photons in the mica are calculated to be

$$\cos\theta = \frac{1}{1.59} = 0.6289$$

and $\theta = 51.0$ degrees.

According to the theory of Frank and Tamm (1937), Cherenkov photons are emitted at more acute angles for charged particles just above their threshold energy and cannot exceed an emission angle of 51.0 degrees in mica, even for the most energetic particles.

Collins and Reiling (1938) and Wyckoff and Henderson (1943) tested the theory of Frank and Tamm by shooting electrons of various energies at mica, and they measured accurately the angles of emission of the Cherenkov photons as a function of electron energy. They could then compare the experimentally obtained emission angles, θ, with those calculated according to the relation cos $\theta = 1/\beta n$. The key component of their experimental arrangement, illustrated in Fig. 6.7, included a conical mirror to reflect the Cherenkov photons such as that designed by Čerenkov (1937b) in his initial experiments with Compton electrons.

The theoretical angles of emission (θ) of Cherenkov photons produced by electrons in mica with an index of refraction, $n = 1.59$, are plotted in Fig. 6.8. According to the Frank and Tamm theory (1937), where cos $\theta = 1/\beta n$, the theoretical angles of emission will vary from zero at the threshold electron energy to the highest emission angle for the relativistic electrons of highest energy where β approaches 1, its highest possible value. Collins and Reiling

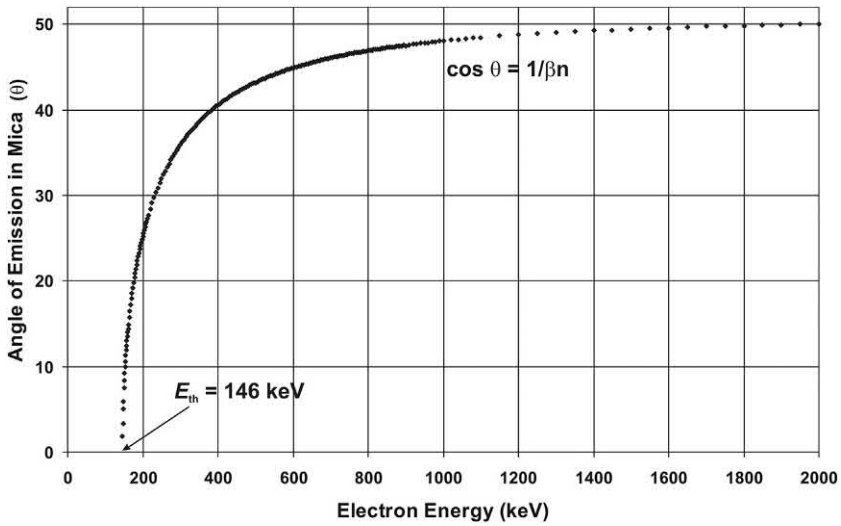

FIGURE 6.8 Cherenkov photon emission angles (θ) in mica of index of refraction, $n = 1.59$, as a function of electron energy calculated according to $\cos\theta = 1/\beta n$. The threshold energy E_{th} of electrons (146 keV) for the production of Cherenkov photons in the mica was calculated according to Eq. (6.39). *From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.*

(1938) and Wyckoff and Henderson (1943) found the experimentally measured angles of emission to agree very closely to the theoretical values over the electron energy range of 240−1900 keV within about 1 degree. In addition to mica, thin films of other transparent media of different index of refraction including thin films of glass and cellophane, were tested by Wyckoff and Henderson (1943), and the measured and theoretically calculated values of θ agreed to within 1 degree. The slight discrepancy between the measured and calculated values was considered due to slight unavoidable bending or imperfections of the thin films used.

We can conclude from the above that, for a particle of given mass and charge, the angle of emission of the Cherenkov photons will depend on the particle phase velocity (β), which is a function of its energy as well as the index of refraction of the medium. The maximum angle of emission of Cherenkov photons will, of course, differ for media of different index of refraction. In the fields of particle and nuclear physics the Cherenkov effect has been exploited for the identification of particles based on their mass and velocity, which in any given medium of known index of refraction, will govern the angle of emission of the Cherenkov photons. The concepts of particle identification by measurement of Cherenkov emissions is discussed further on in this chapter and reviewed in detail by Križan (2017, 2013, 2009, 2007, 2001), Nappi (2011), Iijima (2010). Ullaland (2003), Joram (2002) and Va'vra (2000).

Later in life, approximately 20 years after his historic research on the visible spectrum of the newly discovered radiation, Cherenkov commented on the spatial distribution and the visible spectrum of the radiation in his Nobel Lecture (with writer's comments in brackets) given on December 11, 1958, as follows:

> *If we consider the picture [of the radiation] not in the [2-dimensional] plane but spatially, then the radiation must spread out along the surface of a cone whose axis forms the path of an electrically charged particle while the surface line forms with this axis the angle [θ].*
>
> *If we place [a] photographic plate perpendicular to the beam of high-speed particles [See Fig. 6.1], we shall obtain, in addition to an image of the track of the beam, also a photograph of the radiation in the form of a ring.*
>
> *… we have in our considerations assumed some fixed frequency. In reality, however, the radiation spectrum is continuous. Since the medium exhibits dispersion, i.e., the refractive index is dependent on the frequency, this means that the light of different wavelengths is propagated at angles which, even with strictly constant velocity of the particles, differ somewhat from one another.*
>
> *Thus, the radiation is broken up as in spectral analysis. The radiation cone will consequently show a definite intensity, and in the case of a medium with normal dispersion the spectral red will lie in the inner part of the cone while the violet is on the outside. That this is actually so was shown by a photograph showing part of the ring with a color plate.*

An example of a typical image of the Cherenkov radiation in the form of a ring surrounding a central image of a beam of high-speed particles obtained with modern silicon photomultipliers, rather than photographic film described above by Cherenkov, is illustrated in Fig. 6.9 The ring

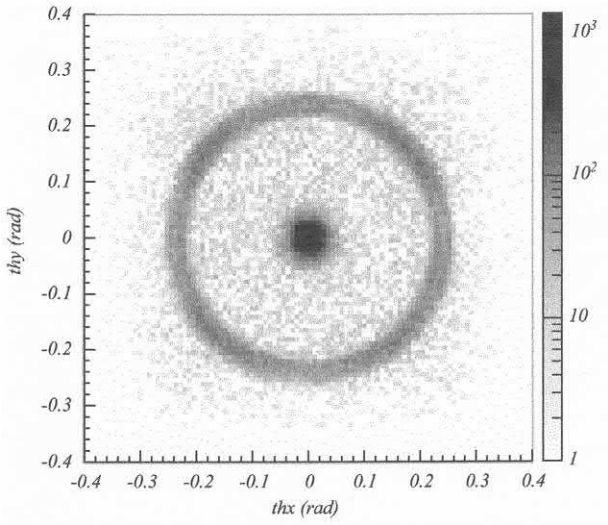

FIGURE 6.9 The distribution of hits in the Cherenkov angle space [*i.e.*, θ in y coordinates (*thy*) against θ in x coordinates (*thx*) imaged with silicon photomultipliers with noise distributions subtracted and without the use of light guides. *From Dolenec et al. (2011), reprinted with permission from Elsevier © 2011.*

image of Cherenkov photons was produced by a 120 GeV/c pion interaction with an aerogel radiator; and the Cherenkov photons emitted were detected by silicon photomultipliers described further on in this chapter. The dark image at the very center of the ring is due to the high-speed particle beam.

F. Photon spectrum and radiation intensity

Cherenkov radiation consists of a continuous spectrum of wavelengths extending from the near ultraviolet region into the visible part of the spectrum peaking at about 420 nm (Kulcsar et al., 1982; Claus et al., 1987). Only a negligible amount of photon emissions is found in the infrared or microwave regions. In Cherenkov's early work, he found the Cherenkov cone of radiation to comprise the visible spectrum (see Fig. 6.1). He observed specifically that the outer ring of the radiation cone was violet and its inner ring was red. Jelley (1958) explains that a medium is always dispersive, and consequently the radiation is restricted to those frequency bands for which $n(\omega) > 1/\beta$, where $n(\omega)$ is the index of refraction at a particular frequency band. Jelley adds that the absorption bands in media, that are transparent at visible wavelengths, limit the radiation to the near ultraviolet and longer wavelengths.

In their classic interpretation of the Cherenkov effect, Frank and Tamm (1937) calculated the total energy, W, radiated by an electron via the Cherenkov effect, through a cylindrical region of medium of length, l, where the axis of the cylinder coincided with the line of motion of the electron. Under the assumption that β is constant over a short length, dl, of the electron track, they derived the equation

$$W = \frac{e^2 l}{c^2} \int_{\beta n > 1} \omega d\omega \left(1 - \frac{1}{\beta^2 n^2}\right) \tag{6.46}$$

where ω is the frequency of the Cherenkov radiation. The lower limit of the integral, $\beta n > 1$, is the threshold condition for the production of Cherenkov photons in any medium. Frank and Tamm (1937) established the equation to be valid provided that l should be large in comparison with the wave length λ of the Cherenkov radiation emitted. Čerenkov (1938c) took Eq. (6.46) of Frank and Tamm and evaluated the energy, W, radiated by an electron taking into consideration that the magnitude of the electron velocity, *i.e.*, the magnitude of β, will vary greatly over the entire path length of travel of the electron. Čerenkov (1938c) thus expressed Eq. (6.46) with β as a variable depending on its length of travel l or:

$$W = \frac{e^2}{c^2} \int \omega d\omega \int_{\beta n > 1} \left(1 - \frac{1}{\beta^2 n^2}\right) dl \tag{6.47}$$

Frank and Tamm (1937) calculated the rate of radiated energy per path length of travel, dW/dl, to be of the order of only several kilovolts per centimeter. Thus, it was found that the electron energy loss via the emission of Cherenkov radiation would be a negligible quantity of energy in comparison to the energy lost by the electron by other mechanisms, such as ionization (This was discussed by Jelley, 1961 as mentioned in III. B.). Čerenkov (1938c) confirmed this through calculations and experimentation and concluded that the radiation expended by β-particles from Ra(B + C), *i.e.*, ^{214}Pb + ^{214}Bi, via the emission of Cherenkov radiation amounts to a value of the order of only 0.1% of the total energy of the particles.

From Eq. (6.46) Frank and Tamm (1937) deduced the equation for the Cherenkov photon radiation intensity, *i.e.*, the number of photons emitted by an electron per path length of travel, as follows:

$$dN = 2\pi\alpha \left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right) \left(1 - \frac{1}{\beta^2 n^2}\right) dl \tag{6.48}$$

where dN is the number of photons emitted in path length dl within the spectral region defined by the wavelengths λ_1 and λ_2, α is the fine structure constant ∼ 1/137, and β and n are the particle phase velocity and the index of refraction of the medium, respectively. From Eq. (6.48), Belcher (1953) assumed the index of refraction to be constant over the spectral range studied and expressed the total

number, N_E, of photons radiated along the track of a particle of initial energy E and brought to rest within the medium as

$$N_E = 2\pi\alpha\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\int_{\beta=\beta_{max}}^{\beta=1/n}\left(1-\frac{1}{\beta^2 n^2}\right)dl \qquad (6.49)$$

where β_{max} is the maximum phase velocity, *i.e.*, the initial phase velocity of the particle, and $1/n$ is the limiting phase velocity of the particle, *i.e.*, the velocity at which Cherenkov photons cease to be produced. Belcher (1953) reduced Eq. (6.49) to read

$$N_E = A\int_{\beta=\beta_{max}}^{\beta=1/n}\left(1-\frac{1}{\beta^2 n^2}\right)dl \qquad (6.50)$$

where $A = 2\pi\alpha[(1/\lambda_1 - 1/\lambda_2)]$. For the spectral range of $\lambda_1 = 3000$ to $\lambda_2 = 7000$ Å, the value of A is calculated to be

$$\begin{aligned} A &= 2\pi\alpha\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right) \\ &= 2(3.14)(0.007297)\left(\frac{1}{3\times10^{-5}\text{cm}}-\frac{1}{7\times10^{-5}\text{cm}}\right) \\ &= 874\ \text{cm}^{-1} \end{aligned} \qquad (6.51)$$

Over the defined spectral range, Eq. (6.50) is reduced to

$$N_E = 874\int_{\beta=\beta_{max}}^{\beta=1/n}\left(1-\frac{1}{\beta^2 n^2}\right)dl \qquad (6.52)$$

Belcher (1953) evaluated the integral defined by Eq. (6.52) by firstly determining the range–energy function for an electron in water ($n = 1.33$ and $\rho = 1.00$ g/cm^3) and Perspex plastic ($n = 1.50$ and $\rho = 1.18$ g/cm^3). He plotted the values of $\left(1-1/\beta^2 n^2\right)$ against the range of electrons in water and Perspex plastic. He then evaluated Eq. (6.52) by graphical integration to obtain the expected values of N_E as a function of electron energy in water or Perspex plastic, which is illustrated in Fig. 6.10. As can be seen in Fig. 6.10, photons are not produced by electrons below 0.175 MeV in the Perspex plastic or 0.260 MeV in water, which are the respective threshold energies for the Cherenkov Effect in these two materials.

Frank and Tamm (1937) made an approximate calculation that a 500 keV electron, which would correspond to $\beta^2 = 0.75$, traveling in water, where $n = 1.33$, would produce approximately 10 photons per 0.1 cm within the visible region between $\lambda_1 = 4000$ Å and $\lambda_2 = 6000$ Å according to Eq. (6.48), i.e.,

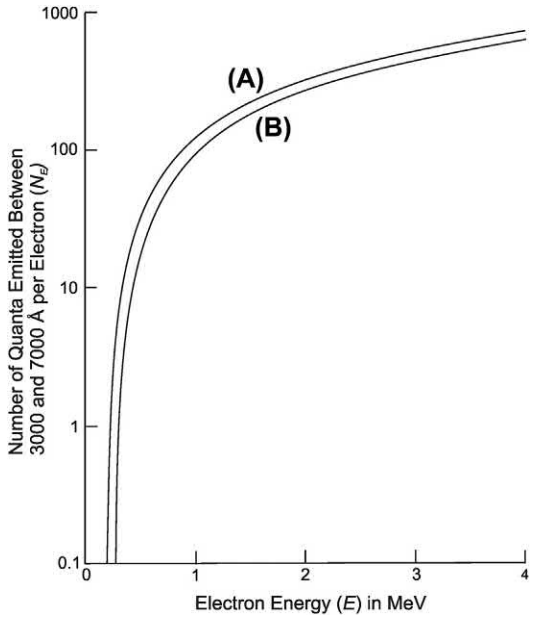

FIGURE 6.10 A plot of the number of Cherenkov photons in the spectral range of 3000–7000 Å produced by an electron in (A) Perspex plastic ($n = 1.50$) and (B) water ($n = 1.33$) over its entire range of travel as a function of electron energy. *From Belcher (1953), reprinted with permission ©1953 The Royal Society.*

$$\begin{aligned} \frac{dN}{dl} &= 2\pi\alpha\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\left(1-\frac{1}{\beta^2 n^2}\right) \\ &= 2(3.14)\left(\frac{1}{137}\right)\left(\frac{1}{4\times10^{-5}\text{cm}}-\frac{1}{6\times10^{-5}\text{cm}}\right) \\ &\quad\left(1-\frac{1}{(0.75)(1.33)^2}\right) \\ &= 94.1\ \text{photons/cm} \approx 10\ \text{photons/0.1 cm} \end{aligned}$$

Their approximation came very close to the above more precise calculations of Belcher (1953), which indicate that a 0.500 MeV electron would produce approximately 20 photons in water (Fig. 6.10). With a range of 0.2 cm in water, the rate of photons production by a 0.5 MeV electron would be 10 photons per 0.1 cm.

The above calculations for the number of photons emitted as a function of a single electron of known energy in a transparent medium are more complex when dealing with β-particles. This is so, because β-particles are emitted from radionuclides with a broad spectrum of energies between 0 and E_{max}. In such a case, Belcher (1953) noted that

it is necessary to combine the function N_E of Eq. (6.49) or (6.50) with the energy distribution function of the electrons released within the medium. He therefore elaborated that, if p_E is the probability of release of an electron possessing energy between the limits E and $(E + dE)$, then the average total intensity I of Cherenkov photon emission per electron is given by the following:

$$I = \int_0^{E_{\max}} p_E N_E dE. \tag{6.53}$$

The property of photon intensity is of particular relevance in studies on the measurement of Cherenkov radiation for particle identification and radionuclide analysis, a subject to be dealt with further on in this chapter. The photon intensity is also expressed in terms of the number of Cherenkov photons created per unit photon energy. As noted by Križan (2001) for particles above the threshold $\beta = 1/n$, that is $\beta > 1/n$, the number of Cherenkov photons emitted per unit photon energy in a medium of particle path length L is

$$\frac{dN}{dE} = L\frac{\alpha}{\hbar c}\sin^2\theta \tag{6.54}$$

where α is the fine structure constant (1/137), $\hbar$ is Planck's constant divided by 2π (*i.e.*, $h/2\pi = 6.582 \times 10^{-16}$ eV·s, c is the speed of light in a vacuum or 2.998×10^{10} cm/s, and θ is, as previously defined, the angle of emission of the Cherenkov photons relative to the direction of travel of the charged particle. Taking the values of the aforementioned constants, the term $\alpha/\hbar c$ of Eq. (6.54) becomes 370 eV^{-1} cm^{-1}. From Eq. (6.54), Križan (2001) calculated, that in 1 cm of water, a particle track where $\beta = 1$ (ultrarelativistic or most energetic particle possible) emits $N = 320$ photons in the spectral range of visible light ($\Delta E \approx 2$ eV). Since a high-energy electron (*e.g.*, 1000 GeV) does not lose significant energy in 1 cm of water, otherwise the angle of emission would diminish as the electron loses energy and its velocity reduces, the above number of 320 photons is calculated as follows:

Since the angle of emission θ of the Cherenkov photons for a particle of given energy and velocity is defined by

$$\cos\theta = \frac{1}{\beta n} \tag{6.55}$$

and, because the charged particle at ultrarelativistic speeds approaches the speed of light in a vacuum or β approaches 1, we can write

$$\cos\theta = \frac{1}{n} \tag{6.56}$$

If water is the medium

$$\cos\theta = \frac{1}{1.333} = 0.75018 \tag{6.57}$$

and then

$$\cos^{-1}0.75018 = 41.4^{\circ} \tag{6.58}$$

Thus, the number of photons emitted (ΔN) over the energy range of the visible spectrum ($\Delta E \approx 2$ eV) in the particle path length of 1 cm in water is calculated according to Eq. (6.54) as

$$\begin{aligned}\Delta N &= L\frac{\alpha}{\hbar c}\sin^2\theta\Delta E \\ &= (1\text{ cm})\left(370\text{ eV}^{-1}\text{cm}^{-1}\right)\left(\sin^2 41.4^{\circ}\right)(2\text{ eV}) \\ &= 320\text{ photons}\end{aligned}$$

In the instrumental detection of Cherenkov photons there is an efficiency factor, which defines the efficiency of an instrument to detect the photons. With an average instrumental detection efficiency of $\varepsilon = 0.1$ over the spectral interval in the example given above, only $N = 32$ photons would be measured. The detection efficiency for Cherenkov photons should not be confused with the term counting efficiency of each particle that interacts with the medium, which is employed in radionuclide analysis, as it will be seen in this chapter that Cherenkov counting efficiencies can be >70% or >0.70.

The number of photons emitted per path length of electron travel in the wavelength interval between λ_1 and λ_2 is calculated by Sowerby (1971) according to

$$\frac{dN}{dl} = 2\pi\alpha z^2\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)\sin^2\theta \tag{6.59}$$

where α is the fine structure constant ($e^2/\hbar c = 1/137$), z is the particle charge ($z = 1$ for electrons or beta particles), and the refractive index of the medium and particle velocity appear in the $\sin^2\theta$ term. Over the visible range of wavelengths from $\lambda_1 = 400$ to $\lambda_2 = 700$ nm, Eq. (6.59) becomes

$$\begin{aligned}\frac{dN}{dl} &= 2(3.14)(.007297)(1)^2 \\ &\quad\left(\frac{1}{4\times10^{-5}\text{cm}} - \frac{1}{7\times10^{-5}\text{cm}}\right)\sin^2\theta \\ &= 490\sin^2\theta\text{ cm}^{-1}\end{aligned} \tag{6.60}$$

Sundaresan (2001) also estimated the number of photons N per path length L to be

$$N/L = 490\sin^2\theta\text{ cm}^{-1}, \tag{6.61}$$

The emission angle θ would diminish as the particle loses energy and velocity. It can be considered constant over particle path lengths where the particle does not undergo significant energy loss.

G. Cherenkov photon emissions and counter geometry

The Cherenkov effect is the result of a physical disturbance caused by the high-energy charged particle along its path of travel resulting in a directional anisotropic emission of light. Therefore, there is no chemical fluorescence nor the relatively long excitation decay times associated with fluorescence.

Conventional liquid scintillation counters equipped with photomultiplier tubes (PMTs) are most often used to count the individual beta-particle emissions by detecting the Cherenkov photons produced by a beta particle that may be emitted from samples containing β-particle-emitting radionuclides in solution within transparent liquid media or deposited onto the surface of other types of media such as glass or plastic. The directional emission of Cherenkov photons is a disadvantage when conventional liquid scintillation spectrometers are used for counting Cherenkov photons. The photocathodes of most liquid scintillation counters consist of two PMTs positioned at 180 degrees relative to each other. This is not an optimum arrangement for the detection of Cherenkov photons; however, reflector material on the surface of the counting chamber walls facilitates the detection of the Cherenkov photons, which otherwise would not reach the PMTs in coincidence. Thus, when conventional liquid scintillation counters are employed for Cherenkov counting, the counting efficiencies are inferior to the theoretical maximum efficiencies.

Extensive treatments of the origin and interpretation of Cherenkov radiation are given by Marshall (1952), Belcher (1953), Cherenkov (1958), Jelley (1958, 1961), Gruhn and Ogle (1980), and Kulcsar et al. (1982), and in a book by the writer (L'Annunziata, 2016), and a comprehensive theoretical and practical treatment of Cherenkov radiation and its application to radionuclide standardization is available in a book by Grau Carles and Grau Malonda (1996a).

IV. Quenching and quench correction

The first demonstration of the potential of counting Cherenkov photons to measure the activity of radionuclides was reported by Belcher (1953), a former colleague of the writer at the International Atomic Energy Agency. He used a single photomultiplier cooled with liquid nitrogen to reduce background due to thermal noise and measured Cherenkov radiation intensity in terms of count rates per mCi of various radionuclides in aqueous solution. With the subsequent development of low-background dual PMT counters, the technique of counting Cherenkov photons has become a very useful tool in the measurement of radionuclide activities. One of the great advantages of Cherenkov counting is the potential radioactivity analysis of the sample in its original state (i.e., aqueous solution or other suitable solvent) without the need to add any reagents. The principle interference is color quenching, which can occur when sample color reduces the Cherenkov photon intensity emitted by a sample to be measured.

Chemical quenching in Cherenkov counting is nonexistent because Cherenkov photons arise from a physical formation of a wavefront in the medium in contrast to chemical fluorescence, which occurs in the liquid scintillation phenomenon. However, color quenching can be very significant in Cherenkov counting, greater than that which may occur in standard liquid scintillation counting techniques, as reported by Elrick and Parker (1968), because Cherenkov photon intensities are weaker and cover a wider spectrum of wavelengths than those produced in scintillation. The counting efficiency in Cherenkov radioassay is determined by one of the quench correction techniques subsequently discussed. The most common quench correction method is based on various mathematical indicators called quench indicating parameters (QIPs), as reported by Tsroya et al. (2012). In practice, Cherenkov counting usually involves quench correction based on indexes used in LSC systems. The QIPs fall into two categories: those based on calculations of parameters from the spectrum of the sample containing the radioactive material, and those based on parameters calculated from the spectra obtained with an external source. In the first category, the conventional methods are based on using the relationship between the pulse height distribution shift and counting efficiency. The parameters used are the sample channels ratio (SCR) and spectral index of the sample (SIS). In studies by Mosqueda et al. (2007) and Vaca et al. (1998), the SCR correction method was used. Takiue et al. (1996) employed the SIS method too, but they mentioned the potential advantage of the external standard method, which they could not use because of the low gamma energy of their external source. A disadvantage of the methods based on the measured samples is that they depend on the activity of the sample and cannot be applied to low-activity samples because of the high statistical uncertainty. There is no such problem when an external radiation source is used. Therefore, most common quench correction methods in liquid scintillation counting use external γ-ray sources. These methods include the external source channel ratio (ESCR), the sample quench parameter of the external standard (SQP(E)), and the transformed spectral index of the external standard (tSIE). The ESCR method is similar to the SCR method, using the ratio between the two channel ranges of the outer source spectrum. Kamp and Blanchard (1971) applied the ESCR method to the external ^{226}Ra—^{241}Am source spectrum for quench correction in Cherenkov counting. Other researchers, e.g., Nascimento (1977) and Elrick and Parker (1968), used an additional high-energy gamma source in the system that could

produce a Cherenkov effect in the sample. In a study by Tarancón et al. (2002a), the SIS, tSIE, and SCR indexes were compared in measurements of the activity of a $^{90}Sr/^{90}Y$ source by means of the Cherenkov counting, LSC, and plastic scintillation techniques.

A. Internal standardization

This method is described in Chapter 6, Volume 1. It is highly accurate, if performed properly. The main disadvantage of this quench correction technique is that it is time consuming, as it requires the counting of each sample before and after the addition of standard.

B. Sample channels ratio

This method is described in Chapter 6, Volume 1 and in previous texts by the writer (L'Annunziata, 1979; 1984a; 1987). The SCR technique was a most popular method of monitoring for quench with the older-generation liquid scintillation counters equipped with a single channel analyzer for data storage and pulse height gain control. Contemporary liquid scintillation analyzers are equipped with a multichannel analyzer (MCA), which permit the facile measurement of a sample spectrum QIP such as SIS or SQP(I) described in Chapter 6, Volume 1. Nevertheless, the SCR technique is accurate and is still used by researchers. The SCR technique is particularly applicable to Cherenkov counting color quench correction when the counter is not equipped with an external standard that emits gamma rays with sufficient energy to produce the Cherenkov effect in sample counting vials. Some examples of the application of the SCR technique to the Cherenkov counting analysis of particular radionuclides will be cited here.

A good example of the SCR technique applied to color quench correction in the Cherenkov counting of ^{32}P and ^{36}Cl can be taken from the work of Fujii and Takiue (1988a). To establish the SCR, the pulse height discriminators of a given counting window (*e.g.*, Channel A) are selected generally to encompass all pulse events, and the discriminator settings for another counting window (*e.g.*, Channel B) are selected to encompass only a part of the pulse height spectrum for the least quenched sample as illustrated in Fig. 6.11. When quench occurs, the ratio of counts in Channel B (Fig. 6.11) to counts in Channel A (B:A) will change as pulse heights shift from right to left (higher to lower magnitude) along the pulse height spectrum. After testing various widths for Channel B, the optimum width of Channel B is selected as that which gives the most linear plot over the greatest range of detection efficiency. Therefore, counting a series of quenched standards containing variable color quench levels similar to those described in Table 6.2 will produce a SCR quench correction curve of percent counting efficiency versus SCR. Examples of SCR color quench correction curves for ^{32}P and ^{36}Cl are illustrated in Fig. 6.12, as reported by Fujii and Takiue (1988a) from counting channels illustrated in Fig. 6.11. The counting efficiency for the SCR quench correction curve is calculated from the count rate of the

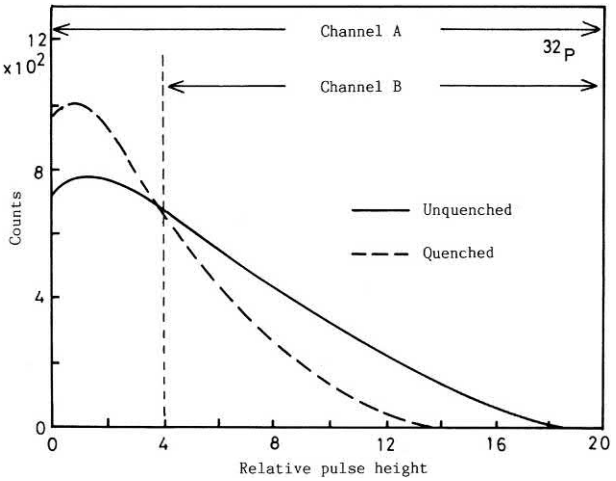

FIGURE 6.11 ^{32}P Cherenkov pulse height distribution and channel settings for the sample channels ratio (SCR) method. The pulse height distribution shifts toward low pulse height with color quenching. *From Fujii and Takiue (1988a), reprinted with permission from Elsevier ©1988.*

wide-open Channel (A) The SCR value of an unknown sample will give the percent counting efficiency from the quench correction curve. The activity of the sample in DPM is then obtained by dividing the count rate from Channel A (the wide-open counting region) by the decimal value of the percent counting efficiency.

There is no set rule for the establishment of window widths in the SCR quench correction method. It is only important, that the wider or most open counting window or channel provide an acceptable or optimum detection efficiency for the radionuclide of interest; and the more narrow window yields an SCR color quench correction curve that yields the most accurate monitor of color quench in the experimental samples. With this in mind, Mosqueda et al. (2006, 2007) carried out statistical analyses to determine the optimum channel widths for the establishment of SCR color quench correction curves for the low-level Cherenkov counting of ^{90}Sr/^{90}Y. The objective of such optimization is to attain optimum lower limits of detection.

In order to determine the relationship between color factor (f) and CR, Todorović et al. (2017) prepared a set of 10 standards of the same ^{90}Sr/^{90}Y activity which was added to a growing concentration of colored attenuation (yellow dye). As the range of the B window should be started from the channel with the highest count rate, four different windows were selected and the CR factor determined. The results of the measurements indicate that the color factor (f) value increases as the channel ratio factor (CR) approaches the reference value (for which f = 1). According to certain published data, the dependence f(CR), over a wide range from 0.2 to 1, obeys a second order polynomial fit (Vaca et al., 1998; Mosqueda et al., 2007), although the results obtained in the examined range very well describe a linear fit, as shown in Fig. 6.13, and as reported in Todorović et al. (2017).

The SCR technique has been applied to color quench correction in the Cherenkov counting of several radionuclides. Stubbs and Jackson (1967) prepared a series of color-quenched standards in liquid scintillation counting vials each containing ^{32}P of the same activity (1.85 kBq) and increasing amounts of Scarlet R or Naphthol Yellow S dye as color quencher. The quantity of dye per vial ranged from 0.01 to 3.00 mg. The SCR technique has been employed successfully for counting efficiency determinations in the Cherenkov counting of ^{42}K in biological samples by Moir (1971) and of ^{34m}Cl, ^{36}Cl, and ^{38}Cl, as well as ^{32}P by Wiebe et al. (1980), who used a 1% solution of potassium dichromate in water as the color quenching agent for the preparation of standard quench correction curves.

The SCR technique was also used for the determinations of ^{36}Cl and ^{32}P in tissue solubilizer solutions (see Bem et al., 1983). The SCR technique for the color quench correction in the Cherenkov counting of ^{90}Y was reported by Torres et al. (1996) in the environmental analysis of ^{90}Sr. The writer has employed the SCR quench correction technique successfully for the assay of ^{32}P in water using 0.01% CrO_3 as a quenching agent (L'Annunziata, 1984a, 1987). Increasing amounts of CrO_3 solution, which is yellow in color, are added to a series of liquid scintillation vials, each containing the same activity of ^{32}P standard (*e.g.*, 3.7 kBq/mL) as described in Table 6.2. Water is added to bring the quenched standards to a uniform and optimum volume. Also 0.01% aqueous $K_2Cr_2O_7$, which is yellow in color, serves as a good quenching agent for the preparation of quenched standards (L'Annunziata, 1987).

Although a yellow color is used in the above procedure, Stubbs and Jackson (1967) and Bem et al. (1980) report identical SCR quench correction curves when either a yellow or a red dye is employed as the quenching agent. The SCR technique for quench correction has been employed successfully by Frič and Palovčíková (1975) and Karamanos et al. (1975) for the assay of ^{32}P and ^{210}Pb, Carmon and Dyer (1987) for the Cherenkov assay of ^{106}Ru, Takiue et al. (1993, 1996) for the Cherenkov measurements of ^{36}Cl, ^{32}P, and ^{90}Sr(^{90}Y), and Vaca et al. (1998) and Tarancón et al. (2002a) for the Cherenkov efficiency calibration of ^{90}Y colored samples. For low-activity samples, Tarancón et al. (2002a) found the SCR technique and the sample spectrum quench indicating parameter (SIS) suitable for color quench correction in the Cherenkov counting of ^{90}Sr/^{90}Y at low level in water samples with relative errors of <5%. They consider the SCR method the better option of the two quench correction techniques for color quench correction in ^{90}Sr/^{90}Y measurements, as the SCR method was found to be less dependent on the sample activity level. This was due to the fact that the SIS quench indicating parameter is dependent on the measurement of the total spectrum, which includes the background spectrum; whereas, the windows used for the SCR technique in the low-level measurement of ^{90}Sr/^{90}Y can be chosen to minimize the contribution of the background spectrum.

C. Sample spectrum quench indicating parameters

Modern liquid scintillation analyzers are equipped with a MCA, which permits the measurement of a sample spectrum quench-indicating parameter (QIP) such as SIS or SQP(I) described in Chapter 6, Volume 1. The use of a sample spectrum quench-indicating parameter to correct for color quench in Cherenkov counting offers several advantages over the previously described SCR quench correction technique, among which are the following: (1) the time consuming procedure of testing several channel region settings to produce the most linear SCR quench correction curve is avoided, (2) error arising from different count rates in two counting regions required to produce a SCR are avoided, and (3) computer automation in the measurement of the sample spectrum and the QIP associated with the sample spectrum results in ease of preparation and error reduction in generating the plot of the quench correction curve and in the automated reading of the quench correction curves to determine counting efficiencies of unknown samples. The accuracy of the determination of the sample spectrum QIP [*i.e.*, SIS or SQP(I)] is sample count-rate dependent; and for low-level counting a sample must be counted for sufficient time to attain a well-defined sample pulse height spectrum from which the instrument will measure the sample spectrum QIP.

The use of a sample spectrum QIP requires first a determination of an optimum counting region, which is described subsequently.

1. Counting region

The counting region must first be defined by observing the pulse height spectrum of the Cherenkov photons with the computer monitor display from the MCA of the liquid scintillation analyzer. A colorless sample of the radionuclide of interest is placed into a plastic liquid scintillation vial; and the sample pulse height spectrum is observed as illustrated in Fig. 6.14. Plastic counting vials are recommended, instead of glass, for highest Cherenkov photon detection efficiency and lower backgrounds (see Section V.B of this chapter). A colorless sample is selected, as this would represent the least quenched sample achievable. The pulse heights originating from Cherenkov radiation in water do not generally exceed the equivalent of ~50 keV for pulse height spectra calibrated on an energy scale. This may differ for other instruments that do not use such a scale; however, the limits of the pulse height spectra can be determined easily on the computer monitor output from the MCA. For the example illustrated in Fig. 6.14, the counting region can be defined by setting the lower level (LL) discriminators and upper level (UL) discriminators at 0–30 keV, respectively.

2. Quench correction

Although there is no chemical quench in Cherenkov counting, color quench correction is necessary if samples are colored even to a slight extent. In many applications of

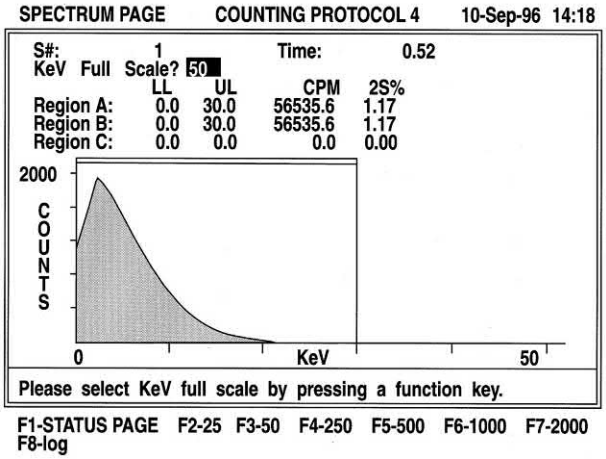

FIGURE 6.14 Pulse height spectrum produced by Cherenkov photons from a sample of ^{32}P in water as seen on the computer monitor of a PerkinElmer Tri-Carb 2300 TR liquid scintillation analyzer. A counting region of 0–30 keV was selected to encompass all pulse heights originating from the ^{32}P radionuclides in the sample. *From L'Annunziata (1997), © 1997–2019 PerkinElmer, Inc. Printed with permission.*

biology, biochemistry, environmental monitoring, and agricultural research, among other fields, the radionuclide of interest [*e.g.*, ^{32}P, ^{89}Sr, $^{90}Sr/^{90}Y$] must be analyzed in animal or plant tissue. The tissue may be ashed in a muffle furnace to destroy the organic matter and to put the radionuclide in soluble form. Then the ash may be dissolved in dilute acid. This may leave the sample colorless or at times with only a slight yellow color. Other applications may find the radionuclide already in solution; and it may be desirable not to alter the sample chemically so that the sample may be counted directly. This would permit other studies to be carried out on unadulterated samples. If samples are colored to any extent and decolorization is not performed, a color quench correction curve will be needed.

A color quench correction curve is prepared from a series of color-quenched standards of the nuclide of interest, such as described in the previous Section IV.B of this chapter. The quenched standards can be prepared by adding varying amounts of aqueous coloring agent, such as 0.01% CrO_3 or 0.01% $K_2Cr_2O_7$, to a series of scintillation counting vials as formulated in Table 6.2. A known activity of the radionuclide of interest is added to each vial and the sample volumes are brought up the optimum volume or the volume to be used for the experimental samples. It is important to keep in mind that the volume of the quenched standards, the type of counting vials used (*e.g.*, plastic or glass), and the counting region selected for the quench correction curve should be the same as those used for the analysis of unknown samples.

The quench standards are counted in the optimum region, such as the region of 0–30 keV illustrated in Fig. 6.14; and the count rates (CPM) and QIP of each of the color-quenched standards are recorded. From the count rates and the known disintegration rates of each standard, the counting efficiency of each color-quenched standard is calculated as follows:

$$E_{std} = \frac{CPM_{std}}{DPM_{std}}, \tag{6.62}$$

where E_{std} is the counting efficiency of the quenched standard, CPM_{std} is the count rate of the standard obtained in the previously defined counting region, and DPM_{std} is the known disintegration rate of the quenched standard. Each calculated value of E_{std} is plotted against the pulse height spectrum QIP (*e.g.*, SIS, or SQP(I)) as illustrated in Fig. 6.15. The quench correction curve illustrated in Fig. 6.15 is a plot of the counting efficiency versus the SIS for the radionuclide ^{86}Rb. It was prepared from seven quenched standards in seven counting vials containing a known and exact activity of ^{86}Rb and increasing concentrations of CrO_3 over the range of 0%–0.005% as reported by L'Annunziata and coworkers (see Noor et al., 1996). This CrO_3 concentration range fits within the range of CrO_3 concentrations of the standards described in Table 6.2.

The SIS is derived from the mean pulse height of the spectrum. The magnitude of the SIS provides a measure of the photon intensities escaping the counting vials. This serves as an excellent QIP for Cherenkov counting. Via multichannel analysis, the liquid scintillation analyzer measures the SIS for each quench standard and calculates the counting efficiency of each standard according to Eq. (6.62). The quench correction curve is stored in the memory of the LSA computer; and it is used for the automatic determination of counting efficiencies of all unknown experimental samples from the value of the SIS of each sample. Therefore, in practice, when an experimental

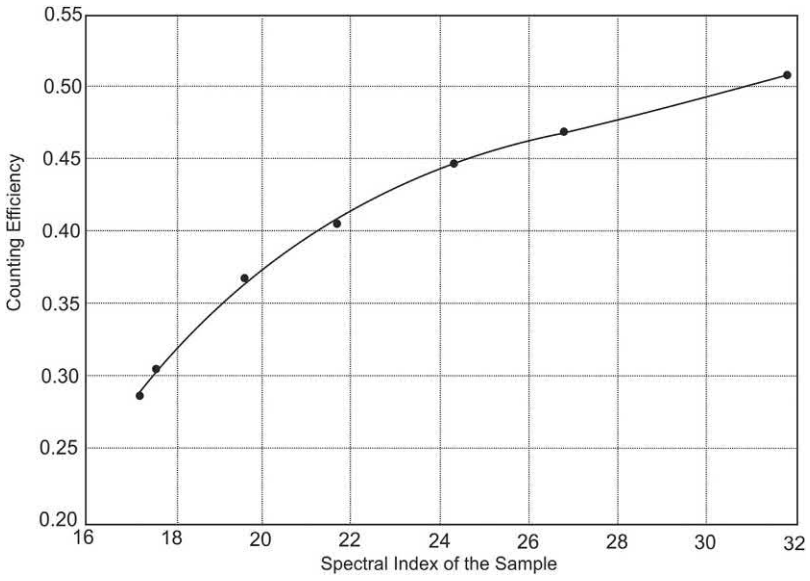

FIGURE 6.15 Color quench correction curve for the Cherenkov counting efficiency determination of ^{86}Rb in water using the Spectral Index of the Sample (SIS) as the quench-indicating parameter. Polyethylene plastic vials were used and the volumes of standards were 15 mL. *From L'Annunziata and coworkers (see Noor et al., 1996), reprinted with permission from Elsevier © 1996.*

sample of unknown activity is counted, its count rate (CPM) is measured in the specified counting region and the SIS of the sample is determined by the LSA. The instrument computer program will take the value of the SIS and extract the sample counting efficiency from the stored color quench correction curve of counting efficiency versus SIS. The instrument will then calculate and print out the activity of the experimental sample according to the equation

$$DPM_S = \frac{CPM_S}{E} \tag{6.63}$$

where DPM_S is the activity in disintegrations per minute of the radionuclide sample, CPM_S is the Cherenkov photon count rate of the radionuclide sample in the counting region selected (*e.g.*, 0−30 keV of Fig. 6.13), and E is the Cherenkov photon counting efficiency of the radionuclide sample obtained from the quench correction curve.

The SIS quench indicating parameter was used successfully by Blasiyh Nuño and Korob (2007) for the preparation of color quench correction curves in the Cherenkov counting of ^{234m}Pa and ^{231}Th with optimum detection efficiencies of 63% and 1.6%, respectively. Similar detection efficiencies and SIS values for ^{234m}Pa were measured by Alamelu and Aggarwal (2009). Quantitative activity recoveries are obtained when using SIS as the QIP as tested by the writer for ^{32}P sample activities (L'Annunziata, 1997). The sample spectrum quench indicating parameter was utilized successfully by Torres et al. (1996) for color quench correction in the Cherenkov counting of ^{90}Y for the analysis of ^{90}Sr in environmental samples.

When the Cherenkov photon count rates are low, as in the measurement of environmental samples, error can occur in the measurement of the SIS because at low activity levels a long counting time is required to measure the sample spectrum quench indicating parameter. Samples should be counted for sufficient time to reach a % 2 sigma (% 2S) of 0.5% standard deviation of the count rate in order to get a good measurement of the sample spectrum upon which the value of the QIP depends. Consequently, when count rates are low, caution should be taken when using the sample spectrum QIP as described previously in Section IV.B. Alternatively, an external standard QIP may be used with certain instruments that are equipped with external standards emitting gamma-radiation of sufficient energy to produce significant Cherenkov photons in the sample vials from Compton electrons. This is described in the following Section IV.D.

D. External standard quench correction

Ross (1980), Smith (1981) and Takiue et al. (1996) reported that the use of external standards is not always applicable to quench correction in Cherenkov counting, because the external standards commonly supplied with some liquid scintillation counters produce Compton electrons from γ-ray interactions, which are too far below the threshold energy for the production of Cherenkov radiation in sample counting vials. However, commercial liquid scintillation analyzers of LKB Rack Beta Instruments are equipped with an ^{226}Ra external standard, which emits considerable quantities of high-energy gamma radiation from daughter nuclides in its decay chain, can produce appreciable numbers of Compton electrons with energies above the Cherenkov threshold of 262 keV in water. A quench-indicating parameter based on the ^{226}Ra external standard, known as the G-number (G #), was patented by Grau Carles and Grau Malonda (1992) to permit the liquid scintillation quench correction of samples under extreme levels of quench where Cherenkov counting in liquid scintillation analysis would predominate. The writer envisages that the G # could be applied also to color quench correction when the Cherenkov Effect is the only source of photons. The G # is described in Section V.C.6 of Chapter 6, Volume 1 and by Grau Carles et al. (1993a).

A more recent study of external standard color quench correction in low-level Cherenkov counting of ^{90}Sr/^{90}Y was made by Tsroya et al. (2009). They demonstrated the use of the ^{152}Eu external standard that is equipped with the PerkinElmer Quantulus low-level LSC, for Cherenkov counting color quench correction. The ^{152}Eu external standard decays by EC in 72.1% of the decays to ^{152}Sm and by negatron (β^-) emission in the remaining 27.9% of the nuclear decays to ^{152}Gd, and only a trace 0.02% of the nuclides decay by positron (β^+) emission (see NuDat 2.7, 2018) and Appendix A. The nuclear decay of the ^{152}Eu external standard is followed with abundant γ-ray emissions of energy capable of producing Cherenkov photons in water. The relevant γ-ray lines with their energies in MeV and their intensities in % are the following: 1.41 MeV (22%), 1.13 (13%), 1.09 (12%), 0.965 (15%), and 0.779 (14%). The threshold Compton electron energy for the production of Cherenkov photons in water is 0.262 MeV or 262 keV as calculated previously by Eq. (6.38); and the threshold γ-ray energy for the production of Compton electrons of 0.262 MeV in water is 0.421 MeV as determined in Section XI of this chapter. All of the γ-ray energy lines from ^{152}Eu decay are well above the gamma threshold energy. Tsroya et al. (2009) demonstrate that the ^{152}Eu external standard yields excellent Cherenkov photon pulse height spectra with a simple 10-min counting time; and the area under the pulse height spectra is a function of the color quench in the sample. Fig. 6.16 illustrates six pulse height spectra produced by aqueous samples quenched with increasing amounts of $K_2Cr_2O_7$ quenching agent, which produces a yellow color. The pulse height spectra move from right to left or from higher to lower pulse height as a function of sample color quench; and the total area under

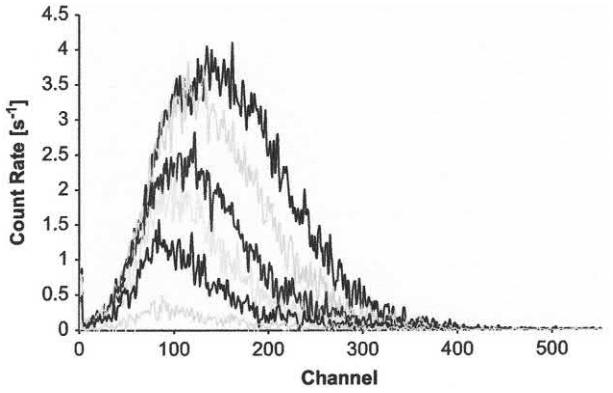

FIGURE 6.16 Cherenkov pulse height spectra obtained with the ^{152}Eu external source of a PerkinElmer Quantulus 1220 LSC for different $K_2Cr_2O_7$ concentrations in the range of 6.67−4050 mg/L. *From Tsroya et al. (2009), reprinted with permission from Elsevier © 2009.*

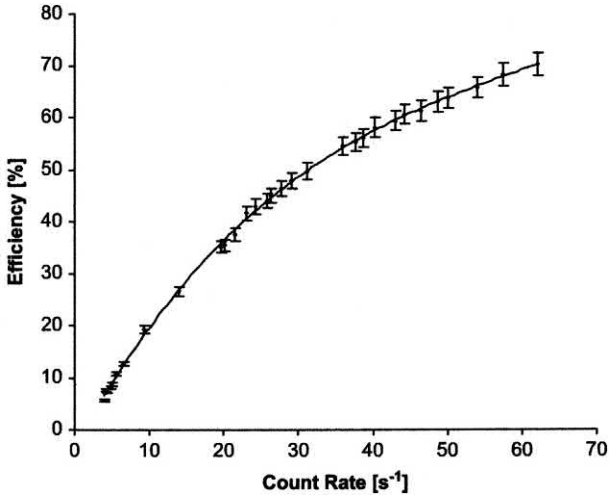

FIGURE 6.17 Quench correction curve for the Cherenkov counting of ^{90}Sr/^{90}Y based on an ^{152}Eu external source. The statistical uncertainty of the count rate was in the range of 0.5%−1.5% and is not shown in the figure. *From Tsroya et al. (2009), reprinted with permission from Elsevier © 2009.*

the pulse height spectra or the external standard counts also diminishes with quench as illustrated in Fig. 6.16.

Tsroya et al. (2009) prepared color-quenched standards for Cherenkov counting with a series of counting vials containing 35.5 Bq of ^{90}Sr/^{90}Y standard in secular equilibrium and increasing amounts of $K_2Cr_2O_7$ color quenching agent in the range of 6.67−4050 mg/L in 20 mL of water in polyethylene plastic vials. The quenching agent yields increasing intensities of yellow color with concentration. The quench correction curve was obtained by counting each vial of the series of quenched standards for a period of 10 minutes with and without exposure to the ^{152}Eu external source of the Quantulus LSC and plotting the detection efficiency versus the external source count rate, as illustrated in Fig. 6.17.

The importance of the application of the external ^{152}Eu standard to the determination of color quench is the potential for accurate external-standard quench correction in low-level Cherenkov counting. Tsroya et al. (2009) calculated the ^{90}Y minimum detectable activities (MDAs) to range from 5.74 to 63.0 mBq/mL over the range of detection efficiencies of 68.5% for clear unquenched samples to 5.35% for highly color-quench samples with corresponding backgrounds of 0.018 s^{-1} to 0.0084 s^{-1} and 10 minutes. counting times.

Tsroya et al. (2012) also compared the performances of color quenching corrections in the SCR and External Standard Area Ratio (ESAR) methods by using various conventional parameters (SIS, tSIE, SQP(E)). The Quantulus 1220 (Wallac Oy, Finland) and measurements of activities of ^{90}Sr/^{90}Y in aqueous solutions were used for the experiments. In the SCR method, the shift in the pulse-height spectrum due to color quenching is measured by the ratio of the counts in two different windows: window B, which corresponds to the high-energy region of the spectrum, and window A, which usually includes the whole spectrum. The ESAR method, initially proposed by Tsroya et al. (2009), consists of two stages. In the first stage, the pulse height spectra with and without the external ^{152}Eu source are stored, and by subtraction the net spectrum of the external source is obtained. The area of this net spectrum is used as an indicator to determine the quench correction factor. In the second stage, the sample is counted for a preset time chosen to achieve the desired statistical accuracy. The activity is calculated from the spectrum obtained in the second stage using the quench correction factor obtained in the first stage. For this purpose, the ratio of the counts in Channel B to the counts in Channel A as a function of the quencher concentration $K_2Cr_2O_7$ was calculated for different settings of Window B, while Window A was left constant to include the whole spectrum. Five ranges were tested for Window (B). It was shown that the most sensitive ranges in Window B are Channels 100−1024, and the greatest change in sensitivity is observed in $K_2Cr_2O_7$ concentrations up to 100−150 mg/L. The measurements with the ^{90}Sr/^{90}Y solution for the SCR method for the same window give the highest sensitivity change in Channels 150−250. The ESCR and SCR dependence on quencher concentration can be seen in Figs. 6.18 and 6.19.

In order to determine the optimal setting for Window B, a polynomial function was found to fit the data of each graph, and its derivative was calculated. The derivative was used for the estimation of the optimal window range for the measurement of low-level activities. A comparison of the performances of the different correction methods was made by using the measured spectra and a calculation of the QIP values. The performance of the method at different

quencher concentrations was normalized to the unquenched value of the specific indicator. It was shown that only the proposed External Source Area Ratio (ESAR) method is adequate for practical use in the whole range of the quencher concentrations, because the QIP value changes monotonously with a high sensitivity to the concentration. The application of the statistical uncertainties to the analysis of each method showed that for the low quencher concentration and the external source, the relative standard deviations of the different methods are similar, ranging from 1.18% to 1.99%. This increases with increases in the concentrations. The smallest increase in the relative standard deviation is for the SIS method (by a factor of 2.19), while the largest (by a factor of 4.62) is for the SQP(E) method. The change for the ESAR method is by a factor of 2.58. However a test of the performance of the ESAR and other methods by means of a comparison of the calibration curves of each method (one for QIP vs. efficiency was constructed) showed the advantages of the ESAR method. The calibration curves were used to quantitatively determine ^{90}Sr concentrations in spiked samples. QIPs were calculated for each spectrum using each of the quench correction methods, and the activity was evaluated using the corresponding calibration curve (polynomial fit). For low quencher concentrations, all methods (except SQP(E)) ensure an accurate determination with small standard deviations. With increases in quencher concentration up to 900 mg/L, a reasonably accurate determination remains for all the methods but with much higher relative standard deviations except for the ESAR method. Further increases in quencher concentration result in a deterioration of the accuracy for all methods, except ESAR, to the limits of eligibility. The ESAR method, even at a high quencher concentration, gives an acceptable result with a deviation of about 8% from the target value.

The ESAR method described here is preferable for low levels; and it is the most sensitive correction method as it works over a very wide range of quenching degrees. Tsroya et al. (2013a, 2013b) exploited these characteristics for the development of the methodology for ^{90}Sr determination in highly quenched samples like urine and milk. For ^{90}Sr determination in urine samples, an efficiency calibration curve specific for urine was prepared for a wide range of quenching levels. The influence of the color fading effect on the quench level due to changes in urine color over time was examined. As shown in Fig. 6.20, ESAR rises over time, so the correction is performed for delayed counting.

The ESAR color quench correction method provides an accuracy of results within a range of ±11.5%. Before counting, the separation method for potassium removal was employed due to the possible contribution of ^{40}K in the Cherenkov measurement. A similar approach was used in

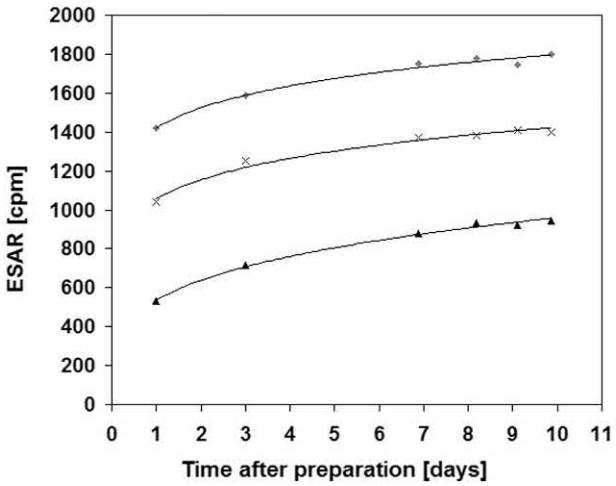

FIGURE 6.20 Dependence of the color quench parameter (ESAR) on the time elapsed after preparation for three samples with different quench levels. *From Tsroya et al. (2013a); reprinted with permission from Elsevier © 2013.*

the method developed for ^{90}Sr determination in different kinds of milk samples (Tsroya et al., 2013b).

Low-level Cherenkov counting of ^{228}Ac for ^{228}Ra analysis in natural water samples with the Quantulus 1220 LSC is reported by L'Annunziata and coworkers (see Aleissa et al., 2008). They report a calculated MDA of 3.24 dpm/L with a Cherenkov photon detection efficiency of 10.9% for ^{228}Ac and a Cherenkov background count rate of 0.317 cpm.

In contrast to conventional Cherenkov counting, in the Triple to Double Coincidence Ratio (TDCR) technique, external calibration is not needed because the effects of color quenching on the Cherenkov efficiency can be automatically corrected based on the measured TDCR values (Kossert, 2010). However, Tayeb et al. (2014) examined the effect of color quenching on ^{90}Y TDCR efficiency. Yellow and brown colorants were chosen because the absorption spectra extended from 350 to 500 nm for yellow and 350−600 nm for brown. These fall in the spectral response range of the TDCR instrument PMTs (commercially available Hidex 300 SL, Electron Tubes 9102 KA PMTs, sensitivity range 290−630 nm, peaking at 370 nm). As illustrated in Fig. 6.21, the ^{90}Y counting efficiency gradually decreased as the light absorption of the colorant increased; and the TDCR correction for the effects of geometry and quenching can yield a difference between the measured and expected activities within 7.5%.

The TDCR technique was primarily developed for radionuclide standardization, as described in Section IX.C of Chapter 6, Volume 1, and the reader can find the principle of the methodology there. The principle of TDCR Cherenkov counting in radionuclide standardization and in the routine analysis of radionuclide activity is discussed further on in this chapter.

V. Cherenkov counting parameters

The detection efficiencies in Cherenkov counting may be optimized by controlling several counting parameters in addition to the optimum counting region settings previously described. These parameters, which are easily controlled, are discussed subsequently.

A. Sample volume

The detection efficiency of Cherenkov photons can be dependent significantly on the sample volume. The optimum volume may differ from one instrument to another and even from one nuclide to another measured with the same instrument as well as the type of vial used (*e.g.*, glass or plastic). For example, Clausen (1968) reported an optimum volume of 10−11 mL for the Cherenkov counting of ^{32}P with the liquid scintillation counter used. This volume dependence was also tested by Wiebe et al. (1980) for the Cherenkov counting of ^{34m}Cl, ^{36}Cl, ^{38}Cl, and ^{32}P and, for the same instrument, the volume dependence was greatest for ^{38}Cl. The volume in this case also affects the pulse-height spectral shape. This effect was explained by Wiebe et al. (1980) on the basis of the extended range (up to 2.5 cm in water) of the high-energy beta particles emitted from ^{38}Cl ($E_{max} = 4.91$ MeV), which would, for the larger volumes (>4 mL), give rise to more pulses at greater pulse heights. The extended range in water provided by the larger sample volumes also results in an increase in the number of photons produced owing to the longer particle path length of travel. This consequently results in an increase in the probability of producing a detectable pulse. Several other works may be cited where volume effects on the Cherenkov counting efficiency of various nuclides were studied including the following: ^{214}Bi and ^{214}Pb by Al-Masri and Blackburn (1995a); ^{119m}Cd by Ramesh and Subramanian (1997); ^{32}P by L'Annunziata (1997), BenZikri (2000), and L'Annunziata and Passo (2002); ^{86}Rb by L'Annunziata and coworkers (see Noor et al., 1996); and ^{90}Y by Coursey et al. (1993) and L'Annunziata and Passo (2002); and ^{90}Y(^{90}Sr) by Tayeb et al. (2014); and ^{89}Sr, ^{90}Y(^{90}Sr) by Grahek et al. (2012) and Coha et al. (2016).

Volume effects are clearly discernible between different vial types, such as glass and plastic vials, as illustrated in Fig. 6.22. The figure also illustrates that the effect of volume on counting efficiency is more significant in glass then plastic vials. This was also observed in studies by Vaca et al. (1998) and L'Annunziata and Passo (2002) comparing plastic and glass vials in the Cherenkov counting of ^{90}Y. The effects of vial type are discussed in the next section of this chapter. It is important, therefore, that each

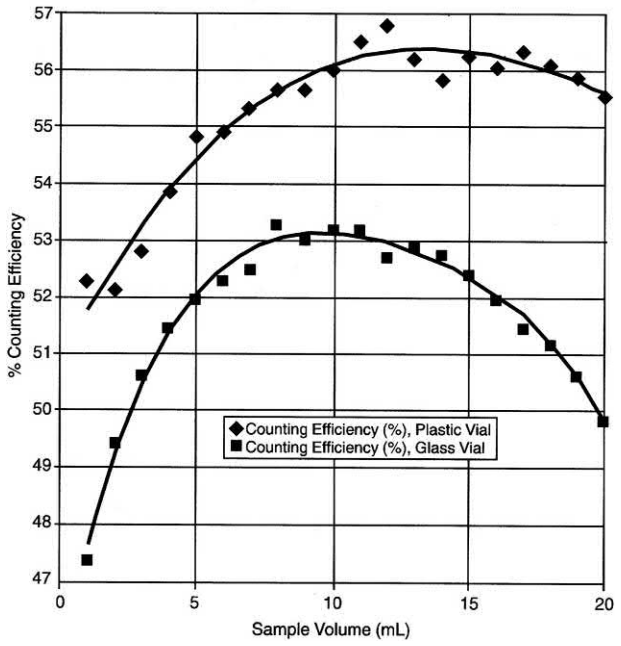

FIGURE 6.22 Effect of sample volume on the Cherenkov counting efficiency of ^{32}P in water with polyethylene plastic and glass counting vials measured with a PerkinElmer Tri-Carb 2300 TR liquid scintillation analyzer. *From L'Annunziata and Passo (2002), reprinted with permission from Elsevier © 2002.*

instrument, vial type, and radionuclide to be analyzed by Cherenkov counting be tested for sample volume effects. These tests can be performed as follows:

1. Place a small volume (e.g., 1.0 mL) of a known activity (DPM) of the aqueous solution of the radionuclide of interest into a 20-mL capacity counting vial.
2. Determine the count rate (CPM) of the sample in the appropriate counting region that encompasses the entire Cherenkov photon pulse height spectrum (e.g., 0–30 keV), and calculate the percent counting efficiency $(\%E)$ according to the equation

$$\%E = \frac{CPM}{DPM}(100) \tag{6.64}$$

3. Add an additional 1.0 mL of pure water to the sample in the counting vial to increase the total volume to 2.0 mL.
4. Recount the sample in the same counting region and calculate again the new counting efficiency according to Eq. (6.64).
5. Repeat steps 3 and 4 until a total sample volume of 20 mL is reached.
6. The $\%E$ versus sample volume is then plotted.

As illustrated in Fig. 6.22, sample volume can have a significant effect on sample count rate and detection efficiency. The effect of sample volume on counting efficiency is greater in glass counting vials, higher counting efficiencies are observed with plastic vials, and only very small changes in counting efficiency ($\sim$1%) occurred in polyethylene plastic vials when sample volumes varied from 9 to 20 mL for the particular vials, radionuclide, and instrument used for these tests. The effect of sample volume on detection efficiency is due to the directional characteristics of Cherenkov radiation. Because Cherenkov photons are emitted at specific angles to the direction of travel of the β particle, changes in volume can affect the angles of deflection by the reflector material in the surrounding counting chamber walls *vis-à-vis* the face of the PMTs. However, plastic counting vials disperse the radiation, reducing its directional properties, whereby the effect of sample volume on detection efficiency is further reduced. Also plastic generally has a higher index of refraction than glass, which would lower the threshold energy for the production of Cherenkov photons by beta particles traveling through the vial walls. The advantages of plastic counting vials in Cherenkov counting are explained further in the following Section V.B of this chapter.

Obviously, if reproducible counting efficiencies are to be maintained, it is necessary that the optimum counting volume be determined experimentally for the particular instrument, vial type, and nuclide employed and that this volume be used for every sample. This can be confirmed with results from literature. Grahek at al. (2012) showed that the detection efficiency of ^{89}Sr and ^{90}Y(^{90}Sr) on the Tri-Carb 2770 TR/SL counter in low-level count mode (LLCM) is higher in plastic than in a glass vial, rises with volume up to 10 mL, and becomes constant from 10 to 16 mL for both types of vial. Coha et al. (2016) examined the influence of the volume of different media on ^{89}Sr and ^{90}Y detection efficiency in low potassium borosilicate glass vials with three different types of instrument with one, two and three PMTs: the Triathler, Tri-Carb 3180 TR/SL and Hidex 300 SL. They showed that the detection efficiency of ^{89}Sr increases with the sample volume to a maximum in the volume interval between 8 and 14 mL, and then slightly decreases depending on the device and type of media used. For ^{90}Y(^{90}Sr), the detection efficiency is constant for volumes above 8 mL when measured with the Tri-Carb, but again slightly decreases with the Hidex 300 SL and Triathler above 14 mL, as illustrated in Fig. 6.23.

Tayeb et al. (2016) examined the influences of volume and counting vial type and size on the Cherenkov counting efficiency of ^{90}Y for the Hidex 300 SL counter. The effects were evaluated using various volumes of 0.1 M HCl. They showed that the counting efficiency of ^{90}Y was in the range of 69%–73% for plastic vials and 59%–64% for glass vials. No observable differences occurred in the counting efficiencies of either plastic vials or glass vials when sample volumes changed, as shown in Fig. 6.24. The

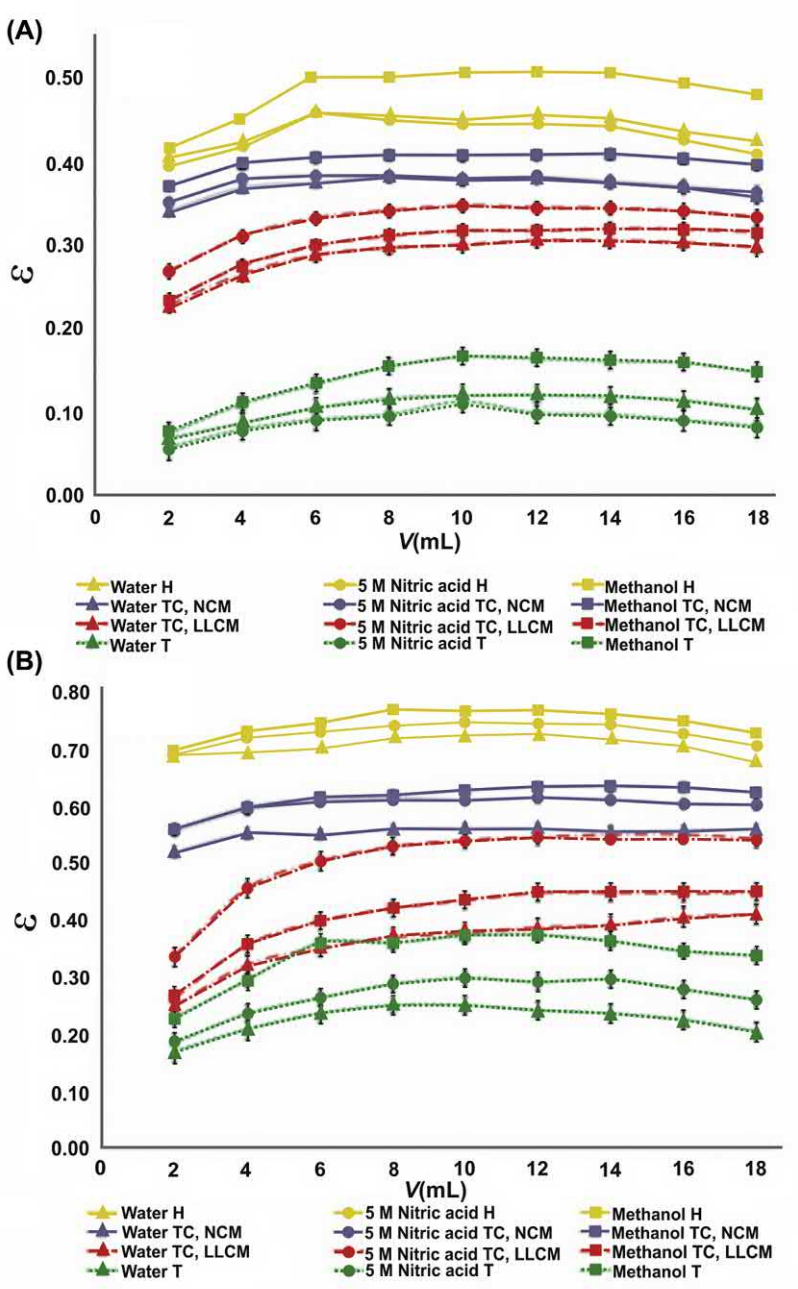

FIGURE 6.23 Dependence of Cherenkov detection efficiency of (A) ^{89}Sr (A *200 Bq) and (B) ^{90}Sr/^{90}Y (A*60 Bq) on volume of different solvents in glass vials. Hidex 300 SL (H), Tri-Carb (TC) in LLCM and NCM and Triathler (T) were used. Counting time was 20 minutes. *From Coha et al. (2016), reprinted by permission from Springer Nature © 2016.*

average counting efficiencies of the glass vials were lower than in the plastic vials by 8% and 10% for each of the 7 and 20-mL vials, respectively.

B. Counting vials

Plastic counting vials produce higher Cherenkov counting efficiencies than glass vials. Because a significant fraction of Cherenkov radiation is emitted in the ultraviolet region, one might assume that the improved detection efficiency in plastic vials is due to the transmission of the UV radiation by the plastic; however, the UV radiation could be absorbed by the glass face of the PMT. Increased Cherenkov detection efficiency provided by plastic counting vials is considered to be due in part to the dispersive or scattering effects of the plastic on the directional (anisotropic)

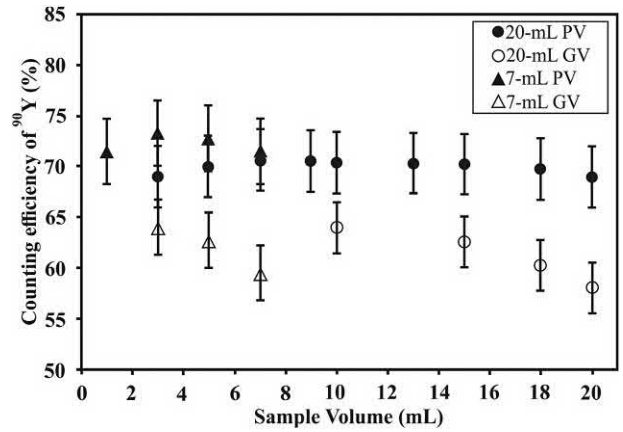

FIGURE 6.24 Counting efficiency of ^{90}Y counted in plastic (PV) and glass vials (GV) as a function of sample volume. Cherenkov photons according to Kellogg (1983) and Grau Carles and Grau Malonda (1996a). As described by Takiue et al. (1996), the use of plastic vials changes the directional nature of Cherenkov photons to an isotropic emission, which increases the photon capture efficiency of the PMTs. The pulse height spectra resulting from Cherenkov photons transmitted by plastic and glass counting vials containing ^{86}Rb in water were compared by L'Annunziata and coworkers (see Noor et al. 1996). The photons emitted from the plastic vials were of higher number and pulse height than those emitted by glass vials. The optimum Cherenkov counting efficiency of 53% for ^{86}Rb was obtained with polyethylene plastic vials compared to a 43% counting efficiency when glass vials were used. A similar affect was observed by L'Annunziata and coworkers (see Aleissa et al., 2008) in the Cherenkov counting of ^{228}Ac. The pulse height spectrum from Cherenkov photons produced by aqueous solutions of ^{228}Ac in plastic vials was larger than that produced in glass vials as illustrated in Fig. 6.25 where the optimum detection efficiency of 10.9% was obtained when polyethylene plastic vials were used and 6.6% with glass vials.

Another factor for the improved Cherenkov counting efficiencies obtained with plastic vials over glass vials was demonstrated by L'Annunziata and Passo (2002) with dry samples of ^{90}Y to be due to the higher index of refraction of polyethylene plastics ($n = 1.50-1.54$) compared to that of borosilicate glass ($n = 1.468-1.487$). The higher index of refraction of the plastic yields a lower beta-particle threshold energy for the production of Cherenkov photons when beta particles pass through the walls of the counting vial. The threshold energies for the production of Cherenkov photons in polyethylene plastic and borosilicate glass are calculated according to Eq. (6.38) to be 167 and 183 keV, respectively.

Ross (1980) and Kellogg (1983) reported that polyethylene vials give significantly higher counting efficiencies and lower backgrounds than glass vials. Furthermore, polystyrene vials can offer an improved counting efficiency, which may be due to a weak scintillation effect in the polystyrene. Mietelski et al. (2006) measured slightly increased Cherenkov counting efficiencies for ^{90}Sr/^{90}Y when pieces of polystyrene were immersed into the aqueous solutions prior to counting. In addition to improved counting efficiency, plastic counting vials produce lower backgrounds than glass vials as demonstrated in the Cherenkov counting of ^{90}Y by Passo and Cook (1994), Vaca et al. (1998), and L'Annunziata and Passo (2002), Cherenkov counting of ^{32}P by L'Annunziata (1997), and Cherenkov counting of ^{188}Re by Kushita and Du (1998). Therefore, plastic counting vials provide higher Cherenkov counting figures of merit (FOMs). The term figure of merit is used to optimize sample counting conditions. It is calculated as

$$FOM = \frac{E^2}{B}, \tag{6.65}$$

where E is the counting efficiency expressed as a percent and B is the background count rate in counts per minute

(CPM). By increasing counting efficiency and/or reducing background, we improve the FOM and the sensitivity of the instrument to measure the radioactivity of the sample. The counting efficiencies, backgrounds, and calculated FOMs for polyethylene plastic and low-potassium glass vials in the Cherenkov counting of ^{32}P in water are listed in Table 6.3, and similar data for the Cherenkov counting of ^{90}Sr(^{90}Y) in water are provided in Table 6.4. The FOM of the Cherenkov counting of ^{32}P is more than doubled on shifting from glass to polyethylene plastic counting vials, and the FOM for the Cherenkov counting of ^{90}Sr(^{90}Y) is improved by almost threefold when shifting glass vials in normal count mode (NCM) to polyethylene plastic vials in LLCM. This is the case for either a wide-open Cherenkov photon counting region of 0–30 keV according to data provided in Table 6.4 or an optimized counting region (*i.e.*, a narrower counting region providing optimized FOMs), as demonstrated by data in Table 6.4. The LLCM listed in Table 6.4 refers to a patented pulse discrimination (TR-LSC) method of reducing background Chapter 6, Volume 1.

In the context of sensitivity enhancement, Grahek et al. (2012) extensively investigated the influence of vial type and media on the background fluctuation and detection efficiency of ^{89}Sr and ^{90}Y(^{90}Sr). They tested the performance of the TriCarb 2770 TR/SL and 3180 TR/SL in a fully open-counting region (0–2000 keV) and LLCM with the aim of maximizing sensitivity in real counting conditions. The background fluctuation was examined by measuring empty and media-filled (nitric acid, water, ethanol, methanol) glass and plastic vials. The measurement was performed by counting each vial for 100 minutes 10 times in controlled conditions, where the temperature and humidity in the counting room were 18–24°C and 35%–55%, respectively. The reported average background level for the different media is about 25% higher for glass vials in relation to plastic vials for both empty and filled vials. An examination of the influence of vials and media (water, nitric acid, methanol, ethanol) on ^{89}Sr and ^{90}Y(^{90}Sr) detection efficiency confirmed that efficiency in plastic vials is higher than in glass vials for both isotopes in all examined media. However, a decrease in the detection efficiency of both isotopes with an increase in the concentration of nitric acid in plastic vials was observed, while in glass vials efficiency slightly increased. The authors attributed these facts to the reaction of HNO_3 at higher concentrations with the plastic vial walls. They assumed that the reaction reduces vial transparency and causes the absorption of photons in the wall, reducing detection efficiency. All results are summarized in Tables 6.5–6.7.

In thorough studies made on the accuracy and reliability of Cherenkov counting, Takiue et al. (1993, 1996) demonstrates a further advantage of plastic over glass counting vials. They used methyl red and bromocresol green as color quenching agents to study the accuracy of quench correction curves based on the SCR or SIS as quench-indicating parameter for the Cherenkov counting of ^{90}Sr(^{90}Y), ^{32}P, and ^{36}Cl in glass and plastic vials for both turbid and clear samples. Turbid samples were prepared by adding small amounts of milk to the aqueous counting medium. The quench correction curves for turbid and clear solutions of the radionuclides were different in glass vials, where the turbid solutions provided higher counting efficiencies as

illustrated in Fig. 6.26. This is probably a result of the dispersion of the directional Cherenkov radiation by the turbidity. However, Takiue et al. (1996) demonstrate that plastic vials give identical quench correction curves for either turbid or clear solutions. All values of percent counting efficiency and quench-indicating parameter fall directly on the same quench correction curve for both turbid and clear solution when plastic counting vials are used, as illustrated in Fig. 6.26.

Cherenkov counting with aqueous samples in plastic vials offers an added advantage because samples may be stored in these vials indefinitely. Relatively short-lived nuclides (*e.g.*, ^{32}P, $t_{½} = 14.3$ days) can be stored as aqueous solutions in the plastic vials until they decay to

background levels, permitting sample disposal as simple water (see Kellogg, 1983).

Milanović and Grahek (2015) reported for Tri-Carb measurements, that the Cherenkov detection efficiency for ^{89}Sr and ^{90}Y increased when a small plastic vial is inserted in the outer 20 mL vial (holder) and filled with liquid. This corresponds with Kellogg's (1983) enhancement of detection efficiencies when using a combination of 5 mL polyethylene inserted in glass 20 mL vials. Coha et al. (2016) extended their examination to different types of instrument, with one, two and three PMTs: the Triathler, Tri-Carb 3180 TR/SL, and Hidex 300 SL. For determining detection efficiency, the procedure shown in Fig. 6.27 was followed.

A series of aqueous solutions containing radionuclides (^{36}Cl, ^{89}Sr, ^{32}P, and ^{90}Sr/^{90}Y) were prepared and counted on the Hidex 300 SL and Tri-Carb 3180 TR/SL. After efficiency determinations, the outer vials were filled with water and the samples were recounted. The results, summarized in Table 6.8, demonstrate that the detection efficiencies did not significantly change for the Hidex 300 SL but did increase for the Tri-Carb 3180 TR/SL. To explain this phenomenon, the authors took into consideration four main factors: geometrical changes, the penetration of high-energy β-particles into the water in the volume of the outer vial, the absorption and scattering of the Cherenkov photons, and the efficiency limits imposed by the construction of the detection systems.

The authors reported that the detection efficiency for the Hidex 300 is energy dependent, so that for low energies, charged particles cannot penetrate into the surrounding water, i.e., the Cherenkov photons are absorbed and scattered in the water and the overall efficiency is lower compared to a situation when only air is present, while high-energy charged particles penetrate into the surrounding water where they cause additional Cherenkov emissions. As a fraction of such particles is energy dependent and increase from ^{89}Sr to ^{90}Sr/^{90}Y, this process can compensate losses of the primary Cherenkov photons in the surrounding water and results with almost constant detection efficiency. They also assumed that the three PMTs of the Hidex with refiection paint encompass fully the cylindrical geometry of the vial. For Tri-Carb measurements, it is assumed that not all of the photons from the inner vial are detected by the two PMTs; and that a significant fraction of Cherenkov photons are generated in the wall of the inner vial, where most of the β-radiation is absorbed. They assumed that the light scattering in the surrounding water results in more isotropic radiation, which can be more efficiently detected due to the principle of Tri-Carb time-resolved technology. This correlated with the large efficiency increase for counting in LLCM. To additionally test these hypotheses, a set of experiments with labeled ink solutions, a blackened inner vial, and outer ink solution was carried out. The sample of black ink spiked with the radioactive standard was used as the sample in the inner vial. The authors reported that the efficiencies are remarkably high on the Hidex 300 SL (except for lower-energy ^{36}Cl), whereas on the Tri-Carb the efficiency for ^{90}Y is 14% and only 5% in LLCM (see Table 6.8). They assumed that the Cherenkov light was totally absorbed by the ink and that the measured efficiency represents a fraction of the Cherenkov photons originating from interactions in the walls of the inner and outer vials. Therefore, in the following experiment, the outer walls of the mini-vials were blackened with black paint. In this case, the Hidex 300 SL and Tri-Carb still detected some events of ^{90}Y. In such cases, and whether water or ink was present as the sample in the inner vial, the Cherenkov detection efficiency of ^{90}Y was 10% for the Hidex 300 SL and 8% for the Tri-Carb. This was attributed to the production of Cherenkov photons by the passing of high-energy electrons through the walls of the mini-vials. It was shown that mini-vials surrounded with ink solution result in negligible detection

efficiencies. However, when they were surrounded by water, the detection efficiencies increased. The greatest increase (about 2.5 times) was observed for ^{90}Y in LLCM on the Tri-Carb. The authors stated that the test with ink indicates the possibility of using Cherenkov counting for activity determination in highly quenched samples and that two radionuclides may be discriminated in a mixture by deliberately changing color quench (Coha et al., 2016).

Todorović et al. (2017) investigated the influence of the type of scintillation vial on the Cherenkov background of the Quantulus 1220. The variations in background in the polyethylene plastic vials, high-performance glass vials and low ^{40}K glass vials for the 20 mL volume distilled water samples are presented in Table 6.9.

The background measured with the glass vial is higher than that obtained with the plastic vial by almost one order of magnitude (Table 6.9) because of the presence of natural ^{40}K and U isotopes in the glass, which makes it unadvisable for low-level counting. In addition, due to the effects of the dispersion or scattering of anisotropic (oriented) photons in plastic, their distribution becomes isotropic, causing increases in the counting efficiency. Polyethylene also has a higher refractive index (n = 1.5−1.54) than borosilicate glass (n = 1.468−1.487), which decreases the energy threshold for Cherenkov radiation production from 183 to 167 keV. As a consequence of the above results, polyethylene plastic vials were selected for the current analysis. A sample volume of 20 mL was chosen for routine analysis in order to minimize the color effects and maximize the volume useful for the sample solution.

From the data and examples described above, it is clear that polyethylene plastic vials give the highest Cherenkov counting efficiencies and most accurate results when compared with glass counting vials. Glass vials can give higher counting efficiencies if wavelength shifters are used, as discussed in the following.

TABLE 6.9 Optimal type of scintillation vial selection (for channel 130−430).

Vial type	Efficiency E [%]	Background B [cpm]	$FOM = \frac{E^2}{B}$
Polyethylene vial	45.86(9)	0.48	4383

C. Wavelength shifters

The ultraviolet component of Cherenkov radiation, which may pass plastic vials, can be absorbed partially by the glass of the PMT. Certain compounds, such as the sodium and potassium salts of 7-amino-1,3-naphthalenedisulphonic acid (ANDA) in 100 mg/L concentration, are successfully employed as wavelength shifters by absorbing the ultraviolet photons and reemitting them isotropically in the visible region, as demonstrated by Parker and Elrick (1966, 1970) and Elrick and Parker (1968). Wavelength shifters, as defined by Dai et al. (2008) are generally fluorescent organic chemicals containing polyaromatic hydrocarbons or heterocycles in their molecular structure, which absorb photons and reemit them at longer wavelengths. Also, the directional character of Cherenkov photons and the ultimate emission of their shorter wavelengths are reduced by the emission of the radiation in all directions at longer wavelengths more efficiently detected by PMTs.

Lauchli (1969, 1971) reported that weak beta-particle emitters such as ^{36}Cl require 5 mM ANDA, and strong beta-particle emitters, such as ^{86}Rb and ^{40}K, require 2.5 mM ANDA for optimum counting efficiencies. ANDA was demonstrated to be useful for the routine counting of ^{36}Cl, ^{40}K, and ^{86}Rb in plant materials, providing counting efficiencies of 13%, 79%, and 61%, respectively, for samples containing 1 g of digested plant tissue, and 23%, 93%, and 70%, respectively, for samples not containing plant tissue. Only a small increase in Cherenkov counting efficiency of ^{188}Re from 53% to 55% in glass vials with the addition of 100 mg/L of ANDA was demonstrated by Kushita and Du (1998); however, the counting efficiency slightly dropped from 58% to 54% with the addition of ANDA wavelength shifter in plastic vials. This effect is unusual and unexplained. The writer can only note that ^{188}Re emits higher-energy beta particles [*i.e.*, three beta transitions of 2120 keV (79% intensity), 1970 keV (20% intensity), and ∼1900 keV (1% intensity)] than all other radionuclides studied with wavelength shifters, and possibly a greater fraction of the Cherenkov photons are created in the visible rather then the ultraviolet.

In most cases, significant increases in Cherenkov counting efficiencies are achievable with wavelength shifters, which could be advantageous if the sample is not needed for further studies or chemical analysis, for which the wavelength shifter may act as a contaminant. ANDA may also be employed as a wavelength shifter in the Cherenkov counting of ^{59}Fe as reported by Kannan (1975).

Frič and Finocchiaro (1975) found anthranilic acid and quinine to be effective as wavelength shifters for the Cherenkov counting of ^{32}P. Concentrations of 10^{-3} M anthranilic acid and 2×10^{-3} M quinine increased the counting efficiency of ^{32}P from 47.2% to 58.4% and from 47.2% to 54%, respectively. Bezaguet et al. (1979) reported

an increase in the light output by a factor of about 3.8 when ANDA is employed as a wavelength shifter at a concentration of 10 mg/L.

Many chemical compounds have been tested for their wavelength shifting properties. Some are sensitive to pH, salt concentration, and storage in the sample solution for periods of several hours, a few days, or weeks. van Ginkel (1980) tested the stability and wavelength-shifting properties of several organic compounds, and some of their properties are listed in Table 6.10. The pH sensitivity of wavelength shifters has been studied in detail by Kellogg (1983); and it was demonstrated that the use of wavelength shifters is not appropriate when the sample pH can vary to a significant degree. Sample pH can affect the fluorescent properties of the wavelength-shifting molecule and consequently cause the counting efficiency to vary.

Also Ross (1971), Paredes et al. (1980), and Bem et al. (1983) indicated that care should be exercised when wavelength shifters are used, because some shifters show chemical decomposition over several hours. This can lead to color quenching and a reduction in counting efficiency. The tremendous increase in detection efficiency of ^{32}P from 55.5% in pure water to 85% in a high concentration of sodium salicylate (1 g/mL), as seen in Table 6.10, is reportedly due to an increase in the index of refraction, which would lower the threshold energy for the production of Cherenkov photons by beta particles in water. Sodium salicylate was tested by L'Annunziata and coworkers (see Aleissa et al., 2008) and found to increase the Cherenkov photon detection efficiency of ^{228}Ac from 10.9% to 38% for the analysis of ^{226}Ra after adding 1.4 g of sodium salicylate to each polyethylene counting vial containing 14.0 mL of ^{228}Ac in aqueous solution after the isolation of the ^{228}Ac off of a Diphomix ion exchange column. Sodium salicylate should be tested for each application because, as noted in Table 6.10, it is highly susceptible to pH and ionic strength. It can exhibit color under certain conditions. Peck et al. (1998) reported an enhancement of ^{210}Bi detection efficiency in the presence of Triton X-100 and sodium salicylate of 97%. In order to enhance the Cherenkov efficiency of ^{90}Sr, Reddy et al. (2017) compared the effect of glycerol and sodium salicylate as wavelength shifters on ^{90}Sr detection efficiency by means of Cherenkov measurement. They showed that the Cherenkov detection efficiency of ^{90}Sr depends on the concentration of the wavelength shifters, and was enhanced 3.8–7.5 times with the addition of sodium salicylate, while the addition of glycerol doubled the detection efficiency, as illustrated in Table 6.11.

Wang et al. (2018) also used sodium salicylate to enhance the detection efficiency of Cherenkov photons. In this study, authors found that the addition of sodium salicylate could significantly increase the counting efficiencies of ^{210}Pb/^{210}Bi in aqueous samples. Meanwhile, a sharp increase of the counting efficiency for the alphas from ^{210}Po was also observed with the addition of high concentration of sodium salicylate, implying that scintillation light photons are produced. At low concentration (<0.5 mg g^{-1}) of sodium salicylate, only a small increase in Cherenkov counting efficiency for ^{210}Bi by the wavelength-shifting effect could be observed. Meanwhile, the Cherenkov counting efficiency for ^{210}Bi at high concentration (>1 mg g^{-1}) of sodium salicylate would significantly increase due to the scintillation effect.

TABLE 6.10 Effect of different wavelength shifters, dissolved in distilled water, on the counting of Cherenkov radiation from ^{32}P, using polyethylene counting vials, vial constituents of 10 mL, an amplifier gain of 30%, and discriminator settings of 20–1000.[a]

PPO has excellent wavelength shifting properties in Cherenkov counting. However, it cannot be incorporated directly into water. Takiue et al. (1984) devised a method for introducing PPO into water in the form of a micelle by first preparing a PPO−ethanol solution. A 2-mL sample of PPO−ethanol is added to 13 mL of aqueous solution of ^{32}P for Cherenkov counting. The counting efficiency for ^{32}P was 68.4% (optimum), which was 1.6 times as high as that measured with conventional Cherenkov counting (42.3%). The optimum concentration of PPO in the counting vial was reported to be 0.02 g/L. Although the use of such a wavelength shifter can significantly increase the counting efficiency, it must be kept in mind that the detection process is no longer a purely physical one, and thus, chemical quenching becomes possible. Takiue et al. (1996) increased the Cherenkov counting efficiency of ^{32}P in water from 50% to 65% using 4-methylumbelliferone as a wavelength shifter while demonstrating that turbid and clear samples of ^{32}P in glass scintillation vials give the same quench correction curve when wavelength shifter is used.

A disadvantage of wavelength shifters in certain circumstances can be that the counting sample may be rendered useless for subsequent chemical tests or analyses, because the wavelength shifter may act as a contaminant and interfere in these analyses. In the biosciences Cherenkov counting of ^{32}P can be advantageous when the sample is left in an unadulterated form in aqueous solution whereby the ^{32}P can be analyzed and the sample used for subsequent biological or chemical tests.

Some aromatic wavelength shifters and solvents of high refractive index act as scintillants and, for this reason, Cherenkov counting with these compounds as solvents is at times referred to as Cherenkov−scintillation counting. An example is methyl salicylate, which has a high refractive index ($n = 1.5369$); and according to Eq. (6.38), the calculated beta-particle energy threshold for Cherenkov production is reduced from 262 keV in water ($n = 1.333$) to 162 keV in methyl salycylate ($n = 1.5369$).

Wiebe et al. (1978) reported counting efficiencies of 50.3% and 14.4% for ^{18}F and ^{14}C in methyl salicylate in the coincidence counting mode. Higher counting efficiencies were obtained in the singles counting mode. This mode of counting is discussed later in this chapter. The SCR method was employed to determine counting efficiencies, and the standard curves (%E vs. SCR) were prepared using chlorobenzene or dimethyl sulphoxide as a quenching agent. In the case of ^{18}F measurement, the methyl salicylate acts as an efficient Cherenkov−scintillation medium, because both Cherenkov and scintillation phenomena occur. Positrons are emitted from ^{18}F ($E_{max} = 636$ keV), well over the beta-particle threshold energy for Cherenkov production. However, the beta particles emitted from ^{14}C ($E_{max} = 155$ keV) do not reach the threshold energy for Cherenkov production in methyl salicylate, and consequently this solvent only serves as an inefficient scintillation flour for ^{14}C.

To keep the advantages of using a wavelength shifter while still counting under pure Cherenkov conditions free of chemical quenching, Ross (1976) and Takiue and Ishikawa (1978) fabricated a counting vial containing two chambers, which separate the sample from the wavelength-shifting solution (see also L'Annunziata, 1984a, 1987). The vial consists of an outer chamber used to contain the wavelength-shifting solution, and an inner chamber of approximately 10-mL volume contains the radionuclide and solvent (*e.g.*, water). The wavelength-shifting solution is sealed permanently in the outer chamber by an all-glass seal. The entire inner vial is made of quartz so that the ultraviolet radiation can pass the inner chamber wall before reaching the solution of wavelength shifter. The vials are reusable, and to prevent contamination the sample can be

contained in a polyethylene bag placed within the inner chamber. Ross (1976) reported an increase in counting efficiency of ^{89}Sr by a factor of 1.88 when dimethyl-POPOP is used in the wavelength-shifting chamber as compared to pure water. Greater improvements in counting efficiency would be expected for lower energy beta-particle emitters such as ^{36}Cl. The main disadvantage of this technique is that the volume of sample that may be conveniently counted is reduced by a factor of two. This method of Cherenkov counting has not had many recent applications.

Another approach to the application of wavelength shifters external to the sample solution is the application of a thin film or coat of wavelength shifter onto the faces of the PMTs devised by Grande and Moss (1983). Pure quartz and plastic vials are transparent to the ultraviolet fraction of Cherenkov photons. However, this ultraviolet radiation can be absorbed in part by the glass faces of the PMTs. This absorption is obviated by the application of a coating of wavelength shifter to the glass PMT face. The coating designed by Grande and Moss (1983) consists of 5.7% p-terphenyl and 3.1% bis-MSB in a polyethyl methacrylate matrix. The transparent coating has an average quantum efficiency of 91% in the wavelength range of 200−400 nm.

Dai et al. (2008) tested several water-soluble wavelength shifting compounds including coumarin derivatives to increase the Cherenkov photon detection efficiency for the Sudbury Neutrino Observatory (SNO) heavy water Cherenkov detector. They found the water soluble carbostyril 124 and Alexa Fluor 350 increased the detection efficiency of Cherenkov photons. A concentration of only 15.4 ppm of carbostyril 124 resulted in an increase in the net gain of 4.4 ± 0.5. The wavelength shifters tested were pH-insensitive with strong absorbency below 350 nm and high reemission between 350 and 500 nm wavelength. These wavelength shifting compounds show potential for the Cherenkov counting of radionuclides; but they have not been tested yet for this purpose.

D. Ionic liquids

Ionic liquids (ILs) are organic salts with melting points near room temperature, with 100°C as the agreed arbitrary upper limit (Weingärtner, 2008). The ionic nature of these liquids gives them distinctive physicochemical properties compared with traditional organic solvents, which are mostly toxic, volatile, and flammable, while the chemical characteristics of either cation and/or anion give ILs a tunable solvation power (Welton, 1999; Isik et al., 2014). A moderate thermal stability, low flammability, and good conductivity are some of the remarkable features that justify their nascent application, e.g., in nuclear technology (Sun et al., 2012). Mirenda et al. (2018) proposed the use of a novel fluorescent IL, 1-butyl-3-methylimidazolium 8-hydroxypyrene-1,3,6-trisulfonate (BMIMHPTS), to act as a wavelength shifter of the Cherenkov photons generated from 1-butyl-3-methylimidazolium chloride (BMIMCl). They found that ^{18}F and ^{32}P efficiencies increase up to 124% and 14%, respectively, compared with the values obtained with pure BMIMCl. With this improvement, IL mixtures become a good alternative, when using the TDCR−Cherenkov technique, in standardizing radionuclides with electron emission energies close to the threshold energy in water (~260 keV). As an advantage compared to other solvents, they concluded that an IL mixture can be reused, in the case of short-lived radionuclides, by simply removing all the water content in a vacuum oven.

E. Refractive index

From Eqs. (6.38) and (6.39), it is evident that the energy threshold for the production of Cherenkov radiation by electrons (beta particles) is a function of the refractive index. An increase in the refractive index of the medium should lower the energy threshold for the production of Cherenkov photons and increase the detection efficiency for a beta-particle emitting radionuclides. The detection efficiency should increase to some extent for all beta-emitting nuclides with an E_{max} above the threshold energy in pure water, because the beta-particle energies constitute a broad spectrum between zero and E_{max}.

Ross (1969) found that the Cherenkov Effect and detection efficiencies are significantly increased only for radionuclides that have a low beta-particle E_{max}, as illustrated in Table 6.12. This may be explained by the fact that a smaller fraction of the total beta-particle energy spectra of high-energy beta particle-emitting nuclides is below 262 keV.

Wiebe and Ediss (1976) reported very high Cherenkov counting efficiencies for ^{36}Cl ($E_{max} = 714$ keV) using a high-refractive index methyl salicylate ($n = 1.5369$) as the counting medium. Counting efficiencies of 82.4% and 91.6% were reported, depending on the counter employed. The high counting efficiencies were reported to be due not only to the increased refractive index (thus lowered Cherenkov threshold energy) but also to the wavelength-shifting and scintillation properties of this solvent, as discussed in the previous Section V.C of this chapter.

The high refractive indexes of concentrated solutions of sodium salicylate in water (100−1000 g/L) provided significant increases in counting efficiency of ^{32}P (see Table 6.10). Likewise, as discussed in the previous Section V.C of this chapter, sodium salicylate increased the Cherenkov photon detection efficiency of ^{228}Ac from 10.9% to 38% for the analysis of ^{226}Ra after adding 1.4 g of sodium salicylate to each polyethylene counting vial containing 14.0 mL of ^{228}Ac in aqueous solution (Aleissa et al., 2008).

Wang et al. (2018) conducted experiments to test the effect of the refractive index on the Cherenkov counting

efficiency of ^{210}Bi. However, the increase in the counting efficiency of ^{210}Bi by adding sodium salicylate could have been attributed either to the wavelength shifting effect or the change of refractive index. In order to check the sole effect of the refractive index, with no interference from wavelength shifter on Cherenkov efficiency, sodium chloride (NaCl) solutions were also prepared for comparison. As shown in Table 6.13, the changes in the refractive indices for the NaCl solutions were very close to those for the sodium salicylate solutions at the same concentrations of the added salt. For the NaCl samples, a very small increase in counting efficiency was observed with increasing NaCl concentrations (i.e., refractive index), which was very different from the sharp increase noted for the sodium salicylate samples as illustrated in Fig. 6.28.

Wang et al. (2018) also found that after adding 10 mg g^{-1} of sodium salicylate to the NaCl samples, the counting efficiencies dramatically increased but the refractive indices increased only a little. This demonstrated that the significant increase in the counting efficiency with the addition of sodium salicylate was not due to the change of the refractive index. For the NaCl + 10 mg g^{-1} sodium salicylate (SS) samples, the counting efficiency decreased

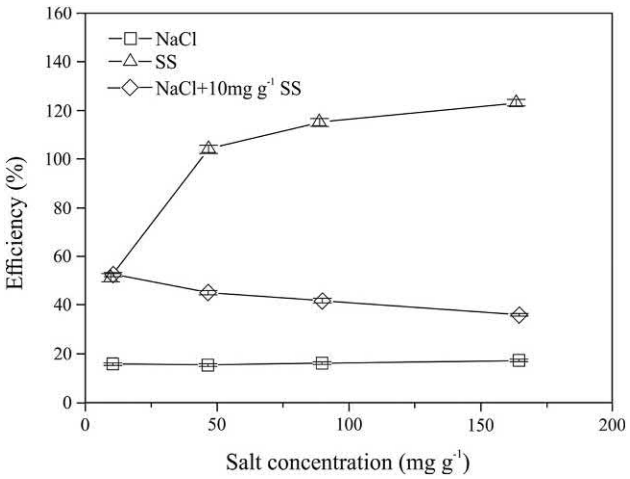

FIGURE 6.28 The counting efficiency of ^{210}Bi (using ^{210}Pb standard) as a function of salt concentration (refractive index). *From Wang et al. (2018), reprinted with permission from Elsevier © 2018.*

with an increase in NaCl concentration (see Fig. 6.28), possibly due to chemical quenching caused by chloride ions acting as chemical scavengers for the excitation state of the sodium salicylate molecules, which was reported by

van Ginkel (1980). The results imply that, with the addition of 10 mg g^{-1} or more of sodium salicylate, the detection of scintillation light rather than Cherenkov photons may have contributed to a significant portion of the counting efficiency, since the Cherenkov counting would not have been affected by chemical quenching. These results demonstrate that a small increase in the refractive index with the addition of sodium salicylate (from 1.3333 with no SS to 1.3695 with 163 mg g-1 of SS added) would contribute a negligibly small amount to the dramatic increase of the counting efficiency (from 15.5% to 122.9%, Table 6.13).

A unique approach is the use of very high index of refraction ($n = 2.1$) transparent ceramic plates to measure Cherenkov photons produced by the low-energy beta emitting radionuclides ^{14}C ($E_{max} = 155$ keV) and ^{45}Ca ($E_{max} = 258$ keV) reported by Takiue et al. (2004) and Minowa et al. (2009). Initial studies were carried out by Takiue et al. (2004), who deposited ~0.02 mL of ^{14}C or ^{45}Ca solution onto thin transparent polyester film and dried at room temperature. The deposited radionuclide was covered with another layer of polyester film to avoid contamination; and the radionuclide in the polyester film sandwich was placed between two very fine transparent high-refractive-index ($n = 2.1$) ceramic plates having dimensions of 25 × 10 mm and 0.4 mm thickness. The polyester film prevented contamination of the high refractive index ($n = 2.1$) ceramic plates permitting their repetitive use. The sandwich of ceramic plates containing the radionuclide of interest (*i.e.*, ^{14}C or ^{45}Ca) was mounted vertically in a 20-mL glass liquid scintillation counting vial and counted in a PerkinElmer Tri-Carb 2750 TR LSC. These initial tests yielded Cherenkov photon detection efficiencies of 1.5% and 2.3% for ^{14}C and ^{45}Ca, respectively. This was the first report of the detection and counting of Cherenkov photons from the low-energy beta particles emitted by ^{14}C or ^{45}Ca. The very high index of refraction of the ceramic plates ($n = 2.1$) lowers the threshold energy for the production of Cherenkov photons by beta particles, according to Eqs. (6.38) and (6.39) described previously, from 262 keV (when water is the medium, $n = 1.333$) to 70 keV (when the ceramic plate is the medium, $n = 2.1$). Further studies by Minowa et al. (2009) were carried out with an improved translucent ceramic, LUMICERA, developed by the Murata Manufacturing Co., Ltd., Kyoto, Japan. In this case the Cherenkov counting of ^{14}C was performed in a microplate format with a PerkinElmer MicroBeta plate counter. Minowa et al. (2009) applied and dried carbon-14 between two sheets of polyethylene film as described above and sandwiched the film between two sheets of the LUMICERA ceramic plates placed onto a filter plate cassette for counting with the PerkinElmer MicroBeta plate counter, as illustrated in Fig. 6.29. They report a Cherenkov photon counting efficiency of 5.0 ± 0.5 for ^{14}C. This report demonstrates an improvement in the

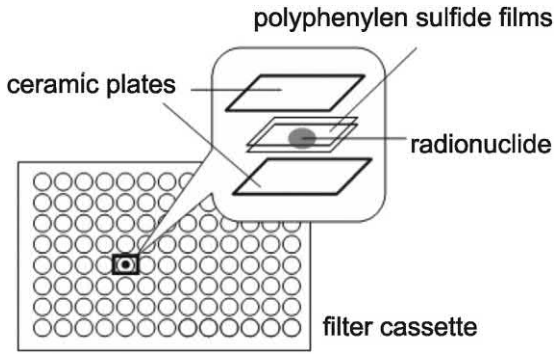

FIGURE 6.29 Arrangement for the Cherenkov counting of ^{14}C in a microplate format with high-refractive-index ceramic plates. *From Minowa et al. (2009). Printed with permission from Radiocarbon, University of Arizona © 2009 Arizona Board of Regents on behalf of the University of Arizona.*

Cherenkov counting of weak beta emitters, such as ^{14}C, and the potential of using a microplate format for the Cherenkov counting of weak beta emitters, such as ^{14}C ($E_{max} = 155$ keV), ^{35}S ($E_{max} = 167$ keV, and ^{45}Ca ($E_{max} = 257$ keV).

Mirenda et al. (2018) concluded that the relatively high refractive index of BMIMCl makes it very convenient for this kind of measurement. BMIMCl/BMIMHPTS mixtures were prepared with the addition of weighted amounts of both ILs. The density of all solutions was 1.07 g/mL. The samples were heated at 60°C in a water bath, and mixed for a day with magnetic stirring to ensure complete homogenization. Afterward, the mixtures were cooled to room temperature. All measurements were performed at the thermostatic condition of 20°C. The refractive indices of the IL mixtures were measured at 589.3 nm in a thermostatized Abbemat 300 automatic refractometer (Anton Paar). The values obtained for BMIMCl with and without BMIMHPTS were n = 1.509(1).

F. Sample physical state

The measurement of radionuclides by the production and counting of Cherenkov photons is not restricted to liquid samples, as discussed previously in Section V.E, where the counting of dried ^{14}C and ^{45}C on ceramic plates was discussed. Also, Cherenkov radiation may be counted with dry and solid samples in plastic or glass counting vials. This is discussed in the following Section VI of this chapter.

VI. Cherenkov counting in the dry state

The Cherenkov counting of ^{14}C and ^{45}Ca in the dry state on high-refractive-index ceramic plates was discussed previously in Section V.E. The Cherenkov counting of radionuclides in the dry state can, under certain circumstances, be more advantageous such as in the analysis of

biochemicals on filter material, electrophoresis gels, thin-layer chromatograms, and paper swipes taken for radioactivity monitoring. In some circumstances, particularly with high-energy beta emitters, such as ^{90}Y, the Cherenkov counting in the dry state can yield FOMs comparable to Cherenkov counting in aqueous solution.

The first report of the Cherenkov counting of a radionuclide in the dry state was provided by Hülsen and Prenzel (1968), who analyzed the activity of ^{32}P tracer nuclide in green algae by counting the Cherenkov photons. The dry algal matter was collected on glass fiber filter and deposited into glass or plastic counting vials. They reported a counting efficiency of 13% for ^{32}P in the dry state in glass vials and a twofold increase in counting efficiency when plastic vials were used. More modern instrumentation can yield higher counting efficiencies. Berger (1984) reported a 25% counting efficiency of Cherenkov radiation from ^{32}P in the dry state compared to a 56% counting efficiency with the nuclide in aqueous solution. The method of Berger (1984) involved measuring ^{32}P on dry glass filters placed flat on the bottom of air-filled glass scintillation vials. He demonstrated the analysis of dry samples of ^{32}P in recombinant DNA procedures where enzyme-catalyzed reactions were carried out in volumes of 10 μL or less. In this case, the ^{32}P samples were deposited onto glass fiber filters, dried under heat lamps, and then inserted into glass counting vials yielding a counting efficiency of $25 \pm 1\%$ using a conventional LSA. The Cherenkov radiation is produced in the glass wall of the scintillation vial. The air in the vial makes no detectable contribution to the production of Cherenkov radiation, as air has a very low index of refraction (see Table 6.1).

Bunnenberg et al. (1987) describe the Cherenkov counting of radionuclides on aerosol filters in the dry state. The filters of 50-mm diameter are sealed in polyethylene foil to avoid contamination and loss of activity. The filters are rolled and inserted into the borehole of solid Plexiglas with the shape of a normal 20-mL scintillation vial. The Cherenkov photon emissions are measured with a conventional liquid scintillation analyzer. Cherenkov counting efficiencies of 44.2% and 65.8% were reported for the measurement ^{89}Sr and ^{90}Sr(^{90}Y) in the Plexiglas vials.

Counting efficiencies of 10% and 14% are reported for the Cherenkov counting of ^{32}P in the dry state in the sample wells of 24-well and 96-well OptiPlates, which are white microplates used with a microplate scintillation and luminescence counter (see Anonymous, 1996). Counting efficiencies are increased with the addition of water to the sample in the microplate wells; however, the possibility of analyzing ^{32}P samples in the dry state without any additive, even water, is a good option to have available.

There are numerous examples of the Cherenkov counting of ^{32}P in the dry state and a few will be cited including the following: dried Whatman filters, millipore filters, nitrocellulose filters, and Nytran membrane filters (Jeske et al., 2015; Sharifulin, 2015; Hunter et al., 2014; Mori et al., 2012; Shehata et al., 2012; Schuster et al., 2010; Arutyunova et al., 2003; Tan et al., 2003; Drobnies et al., 2002), 96-well glass fiber filtration plates (Luo et al., 2018), glutathione sepharose resin beads (Rajyaguru et al., 2012), lyophilized 5′-nucleotide monophosphates (Lehmann and Bass, 1999), precipitated covalent histone−DNA complexes (Angelov et al., 2000), dried samples on Whatman phosphocellulose paper and filter discs (Golub et al., 2011; Kisseljova et al., 2010; Schmöle et al., 2010; Torres-Marquez et al., 2010; Lynn Bostrom et al., 2009; Kuznetsov et al., 2004; Luciani et al., 2000), dried polyacrylamide gels (Masłyk et al., 2018; Grundt et al., 2017; Xu et al., 2015; Yip et al., 2014; Janeczko et al., 2012; Bastin-Coyette et al., 2011; Beauchesne et al., 2009, 2010; Frączyk et al., 2010; Sunil et al., 2007; Gallo et al., 2006; Bélanger et al., 2002; Gittens et al., 2002), and dried DE-81 and P81 ion exchange paper and filters associated with kinase polymerase activity studies (Ampofo et al., 2010; Meng et al., 2010; Alto et al., 2006; Ivanov et al., 2006; Moore et al., 2002).

Although ^{32}P samples on filter discs and other materials can be counted in the dry state in conventional counting vials, it should be noted that this would be recommended only when it is necessary to keep the samples in the dried state or it is necessary to control the counting geometry (*e.g.*, samples that will not dissolve off the filter discs). If, however, the material on the filter discs is water soluble and adding water to the counting vial to the optimum Cherenkov counting volume would assure removal of the ^{32}P-labelled molecules into the aqueous medium, the Cherenkov detection efficiencies would be increased considerably. This is due to the fact that an optimum counting volume of water in the counting vial would serve as a medium for the production of Cherenkov photons in addition to the walls of the counting vial.

A linear logarithmic relationship between Cherenkov counting efficiencies and average energies of the emitted beta particles and internal conversion electrons was demonstrated by Morita-Murase et al. (2000). For this study they used standards of ^{32}P, ^{36}Cl, ^{60}Co, and ^{137}Cs in the dry state, and the counting efficiencies reported for the particular dry sample geometries were $38.8 \pm 0.1\%$, $5.2 \pm 0.03\%$, $0.69 \pm 0.02\%$, and $4.98 \pm 0.13\%$, respectively. Based on these results and the correlation that exists between Cherenkov counting efficiency and logarithm of the γ-ray energy, they estimated that the Cherenkov counting efficiencies of ^{214}Pb and ^{214}Bi due to γ-rays would be $0.003 \pm 0.0006\%$ and $0.09 \pm 0.003\%$, respectively.

Much attention is focused on the production and applications of ^{90}Y in the form of radiopharmaceuticals for medical research and cancer treatment (*e.g.*, Bobin et al.,

2017; Drude et al., 2017; Goel et al., 2017; Kossert et al., 2016; Wright et al., 2016; Lee et al., 2015; Satterlee et al., 2015; Volotskova et al., 2014; Burdick et al., 2011; MacKie et al., 2011; Nardelli et al., 2011; Nicolas et al., 2011; Sato, 2011; Šrank et al., 2010; Xiques Castillo et al., 2009, 2010) as well as the concern for ^{90}Sr(^{90}Y) in the environment and Cherenkov counting methods for the analysis of ^{89}Sr + ^{90}Sr/^{90}Y (*e.g.*, Uesugi et al., 2018; Herranz et al., 2017; Pan et al., 2017; Holmgren et al., 2014, 2016; Tayeb et al., 2016; Zhou et al., 2016; Grahek and Rožmarić-Mačefat, 2005, 2006, 2013; St-Amant et al., 2011; Groska et al., 2012; Vesely et al., 2011; Vajda and Kim, 2010; Maxwell and Culligan, 2009a,b,c; O'Hara et al., 2009; Tsroya et al., 2009, 2012, 2013a,b). Cherenkov counting has proven to be among the most facile and inexpensive method of analysis for ^{90}Y in aqueous solutions at relatively high detection efficiencies of 39%−68% (Coursey et al., 1993). The Cherenkov counting of ^{90}Y in the dry state was proposed as a practical alternative and tested by L'Annunziata and Passo (2002). The Cherenkov counting of dry samples can exhibit the deleterious effect of self-absorption; and thus would be recommended only when necessary such as the radionuclide sample adhered to a filter disc or smear, which cannot be released into soluble form. The detection efficiency for ^{90}Y in the dry state in polyethylene plastic vials was slightly higher than that obtained for ^{90}Y in 20-mL of water in glass vials (Table 6.14). Also, the Cherenkov counting backgrounds are lower in the plastic vials than those obtained with glass counting vials. The counting efficiencies of ^{90}Y in Table 6.14 were measured with standards of ^{90}Sr(^{90}Y) in secular equilibrium; and the ^{90}Sr contribution to the Cherenkov counting efficiencies can be ignored since the maximum Cherenkov counting efficiency for ^{90}Sr is only ~ 1% as reported by Rucker (1991), Chang et al. (1996), and Cook et al. (1998).

Higher Cherenkov counting efficiencies are obtained with plastic counting vials over glass vials as explained in Section V.B of this chapter, and this remains regardless of whether or not the samples are counted in the dry state or in solution. The higher index of refraction of polyethylene plastic ($n = 1.50-1.54$) over borosilicate glass ($n = 1.468-1.487$) yields a lower beta-particle threshold energy (167 keV) for the production of Cherenkov photons in plastic as compared to the energy threshold in glass (183 keV). In the dry state, air is the only medium in addition to the vial walls for the production of Cherenkov photons. Air has a low index of refraction ($n = 1.00027712$) at the Sodium D line at STP (Haynes, 2011). According to Eqs. (6.38) and (6.39), electrons would have to exceed the threshold energy of 2.12×10^4 keV or 0.0212 GeV for the production of Cherenkov photons in air. Consequently, no Cherenkov photons are produced by beta particles in air, and only the counting vial walls are the source of Cherenkov photons from sample beta-particle emissions when the samples are in the dry state. Gases as media for the production of Cherenkov photons are limited to the measurement of high-energy particles in the upper MeV and GeV regions, as noted in Table 6.1 earlier in this chapter. Iodice et al. (1998) calculated the threshold energy for the production of Cherenkov photons by electrons or positrons in CO_2 at STP ($n = 1.00041$) to be 0.017 GeV.

When counting radionuclide samples in the dry state, it is expected that increasing the wall thickness of the plastic would increase the Cherenkov counting efficiency (L'Annunziata and Passo, 2002). Increasing the path length of travel of the beta particles in the plastic should increase the number of Cherenkov photons according to Eq. (6.54) or, according to Sundaresan (2001), over the visible range of Cherenkov wavelengths (400−700 nm) the number of Cherenkov photons produced per path length of travel can be approximated according to Eq. (6.61) described previously in this chapter. The Cherenkov counting efficiencies for ^{90}Y in the dry state in polyethylene plastic vials listed in Table 6.14 were produced in vials of 1-mm thickness. Thicker-walled (2 mm) plastic counting vials are available

TABLE 6.14 Cherenkov counting of ^{90}Sr(^{90}Y) in the dry state and in water.[a]

		^{90}Y counting efficiency (%)		Background (cpm)		FOM[c]

commercially (MaxiVial, PerkinElmer, Inc). The counting efficiencies listed in Table 6.14 for air-dried samples leave the samples at the bottom of the counting vial. Because of the counting geometry effects described previously in Section V.A for samples of low volume vis-à-vis the PMT centers, increased Cherenkov counting efficiencies are expected if the dried samples (*e.g.*, dried aqueous samples, filter or swipe material) are elevated on a 1-cm-thick polyethylene plastic disk of a suitable diameter placed on the bottom of the counting vial. The elevated sample should reduce the geometry effect as well as increase the amount of plastic medium in the vial to enhance the production of Cherenkov photons.

Caution is recommended when counting samples in the dry state because of self-absorption that will occur to varying degrees depending on the sample thickness and density. Self-absorption, that is, the absorption of beta-particle radiation by the sample, can reduce significantly the detection efficiency. If the sample thickness is such that self-absorption may occur at any appreciable extent or be suspect, an internal radionuclide standard could be used to determine the degree to which self-absorption occurs. Such an internal standard is first applied to a dissolved sample, which is then dried before counting. The effect of the amount of dry residue on the Cherenkov counting efficiency of the standard can be measured by varying the amounts of residue that would occur after sample drying. If, on the other hand, Cherenkov counting is carried out on dry filter material or smear material placed within counting vials, the effect of the filter material on self-absorption can be tested by adding radionuclide standard solution to the filter material. The filter material is then dried and counted. Cherenkov detection efficiencies for standards counted with and without the presence of filter material will provide a quantitative measure of self-absorption.

VII. Radionuclide analysis with silica aerogels

One of the principle advantages of analyzing radionuclides by counting Cherenkov photons is that no interference will arise from radionuclides in the sample with decay emissions below the threshold energy of the detector medium for the production of Cherenkov photons. Thus, when water is the detector medium ($E_{th} = 262$ keV), there is no interference from radionuclides such as ^{3}H ($E_{max} = 18.6$ keV), ^{14}C ($E_{max} = 156$ keV), and ^{35}S ($E_{max} = 167$ keV). However, interfering radionuclides, such as ^{60}Co ($E_{max} = 315$ keV), ^{89}Sr ($E_{max} = 1490$ keV), and ^{137}Cs (two beta branches: $E_{max} = 514$ keV at 94% intensity and $E_{max} = 1180$ keV at 6% intensity), which have beta-spectral maximal energies above the Cherenkov threshold energy of 262 keV for water, are present in samples sometimes encountered in the environment particularly where fission-product contamination is of concern. For the Cherenkov analysis of $^{90}Sr(^{90}Y)$ in the environment, Brajnik et al. (1994, 1995) and Pestotnik et al. (2002, 2008) demonstrated the discrimination against the interfering radionuclides by the use of low-refractive index silica aerogel counting medium.

Silica aerogel is a highly porous and transparent solid material. Aerogels are described by Fricke and Tillotson (1997) as transparent, highly porous, open cell, low density foams. A silica aerogel has an index of refraction that varies according to its density, which can be controlled during its manufacture over the range of $n = 1.005$ to 1.26. Some reviews on the production, properties, and applications of silica aerogels are given by Sashkina et al. (2018), Smirnova and Gurikov (2018), Vareda et al. (2018), Deng et al. (2017), Duan et al. (2016), Tabata et al. (2016, 2015, 2012, 2010), Adachi et al. (2011, 2008, 1995), Barnaykov et al. (2011), Rivas Murillo et al. (2010). An excellent history of silica aerogel discovery and production together with aerogel characteristics and applications are related by Fricke and Tillotson (1997). The first aerogels were produced by the pioneer Steven S. Kistler (1931, 1932) during the time that he was teaching at the College of the Pacific in Stockton, California, which is described in historical accounts by Ayers (2000) and Hunt and Ayers (2011). Kistler reasoned that gels consisted of a suspension of independent solid and liquid phases whereby, if the liquid phase were removed from the gel quickly in a nondisturbing manner, the solid phase would remain behind as a porous material with the same shape as the original gel suspension. Modern silica aerogels were later produced by Nicolaon and Teichner (1968), who devised the use of organosilanes for the preparation of aerogels, which has developed into the modern sol-gel method.

The production of silica aerogels is described in works cited in the previous paragraph and in a patent held by Matsushita Electric Works, Ltd. (1992). In brief, silica aerogels are produced firstly with the formation of silica alcogel $\{SiO_2\}_n$ by the polycondensation of orthosilicic acid, $nSi(OH)_4$, formed via the hydrolysis of tetramethoxysilane (TMOS), $Si(OCH_3)_4$, in methanol solution in the presence of ammonia as catalyst according to the following:

$$n\mathrm{Si(OCH_3)_4} + 4n\mathrm{H_2O} \xrightarrow{\mathrm{NH_3}} n\mathrm{Si(OH)_4} + 4n\mathrm{CH_3OH} \quad (6.66)$$

$$n\mathrm{Si(OH)_4} \longrightarrow \{\mathrm{SiO_2}\}_n + 2n\mathrm{H_2O} \quad (6.67)$$

The concentrations of ammonia and solvent (*e.g.*, ethanol) used in the polymerization are varied to adjust to the desired density and refractive index of the final product. For example, silica aerogel refractive indices are reported to range from 1.0275 to 1.0324 for aerogel densities that vary from 0.0985 to 0.1140 g/cm^3 (Ishino et al., 2001); and an

aerogel with a refractive index below 1.005 has been developed with the very low density of 0.02 g/cm^3 (Tabata et al., 2010). The final product of silica aerogel is obtained by drying at a supercritical point to remove the ethanol solvent and transform the alcogel into silica aerogel without creating cracks in the porous substance or volume shrinkage. Aerogels exhibit a crushing strength of about 10 kg/cm^2 and are prepared in various sizes to accommodate particular instrumental configurations (*e.g.*, 10−30 cm in diameter and 2−5 cm thickness) for radionuclide analysis or studies of relativistic particles in high energy physics. The development of aerogel detectors with light guides containing wavelength shifter between the aerogel and phototubes to increase light collection has been studied by Barnykov et al. (1998). Also, silica aerogels have been prepared doped with fluors to increase the efficiency of detection of Cherenkov photons (Bockhorst et al., 1995). Silica aerogels are available commercially from several producers in North America, Europe, and Asia; and the names of the commercial suppliers are listed by Smirnova and Gurikov (2018).

Brajnik et al. (1994, 1995) and Pestotnik et al. (2002) selected a silica aerogel with an index of refraction of $n = 1.055$, which would yield a threshold energy of 1092 keV (1.09 MeV) according to Eqs. (6.38) and (6.39), to create a detector system for the analysis of ^{90}Sr/^{90}Y in the environment via the exclusive Cherenkov counting of the daughter ^{90}Y ($E_{max} = 2280$ keV). Other beta-emitting radionuclides such as ^{137}Cs, ^{60}Co, and ^{89}Sr, which are normally encountered in the environment would not cause any significant interference, as their beta-energy spectral end points (E_{max}) are well under the aerogel Cherenkov threshold energy with the exception of ^{89}Sr. In the case of ^{89}Sr, only a small fraction of its beta particles extend beyond 1092 keV, and covering the aerogel detector entrance and sides with aluminum foil further discriminated against any interference of this nature while, at the same time, improve the light collection efficiency. They placed a multiwire proportional chamber (MWPC) between the radionuclide source and silica aerogel detector. The beta source is placed directly on the MWPC, and in coincidence mode the background count rates were reported to be as low as 2 counts per hour or 0.033 CPM yielding detection limits as low as 0.1 Bq for ^{90}Sr(^{90}Y).

Further advances were made by Pestotnik et al. (2008) in the development of Cherenkov detector for ^{90}Sr. They obtained an aerogel with greater transparency for Cherenkov photons in the wavelength of highest photomultiplier sensitivity and with a lower index of refraction, $n = 1.047$, with 40 mm transmission length at $\lambda = 400$ nm. At the index of refraction, $n = 1.047$, the threshold energy for the production of Cherenkov photons by a beta particle is 1213 keV or 1.21 MeV, which further discriminates against ^{89}Sr beta particles. The aerogel Cherenkov detector for measuring ^{90}Sr is illustrated in Fig. 6.30. It consists of an aerogel Cherenkov radiator measuring $5 \times 5 \times 5$ cm coupled to a multiwire proportional counter (MWPC) and two Hamamatsu multianode photomultipliers. The aerogel radiator is covered with an aluminized mylar foil to increase light yield to the photomultipliers. All radiations escaping from a sample (*e.g.*, beta and gamma) pass through the MWPC before entering the aerogel Cherenkov radiator. A charged particle, such as a beta particle, will create ionization in the MWPC and thus register the event as a positive hit to trigger data acquisition. A gamma ray passing through the MWPC could thereby be rejected, thus reducing background. A scintillation detector illustrated above the apparatus in Fig. 6.30 was used to detect and veto background cosmic-ray particles.

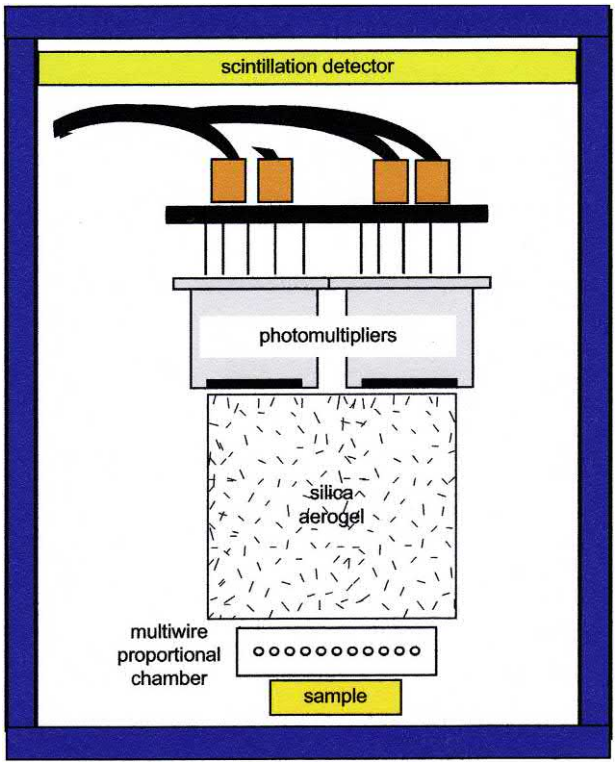

FIGURE 6.30 Silica aerogel Cherenkov detector for measuring ^{90}Sr activity. *From Pestotnik et al. (2008), reprinted with permission from Elsevier © 2008.*

Pestotnik et al. (2008) calibrated the detector with four radionuclide sources, namely, ^{137}Cs, ^{32}P, ^{90}Sr/^{90}Y, and ^{42}K. Radionuclide relative detection efficiencies were measured by dividing the number of Cherenkov photon events with the number of events registered by the MWPC. The efficiencies of the sources tested were plotted against their beta-particle energy maxima (E_{max}), which is illustrated in Fig. 6.31. The detection efficiencies are a function of the beta spectra end-point energies of the radionuclide source. The relative detection efficiency for ^{90}Sr/^{90}Y was 0.024, which is more than a twofold improvement over the

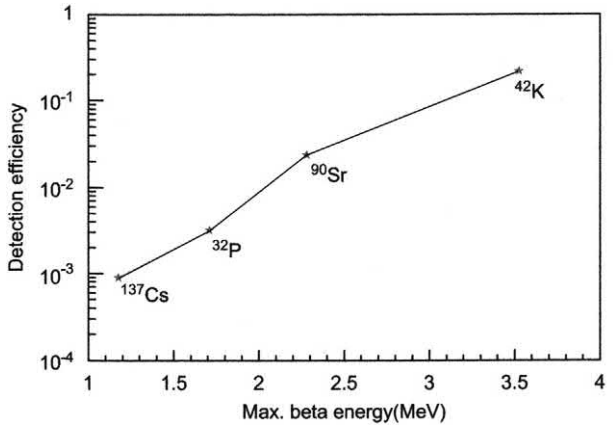

FIGURE 6.31 Cherenkov photon detection efficiency of the aerogel Cherenkov counter defined as count rate divided by appropriate activity as a function of beta spectrum end-point energy. *From Pestotnik et al. (2008), reprinted with permission from Elsevier © 2008.*

earlier detector developed by Pestotnik et al. (2002). The activity of ^{90}Sr is easily determined from the ^{90}Y activity, as both radionuclides would have the same activity if in secular equilibrium at the time of analysis, or by calculation, from the time interval that the ^{90}Y was separated from its ^{90}Sr parent. The low backgrounds achieved demonstrate the potential of this silica aerogel Cherenkov detector design as a radiation monitor for ^{90}Sr/^{90}Y in the environment.

A further development is an aerogel Cherenkov counter for the monitoring of fission products in the environment derived from the work of Ito et al. (2016a,b, 2014) and Ijima et al. (2014, 2013). This work arose as a consequence of the Fukushima nuclear accident from the need to monitor ^{90}Sr/^{90}Y in the environment in the presence of beta-emissions from ^{137}Cs and ^{40}K. They utilized a Cherenkov silica aerogel radiator with a refractive index of 1.034, which has a beta-particle threshold energy capable of detecting beta-particles from the ^{90}Sr daughter ^{90}Y ($E_{max} = 2280$ keV) within a background of beta-particles of ^{137}Cs ($E_{max} = 1180$ keV, 6% and 0.514 keV, 94%) and ^{40}K ($E_{max} = 1325$ keV) as well as discriminate from gamma-ray background radiation. The detector is most sensitive to beta radiation from ^{90}Sr/^{90}Y with a reduced sensitivity to radiation from other sources.

The basic design of the detector, described by Ito et al. (2016a), is illustrated in Fig. 6.32. The trigger component consists of scintillating fibers with fiber ends connected to PMTs (not illustrated). The trigger will register incoming beta-particles and cosmic-ray muons. The aerogel Cherenkov counter consists of silica aerogel of 30 mm thickness with an index or refraction $n = 1.034$, which has a threshold energy of 1498 keV for the production of Cherenkov photons by beta-particles as calculated according to Eq. (6.38) or 6.39. This threshold energy is sufficient to discriminate the ^{90}Y beta particles ($E_{max} = 2280$ keV) from the ^{137}Cs and ^{40}K beta-particle emissions that possess energies below the 1498 keV threshold. The Cherenkov photons produced in the aerogel are detected by means of a light guide consisting of wavelength shifting fibers (WLSFs), which absorb the Cherenkov photons and reemit them shifted to a longer wavelength. The WLSFs are of two types consisting of a purple to blueshift and a blue to greenshift. PMTs (not illustrated in Fig. 6.32) provide a readout of the Cherenkov photon emissions over a photosensitive area of 300 cm^2. The veto component, consisting of a plastic scintillator measuring 400 × 200 × 5 mm coupled to a PMT (not illustrated), provides signals to suppress background events due to cosmic-ray muons. A 10 mm block of aluminum set between the aerogel

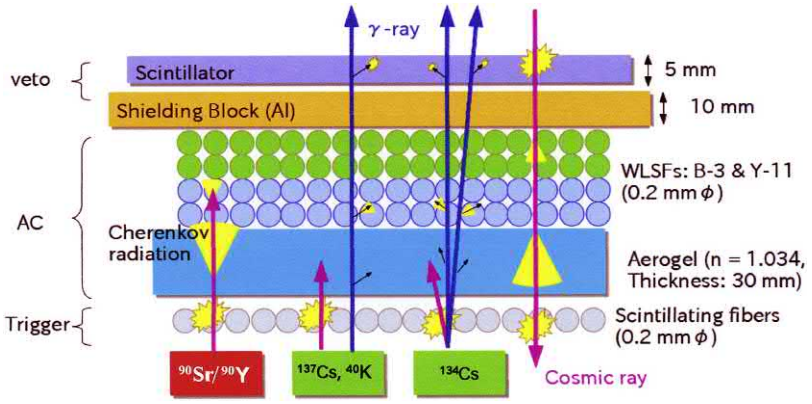

FIGURE 6.32 A sketch of the structure of the real-time ^{90}Sr counter comprising the trigger counter (Trigger) consisting of scintillating fibers, the aerogel Cherenkov (AC) counter with wavelength-shifting fibers (WLSFs), and the veto counter (veto) for the suppression of cosmic-ray background radiation. The magenta, blue, and back arrows represent the charged beta-particle, gamma ray, and knocked-out electron (e.g., Compton electron), respectively. The yellow cone shapes and spreading shapes denote Cherenkov radiation and scintillation emissions, respectively. Color is visible in the electronic version of the book. *From Ito et al. (2016a,b). Identification of 90Sr/40K based on Cherenkov detector for recovery from the Fukushima nuclear accident. JPS Conf. Proc. 11, 07002, https://doi.org/10.7566/JPSCp.11.07002, © The Author(s).*

Cherenkov (AC) counter and veto scintillation detector will block all beta particles while permitting the detection of gamma rays from the isotopes of ^{137,134}Cs and ^{40}K, as illustrated in Fig. 6.32. Ito et al. (2016a) calculated the detection limits for ^{90}Sr to be 52 ± 8 Bq/kg in seafood and 1.7 ± 0.3 Bq/kg in seawater with this real-time ^{90}Sr counter having an effective area of 300 × 100 mm.

A similar detector design was developed by Ito et al. (2018) for the measurement of ^{214}Bi by the counting of Cherenkov photons produced in silica aerogel. The detector would enable the real-time study of ^{214}Bi, which is one of the radon progenies, which may remain airborne contributing to the increasing number of lung cancer cases worldwide as the elderly population increases. An aerogel radiator with a refractive index $n = 1.041$ was utilized, which has a threshold energy of 1328 keV for beta particles calculated according to Eq. (6.38) or 6.39. Bismuth-214 emits beta-particles with maximum energy of 3270 keV. Thus, a large number of the beta-particle emissions from ^{214}Bi possess energies above 1328 keV capable of producing Cherenkov photons in the aerogel while discriminating against background radiation from radionuclides emitting beta-particles with a lower energy maximum. Ito et al. (2018) demonstrate that the ^{214}Bi beta-particle events in the detector are recorded when they are registered in both the scintillating fibers and aerogel radiator, but not the veto counter. Cosmic-ray muons will register events in all of the three detectors, namely, the veto counter, Cherenkov radiator and scintillation fibers.

VIII. Cherenkov counting in microplate format

The measurement of radionuclides by liquid scintillation in a microplate format is described in detail in Chapter 6, Volume 1 (Liquid Scintillation Analysis: Principles and Practice) and Chapter 9 (Solid Scintillation Analysis) of Volume 1. These sections describe the design and operation of multiple detector systems for the simultaneous analysis of up to 12 samples in a 24-, 96-, or 384-sample well microplate. In addition to the simultaneous analyses of samples by liquid and solid scintillation in a microplate format as described in Chapters 6 and 9 of Volume 1, a microplate scintillation and luminescence counter can be used to analyze Cherenkov radiation from high-energy β particle-emitting radionuclides, such as ^{32}P and ^{86}Rb.

The sample wells of microplates have a considerably smaller sample capacity than liquid scintillation counting vials. Consequently, the Cherenkov counting efficiencies and sample count rates achievable are lower with samples in the microplate format. Nevertheless, the high sample throughput available with microplate counters with a 12-phototube assembly allowing the simultaneous counting of up to 12 samples (see Chapters 6 and 9 of Volume 1) make Cherenkov counting of samples in the microplate format an attractive option.

The radionuclide ^{32}P with an $E_{max} = 1710$ keV and ^{86}Rb, which decays by two beta branches with an $E_{max} = 1770$ keV at 88% intensity and $E_{max} = 680$ keV at the remaining 22% intensity, yield suitable Cherenkov counting efficiencies in the limited sample volumes of 1.5 mL and 350 μL for the 24-well and 96-well microplates, respectively. The high sample throughput and inexpensive sample analysis possible with Cherenkov counting make the microplate format of Cherenkov counting very appealing. Most applications are in the biosciences and some examples may be obtained from the following works: Cherenkov counting of ^{32}P in a microplate format (Latz et al., 2013; Strandin et al., 2011; Talbot et al., 2010; Dherbecourt et al., 2006; Roof et al., 2006; Cutshall et al., 2005; Laroche-Joubert et al., 2003, 2002; Deschênes and Doucet 2000) and Cherenkov counting of ^{86}Rb in a microplate format (Talka et al., 2015, 2013; Töpfer et al., 2008; Bogdanova et al., 2005; Kuo et al., 2005; Castle et al., 2003; Brek Eaton et al., 2003; Völkel et al., 2001; Berenbrink et al., 2000).

Some detector and sample properties should be considered to optimize Cherenkov counting of samples in microplates. These are described subsequently.

A. Sample-to-sample cross-talk

In the case of the microplate counter design, where up to 12 PMTs are automatically situated above or on top of as many as 12 sample wells in close proximity there exists the possibility of sample-to-sample cross-talk. This can occur when the β-particle energy is of sufficient magnitude to be able to travel from one sample well to an adjacent well and cause interference by creating Cherenkov photons in the well of a neighboring sample.

Sample-to-sample cross-talk can be determined by adding a radioactivity spike (*e.g.*, ^{32}P in water) to one sample well and only pure water to the surrounding eight sample wells of the microplate. The percent cross-talk can then be calculated by determining the count rates above background in the wells containing only water as a percentage of the radioactivity detected by the PMT above the sample well containing the ^{32}P spike.

The percent cross-talk and percent detection efficiencies in the Cherenkov counting of ^{32}P were tested with the PerkinElmer TopCount microplate counter, which utilizes up to 12 adjacent PMTs above 12 adjacent microplate sample wells. These are listed in Table 6.15 together with background measurements for samples in 24- and 96-well OptiPlates as well as the 96-well UniFilter and 96-well FlexiFilter microplates. The filter microplates are

TABLE 6.15 Cherenkov counting performance in 96- and 24-well OptiPlate microplates and 96-well UniFilter and FlexiFilter microplates with a PerkinElmer TopCount scintillation and luminescence counter.[a]

Microplate type	Cross-talk (%)	Counting efficiency (%)	Background (CPM)
96-well OptiPlate (200 µL sample)	0.4	25	20
24-well OptiPlate (1.0 mL sample)	0.3	25	93
UniFilter-96 GF/B (wet, 20 µL)	1.0	24	38
FlexiFilter nylon (wet, 20 µL)	2.0	25	38

described in Chapters 6 and 9 of Volume 1. The percent cross-talk values for Cherenkov counting, listed in Table 6.15, are low in all cases and generally negligible for the 200 µL and 1.0 mL samples in the 96- and 24-well OptiPlates. The detection efficiencies of 25% are about one-half the efficiencies attainable with Cherenkov counting using the conventional liquid scintillation analyzer. However, the high sample throughput for unattended counting offered by microplate counting is the trade-off, which might be preferred. For example, up to 40 microplates can be stacked in a TopCount microplate counter allowing for the unattended analysis of up to 3840 samples when a 96-well microplate is used (i.e., 96-wells × 40 plates).

B. Sample volume effects

The effects of sample volume on the Cherenkov counting efficiency of ^{32}P in 96- and 24-well microplates are provided in Table 6.16. The volume effects are significant for the relatively small sample volumes tested in the 96-well microplates, which can have a total capacity of 350 μL per sample well. For the larger sample sizes of 500−1500 μL of the 24-well microplates, there is no significant effect of sample volume on the Cherenkov detection efficiency.

The larger volumes of water in the 24-well microplate provide a greater probability for a larger number of high-energy β particles to have a longer path of travel in the aqueous medium for the production of Cherenkov photons. Samples of very small aqueous volume will have less detector medium (i.e., water) for Cherenkov photon production. A significant number of beta particles near the sample surface can escape into the air or microplate wall without producing any significant Cherenkov effect. The larger sample sizes of the 24-well microplate provide, for the most part, higher counting efficiencies than smaller samples of the 96-well plates.

Cherenkov counting of ^{32}P in samples in the dry state in 96- and 24-well OptiPlates is also possible, albeit at a lower detection efficiency (see Table 6.16).

TABLE 6.16 Cherenkov counting performance versus volume of aqueous sample of ^{32}P in 96-well and 24-well OptiPlate microplates with a PerkinElmer TopCount scintillation and luminescence counter.[a]

96-Well OptiPlate		24-Well OptiPlate	
Sample size (µL)	Counting efficiency (%)	Sample size (µL)	Counting efficiency (%)
Dry	10	Dry	14
10	12	500	22
25	14	1000	22
50	15	1500	23
100	18	–	–
300	26	–	–

C. Quench correction

As previously discussed, there is no chemical quench in Cherenkov counting. However, color in the sample will absorb Cherenkov photons, reduce pulse heights, and consequently reduce counting efficiency. Therefore, when samples are colored, it is important to determine the degree of quench in each sample well of the microplate sample holder and determine the counting efficiency of each sample. From the counting efficiency, the sample activities in disintegrations per minute can be determined.

Because up to 12 samples can be counted simultaneously in a microplate scintillation counter and high sample throughput is generally a requirement with this type of counter and sample format, the most automated method of measuring sample quench and counting efficiency is to utilize a sample spectrum quench-indicating parameter (QIP), such as SIS, as previously described in Section IV.C.2 of this chapter.

The MicroBeta and TopCount microplate scintillation counters utilize the Spectrum Quench Parameter of the Isotope (SQP(I)) and the transformed Spectral Index of the Sample (tSIS) as a sample spectrum QIP. The tSIS is similar to the SIS used with the conventional liquid scintillation analyzers. These QIPs are described in detail in Chapter 6 of Volume 1. The SQP(I) and tSIS measure the magnitudes and other characteristics of the sample pulse height spectrum to provide a parameter to measure the degree of quench in the sample. Color quench in Cherenkov counting reduces Cherenkov photon intensities emitted by a sample and consequently reduces the sample pulse height spectrum according to the degree of quench. For example, the tSIS is a unitless number that reflects the magnitude of the pulse height spectrum; that is, as the quench level of a sample increases, the magnitude of the sample pulse height spectrum diminishes together with the value of the tSIS. The scintillation and luminescence counter can measure automatically the value of the QIP for each sample directly from the Cherenkov pulse height spectrum of the sample. It is necessary, therefore, only to establish a quench correction curve of percent counting efficiency versus the QIP from a set of color quench standards of the nuclide under study (e.g., ^{32}P, ^{86}Rb or other high-energy beta emitter) in water. From such a curve stored in the memory of the instrument computer, the microplate counter can determine automatically the Cherenkov counting efficiency of each sample in each well from the QIP value of each sample. It is important to keep in mind that the color quench correction curve is good only for a particular radionuclide, instrument, and microplate format and type of microplate. The procedures to follow for the preparation of quenched standards and the preparation of a quench correction curve for the Cherenkov counting in microplate sample format is available from the instrument supplier and from PerkinElmer by Anonymous (1993, http://www.perkinelmer.co.jp/Portals/0/resource/products_ls/ls_cocktails/pdf/tca-015.pdf), which is adaptable to any microplate scintillation counter.

From the sample count rate (CPM), the microplate analyzer automatically calculates the counting efficiency of each quenched standard using the DPM value of the radionuclide standard and the simple relation %E = CPM/DPM. The analyzer will also determine automatically the values of QIP from the pulse height spectra of each color-quenched standard in each sample well, and the quench correction curve of percent counting efficiency versus QIP (e.g., SQP(I) or tSIS) will be plotted automatically and stored in the memory of the analyzer computer. An example of a typical color quench correction curve is illustrated in Fig. 6.33. The DPM of ^{32}P of subsequent unknown experimental samples can be determined automatically by the analyzer by measuring the count rate (CPM) and the QIP of each sample. From the QIP value of a given sample and the color quench correction curve, the instrument will determine the counting efficiency of the sample. It will use the decimal value of the percent counting efficiency and the count rate of the sample to calculate the disintegration rate (DPM) of the sample.

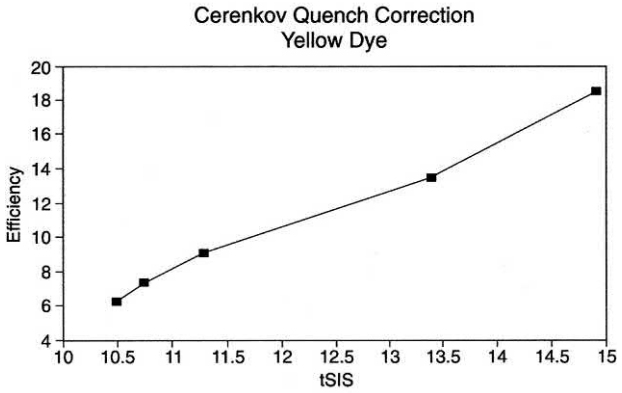

FIGURE 6.33 Example of a typical color quench correction curve for the Cherenkov counting of ^{32}P with a microplate scintillation and fluorescence counter (e.g., MicroBeta or TopCount). *From Anonymous (1996), ©1996–2018 PerkinElmer, Inc. IX. Multiple radionuclide analysis

A. Sequential Cherenkov and liquid scintillation analysis

The conventional measurement of dual β particle-emitting radionuclides in the same sample by liquid scintillation analysis requires three or four quench correction curves for the determination of the same number of counting efficiencies depending on the method used, for example, exclusion and inclusion dual-region analysis, as described in Chapter 6, Volume 1. The methods can be considered tedious sometimes for the inexperienced in these techniques, particularly when preset optimum counting regions have not been established and set by the instrument manufacturer. When radionuclide mixtures consisting of two radionuclides, one of which emits beta particles with an energy maximum exceeding the threshold energy for the Cherenkov Effect in water ($E_{max} > 262$ keV) and the other radionuclide with an energy maximum < 262 keV and no interfering gamma-radiation of energy > 422 keV (threshold energy for the Cherenkov effect via Compton electrons), the activities of the two radionuclides may be resolved by a combination of Cherenkov counting followed by liquid scintillation counting (LSC).

1. Sequential Cherenkov counting and efficiency tracing

In this approach to dual radionuclide analysis, Cherenkov counting is used to obtain the activity of one of two radionuclides in a mixture; and the subsequent liquid scintillation counting (LSC) by efficiency tracing provides the total activity of the two nuclides. By difference, the activities of each radionuclide may be found. Fujii and Takiue (1988a,b) developed a simplified method of analyzing mixtures of dual radionuclides, which has a single requirement, namely that one of the radionuclides of the dual mixture emit β particles with an $E_{max} > 262$ keV in sufficient number to be measurable by Cherenkov counting in aqueous solution. The method of Fujii and Takiue (1988a,b) involves sequential Cherenkov and LSA counting; and it was developed for both dual β emitters and dual $\alpha-\beta$ emitters as mixtures. The method is described subsequently.

Examples of nuclide pairs that meet the above β-particle energy criterion are $^{32}P-^{14}C$, $^{32}P-^{35}S$, $^{32}P-^{45}Ca$, $^{32}P-^{33}P$, $^{36}Cl-^{35}S$, and $^{36}Cl-^{45}Ca$, among others. Some of these nuclide pairs proved to be useful tools in the elucidation of reaction mechanisms and pathways in studies of biosynthesis, as reviewed by L'Annunziata (1984b). The method involves first counting the Cherenkov photons of an aqueous solution of a nuclide pair to determine the activity or DPM of the high-energy radionuclide of the pair (*e.g.*, ^{32}P or ^{36}Cl of the above examples). Scintillation cocktail is then added to the aqueous solution of the nuclide pair, and the total activity (*e.g.*, DPM) of the sample is determined by the efficiency tracing (ET-DPM) method. The activity of the low-energy β emitter of the dual-radionuclide mixture is determined by difference between the total DPM of the sample and the DPM of the higher energy β emitter measured by Cherenkov counting.

The ET-DPM method, that is used here, is described in Section V.F.3 Chapter 6, Volume 1. It should not be confused with the CIEMAT/NIST efficiency tracing, which is a primary standardization technique also described in Chapter 6, Volume 1. The ET-DPM method was first described by Takiue and Ishikawa (1978), developed further by Ishikawa et al. (1984), Fujii and Takiue (1988a,b), and demonstrated for practical activity measurements by L'Annunziata and coworkers (see Noor et al., 1996) and Takiue et al. (2004). The following is an outline of the procedure based on the method developed by Fujii and Takiue (1988a):

1. An aqueous sample containing the dual-radionuclide mixture is counted in a 20-mL polyethylene plastic liquid scintillation counting vial in a counting region, which will receive the pulse events from Cherenkov photons. A typical counting region is 0–30 keV for LL and UL discriminator settings for pulse heights calibrated on an energy scale. The recommended volume of the solution to be counted is 5 mL. The volume should be constant for all samples, and this volume should be the same as the color quenched standards used to determine the Cherenkov color quench correction curve.

   Note 1: As described in Section V.B of this chapter, polyethylene plastic vials give higher counting efficiencies than glass vials, and the effect of sample volume on Cherenkov counting efficiency is reduced with the polyethylene plastic vials. Therefore, plastic vials are recommended over glass vials.

   Note 2: The sample volume of 5 mL is selected because the Cherenkov counting efficiency can be reduced markedly at volumes of less than 5 mL depending on the instrument (see Fig. 6.22), and room must remain in the vial to add scintillation fluor cocktail at a later step in the procedure. It is important to keep the aqueous sample at a constant volume (e.g., 5 mL), because sample volume will affect Cherenkov counting efficiency. If the sample volume is less than 5 mL add water to the counting vial to bring the volume up to 5 mL before analysis by Cherenkov counting.
2. Use a color quench correction curve to determine the Cherenkov counting efficiency of the sample and to convert the count rate (CPM) to disintegration rate (DPM) of the higher energy β emitter of the dual-nuclide mixture. See Section IV of this chapter on methods of color quench correction.

   Note: Chemical quench does not occur in Cherenkov counting. Even if samples are colorless, it is convenient to use a color quench correction curve for Cherenkov counting, because most modern liquid scintillation analyzers are programmed to provide automatic DPM calculations of experimental samples via a quench correction curve. Also, the use of an established color quench correction curve in Cherenkov counting will eliminate a possible source of error in counting efficiency determinations, as the writer has experienced that even a very slight color can produce significant quench in Cherenkov counting.
3. Add 10 mL of a liquid scintillation fluor cocktail to the aqueous sample in the scintillation vial after Step 2 is complete.

   Note: A fluor cocktail should be selected that will mix homogeneously with the 5 mL of aqueous sample. See Chapter 7, Volume 1 for information on the selection of fluor cocktails. Some examples of suitable fluor cocktails are Ultima Gold XR and Insta-Gel, which have high water holding capacities; the latter fluor cocktail forms a homogeneous gel at high water loads.

4. Determine the total DPM of the sample using the Efficiency Tracing with ^{14}C DPM method (ET-DPM). This method is simple and it is described in detail in Section V.F.3 of Chapter 6, Volume 1. The method will give the total DPM of the sample automatically without any need for a quench correction curve. The total DPM of the sample, therefore, represents the sum of the activities of the two radionuclides in the mixture.
5. Subtract the activity (DPM) of the higher-energy radionuclide determined by Cherenkov counting of the sample in Step 2 from the total sample DPM determined in Step 4 to yield the activity in DPM of the lower-energy β emitter of the dual radionuclide mixture.

This method can also be applied to the analysis of dual mixtures of alpha- and beta-emitting radionuclides as demonstrated by Fujii and Takiue (1988b). Alpha emitters will not give rise to Cherenkov photons because the threshold energy for the production of Cherenkov radiation by α particles in water medium is >1000 MeV or $>10^6$ keV as explained by Fujii and Takiue (1988b), and as calculated according to Eq. (6.39) discussed earlier in this chapter. Many radionuclides that decay by the emission of α particles also emit γ rays. However, γ radiation from α-emitting radionuclides would interfere with this method when the γ radiation possesses an energy >0.422 MeV to produce Compton electrons >0.262 MeV of energy sufficient to produce Cherenkov photons. Consequently, the above method of analysis of dual-radionuclide mixtures is applicable to α- and β-emitting radionuclide pairs when the β emitter of the pair has β-particle emissions of sufficient number in excess of 262 keV energy to produce measurable Cherenkov radiation, and the α-emitter does not have accompanying gamma emissions of energy in excess of 0.422 MeV. The method was demonstrated by Fujii and Takiue (1988b) with the ^{32}P–^{241}Am radionuclide pair. Quantitative activity determinations of the two radionuclides are obtained according to the procedure just described. When the mixture is first counted in water, the Cherenkov radiation is measured from the ^{32}P to provide the DPM of that radionuclide only. Adding liquid scintillation fluor cocktail to the aqueous mixture and subsequent analysis by the ET-DPM method provides the total DPM of the $^{32}P + {}^{241}Am$ mixture. Subtraction of the ^{32}P DPM obtained by Cherenkov counting from the total DPM of the mixture provides the activity of the ^{241}Am. The theory and practice of ET-DPM for β emitters as single nuclides or mixtures is described in detail in Section V.F.3 of Chapter 6, Volume 1. The application of the method to mixtures of α and β emitters was demonstrated by Fujii and Takiue (1988b), and an example of efficiency tracing curves for a ^{32}P–^{241}Am mixture is given in Fig. 6.34. As illustrated in the Figure, the curves are extrapolated to 100% counting efficiency where CPM = DPM irrespective of quench

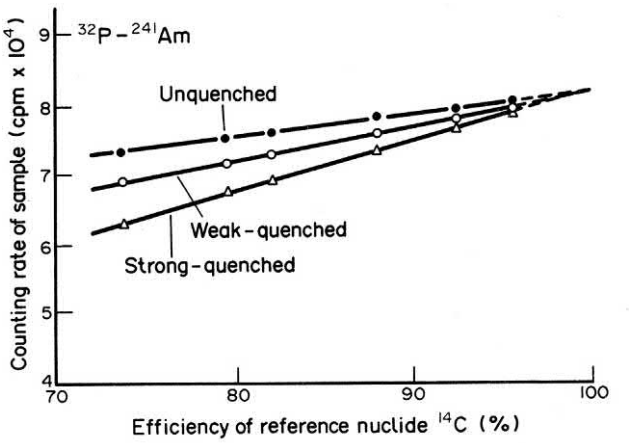

FIGURE 6.34 Efficiency tracing curves of a ^{32}P–^{241}Am mixture at three levels of quench. Each extrapolated value up to 100% counting efficiency provides the total activity of the sample to be measured. *From Fujii and Takiue (1988b), reprinted with permission from Elsevier © 1988.*

level. See Section V.F.3 of Chapter 6, Volume 1 for detailed information on this technique. The method should be applicable to many dual mixtures of α and β emitters when the β emitters can be measured by Cherenkov counting.

The sequential Cherenkov and LSA method was successfully employ by Morel and Fardeau (1989) for the analysis of ^{32}P–^{33}P in studies of phosphate fertilizer use efficiency. The writer and coworkers (see Noor et al., 1996) have applied the sequential Cherenkov counting and LSA analysis by ET-DPM method to analyze the triple-radionuclide mixture of ^{86}Rb–^{35}S–^{33}P. The total DPM of the mixture was determined by the ET-DPM method and the activity of ^{86}Rb of the triple-radionuclide mixture was determined by Cherenkov counting in water with 100% recoveries for several activity proportions of the triple-radionuclide mixture, as illustrated in Table 6.17. The difference of the two measurements provided the activities of the $^{35}S+{}^{33}P$ mixture. The activities of the ^{35}S and ^{33}P are determined by liquid scintillation analysis of the dual mixture after the ^{86}Rb decays to a negligible level according to its half-life ($t_{1/2}= 18.8$ days).

2. $^{89}Sr + {}^{90}Sr(^{90}Y)$ analysis by Cherenkov counting with subsequent LSA

Another example of a nuclide pair, which receives much interest and which can be analyzed by sequential Cherenkov and liquid scintillation counting, is freshly isolated ^{89}Sr–^{90}Sr (Walter et al., 1993; Poletiko et al., 1994; Clark, 1995; Martin and Odell, 1998; Heckel and Vogl, 2009; Kim et al., 2009a,b; Tovedal et al., 2009; Vajda and Kim, 2010; Groska et al., 2012; Grahek et al., 2012; Olfert et al., 2014; Dai and Kramer-Trembly, 2014; Tayeb et al., 2016; Holmgren Rondahl and Ramebäck, 2018). This method of

[b]*in hundreds.*

approach to the analysis of $^{89}Sr + ^{90}Sr(^{90}Y)$, requires firstly the radiochemical separation of $^{89}Sr + ^{90}Sr$ in a strontium fraction separate from all other chemical elements or radionuclides of the sample. The separation of strontium, by chemical fractionation of strontium or by ion exchange separation with a Sr-specific resin, yields $^{89}Sr + ^{90}Sr$, which is analyzed immediately by Cherenkov counting. If the freshly separated $^{89}Sr + ^{90}Sr$ is counting immediately for a relatively short counting time, ingrowth of ^{90}Y daughter can be neglected (Kim et al., 2009a,b). After 1 hour of preparation of freshly isolated $^{89}Sr + ^{90}Sr$, the ingrowth of ^{90}Y daughter with ^{90}Sr parent is only 1.06% of the maximum ^{90}Y activity of secular equilibrium (L'Annunziata, 1971), which is calculated according to Eq. (1.574) provided in Section XVII.C of Chapter 1, Volume 1. Cherenkov counting of the freshly isolated $^{89}Sr + ^{90}Sr$ provides the activity of the ^{89}Sr ($E_{max} = 1490$ keV). The contribution of ^{90}Sr ($E_{max} = 546$ keV) to the Cherenkov effect is very low and ignored. Its Cherenkov photon detection efficiency is only ~1%.

Once the ^{89}Sr activity is determined by Cherenkov counting of the freshly isolated $^{89}Sr + ^{90}Sr$, liquid scintillation cocktail is added to the counting vial; and the radiation from the $^{89}Sr + ^{90}Sr(^{90}Y)$ is then detected by liquid scintillation counting. The time of radiochemical separation of the strontium (*i.e.*, time of isolation of $^{89}Sr + ^{90}Sr$) must be recorded, as it is necessary to calculate the contribution of ^{90}Y to the count rate arising from the ingrowth of ^{90}Y from the time of separation of ^{90}Sr to the time of counting (see Section VIII.A.2.b of Chapter 6, Volume 1.). Kim et al. (2009a,b) recommends the subtraction of the ^{89}Sr activity determined by Cherenkov counting from the total activity $^{89,90}Sr$. The ^{89}Sr activity, measured by Cherenkov counting, may be imputed into Eq. (6.47) of Chapter 6, Volume 1. for the calculation of the ^{90}Sr activity. Heckel and Vogl (2009) describe the radiochemical elution of strontium on a column of Sr resin with 7 mL of 0.05M HNO_3 followed by the immediate Cherenkov counting of the dilute nitric acid eluate for the measurement of ^{89}Sr activity. The method is illustrated in Fig. 6.35. Cherenkov counting is followed by the X-ray fluorescence analysis of the elemental strontium in the eluate to measure the chemical yield. Liquid scintillation cocktail is then added to the vial to measure the radiation emissions of $^{89}Sr + ^{90}Sr(^{90}Y)$. They used a spectral deconvolution method to calculate the activities due to ^{89}Sr and ^{90}Sr. The spectral technique of dual LSA counting regions described by Kim et al. (2009a,b) may also be used (see Section VIII.A.2.b of Chapter 6, Volume 1.).

The detection procedures are summarized by Holmgren-Rondahl and Ramebäck (2018), as illustrated in Fig. 6.36. Holmgren-Rondahl and Ramebäck (2018) tested the method of spectrum deconvolution and the method of spectrum subtraction in combination with Cherenkov measurements to reach the optimal conditions for the determination of unknown activity ratios of $^{89}Sr/^{90}Sr$ in radiological emergency situations. The determination methodology is shown in Fig. 6.35. After separating the strontium in the Sr column with 8M HNO_3, there follows: (A) determination of ^{89}Sr by means of Cherenkov counting; (B) ^{90}Y separation from ^{90}Sr on Sr resin column with 8M HNO_3 and Cherenkov counting of the ^{90}Y and the subsequent addition of an Optiphase HiSafe 3 cocktail in a fraction of strontium, and measuring $^{89,90}Sr$ using the subtraction method, (C) adding the scintillation cocktail Optiphase HiSafe 3 to the Sr fraction and measuring $^{89,90}Sr$ using spectrum deconvolution. Sample aliquots prior to cocktail addition were taken for yield determinations in

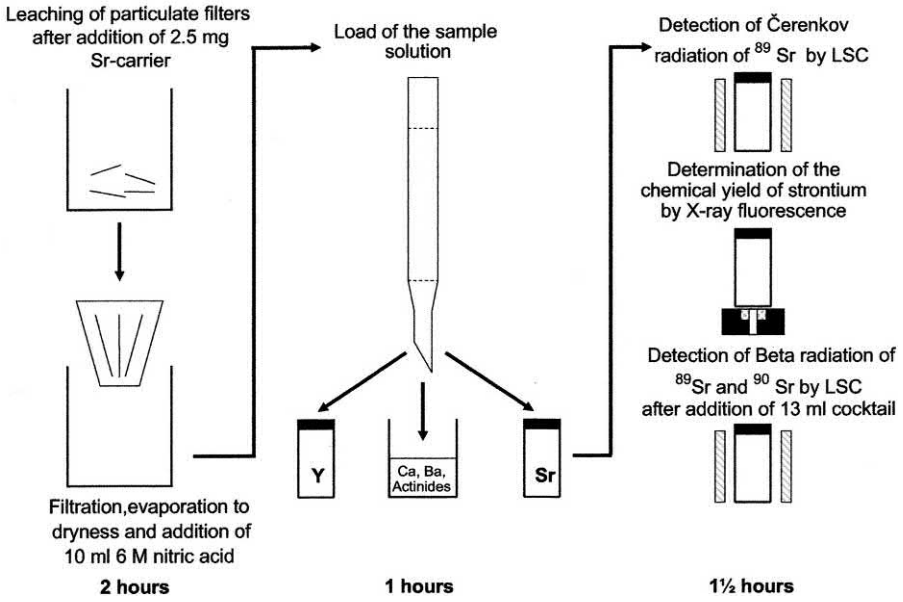

FIGURE 6.35 Radiochemical separation of strontium on a column of Sr resin. The Sr is eluted with a final volume of 7 mL of 0.05 M HNO_3 into a liquid scintillation counting vial. The vial is analyzed immediately thereafter by Cherenkov counting for ^{89}Sr, followed by X-ray fluorescence analysis for total strontium to determine the chemical yield, and finally liquid scintillation cocktail is added for the liquid scintillation counting of $^{89}Sr + {}^{90}Sr(^{90}Y)$. *From Heckel and Vogl (2009f), reprinted with permission from Elsevier © 2009.*

inductively coupled plasma–optical emission spectrometry (ICP-OES). The analysis time and uncertainty measurement for each particular method was calculated. The method of spectrum subtraction and deconvolution results in a high measurement uncertainty for ^{90}Sr, especially in the case of large ^{89}Sr/^{90}Sr activity ratios, implying that the obtained results are in fact below the detection limit for ^{90}Sr. The method of Cherenkov measurement of ^{89}Sr immediately after strontium separation and ^{90}Y after the second separation from strontium gave the lowest measurement uncertainty for the entire range of different activity ratios. Therefore, it can be concluded that this method has an advantage over the others, regardless of the time horizon, due to the separation of yttrium.

A similar approach was used earlier Groska et al. (2012). They described the radiochemical separation of strontium and yttrium in columns of Sr and DGA resin followed by the immediate Cherenkov counting of both fractions. Cherenkov counting is followed by the atomic absorption spectrometric determination of the elemental strontium and yttrium in the eluate to measure the chemical yield. A ProSafe HC scintillation cocktail is used to measure the activities of ^{89}Sr + ^{90}Sr(^{90}Y) in the strontium fraction. It is measured three times: immediately after Sr separation by Cherenkov technique, right after the Sr eluate is mixed with a scintillation cocktail, and 2 weeks later.

The yttrium fraction is measured immediately after elution by Cherenkov counting. The activities of ^{89}Sr and ^{90}Sr are calculated by a combination of LSC and Cherenkov measurement in both yttrium and strontium fractions. Groska et al. (2012) in the same paper also described a method for the determination of ^{89,90}Sr in liquid radioactive waste in which ^{91}Y is present. ^{91}Y as a pure beta emitter with $E_{\beta max} = 1.55$ MeV produces Cherenkov photons and interferes with ^{90}Y during Cherenkov counting.

Therefore, the radiochemical separation of strontium from yttrium in Sr resin and radiation measurement of ^{89}Sr + ^{90}Sr(^{90}Y) by liquid scintillation counting is used for quantification of ^{89}Sr and ^{90}Sr. The individual determination of ^{90}Y and ^{91}Y is also possible by means of a combination of Cherenkov and LSC counting, as described by Zhu et al. (1990).

Tayeb et al. (2016) used a similar separation method, but improved radiochemical separation by using double stacked Sr-resin cartridges which enable minimal loss of Sr and improve chemical yield by at least 25%. Strontium and yttrium were eluted from the Sr and DGA column with 8 mL of deionized water and 9 mL of 0.05M HCl respectively, followed by the immediate Cherenkov counting of the strontium fraction for ^{89}Sr activity determination. The method is illustrated in Fig. 6.79 in section XIV B of this chapter. After Cherenkov counting, an aliquot of the sample is withdrawn for chemical yield determination by means of ICP-MS. An Ultima gold AB scintillation cocktail is then added to both the Y and Sr fractions to measure the activities of ^{89}Sr + ^{90}Sr(^{90}Y) and ^{90}Y. The activities of ^{89}Sr and ^{90}Sr are calculated according to the methodology described in the IAEA report (IAEA, 2013).

B. Cherenkov analysis with wavelength shifters

Dual-radionuclide analysis by Cherenkov counting by the same conventional methods (*e.g.*, dual-region counting) used in liquid scintillation analysis is not practical, because of the high degree of overlap of the pulse height spectra of Cherenkov photons of the β emitting radionuclides. To overcome this difficulty and still make dual-radionuclide analysis possible by Cherenkov counting, Fujii and Takiue (1988c) developed a method that utilizes only one counting region while measuring the changes in the pulse height distributions and counting efficiencies of the two radionuclides in the mixture before and after the addition of wavelength shifter.

As described in Section V.C of this chapter, the addition of wavelength shifter to a sample containing β emitters, which produce Cherenkov radiation in a medium such as water, changes both the emission wavelength and the directional anisotropic nature of the Cherenkov photons into isotropic emissions. Hence, these effects of wavelength shifters improve the photon capture potential of the Cherenkov radiation by the PMTs, which increases the Cherenkov counting efficiencies of the two radionuclides in a mixture. In general, the effect of wavelength shifter on counting efficiency is greater for lower-energy β emitters (*e.g.*, ^{36}Cl) than for higher-energy β emitters (*e.g.*, ^{32}P). The effects of wavelength shifter on the Cherenkov pulse height spectra produced by ^{32}P and ^{36}Cl are illustrated in Fig. 6.37. If the effects of wavelength shifter on the counting efficiencies are significantly different, the method of Fujii and Takiue (1988c) may be applied to the DPM measurements of dual radionuclides in a mixture by Cherenkov counting. The method is based on the following simple conditions and equations:

A sample containing a mixture of two β-emitting radionuclides, whereby both radionuclides produce Cherenkov radiation in a nonscintillating medium (*e.g.*, water), will give different count rates n_A and n_B when counted without and with wavelength shifter, respectively according to the equations

$$n_A = D_1 e_{1A} + D_2 e_{2A}, \tag{6.68}$$

and

$$n_B = D_1 e_{1B} + D_2 e_{2B}, \tag{6.69}$$

where D_1 and D_2 are the activities (*e.g.*, DPM) of the two radionuclides, and e_{1A}, e_{1B}, e_{2A}, and e_{2B} are the counting efficiencies of the two radionuclides in the counting conditions without and with the wavelength shifter, respectively.

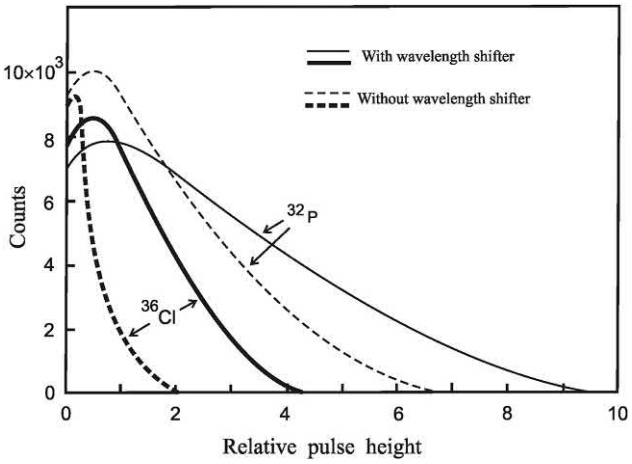

FIGURE 6.37 Pulse height distributions in ^{32}P and ^{36}Cl Cherenkov measurements without and with wavelength shifter (PPO: 0.03 g/L). The samples have the same activity. *From Fujii and Takiue (1988c), reprinted with permission from Elsevier © 1988.*

Eqs. (6.68) and (6.69) are solved simultaneously for the two unknown values D_1 and D_2 to give

$$D_1 = \frac{n_A e_{2B} - n_B e_{2A}}{e_{1A} e_{2B} - e_{1B} e_{2A}}, \tag{6.70}$$

$$D_2 = \frac{n_A e_{1B} - n_B e_{1A}}{e_{1B} e_{2A} - e_{1A} e_{2B}}. \tag{6.71}$$

We can see the similarities of the above Eqs. (6.68) to (6.71) with Eqs. (6.38) and (6.39) of Chapter 6, Volume 1. The equations defining count rates and disintegration rates for radionuclides producing Cherenkov radiation are derived from data produced in one counting region only, whereas, the similar equations described in Chapter 6, Volume 1 are derived from data originating from two different counting regions.

Eqs. (6.70) and (6.71) are solved for the disintegration rates of the two radionuclides by determining the count rates from the sample and counting efficiencies of the radionuclides without and with the introduction of wavelength shifter. An outline of the procedure used by Fujii and Takiue is as follows:

1. Only one counting region is used. This can be defined by setting the LL and UL discriminators to encompass the entire Cherenkov pulse height spectrum in its highest pulse height distribution possible, that is, when wavelength shifter is present.
2. After defining the counting region, 10 mL of the sample in a water medium is counted in a scintillation counting vial without wavelength shifter to yield the count rate n_A.
3. Wavelength shifter is introduced into the sample by adding 2 mL of one of the following solutions: 0.03 g/L PPO in ethanol or 0.2 g/L of 4-methyl-umbelliferone. The sample is counted again to yield the count rate n_B.
4. Counting efficiencies are determined by taking two other 10-mL aliquots of the unknown sample, adding 0.1 mL of reference standards of the two radionuclides of the mixture, and counting before and after the addition of wavelength shifter. The internal standardization technique is described in Section V.A of Chapter 6, Volume 1.

Fujii and Takiue (1988c) demonstrate quantitative recoveries with this technique for the ^{32}P–^{36}Cl and ^{86}Rb–^{36}Cl radionuclide mixtures.

Other radionuclide mixtures could be analyzed by this method provided that the ratios e_{1A}/e_{1B} and e_{2A}/e_{2B} of increase of the Cherenkov counting efficiencies are significantly different from each other because Eqs. (6.68) and (6.69) cannot be solved when e_{1A}/e_{1B} is equal to e_{2A}/e_{2B}. According to Fujii and Takiue (1988c), the magnitude of the increase of Cherenkov counting efficiency with the addition of wavelength shifter for lower-energy β emitters is larger than that for higher-energy β-emitters (Ross, 1976; Takiue et al., 1984). For example, in the case of the ^{36}Cl and ^{32}P mixture, Fujii and Takiue (1988c) report that the increase of Cherenkov counting efficiency (27%) for ^{36}Cl with PPO wavelength shifter is 2.9 times as high as the counting efficiency (9.5%) without wavelength shifter. This was larger than the increase, by the order of magnitude of 1.2, for the ^{32}P Cherenkov counting efficiencies after the addition of wavelength shifter.

X. Radionuclide standardization

The concepts of radionuclide standardization by liquid scintillation, that is, the determination of the absolute activity of samples, upon which the activity of other samples is traceable, are described in detail in Chapter 6 of Volume 1 and Chapter 7 of Volume 2. Radionuclide standardization is not used generally to determine sample activities in the routine measurement of radionuclides in applied research or radionuclides in the environment; rather, radionuclide standardization is a technique required to determine the absolute activity of a sample often to less than 1% uncertainty as a primary standard upon which the activities of other standards may be traced.

Liquid scintillation analysis (LSA) is often used for the standardization of radionuclides because of the higher detection efficiencies achieved in LSA compared to Cherenkov counting. However, under certain circumstances, as explained by Grau Carles and Grau Malonda (1995) and Grau Malonda and Grau Carles (1998a,b), Cherenkov counting can be advantageous in the calibration of certain radionuclides where the detection of low-energy electrons by LSA can complicate the elaboration of the standardization model. In the case of Cherenkov counting, the Cherenkov energy threshold (262 keV in pure water) serves

as a discriminator for low-energy electrons, that is, only electrons of energy above the Cherenkov threshold energy (*i.e.*, $E > 262$ keV) in water are detected and only these electron energy distributions are included in the calculation of the detection efficiency. The concepts and techniques that have been applied to the standardization of radionuclides by Cherenkov counting are included in this section.

A. Cherenkov counting efficiency—detection probability function, CHEREN

The first development of a Cherenkov counting technique, which may be applied universally to the standardization of all radionuclides that emit radiations (beta or gamma) producing the Cherenkov effect, was reported by Grau Carles and Grau Malonda (1995, 1998). The objective of this work was to develop a method for the computation of the Cherenkov counting efficiency, which should correct for previously unexplained discrepancies in the predicted and experimental values. The differences in experimental counting efficiencies between ^{36}Cl and ^{204}Tl serve as an example of such a discrepancy, where the counting efficiency of ^{36}Cl ($E_{\max} = 710$ keV) is 70% greater than the counting efficiency of ^{204}Tl ($E_{\max} = 763$ keV). Although the maximum energy of the β emissions of ^{36}Cl is less than that of ^{204}Tl, the experimental counting efficiency of ^{36}Cl is extraordinarily much greater than that of ^{204}Tl.

New concepts were introduced by Grau Carles and Grau Malonda (1995) to explain unusual Cherenkov counting efficiencies such as those presented in the above example of ^{36}Cl and ^{204}Tl.

These concepts are (1) intrinsic Cherenkov counting efficiency, ε_k, which is the ratio between counted pulses and emitted particles over the Cherenkov energy threshold, and (2) Cherenkov yield, r_k, which is the ratio between emitted particles over the Cherenkov energy threshold and the total number of emitted particles. These terms, to be further defined subsequently, were used to explain the unusual behavior of ^{36}Cl and ^{204}Tl by showing that the intrinsic Cherenkov counting efficiencies of the two radionuclides were similar (10%), whereas the Cherenkov yields of the two differ significantly, namely 65% for ^{36}Cl and 40% for ^{204}Tl.

The method requires prior calibration with two standards, namely ^{36}Cl and ^{32}P, upon which the counting efficiency of any other radionuclide with β emissions or Compton electron energies greater than the Cherenkov threshold energy may be determined. Grau Carles and Grau Malonda (1995) used the new concepts of intrinsic Cherenkov counting efficiency and Cherenkov yield to define the Cherenkov counting efficiency ε_c according to the equation

$$\varepsilon_c = r_k \varepsilon_k, \tag{6.72}$$

where r_k is the Cherenkov yield (*i.e.*, the ratio of the emitted particles over the Cherenkov threshold energy to the total number of emitted particles) and ε_k is the intrinsic counting efficiency (*i.e.*, the ratio of the counted pulses to the emitted particles over the Cherenkov threshold energy), that is,

$$\begin{aligned}\varepsilon_c = r_k \varepsilon_k &= \frac{\text{emitted particles} > E_{th}}{\text{total \# of emitted particles}} \\ &\times \frac{\text{counted pulses}}{\text{emitted particles} > E_{th}} \\ &= \frac{\text{counted pulses}}{\text{total \# of emitted particles}}\end{aligned}$$

where E_{th} is the Cherenkov threshold energy. The Cherenkov yield was obtained by Grau Carles and Grau Malonda (1995) from the β-particle distributions as follows:

$$r_k = \frac{\int_{W_k}^{W_m} N(W)dW}{\int_1^{W_m} N(W)dW}, \tag{6.73}$$

where W_k and W_m are the Cherenkov threshold energy and the maximum β-particle or end-point energy, respectively, and $N(W)$ is the β-particle energy distribution.

The intrinsic Cherenkov efficiency is achieved by counting pulses arising from Cherenkov photon events and relating the number of counted pulses with the detection probability $f(W)$ according to the equation

$$\varepsilon_k = \int_{W_k}^{W_m} N(W) f(W) dW. \tag{6.74}$$

Eq. (6.74) can be used to calculate the counting efficiency of any β emitter, with a known $\beta-$particle energy distribution $N(W)$ over the Cherenkov threshold energy, once the function $f(W)$ is known. The Cherenkov counting efficiency for pure β-particle emitters, which is the ratio of detected to emitted particles is then defined by Grau Carles and Grau Malonda (1998) as

$$\varepsilon_C = \int_{W_k}^{W_m} N(W) f(W) dW \Big/ \int_1^{W_m} N(W) dW \tag{6.75}$$

The end-point energy or energy maximum, W_m, and the Cherenkov threshold energy W_k, are expressed in units of rest mass, that is,

$$W = 1 + \frac{E[\text{keV}]}{511} \tag{6.76}$$

and E is the β-particle energy in keV and 511 is the energy equivalence of the beta-particle rest mass in keV. They defined the emission probability $N(W)$ for a β-particle in the energy range between $W + dW$ as

$$N(W) = C(W)(W-1)^{1/2}(W_m - W)^2 \times WF(Z,W)dW \tag{6.77}$$

where the functions $F(Z,W)$ and $C(W)$ are the electron density ratio (or Fermi function) and the shape factor function of the beta transition, respectively; and Z is the atomic number of the daughter nuclide. The beta spectrum shape factor is an important component of the Cherenkov counting efficiency calculations.

According to the solution of Grau Carles and Grau Malonda (1995, 1998), the function $f(W)$ is zero for energies below the threshold energy, W_k, and unity for electrons (β particles) that have sufficient energy for total detection, that is, the detection probability is nearly 1 for electrons of $E > 1$ MeV or 1000 keV in water. In the regions intermediate to these limits, the detection probability increases exponentially according to the following:

$$\begin{aligned} f(W) &= a(W - W_k)^n, && W_k \le W < W_u \\ f(W) &= 1, && W \ge W_u \end{aligned} \tag{6.78}$$

where W_u is the minimum energy that corresponds to the total detection and a and n are parameters defined by least squares fitting using the radionuclides ^{36}Cl and ^{32}P as standards. When all of the β particles are partially detected $W_m < W_u$, the minimum condition is defined as

$$\min \sum_{i=1}^{\nu} \left[\varepsilon_{k_i} - a \int_{W_k}^{W_m} N_i(W)(W - W_k)^n \, dW \right]^2 \tag{6.79}$$

where ν is the total number of radionuclides involved in the fitting. When $W_m > W_u$ the minimum condition is defined as

$$\min \sum_{i=1}^{\nu} \left[\varepsilon_{k_i} - a \int_{W_k}^{W_u} N_i(W)(W - W_k)^n dW - \int_{W_u}^{W_m} N_i(W) dW \right]^2. \tag{6.80}$$

Both of the above conditions are used to characterize the parameter n and obtain the values of a and W_u by least-squares fitting.

Using ^{36}Cl and ^{32}P as standards, Grau Carles and Grau Malonda applied Eqs. (6.78)–(6.80) to obtain the detection probability function $f(W)$ for the particular liquid scintillation spectrometer they used as follows:

$$f(W) = 0.5424(W - 1.5004)^{1.60}$$

$$1.5005 \le W < 2.9662$$

$$f(W) = 1, W \ge 2.9662$$

The value of 1.5004 for W_k was calculated in light of the fact that the ^{36}Cl and ^{32}P standards were counted in 15 mL of 1M HCl instead of pure water. The index of refraction of 1M HCl reduces the Cherenkov threshold energy to 255.7 keV. Therefore, W_k is calculated as

$$W_k = \frac{255.7\text{keV}}{511\ \text{keV}} + 1 = 1.5004$$

The importance of this technique is that the above detection probability function, once determined, can then be used to calculate the counting efficiency of any other radionuclide that emits β particles or γ rays that produce Compton electrons, over the Cherenkov threshold energy of 255.7 keV in 15 mL of 1M HCl with the particular liquid scintillation spectrometer used. If the solution type (i.e., counting medium), solution volume, vial type, or instrument is changed, the detection probability function is refitted.

Grau Carles and Grau Malonda (1995) reported good agreement between experimental and computed counting efficiencies, as illustrated in Table 6.18. The counting efficiencies of ^{36}Cl and ^{32}P of Table 6.18 show no discrepancy between experimental and calculated values because these two nuclides are used as the standards. The nuclides ^{60}Co and ^{137}Cs deserve attention because both are β and γ emitters.

In the case of ^{60}Co, the β-particle emissions make a negligible contribution to the production of Cherenkov photons; however, its two γ-ray emissions of 1.33 and 1.17 MeV produce Compton electrons of sufficient energy to yield Cherenkov radiation. Therefore, the Cherenkov counting efficiency calculation for ^{60}Co is calculated according to

$$\varepsilon = \varepsilon(\gamma_1) + \varepsilon(\gamma_2) - \varepsilon(\gamma_1)\varepsilon(\gamma_2), \tag{6.81}$$

TABLE 6.18 Experimental and computed Cherenkov counting efficiencies.[a]

Nuclide	Efficiency experimental	Efficiency computed	Discrepancy (%)
^{36}Cl	0.0666	0.0666	0.0
^{204}Tl	0.0402	0.0404	0.6
^{89}Sr	0.374	0.377	0.9
^{32}P	0.468	0.468	0.0
^{90}Sr + ^{90}Y	0.620	0.631	1.8
^{60}Co	0.0561	0.0556	0.7
^{137}Cs	0.0493	0.0475	3.7

[a] *From Grau Carles and Grau Malonda (1995) reprinted with permission from Elsevier © 1995.*

where $\varepsilon(\gamma_1)$ and $\varepsilon(\gamma_2)$ are the counting efficiencies for the Compton electrons produced by each of the two γ rays, and the product of the two efficiencies considers the simultaneous Compton interaction of the two γ rays of ^{60}Co.

The application of this method to the standardization of ^{137}Cs is more complicated, because this nuclide decays by two β branches with emissions over the Cherenkov threshold energy. It reaches secular equilibrium with its daughter nuclide ^{137m}Ba, which undergoes a 662-keV γ-ray decay transition that results in 89% abundance of 662-keV γ-ray emissions and 11% abundance of internal conversion electrons, a fraction of which are above the Cherenkov threshold energy.

The above method was successfully used by Navarro et al. (1997) to determine the counting efficiency and activity of ^{234}Th by Cherenkov counting to within 1.5% uncertainty. The computer program, CHEREN, which includes the beta spectrum shape factor as an important component, for the calculation of the Cherenkov counting efficiency is described by Grau Carles and Grau Malonda (1998) together with the calculated Cherenkov counting efficiencies of 39 radionuclides. The influence of the β-spectrum shape factor on the calculated results was demonstrated in this and other works (Grau Carles, 1995; Grau Carles and Grau Malonda, 1995; 1996b; Grau Malonda and Grau Carles, 2002).

B. Anisotropy detection model—CHEREN2

In an effort yet to reduce further the uncertainty in radionuclide standardization by Cherenkov counting, Grau Malonda and Grau Carles (1998a,b) introduced a new model based on two parameters that depend on the measurement conditions and on the equipment, but not on the nature of the radionuclide. The anisotropic character of Cherenkov radiation reduces the experimental counting efficiency and complicates its theoretical computation. According to the new model, the directional character of Cherenkov radiation and the amount of energy that Cherenkov light must transfer to create one photoelectron at the photocathode are defined as two new free parameters (see Section IX, Chapter 6, Volume 1 for the definition of free parameter). This model offers the advantage of calculating the Cherenkov counting efficiency regardless of the refractive index or acid concentration of the medium as well as it allows the inclusion of physical effects of the counting medium such as the effect of liquid density on the electron range or deceleration and the effects of light absorption bands in the near ultraviolet on the Cherenkov radiation.

As explained by Grau Malonda and Grau Carles (1998a,b), the calculation of the counting efficiency of an electron of energy E requires the evaluation of the total number of photons k emitted in the wavelength interval (λ_1, λ_2) per unit path length of electron travel according to Frank and Tamm (1937) described by the equation

$$\frac{dk}{dx} = 2\pi\alpha\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\left(1-\frac{1}{\beta^2 n^2}\right) \tag{6.82}$$

where α is the fine structure constant, n and β are the index of refraction of the medium and electron relative phase velocity previously described in Eqs. (6.29) and (6.30) of this chapter; and the wavelength interval includes those Cherenkov radiation frequencies to which the photocathode of the PMT is sensitive. Because Cherenkov light is emitted as a cone, a given Cherenkov event is mainly oriented toward one of the two photomultipliers of a 2-PMT LSA (e.g., photomultiplier (A), while the other photomultiplier (B) receives light from the same Cherenkov event that is reflected or diffused by the reflective walls of the counting chamber. Grau Malonda and Grau Carles (1998a,b) define the free parameter α as the anisotropy coefficient, which gives the rate of Cherenkov photons directed toward photomultiplier A, and β as the rate of photons directed toward photomultiplier B where

$$\alpha+\beta = 1 \tag{6.83}$$

When $\alpha = 1$ and $\beta = 0$, the anisotropic properties of the LSA is displayed at a maximum when only photomultiplier A detects the Cherenkov photons originating from a given beta-particle emission and no event is recorder by the LSA in coincidence counting. The minimum value for α is 0.5, corresponding to the maximum value for β. The number of Cherenkov photons traveling directly toward photomultipliers A and B are defined as $k\alpha$ and $k(1-\alpha)$, respectively. If s and w represent the transmission probabilities and photocathode quantum efficiencies, respectively, the number of photons generated at the photocathodes of photomultipliers A and B are written as $ksw\alpha$ and $ksw(1-\alpha)$, respectively. With these variables defined and taking the free parameter q as the product of the probabilities s and w under the assumption that the generation of photoelectrons at the PMT photocathode follows the Poisson law, Grau Malonda and Grau Carles (1998a,b) derived the Cherenkov counting efficiency ε_B of pure β emitters as

$$\varepsilon_B = \int_{E_k}^{E_0} N(E)\{1-\exp[-qk(E)\alpha]\}\{1-\exp[-qk(E)(1-\alpha)]\}dE \tag{6.84}$$

where $N(E)$ is the β-particle energy distribution, α and q are two free parameters defined previously, and E_k and E_0 are the Cherenkov threshold and maximum β-particle energies, respectively, and the function $N(E)$ was normalized according to the following:

$$\int_0^{E_0} N(E)dE = 1 \tag{6.85}$$

For radionuclides that decay by internal conversion the counting efficiency calculation defined by Eq. (6.84) was modified by Grau Malonda and Grau Carles (1998a,b) to account for nine possible electron conversion possibilities. Also, for radionuclides that decay by pure gamma-ray emission, the counting efficiency calculation was expressed to account for Compton electrons with energies above the Cherenkov threshold of the counting medium, as well as to include the gamma-photon escape probability. When both gamma-ray emission and internal conversion processes occur in radionuclide decay, the counting efficiency calculation was expressed as a sum according to both decay probabilities.

The robustness of the calculations for Cherenkov counting efficiency was demonstrated by Grau Malonda and Grau Carles (1998a,b) for several radionuclides in a variety of media and sample volumes, in glass or plastic vials, and with two liquid scintillation analyzers (PerkinElmer 2500 TR and LKB Rack Beta); and they obtained very close discrepancies between experimental and computed counted efficiencies. The free parameters α and q were evaluated for the various sample media and vial types. The value of the anisotropy coefficient α remained a constant value of 0.790 while the parameter q increased for plastic vials and took on the values of 0.181 and 0.179 for HCl and water media, respectively. It was found that the free parameter α was independent of the sample medium, volume, vial material or scintillation spectrometer; whereas, the free parameter q depended substantially on the volume of medium, vial material, and slightly on the nature of the solvent or medium. The following serve as examples of computed counting efficiencies expressed as a decimal (i.e., 100% = 1.0) reported by Grau Malonda and Grau Carles (1998b) with the discrepancy between the computed and experimental counting efficiencies expressed as a percent: ^{36}Cl, 0.0913 (−0.88%); ^{204}Tl, 0.0526 (−1.94%); ^{89}Sr, 0.428 (0.92%); ^{32}P, 0.522 (−1.36%); ^{90}Sr, 0.673 (1.17%), ^{210}Bi, 0.1310 (−0.61%); ^{234m}Pa, 0.542 (0.73%); ^{137}Cs + ^{137m}Ba, 0.0722 (0.41%); and ^{40}K, 0.394 (0.76%).

The anisotropy detection model was developed further by Grau Carles and Grau Malonda (2006) with the publication of the computer program CHEREN2 for the determination of Cherenkov counting efficiencies in radionuclide standardizations. The anisotropy detection model is based on the principle that the generation of photoelectrons at the PMT photocathode obeys the Poisson law; and it makes use of two free parameters for the calculation of the Cherenkov counting efficiency, namely, the anisotropy coefficient α, which gives the rate of Cherenkov photons that are emitted directly toward one of the two photomultipliers, and the coefficient q, which is defined as the average energy that the Cherenkov light must possess to create one photoelectron at the PMT photocathode.

Under the assumption that the generation of photoelectrons at the PMT photocathode follows the Poisson law, Grau Carles and Grau Malonda (1996a, 2006) and Grau Malonda and Grau Carles (1998a,b) describe the counting efficiency ε for one electron of kinetic energy E as

$$\varepsilon(E) = \left(1 - e^{-qk\alpha}\right)\left(1 - e^{-qk(1-\alpha)}\right) \tag{6.86}$$

where α and q are the free parameters defined in the previous paragraph, and k is the number of Cherenkov photons generated by the electron. They then generalize Eq. (6.84) for the Fermi β-particle distributions $N(E)$ to define the computed Cherenkov counting efficiency, $\varepsilon_C^{\text{th}}$, for a pure β-particle emitting nuclide in a transparent medium of refractive index n as

$$\varepsilon_C^{\text{th}} = \int_{E_k}^{E_m} N(E)\varepsilon(E)dE \Big/ \int_0^{E_m} N(E)dE \tag{6.87}$$

and for $\beta-\gamma$-ray emitters, for which the γ-ray contribution to the Cherenkov counting efficiency is small (<2%) the following expression is applied

$$\varepsilon_C^{\text{th}} = \sum_{i=1}^{M} p_i \frac{\int_{E_k}^{E_{m_i}} N_i(E)\varepsilon(E)dE}{\int_0^{E_{m_i}} N_i(E)dE} \tag{6.88}$$

where M is the number of β-decay branches, which have transition energies above the β-particle threshold energy, and p_i is the probability of the decay transition. The threshold energy is computed in CHEREN2 (Grau Carles and Grau Malonda, 2006) from the refractive index, n, of the counting medium according to

$$E_k = \frac{m_0c^2}{\left(1 - 1/n^2\right)^{1/2}} - m_0c^2 \tag{6.89}$$

described previously in this chapter (see Eq. 6.39). For the case of the electron or β-particle, Eq. (6.89) is expressed as described previously in this chapter by Eq. (6.38) or

$$E_{\text{th}} = 511 \text{ keV}\left[\left(1 - \frac{1}{n^2}\right)^{-1/2} - 1\right] \tag{6.90}$$

CHEREN2 includes, as previously discussed, the calculation of the counting efficiency of an electron of energy E, which requires the evaluation of the total number of photons k emitted in the wavelength interval (λ_1 to λ_2) per unit path length of electron travel according to Frank and Tamm theory (1937) described by the equation

$$\frac{dk}{dx} = 2\pi\alpha\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)\left(1 - \frac{1}{\beta^2 n^2}\right) \tag{6.91}$$

where $\beta^2 = (W^2 - 1)/W^2$ and $W = E/m_0c^2 + 1$. Grau Carles and Grau Malonda (2006) include into the above equation an energy-to-range relationship in order to integrate the number of photons k emitted along the particle pathway

x, because this number will vary as the particle loses energy along its path of travel. The range of the electron in centimeters is calculated according to the following empirical formula of Flammersfield (1946) described by Paul and Steinwedel (1955).

$$x = 0.11\left(\sqrt{1 + 22.4E^2} - 1\right)/\rho \qquad (6.92)$$

where ρ is the density of the counting medium and E is the kinetic energy of the β-particle in MeV. See Eq. (1.253) of Chapter 1, Volume 1 where this empirical formula is discussed. The numerator of the equation yields the range of the β-particle in units of g/cm^2; and inclusion of the density in the denominator yields the range in units of cm. More precise ranges and graphs are available from the online computer program ESTAR "Electron Stopping Power and Range" available from the National Institute of Standards and Technology (NIST) at https://physics.nist.gov/PhysRefData/Star/Text/method.html (accessed on August 8, 2018).

In the search for the values of the two free parameters α and q in CHEREN2, a constant value of 0.790 for the anisotropy coefficient α is assumed, as this was demonstrated previously to be the case (Grau Malonda and Grau Carles, 1998a,b). The parameter q is then determined in CHEREN2 by making the difference between the computed and the measured counting efficiencies a minimum for two radionuclide standards ^{36}Cl and ^{32}P. These two radionuclide standards were selected by Grau Carles and Grau Malonda (2006) for three reasons, namely, (i) the radionuclide half-lives are sufficiently long, (ii) the maximum-point energy is below 1 MeV in the case of ^{36}Cl ($E_{max} = 0.714$ MeV) and it is over 1 MeV for ^{32}P ($E_{max} = 1.710$ MeV), which allows for the determination of an average value of q yielding the best results, because the Fermi distributions of the two radionuclides cover a wide range of energies, and (iii) the shape factor functions of ^{36}Cl and ^{32}P are well known. The best value for the parameter q is computed in CHEREN2 that simultaneously agrees with the measured counting efficiencies for ^{36}Cl and ^{32}P by defining the parameters q_1 and q_2 according to the two minimization processes

$$\min_{q_1}\left\{\left|\frac{\varepsilon_C^{th}(^{36}\mathrm{Cl}) - \varepsilon_C^{exp}(^{36}\mathrm{Cl})}{\varepsilon_C^{exp}(^{36}\mathrm{Cl})}\right|\right\} \quad \text{and} \quad \min_{q_2}\left\{\left|\frac{\varepsilon_C^{th}(^{32}\mathrm{P}) - \varepsilon_C^{exp}(^{32}\mathrm{P})}{\varepsilon_C^{exp}(^{32}\mathrm{P})}\right|\right\} \qquad (6.93)$$

where ε_C^{th} and ε_C^{exp} are the computed and experimental Cherenkov counting efficiencies. The optimum values for the coefficient q is calculated in CHEREN2 as the average $(q_1 + q_2)/2$. Grau Carles and Grau Malonda (2006) tested CHEREN2 for the Cherenkov counting efficiency determinations of 39 radionuclides with beta emissions over the Cherenkov threshold energy of 255.96 keV in a counting medium of 1M HCl ($n = 1.341$), the vast majority of which were determined with discrepancies of $<1\%$.

Grau Carles and Grau Malonda (2006) note that counting efficiency calculations are strongly dependent on the shape factor function of radionuclide β-particle transitions. Consequently much effort has been placed on the accurate measurement of β-spectra shape factor functions (Grau Carles, 1995, 2005; Grau Carles and Grau Malonda, 1996b; Grau Carles and Kossert, 2006; 2007; Grau Carles et al., 2008).

The computer program CHEREN2 designed by Grau Carles and Grau Malonda (2006) described in the previous paragraphs was utilized by Kossert (2010) of the Physikalisch-Technische Bundesanstalt (PTB) and Kossert et al. (2014) to facilitate the calculation of the radionuclide beta emission spectra and to account for the variations of the beta spectra shape factor functions $C(W)$ in the measurement of Cherenkov counting efficiencies for the standardization of radionuclides with analyzers equipped with three PMTs and utilization of the triple-to-double channels ratio (TDCR) technique. This PTB model was adapted by Thiam et al. (2017) at the Laboratoire National Henri Becquerel taking into account the physical properties of the specific TDCR measurements. The utilization of analyzers equipped with three PMTs for the standardization of radionuclides by the TDCR method is described subsequently in this chapter.

C. TDCR Cherenkov counting

The Triple to Double Coincidence Ratio (TDCR) efficiency calculation technique is applied to the primary standardization of radionuclides by liquid scintillation, as described in detail in Section IX.C of Chapter 6, Volume 1 and by Cherenkov counting as described subsequently in this section. The reader is invited to peruse that material, as these principles will not be reiterated here.

1. Anisotropy detection model

The anisotropy detection model of Grau Malonda and Grau Carles (1998a,b) and Grau Carles and Grau Malonda (2006) described in the previous Section B was developed for the Cherenkov counting standardization of radionuclides with spectrometers containing two PMTs commonly encountered throughout the world. Kossert (2010) and Kossert et al. (2011a, 2014) and Thiam et al. (2017) describe the same model applied to the standardization of radionuclides with spectrometers, which utilize three PMTs and the triple-to-double coincidence ratio (TDCR) efficiency calculation technique.

In this approach, Kossert (2010) applies a new formula for the determination of the anisotropy coefficient α, and

the free parameter q, which is derived from the ratio of triple to double coincidences. As described previously by Eq. (6.91), the anisotropy model applied to the TDCR Cherenkov counting technique includes in the calculation of the counting efficiency of an electron of energy E, the evaluation of the total number of photons k emitted in the wavelength interval (λ_1 to λ_2) per unit path length of electron travel according to the equation of Frank and Tamm (1937) written as

$$\frac{dk}{dx} = 2\pi\alpha\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)\left(1 - \frac{1}{\beta^2 n^2}\right) \tag{6.94}$$

The empirical equation of Flammersfield (1946) described by Paul and Steinwedel (1955),

$$x = 0.11\left(\sqrt{1 + 22.4E^2} - 1\right)/\rho \tag{6.95}$$

described previously, is applied for the range in centimeters of the electron (*i.e.*, β-particle) as a function of electron energy in MeV and density ρ of the counting medium. Kossert (2010) obtained $k(E)$ by the numerical integration

$$k(E) = \int_{\text{th}}^{E} \frac{dk}{dx}\frac{1}{\rho dE/dx}dE \tag{6.96}$$

where dk/dx is computed according to Eq. (6.94) where the limits "th" refer to the Cherenkov threshold energy and E the maximum or end-point β-particle energy; and the electron stopping powers dE/dx are obtained from linear interpolation of values provided by the ESTAR database of the National Institute of Standards and Technology (ESTAR, 2018, https://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html). Kossert plotted the solution to $k(E)$ for 1M HCl, which was used as the solvent for the radionuclide standardization. The Cherenkov photon production as a function of initial electron energy is illustrated in Fig. 6.38.

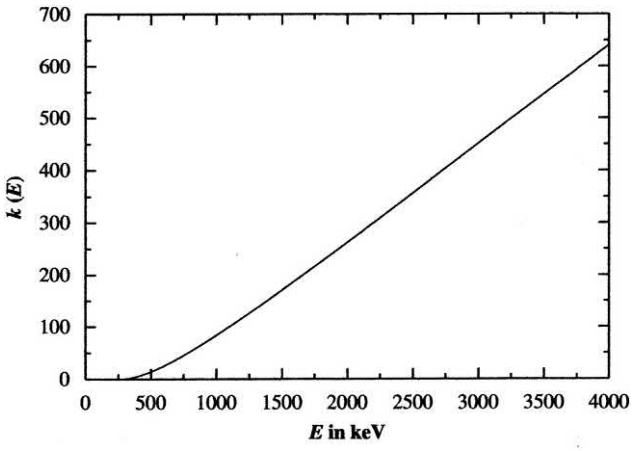

FIGURE 6.38 Number of Cherenkov photons created, $k(E)$, in 1 M mol/L HCl as a function of the initial electron energy. *From Kossert (2010), reprinted with permission from Elsevier © 2010.*

Eqs. (6.84) and (6.85) of Grau Carles and Grau Malonda (1996a,b, 2006) and Grau Malonda and Grau Carles (1998a,b), described previously in this chapter, are combined to give the following expression of the Cherenkov counting efficiency for a spectrometer detection system with two photomultipliers:

$$\varepsilon_2 = \int_{E_{\text{th}}}^{E} N(E)\left(1 - e^{-qk(E)\alpha}\right)\left(1 - e^{-qk(E)(1-\alpha)}\right)dE \tag{6.97}$$

where, as described previously, the coefficient q is a free parameter and α is the anisotropy coefficient.

For measurements with three photomultipliers, Kossert (2010) expresses the Cherenkov counting efficiency for triple coincidences as

$$\varepsilon_T = \int_{E_{\text{th}}}^{E} N(E)\left(1 - e^{-qk(E)\alpha_1}\right)\left(1 - e^{-qk(E)\alpha_2}\right) \times \left(1 - e^{-qk(E)\alpha_3}\right)dE \tag{6.98}$$

where the anisotropy is defined by only one parameter defining the coefficients $\alpha_1 = \alpha$, $\alpha_2 = 3/2(1-\alpha)\alpha$, and $\alpha_3 = 1 - 3/2(1-\alpha)\alpha - \alpha$. Likewise, the Cherenkov counting efficiency for the logical sum of double coincidences was expressed as

$$\varepsilon_D = \int_{E_{\text{th}}}^{E} N(E)\left[\begin{array}{l}\left(1 - e^{-qk(E)\alpha_1}\right)\left(1 - e^{-qk(E)\alpha_2}\right) + \left(1 - e^{-qk(E)\alpha_1}\right)\left(1 - e^{-qk(E)\alpha_3}\right) \\ +\left(1 - e^{-qk(E)\alpha_2}\right)\left(1 - e^{-qk(E)\alpha_3}\right) - 2\left(1 - e^{-qk(E)\alpha_1}\right)\left(1 - e^{-qk(E)\alpha_2}\right) \\ \left(1 - e^{-qk(E)\alpha_3}\right)\end{array}\right]dE \tag{6.99}$$

The Cherenkov radiation is emitted as a cone at a given angle between zero and 41.4 degrees in water dependent on the β-particle energy. Thus, Kossert (2010) considered a solid angle, Ω, of the Cherenkov cone, as a measure of the anisotropy of the Cherenkov photons, and utilized the following semi-empirical formula for the energy-dependent anisotropy coefficient:

$$\alpha(E) = x\left(\frac{2}{3} - \frac{1}{3}\frac{\Omega}{4\pi}\right) = x\left(\frac{1}{2} + \frac{1}{6\beta n}\right) \tag{6.100}$$

where x is the only variable defining the anisotropy; and the value of $x = 0.655$ was used. Kossert utilized the computer program CHEREN2 of Grau Carles and Grau Malonda (2006), which facilitates the calculation of the radionuclide beta spectra and allows for adjusting the beta-spectra shape functions.

This new TDCR Cherenkov counting technique was tested for the activity measurements of the following radionuclides with uncertainties in % reported by Kossert (2010): ^{32}P (0.42%), ^{89}Sr (0.62%), ^{90}Y (0.43%), ^{106}Rh (0.58%), and ^{204}Tl (2.6%). Further work on the TDCR Cherenkov counting technique were reported by Kossert et al. (2011a), which was carried out in light of the fact that initial tests on the standardization of ^{36}Cl revealed high discrepancies with results obtained with liquid scintillation counting. They discovered, that in the case of ^{36}Cl, there was the need to refine the ^{36}Cl shape-factor function in light of beta-spectrum determinations made by Grau Carles (2005) and Rotzinger et al. (2008). Kossert et al. (2011a) derived a new shape-factor function based on the spectral measurements of Rotzinger et al. (2008), which yielded an improved Cherenkov TDCR measurement of ^{36}Cl with a discrepancy of only 0.16% between the calculated and experimental measurement. This also provides confirmation of the beta-spectrum measurements of Rotzinger et al. (2008) for ^{36}Cl.

Kossert (2010) and Kossert et al. (2011a) point out numerous advantages of this technique, particularly in view of the first commercial TDCR liquid scintillation counter (Hidex 300 SL) available from Hidex (Hidex, Oy, Finland). Also, numerous TDCR systems have been constructed worldwide as described in Section IX.C of Chapter 6, Volume 1. Kossert et al. (2011a) reported the first tests indicating that the TDCR standardization method can also be applied with the new Hidex-TDCR counter. The successful application of the commercially available Hidex-TDCR counter to radionuclide standardization by Cherenkov counting is reported by others including Wanke et al. (2012) and Kossert et al. (2014). The Hidex 300 SL TDCR counter commercially available for radionuclide standardization is a modified Hedex 300 SL version of the standard Hidex 300 SL counter referred to as the METRO version. This version provides the coincidences between any pair of the three PMTs. Kossert et al. (2014) compared the Hidex 300 SL (METRO version) with the well-known German home-made TDCR counter of the Physikalisch-Technische Bundesanstalt (PTB) and reported deviations between the experimental and calculated Cherenkov counting efficiencies for ^{90}Y, ^{89}Sr and ^{32}P to be well below 1% for the Hidex 300 SL; and for ^{90}Y the mean relative deviation was less than 0.1%.

Improvements to the free parameter model in the Cherenkov counting standardization technique was introduced by Kossert et al. (2014). These improvements comprise the inclusion of (i) the dependence of the refractive index of water on the wavelength as the threshold energy for the production of Cherenkov photons is wavelength dependent, (ii) the wavelength dependence of the PMT response, and (iii) an account of the potential asymmetry of efficiencies in a detector system with three PMTs. Thus, Kossert et al. (2014) assigned three free parameters to each individual PMT and compared the computed Cherenkov efficiencies for a triple-to-double coincidence ratio (TDCR) system to experimental data for ^{32}P, ^{89}Sr and ^{90}Y. The differences between the calculated and experimental efficiencies were well under 1%.

Mirenda et al. (2014) used a high refractive index 1-butyl-3-methyllimidazolium chloride (BMIMCl) IL (ionic liquid) to standardize an ^{18}F solution. With an index of refraction of $n = 1.54$, the threshold energy for the production of Cherenkov photons is lowered to $\sim$164 keV from $\sim$262 keV for water. Fluorine-18 emits positrons with an E_{max} of 634 keV. The reduction in the threshold energy with the high refractive index IL ($n = 1.54$) made it possible to increase the Cherenkov counting efficiency (ε_D) for the logical sum of double coincidences from $\sim$2% obtained in 1M aqueous solution of HCl ($n = 1.34$) to $\sim$ 7% (Mirenda et al., 2014). They standardized an ^{18}F sample by the TDCR liquid scintillation with ^{18}F in Ultima Gold AB scintillation cocktail and by the TDCR Cherenkov counting method with the ^{18}F in BMIMCl IL. Both methods yielded ^{18}F activities of 67.70 $\pm$ 0.45 Bq/mg and 68.89 $\pm$ 1.62 Bq/mg for the TDCR liquid scintillation and TDCR Cherenkov counting methods.

To improve on the TDCR Cherenkov counting standardization of ^{18}F in the high refractive ionic liquid (BMIMCl), Mirenda et al. (2018) by adding a wavelength shifting highly fluorescent IL, 1-butyl-3-methyllimidazolium-8-hydroxypyrene-1,3,6-trisulfonate (BMIMHPTS) for the Cherenkov counting medium. The BMIMHPTS shifts the emission wavelength of the Cherenkov photons to a wavelength more sensitive to the PMTs. Mirenda et al. (2018) demonstrate that the addition of wavelength shifting BMIMHPTS to the high refractive index BMIMCl IL increased the efficiencies for the logical sum of double coincidences (ε_D) by 124% and 14% for ^{18}F and ^{32}P, respectively. They demonstrate that the addition of BMIMHPTS wavelength shifter breaks the anisotropy of the Cherenkov emission; and the error between the experimental and theoretical efficiencies, for example in ^{32}P, is reduced from 0.64% to 0.27% with one parameter $\alpha = 0.42$ used to describe anisotropic emission of the Cherenkov emission.

Among the advantages of this Cherenkov counting technique are the measurement of ^{90}Y and ^{32}P as standards required for nuclear medicine and the biological sciences, respectively, and the measurement of isotopes of Sr (i.e., ^{89}Sr and ^{90}Sr) and ^{210}Pb useful as standards for applications

in studies of these isotopes in the environment. Also, the method can be used to obtain useful information on the beta spectra of radionuclides in light of the high sensitivity of the method to shape-factor functions.

2. Stochastic GEANT4 model in Cherenkov counting

Bobin et al. (2010) developed a stochastic modeling approach, based on the Monte Carlo code GEANT4, to the TDCR standardization of radionuclides by Cherenkov counting as an alternative to the standard TDCR liquid scintillation technique. The objective of the model was to simulate the various optical processes that occur in the counting chamber as a result of the Cherenkov Effect, which leads to the production of photoelectrons in the three PMTs. They validated the model with measurements of ^{90}Y activity from sources previously standardized by the conventional TDCR liquid scintillation technique.

The GEANT4 simulation toolkit and its applications are described by Agostinelli et al. (2003) and Allison et al. (2006); and recent developments described by Allison et al. (2016), which include refinements to the GEANT4 code. These refinements include a linear decrease in the mean number of Cherenkov photons generated as the radiating particle slows down and a calculation of the reflectivity of optical photons from a metal surface. With GEANT4, Bobin et al. (2010) calculated the coincidences between the photomultipliers by simulating the optical processes that occur inside the TDCR counting chamber as a result of the Cherenkov photons created within the sample solution, sample vial wall, and windows of the three photomultipliers to the ultimate production of photoelectrons at the photocathodes of the three PMTs. Bobin et al. (2010) also confirmed the findings of Thiam et al. (2010) that Cherenkov photons are produced within the windows of the photomultipliers as a consequence of Compton scattering; and that such effects should be included in TDCR efficiency calculations. Thiam et al. (2011) further demonstrated the simulation code GEANT4 as an alternative to the standard model with the standardization of ^{11}C with a relative combined standard uncertainty of 0.85%. which is a radionuclide of short half-life (e.g., ^{11}C, $t_{½} = 20.37$ minutes) and low Cherenkov detection efficiency ($\sim$20%, $E_{max} = 960$ keV). Thiam et al. (2011) emphasize that the GEANT4 code provides an excellent alternative to the standard model; and that the implementation of a stochastic calculation of coincidences between PMTs requires a simulation of the propagation of optical photons from their creation in the optical chamber of the counter to the production of photoelectrons in the PMTs. Also they note that the Cherenkov TDCR measurements for short-lived radionuclides can be a good alternation to liquid scintillation standardization methods, because the measurements are made directly with the radionuclide in aqueous solution where chemical and ionization quenching are nonexistent. Lourenço et al. (2015) demonstrated the use of the GEANT4 code for the standardization of ^{90}Y-labeled resin microspheres used for selective internal radiation therapy (SIRT) for the treatment of liver cancer. Activity concentrations of ^{90}Y were measured with a relative combined standard uncertainty of 0.44%. As an alternative to the classical approach for standardization, Lourenço et al. (2015) point out that the Monte Carlo code GEANT4 toolkit provides all that is needed for the simulation of the transport of the ionizing radiation and the resulting Cherenkov or scintillation photons depending on the method used (Cherenkov counting or LSA). They note that the propagation of each Cherenkov photon produced along the track of the charged particle is simulated with respect to refraction and reflection processes occurring at the interfaces of the components of the optical cavity of the counting chamber. Also, they note that in the GEANT4 modeling, the PMT defocusing is simulated by a second binomial trial using a focusing parameter, which is applied in a similar manner as the free parameter in the analytical model used in liquid scintillation.

a. Production of Cherenkov photons in PMT windows

In the liquid scintillation analysis of γ- and β-γ-emitting radionuclides the response of the liquid scintillation analyzer to the gamma-ray photons is considered a result of cocktail excitation due to Compton electron interactions. Thiam et al. (2010) and Bobin et al. (2010) carried out experimentations and calculations with GEANT4 to demonstrate, that beta- or gamma interactions in the fused-silica windows of the PMTs can produce significant Cherenkov photons; and, that such effects should be included in counting efficiency calculations.

Thiam et al. (2010) placed solid γ-emitting sources of ^{54}Mn (836 keV), ^{137}Cs (662 keV), and ^{60}Co (1173 keV) of known activity within the counting chamber in lieu of a counting vial, as illustrated in Fig. 6.39. For each γ-emitting source they obtained significant responses for double and triple coincidences. They concluded that a strong correlation between the counting of double coincidences and the TDCR ratio indicated that Compton diffusion in the windows of the PMTs leads to the emission of Cherenkov photons. Thiam et al. (2010) point out that the fused silica windows of the PMTs have a refractive index $n = 1.47$ at 400 nm, which would attribute to the windows a Cherenkov threshold energy of 186 keV for electrons, as calculated according to Eq. (6.38) described earlier in this chapter.

Simulation based on the Monte Carlo GEANT4 provided confirmation of the Cherenkov Effect in the PMT windows. Thiam et al. (2010) calculated the double

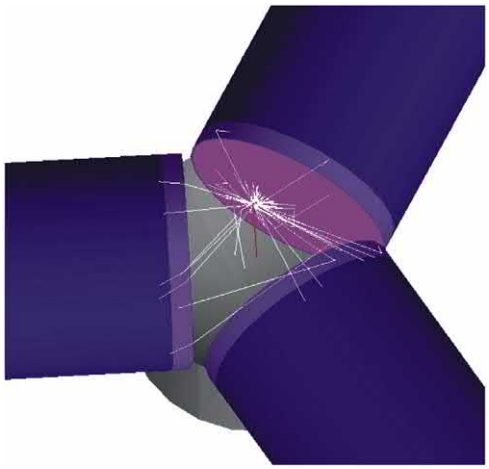

FIGURE 6.39 Tracking of the Cherenkov photons created by Compton diffusion in a photomultiplier window. It illustrates the illumination of the other photomultiplier windows leading to double or triple coincidences. coincidences from the simulated Cherenkov photons refracted at the interface between the fused silica window of a PMT and its photocathode. The experimental and calculated double coincidence efficiencies are provided in Table 6.19. The calculation of the double coincidences included various physical processes such as the creation and propagation of the Cherenkov photons, and refraction and reflections in the optical cavity of the counter. Table 6.19 illustrates also the increase in double coincidence efficiencies proportional with the γ-energies obtained by experiment were confirmed in the simulation. This effect was explained as due to the creation of anisotropic Cherenkov photons along the trajectory of the Compton electrons arising from Compton diffusion in the photomultiplier windows. Cherenkov photons illuminate all photomultipliers leading to double and triple coincidence counting.

TABLE 6.19 Experimental and Calculated Double Coincidence Efficiencies for Different γ-energies.[a]

γ-ray emission	Experimental double coincidence efficiency (%)	Calculated double coincidence efficiency (%)
662 keV (Cs-137)	0.66 (5)	0.56 (7)
835 keV (Mn-54)	1.00 (4)	1.1 (1)
1173 and 1332 keV (Co-60)	4.5 (1)	3.6 (2)

Thiam et al. (2010) conclude that detection efficiency measurements based on the TDCR and CIEMAT/NIST methods of primary radioactivity measurements by liquid scintillation should include the existence of Cherenkov photon generation in the photomultiplier windows. Bobin et al. (2010) provided additional evidence for the production of Cherenkov photons in the fused silica PMT windows by high-energy (>1 MeV) β-particles, that can reach the PMT windows from the counting vial. This is discussed in the following section.

b. Standardization of Yttrium-90

Radionuclide standardization by liquid scintillation requires the determination of a free parameter (see Section IX of Chapter 6, Volume 1). Standardization by Cherenkov counting, as described above by the Anisotropy Model, requires the use of a second parameter, α, the anisotropy coefficient, which characterizes the directional properties of Cherenkov photons. Rather than use an additional free parameter, Bobin et al. (2010) applied the TDCR method to Cherenkov counting using stochastic modeling based on the Monte Carlo code GEANT4. The model was used to calculate the coincidences between the photomultipliers by simulating the various optical processes of the Cherenkov photons emitted by a radionuclide in aqueous solution from a counting vial in a TDCR counter. The stochastic method of the TDCR Cherenkov method was validated with the activity determination of ^{90}Y.

Various tools in GEANT4 were selected by Bobin et al. (2010) and Lourenço et al. (2015) to simulate different physical processes that occur in the optical chamber (illustrated in Fig. 6.40) of the TDCR counter including properties of Cherenkov emission in transparent media (aqueous solution, borosilicate glass vial walls, and fused silica photomultiplier windows), Cherenkov threshold, anisotropic emission, and continuous spectral distributions of the Cherenkov photons. The simulation of electrons and Bremsstrahlung-generated photons were also included. Polyethylene plastic vials were expected to yield better detection efficiencies; however, Bobin et al. (2010) considered it more practical to carry out the initial modeling tests with borosilicate glass vials, which have more defined optical properties (e.g., refractive index and optical transmission).

Bobin et al. (2010) and Lourenço et al. (2015) took into consideration the creation of Cherenkov photons in the wall of the counting vial and fused silica photomultiplier window; although most of the Cherenkov photons arise from the counting solution. When the β-particle energy is sufficient, it can reach the photomultiplier window creating Cherenkov photons in the fused silica of the PMT window.

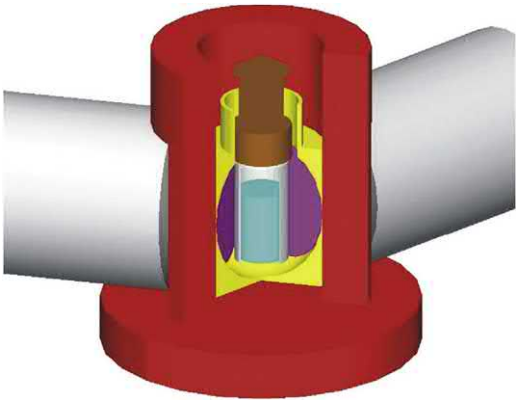

FIGURE 6.40 GEANT4 modeling of the TDCR counter including the counting vial for Cherenkov primary measurements. The counting vial is hung inside the optical chamber using a blackened element. A reflecting Teflon cavity (63 mm diameter) is modeled using a "dielectric-metal boundary with a lambertian-type reflectivity of 95%. For the color version of this figure, the reader is referred to the online version of the book. *From Bobin et al. (2010), reprinted with permission of Elsevier © 2010.*

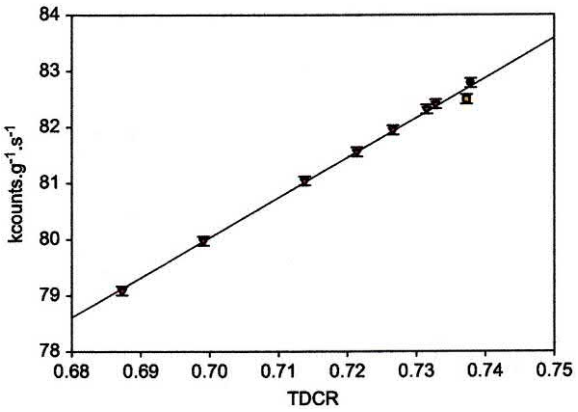

FIGURE 6.41 Counting rates per mass (logical sum of double coincidences) plotted according to the experimental TDCR value in the case of three different ^{90}Y sources. Photomultiplier defocusing was applied to one of these samples (triangular plots). *From Bobin et al. (2010), reprinted with permission of Elsevier © 2010.*

Cherenkov photons can also arise from the PMT window as a consequence of Compton scattering from high-energy Bremsstrahlung radiation from the decelerating β-particle. Bobin et al. (2010) found the effect of Bremsstrahlung to be less significant; however, they determined that as much as $\sim 0.25\%$ of the measured radionuclide activity concentration is due to Cherenkov photons produced outside of the counting solution and vial, *i.e.*, in the PMT windows. To confirm this, they used a black cover around the counting vial to absorb the Cherenkov photons arising from the counting solution and vial wall; and the ^{90}Y detection efficiency to double coincidences amounted to $\sim 1.3\%$. Bobin et al. (2010) tested the modeling, based on GEANT4, using the same procedure applied in the case of TDCR liquid scintillation measurements. For that purpose, systematic trends were checked for activity concentrations determined according to different TDCR values obtained by defocusing the photomultipliers. An example of count rates of the logical sum of double coincidences for three ^{90}Y sources according to various TDCR values are illustrated in Fig. 6.41. The count rates for one of these sources are plotted according to various TDCR values obtained by defocusing the photomultipliers. The stochastic calculations included a simulation of the photomultiplier defocusing to alter the detection efficiency. As explained by Bobin et al. (2010), the calculation of double and triple coincidences is based on a second binomial trial applied to the photoelectrons produced at each PMT bialkali photocathode. With this objective, they used a focusing parameter as the probability of a photoelectron to reach the first dynode. This focusing parameter would be comparable to the free parameter used in the liquid scintillation method described in Chapter 6 of Volume 1. For each experimental TDCR value, the detection efficiency to double coincidences between photomultipliers is calculated by adjusting the focusing parameter.

Maximum ^{90}Y detection efficiencies (double coincidences) of 70% were reported with some variability depending on the shape factors used for the β-spectrum calculation. A homemade code based on the work of Grau Malonda (1999) and Wilkinson (1970) was used to test the simulation sensitivity to the calculated ^{90}Y β-spectrum according to three shape factors. Activity determinations by this stochastic Cherenkov TDCR method agreed with ^{90}Y standardized by the TDCR liquid scintillation method with a relative combined standard uncertainty of 0.37%

Bobin et al. (2010) conclude that Cherenkov counting may be used as an alternative to liquid scintillation, as samples are less sensitive to the time required by liquid scintillation for the chemical stability of samples; and Thiam et al. (2011) report favorable tests for the standardization of the short-lived ^{11}C, which is commonly used in radiopharmaceuticals. Also they conclude, that in the case of γ-emitters, consideration should be given to the emission of Cherenkov photons as a result of Compton scattering in PMT windows in order to avoid biases that can be encountered in the standardization of radionuclides, such as ^{54}Mn (Thiam et al., 2010 and Bobin et al. (2010).

D. Standardization of ^{210}Pb

The first primary standardization of ^{210}Pb by Cherenkov counting was reported by Arinc et al. (2011). This work is quite unique in its approach as it involves a combination of Cherenkov counting of the daughter nuclide ^{210}Bi in combination with the CIEMAT/NIST liquid scintillation efficiency tracing technique. The decay chain of ^{210}Pb, illustrated in Fig. 6.42, is favorable to its standardization by

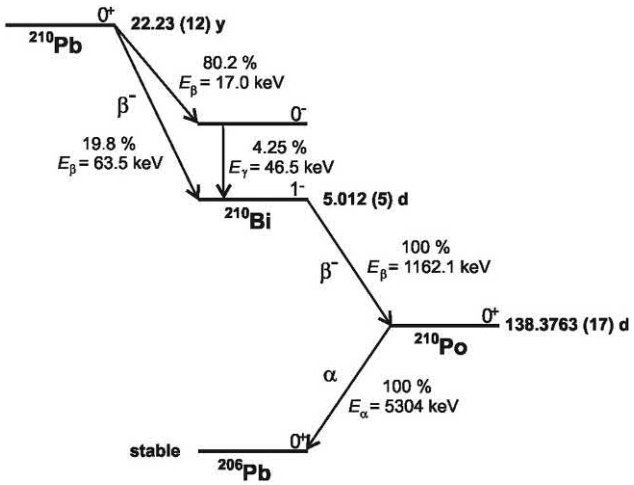

FIGURE 6.42 Simplified decay chain of ^{210}Pb. *From Arinc et al. (2011), reprinted with permission from Elsevier © 2011.*

Cherenkov counting. Only its ^{210}Bi daughter nuclide decays by high-energy β-emission sufficient to produce the Cherenkov Effect. Neither the weak β-particles from the decay from ^{210}Pb, the weak γ-emissions from the decay of ^{210}Bi, nor the α-emissions from the decay of ^{210}Po can interfere with the Cherenkov counting of the ^{210}Bi daughter nuclide in the primary standardization of the ^{210}Pb.

A solution of ^{210} Pb at or near secular equilibrium was standardized by Arinc et al. (2011) by the following basic steps: (1) The ^{210}Po is removed from the ^{210}Pb/^{210}Bi on a column of Sr Spec resin. (2) The ^{210}Pb and ^{210}Bi are separated on a second column of Sr Spec resin. (3) Aliquots of ^{210}Bi are taken and prepared in Ultima Gold liquid scintillation cocktail in counting vials for standardization by the CIEMAT/NIST efficiency tracing technique with ^{3}H (see Chapter 6, Volume 1). (4) Aliquots of ^{210}Bi and ^{210}Pb are taken and placed into separate plastic counting vials with inactive carrier in 2 mol/dm^3 HNO_3 for Cherenkov counting. (5) The Cherenkov count rates of the separated ^{210}Bi and ^{210}Pb samples prepared in the previous step were measured repeatedly and alternately with samples of standardized ^{210}Bi as a function of time for 33 days. (6) The ingrowth and decay of ^{210}Bi in the ^{210}Pb solution; and a least-squares fit to the decay curve of ^{210}Bi was used to determine the activity concentration of ^{210}Pb and ^{210}Bi at the time of separation. General ingrowth and decay calculations relevant to secular equilibrium are provided in an earlier paper by the writer (L'Annunziata, 1971) and described in detail in Chapter 1, Volume 1. The precise calculations used in the case of the secular equilibrium between ^{210}Pb(^{210}Bi) are given by Arinc et al. (2011).

The alternate counting of standardized ^{210}Bi with the separated ^{210}Pb and ^{210}Bi was carried out by Arinc et al. (2011) to determine the Cherenkov counting efficiency as a function of time. An average Cherenkov counting efficiency for the ^{210}Bi was found to be 0.1406 ± 0.0002. The CIEMAT/NIST standardization of the ^{210}Bi required correction for ingrowth of ^{210}Po. Also, for the standardization of ^{210}Bi, the beta shape factor was taken from Grau Carles and Grau Malonda (1996b) and a *kB* value of 0.0075 MeV was used for the standardization. The theoretical counting efficiency of the ^{210}Bi for the CIEMAT/NIST standardization was computed using a National Physics Laboratory beta code based on the EFFY code of García Toraño and Grau Malonda (1985). The ^{210}Pb standardization by Cherenkov counting was reported by Arinc et al. (2011) to have a combined relative standard uncertainty of 0.66%.

E. Routine TDCR activity analysis

The application of the Hidex 300 SL TDCR counter to the routine Cherenkov counting for the activity analysis of radionuclides emitting beta-particles with sufficient energy to produce the Cherenkov effect, such as ^{36}Cl, ^{89}Sr, ^{32}P and ^{90}Sr/^{90}Y, has been demonstrated by Yang et al. (2017), Amano et al. (2016), Coha et al. (2016), Jäggi and Eikenberg (2014), Olfert et al. (2014) and Tayeb et al. (2014). The Cherenkov detection efficiencies of three commercially available liquid scintillation analyzers equipped with differing numbers of PMTs, namely the Hidex 300 SL (3 PMTs), the Tri-Carb 3180 (2 PMTs), and the Triathler (1 PMT), were compared by Coha et al. (2016). With standards of ^{36}Cl, ^{32}P, ^{89}Sr and ^{90}Y, Coha et al. (2016) conclude that the best Cherenkov counting efficiencies are obtained with the Hidex 300 SL (see Fig. 6.43) and when methanol is used as a solvent; and the low-level versions of the Tri-Carb and Hidex 300 SL are comparable in Cherenkov detection efficiency. The lower counting efficiency of a low-level counting mode (LLCM), such as the Tri-Carb LLCM illustrated in Fig. 6.43 is expected, because instrument settings are adjusted to count low-levels of activity with greatly reduced background at a cost of detection efficiency yielding higher FOMs. The Triathler, produced by Hidex, Oy, Finland) is a small and robust portable instrument equipped with only 1 PMT. As reported by Coha et al. (2016), the Triathler instrument is suitable for monitoring of surface contamination via wipe tests from one laboratory to another; and it can be taken into the field for emergency response applications for rapid on site environmental radiation monitoring.

The application of Cherenkov counting in the routine analysis of radionuclide activity is discussed in more detail further on in this chapter.

XI. Gamma ray detection and discrimination

Gamma radiation can produce Cherenkov photons indirectly through gamma-ray photon−electron interactions as the gamma radiation travels through a transparent medium. The number of photons emitted by a Cherenkov detector is generally only approximately 1% of the number emitted by a good scintillator for the same gamma-ray energy loss (Sowerby, 1971). Although the Cherenkov detection efficiencies of gamma radiation are relatively low, unique applications of the Cherenkov Effect for the analysis and discrimination of gamma radiation exist, and the effect plays an important role as a source of background in various methods of radioactivity analysis. One should always be aware of the potential for gamma radiation to produce Cherenkov photons.

An auspicious outcome of the production of Cherenkov photons by gamma radiation is the potential to discriminate against gamma radiation that is of insufficient energy to produce the Cherenkov effect. Gamma rays that penetrate a transparent medium will produce Cherenkov photons via Compton interactions (see Fig. 6.44) provided the gamma-ray photons are of sufficient energy to produce Compton electrons with energies above the threshold energy for the production of Cherenkov photons in that medium. Deleterious background radiation produced by Compton scattering can be reduced with the proper selection of a detector consisting of a Cherenkov radiator with a threshold energy below which Cherenkov photons will not be produced.

The transfer of gamma-ray photon energy (E_γ) to an atomic electron via a Compton interaction produces a Compton electron with energy, E_e, within the range

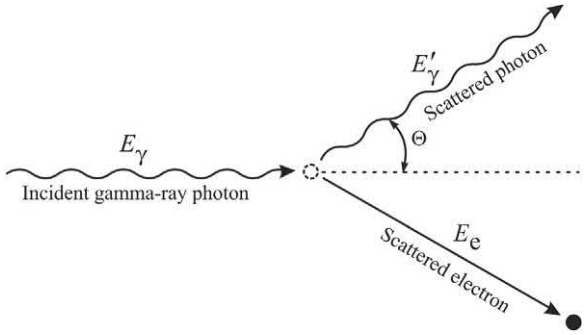

FIGURE 6.44 A Compton interaction whereby an incident gamma-ray photon (E_γ) collides with an atomic electron. Gamma-ray photon energy is transferred to the electron, which is ejected from the atom. The gamma-ray photon is scattered (E'_γ) at an angle (Θ) to the incident photon trajectory. *From L'Annunziata (2016); reprinted with permission from Elsevier 2016.*

between near zero and a maximum. Near zero energy would be transferred to an atomic electron when the gamma-ray photon only glances off the atomic electron; and the maximum energy would be transferred when the gamma-ray photon makes a head-on collision with the atomic electron and the angle of scatter (Θ) is 180 degrees to the incident photon trajectory. The magnitude of the scattered electron energy (E_e) may be expressed by the equation

$$E_e = E_\gamma - E'_\gamma - \phi \tag{6.101}$$

where E_γ and E'_γ are the incident and scattered photon energies, respectively; and ϕ is the electron binding energy. The electron binding energy can be neglected, as it is negligible compared to the incident and scattered photon

energies. Thus, the scattered electron energy (E_e) can be expressed as

$$E_e = E_\gamma - E'_\gamma \tag{6.102}$$

The expression for the scattered photon energy (E'_γ) is a function of the incident photon energy (E_γ), the angle of photon scatter (Θ) and the rest mass of the electron ($m_0c^2 = 0.511$ MeV); and it is written as

$$E'_\gamma = \frac{E_\gamma}{1 + (E_\gamma/0.511)(1 - \cos\Theta)} \tag{6.103}$$

An excellent derivation of Eq. (6.103) is provided by Lilley (2001). When there is a maximum incident photon energy transfer to the atomic electron, there is a head-on collision of the photon with the atomic electron; and the photon is backscattered where $\Theta = 180$ degrees. Thus, under circumstances where there is maximum photon energy transfer to an atomic electron with $\Theta = 180$ degrees, the scattered photon energy is written as

$$E'_\gamma = \frac{E_\gamma}{1 + (2E_\gamma/0.511)} \tag{6.104}$$

And the maximum scattered electron energy is written as

$$E_e = E_\gamma - \frac{E_\gamma}{1 + (2E_\gamma/0.511)} \tag{6.105}$$

where E_γ is the gamma-ray photon energy in MeV and the term $E_\gamma - \left[E_\gamma \big/ \left(1 + \left(2E_\gamma \big/ 0.511\right)\right)\right]$ defines the scattered photon energy at 180 degrees Compton scatter as previously defined in Chapter 1, Volume 1.

To produce Cherenkov photons, the Compton electron must possess energy in excess of the Cherenkov threshold energy, E_{th}, defined by Eq. (6.38) or (6.39) derived previously in this chapter, that is

$$E_{th} = 511 \text{ keV}\left[\left(1 - \frac{1}{n^2}\right)^{-1/2} - 1\right] \tag{6.106}$$

For example, the threshold energy E_{th} for electrons in water, at an index of refraction $n = 1.333$ (at 20°C and at the sodium line, *i.e.*, 589.0 nm), according to Eq. (6.106) is calculated to be 262 keV. (The reader may find small differences in the calculated threshold energy in the literature depending on the index of refraction, which is wavelength specific). A Compton electron must possess, therefore, energy in excess of 262 keV to produce Cherenkov photons in water. In this case, however, the gamma-ray photon must possess an energy in excess of 421 keV calculated according to the inverse of Eq. (6.105) above or

$$E_\gamma = E_e + \frac{E_\gamma}{1 + (2E_\gamma/0.511)} \tag{6.107}$$

where E_e is the maximum Compton electron energy. Thus, from the above Eq. (6.107), the equation for the threshold gamma-ray photon energy for the production of Cherenkov photons from Compton electrons in any transparent medium can be written as

$$(E_\gamma)_{th} = (E_e)_{th} + \frac{(E_\gamma)_{th}}{1 + \left(2(E_\gamma)_{th}/0.511\right)} \tag{6.108}$$

where $(E_\gamma)_{th}$ is the threshold gamma-ray photon energy for the production of Cherenkov photons from Compton electrons and $(E_e)_{th}$ is the threshold electron energy for the production of Cherenkov photons in a transparent medium. For example, if we take the scattered electron energy E_e to be 0.262 MeV, which is the threshold electron energy, $(E_e)_{th}$, for Cherenkov photon production in water, we can calculate the threshold gamma-ray energy for the production of Cherenkov photons in water as

$$\begin{aligned}(E_\gamma)_{th} &= 0.262 \text{ MeV} + \frac{(E_\gamma)_{th}}{1 + \left(2(E_\gamma)_{th}/0.511\right)} \\ &= 0.421 \text{ MeV}\end{aligned} \tag{6.109}$$

Threshold gamma-ray photon energies will vary according to the index of refraction of the medium, and these are provided graphically in Fig. 6.45 for gamma radiation and electrons or beta particles.

Although Cherenkov detection efficiencies for gamma-ray Compton electrons are low, the phenomenon is applied to both detect and discriminate against gamma radiation of energy below the threshold energy for the production of Cherenkov photons. For example, threshold detectors of the proper index of refraction can be selected to provide the following advantages over other low-energy detectors to discriminate against Compton scatter background radiation. A variety of media, which vary significantly in refractive index, can be selected to discriminate against gamma radiation of specific energy. For example, silica aerogels of low refractive index ($n = 1.026$) can be used to discriminate against gamma rays of relatively higher energy (2.0 MeV) while a transparent medium of high refractive index such as flint glass ($n = 1.72$) can serve to discriminate against relatively low-energy gamma radiation (0.25 MeV). Fig. 6.45 illustrates the potential for gamma-ray Compton electron and beta-particle or electron energy discrimination according to refractive index of the detector medium.

Sowerby (1971) points out that Cherenkov detectors provide the following advantages over other detectors for low-energy gamma radiation:

- **(i)** Cherenkov detectors are insensitive to gamma rays of energy less than the Cherenkov threshold energy for the gamma-ray Compton electrons,
- **(ii)** The threshold energy can be set by the refractive index of the transparent medium, and
- **(iii)** The Cherenkov radiator provides instantaneous light emission unlike scintillation light from a phosphor,

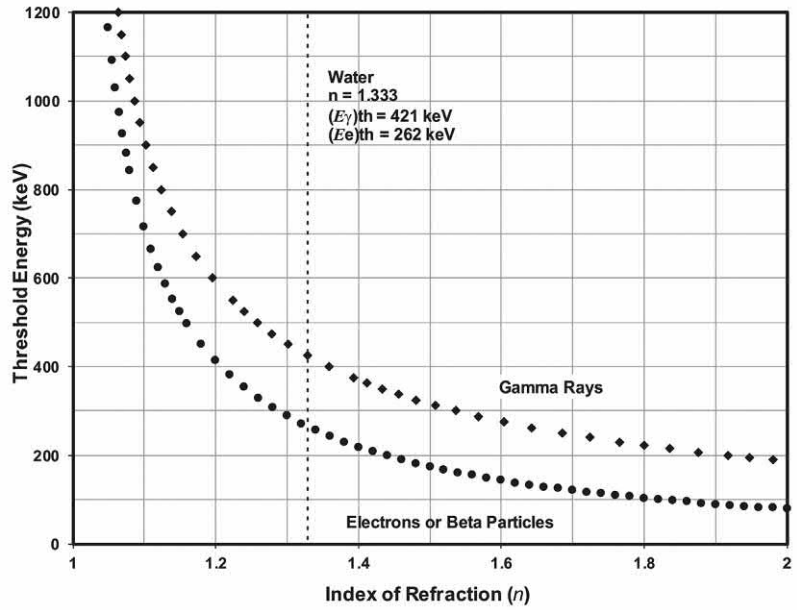

FIGURE 6.45 Threshold energies for the production of Cherenkov radiation as a function of index of refraction of the detector medium for gamma rays and electrons or beta particles. The threshold energies for electrons or beta particles are calculated according to Eq. (6.106), and the gamma-ray photon threshold energies are calculated according to Eq. (6.108) as the gamma rays that yield Compton electrons of the threshold energy via 180 degrees Compton scatter. The vertical broken line at n = 1.33 identifies the index of refraction of water, which crosses at the threshold energy of 262 keV for electrons or beta-particles and 421 keV for Gamma-ray-created Compton electrons. *From L'Annunziata (2016), reprinted with permission from Elsevier © 2016.*

which has a characteristic decay time. Therefore, Cherenkov detectors can provide most accurate timing information.

Rose and Erickson (2015) have calibrated Cherenkov detectors constructed of quartz ($n = 1.4585$ at 588 nm) for the interrogation scanning of cargo containers with monoenergetic photons. They note that scintillator detectors have a decay time measured in microseconds; whereas Cherenkov photon emissions are nearly instantaneous and with fast pulse processing equipment the Cherenkov photons can be measured in picoseconds. They confirm that quartz has unique properties advantageous as a Cherenkov radiator for photon imaging from gamma-ray Compton electrons, which are the following: (i) quartz has a higher density than most materials used as a Cherenkov radiator, such as water or acrylic, permitting the use of smaller detectors to match photon interaction probability, (ii) Quartz is not hydrophilic like many solid scintillation detectors; and it is resistant to thermal expansion in a wide range of operating temperatures (0−40°C), (iii) Due to the available high purity of quartz, it has a high internal reflectivity allowing more Cherenkov photons to reach the PMT, (iv) The quartz can be easily light-proofed; and it is resistant to neutron activation and weather conditions. The index of refraction of quartz (n = 1.4585) provides a 0.191 MeV beta particle or electron threshold energy for the production of Cherenkov photons calculated according to Eq. (6.106) and a gamma-ray Compton electron Cherenkov threshold of 0.336 MeV calculated according to Eq. (6.108). The two threshold energies are illustrated with the vertical broken line for quartz in Fig. 6.46. The calculated gamma-ray Compton electron Cherenkov threshold of 0.336 MeV guarantees that no Compton electron arising from a gamma-ray photon under 0.336 MeV will be detected. Moreover, the calculated gamma-ray Compton electron threshold energies represent the maximum Compton electron energies that arise from head-on collisions of gamma-ray

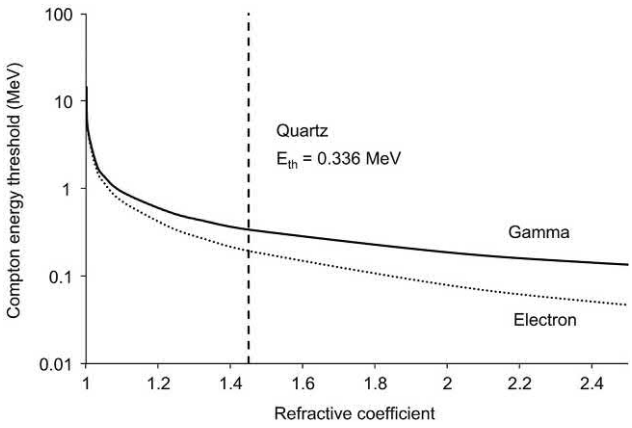

FIGURE 6.46 Compton energy threshold energies on a logarithmic scale (solid Gamma line) are plotted against the refractive index (coefficient). The dotted line is the curve for the beta-particle or electron threshold energies for the production of Cherenkov photons in a transparent medium. The vertical broken line is that of quartz with a refractive index of 1.4585. The line crosses at it Compton energy threshold at 0.336 MeV for the production of Cherenkov photons by gamma-ray Compton interactions and its electron or beta-particle energy threshold of 0.191 MeV for the production of Cherenkov photons in a transparent medium. *Figure from Rose and Erickson (2015); reprinted with permission from Elsevier © 2015.*

photons with atomic electrons. An auspicious outcome is that these interactions are rare, as noted by Rose and Erickson (2015), particularly at lower energies; and in the case of quartz, signal generation from these Compton electrons are low until approximately 0.55 MeV gamma-rays enter the detector, which is referred to as the effective threshold. Thus, in the case of quartz, a large portion of the background radiation is below the effective threshold of 0.55 MeV, which does not produce any signal in the detector.

Rose and Erickson (2015) demonstrate that Cherenkov detectors can be calibrated with gamma-ray energy sources; however, with much lower resolution than that available with scintillation detectors. Cherenkov detectors do not provide the photopeak resolutions available with solid scintillation detectors. By coupling a quartz Cherenkov radiator to a PMT, Rose and Erickson (2015) demonstrated that certain characteristics of the Cherenkov Compton emission spectra, such as tail slopes, inflection points, and shoulder of the emission spectra can be used to assign maximum energy deposition, most probable Compton electron energy corresponding to the energy of the incident gamma-ray photon, and average energy deposition in the Cherenkov detector. Fig. 6.47 illustrates one example of the Cherenkov emission spectra produced by several gamma-ray sources of increasing gamma-ray energy from 662 to 4440 keV. The peaks and shoulders of the spectra illustrated provide information on the average energy transferred to the Compton electron during Compton scattering in the Cherenkov detector. For example, Rose and Erickson (2015) point out that the peak or shoulder at 2.7 MeV in the PuBe spectrum is the average energy transferred to a Compton electron in the 4.4 MeV scattering event. Average energies transferred to a Compton electron by the Co-60 and Th-232 can also be derived from the shoulders of their respective spectra. However, for the lower energy gamma source of Cs-137, the average energy from Compton scattering cannot be derived.

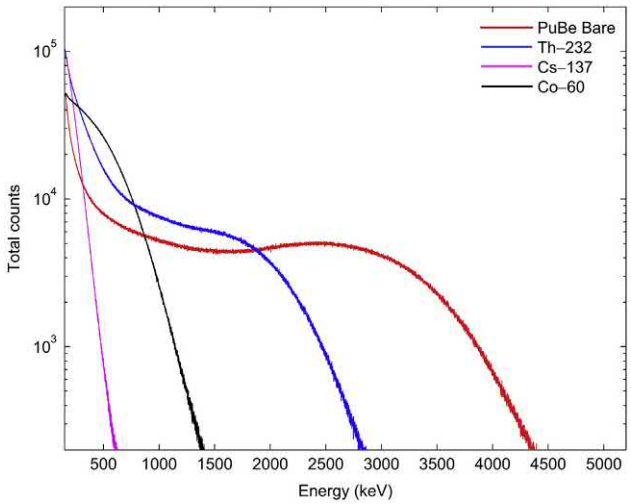

FIGURE 6.47 Calibrated spectral response of a 2-inch (5.08 cm) long quartz Cherenkov detector to gamma-ray sources. The spectra from left to right with photon energy in parenthesis are from Cs-137 (662 keV), Co-60 (1173 and 1332 keV), Th-232 (1614 keV maximum) and PuBe (4400 keV). The color coding of the spectra is visible in the electronic version of the figure. *From Rose and Erickson (2015); reprinted with permission from Elsevier © 2015.*

Another application of gamma-ray detection is the Cherenkov verification technique used in nuclear safeguards to verify the authenticity of irradiated nuclear fuel, which is one of the important tasks performed by the International Atomic Energy Agency (IAEA). The IAEA nuclear safeguards program audits the national declarations of fuel inventories to insure no illicit diversion of nuclear material has occurred. High levels of gamma radiation are emitted by fission products in irradiated nuclear fuel. The irradiated fuel stored under water will produce Cherenkov light as a result of Compton scattering in the water surrounding the fuel. A Digital Cherenkov Viewing Device (DCVD) containing a UV-transmitting lens coupled to a UV-sensitive charge-coupled device (CCD) and image monitor enables the real-time imaging of the UV light portion of the Cherenkov radiation in the presence of normal room lighting (Attas et al., 1990, 1992; 1997; Kuribara, 1994; Kuribara and Nemoto, 1994; Lindsey et al., 1999; IAEA, 2003; Chen et al., 2007; Håkansson and Jonter, 2007; Molander, 2008; Zendel, 2008; Chen et al., 2010; Grape et al., 2010; Branger et al., 2014). The presence of fission products and the nature of their distribution, as indicated by the Cherenkov glow, are used as evidence of fuel verification. As noted by Rossa and Peerani (2013), over 80% of the material currently placed under nuclear safeguards is in the form of spent fuel assemblies. The main goal of nuclear safeguards inspections is to verify that no nuclear material has been diverted to other purposes; and the Digital Cherenkov Viewing Device is used to detect the gross and partial defect from the assembly by viewing the Cherenkov light emitted from Compton electrons and beta-particles emitted from nuclear fuel assemblies stored in water pools (Branger et al., 2014). Gross defect is the replacement of an entire fuel assembly with a dummy made of other material such as natural uranium, while partial defect relates to the removal of fuel pins inside the fuel assembly (Rossa and Peerani, 2013).

XII. Particle identification

Cherenkov counters are applied in particle physics research for the determination of particle mass (m) and velocity (β) for particle identification (PID). Cherenkov detectors of various designs are applied to the discrimination and identification of high-energy particles, among which are threshold and differential Cherenkov counters,

ring-imaging Cherenkov (RICH) detectors, as well as Cherenkov counters that utilize time of propagation (TOP) and time of flight (TOF) measurements. Extensive reviews on the applications of Cherenkov detectors to particle identification are available in the journal literature including Križan (2017, 2013, 2009, 2007), Harnew (2014), Lippmann (2012), Engelfried (2011), Nappi (2011), Iijima (2010), Websdale (2008), Ullaland (2003) and Va'vra (2003). A concise overview of the principles and techniques applied to the application of the Cherenkov effect to particle identification will be given here. For more comprehensive coverage of the instrumentation and techniques, the reader may peruse the extensive review articles cited above.

A. Threshold and differential Cherenkov counters

As defined by Denisov and Stoyanova (2006), *threshold Cherenkov counters* are those than can detect all particles with velocities $\beta > 1/n$, where β is the relative phase velocity of the particle (i.e., v/c or velocity of the particle divided by the speed of light in a vacuum) and n is the refractive index of the detector medium. Lippmann (2012) describes the threshold counter as one which will measure the intensity of the Cherenkov photons to measure particles with velocities exceeding β, and classifies the *differential counter* as one which will focus only Cherenkov photons of a certain emission angle onto a detector and thus detect particles in a narrow interval of velocities, such as described by Abbon et al. (2015) and Lurkin et al. (2017). Also, Križan (2017) defines a threshold counter as one that will discriminate between particles that are below the Cherenkov threshold from those that are above threshold, as only those particles above the Cherenkov threshold will produce Cherenkov photons. The Cherenkov emission angle (θ) is, as described previously by Eq. (6.1), a function of the particle phase velocity and refractive index of the detector medium, or $\cos\theta = 1/\beta n$. A third type of counter described further on in this chapter is the *imaging Cherenkov detector*, which is defined by Lippmann (2012) as the detector that makes maximum use of the available information (Cherenkov angle and number of photons produced) and divided into two main categories, namely, RICH (Ring Imaging Cherenkov) and DIRC (Detection of Internally Reflected Cherenkov light) devices. The DIRC devices include Time-of-Propagation (TOP) Cherenkov counters described further on in this chapter.

Threshold Cherenkov counters consist of Cherenkov detectors of differing refractive index, which may be utilized to discriminate particles of different mass based on the differing Cherenkov threshold energies that the detectors possess for the particles. For example, if we consider a beam of two types of particles of different mass (m), such as pions ($\pi^{\pm}$, $m = 139.6$ MeV/c^2) and kaons ($K^{\pm}$, $m = 493.7$ MeV/c^2), a Cherenkov detector may be selected of a given refractive index (n) such that the particle of higher mass does not produce Cherenkov radiation, as described by Montgomery (2013). This would be the case, if the threshold condition for the production of Cherenkov radiation is not met by the particle of higher mass, that is, $\beta < 1/n$. Sundaresan (2001) describes another example of the application of two Cherenkov detectors of different refractive index, namely silica aerogel ($n = 1.01-1.03$) and pentane ($n = 1.357$) whereby particles of lower mass, such as 10 GeV kaons ($m = 493.7$ MeV/c^2) produce Cherenkov photons in the two Cherenkov detector media, whereas particles of higher mass such as protons ($m = 939.3$ MeV/c^2) produce Cherenkov photons only in the silica aerogel. Siudak et al. (2008) describe the use of a threshold Cherenkov detector of silica aerogel with refractive index $n = 1.05$, which exhibits a very high detection efficiency for pions with momenta $\geq$900 MeV/c. Thus, to detect K^+ particles a huge background of scattered pions could be suppressed using the aerogel Cherenkov detectors. Only the pions would produce Cherenkov photons; the kaons were below the threshold velocity. Adachi et al. (1995) describe a threshold Cherenkov counter for the identification of $\pi^{\pm}$ and $K^{\pm}$ in a particle beam. Silica aerogel with refractive index of 1.0127 with 14-cm thickness was used as the detector and PMTs for the measurement of Cherenkov photons. The threshold momentum for the detection of $\pi^{\pm}$ and $K^{\pm}$ was determined to be 0.863 GeV/c and 3.05 GeV/c, respectively.

Two threshold Cherenkov detectors operated in tandem are described by Asaturyan et al. (2005) for the identification of $\pi/K/p$ particles. Two different aerogel materials were used with index of refraction $n = 1.030$ and 1.015, respectively. The threshold momenta P_{th} in units of GeV/c for muons, pions, kaons, and protons in the two types of aeorogels detector materials are provided in Table 6.20.

The threshold momentum over which a particle of mass, m, will exceed the phase velocity of light in the medium and produce Cherenkov photons, is a function of the

TABLE 6.20 Threshold momenta (P_{th} in GeV/c) for particles in two aerogel threshold detectors of refractive index n.

Type of particle	P_{th} in $n = 1.030$	P_{th} in $n = 1.015$
μ	0.428	0.608
π	0.565	0.803
K	2.000	2.840
P	3.802	5.379

From Asaturyan et al. (2005), reprinted with permission from Elsevier © 2005.

particle mass and refractive index of the medium, n, as described by Asaturyan et al. (2005), according to the expression

$$P_{th}C = \frac{mc^2}{\sqrt{n^2-1}} \tag{6.110}$$

where P_{th} is the threshold momentum for the production of Cherenkov radiation, m is the particle mass, c is the speed of light in a vacuum, and n is the index of refraction of the medium.

Eq. (6.110) is derived from the equation for the total energy (E_{tot}) of a particle described previously (Eq. 1.269) in Section X.E.2 of Chapter 1, Volume 1, namely, the total energy (E_{tot}) of a particle is the sum of its kinetic (K) and rest energies (mc^2) or

$$E_{tot} = K + mc^2 = \gamma mc^2 \tag{6.111}$$

where

$$\gamma = \frac{1}{\sqrt{1-(v^2/c^2)}} = \frac{1}{\sqrt{1-\beta^2}} \tag{6.112}$$

as described previously in Eq. (1.271) of Chapter 1, Volume 1. Thus, Eq. (6.111) can then be expressed as

$$\left(mc^2\right)_{tot} = \frac{mc^2}{\sqrt{1-\beta^2}} \tag{6.113}$$

As the threshold condition of the production of Cherenkov photons is

$$\beta_{th} = 1/n \tag{6.114}$$

we can substitute $1/n$ for β in Eq. (6.113) to give

$$\left(mc^2\right)_{tot} = \frac{mc^2}{\sqrt{1-(1/n)^2}}, \tag{6.115}$$

where

$$\gamma_{th} = \frac{1}{\sqrt{1-(1/n)^2}} = \frac{n}{\sqrt{n^2-1}} \tag{6.116}$$

and Eq. (6.115) can be transposed to

$$\left(mc^2\right)_{tot} = \frac{(mc^2)n}{\sqrt{n^2-1}} \tag{6.117}$$

If the particle phase velocity at the Cherenkov threshold is

$$\beta_{th} = (v/c)_{th} = 1/n \tag{6.118}$$

and we multiply each side of Eq. (6.117) by β_{th} to give the following:

$$\beta_{th}\left(mc^2\right) = \frac{\beta(mc^2)n}{\sqrt{n^2-1}} \tag{6.119}$$

and

$$(v/c)_{th}\left(mc^2\right) = \frac{(1/n)(mc^2)n}{\sqrt{n^2-1}} \tag{6.120}$$

and

$$(mv)_{th}c = \frac{mc^2}{\sqrt{n^2-1}} \tag{6.121}$$

and

$$P_{th}c = \frac{mc^2}{\sqrt{n^2-1}} \tag{6.122}$$

which is the final equation used to calculate the threshold particle momentum for the production of Cherenkov radiation in a medium of refractive index n. For example, the threshold momentum, P_{th}, of the muon for the production of Cherenkov photons in aerogel of refractive index, $n = 1.030$, would be calculated as follows:

The energy equivalence of the muon mass, $m_\mu c^2 = 105.658$ MeV, is obtained from tables of physical constants (NIST, 2018) or calculated according to Eqs. (1.8) to (1.11) described in Chapter 1 of Volume 1; and the threshold momentum calculated as

$$\begin{aligned} P_{\text{th}}c &= \frac{m_\mu c^2}{\sqrt{n^2-1}} \\ &= \frac{105.658\ \text{MeV}}{\sqrt{(1.030)^2-1}} \\ &= 428.14\ \text{MeV} \\ P_{\text{th}} &= 0.428\ \text{GeV}/c \end{aligned} \tag{6.123}$$

which is equivalent to the value quoted in Table 6.20. An aerogel detector with refractive index $n = 1.015$ will yield a minimum momentum for the Cherenkov Effect of 0.608 GeV/c calculated according to Eq. (6.122).

The difference in count rates from Cherenkov photons produced in the two detectors yield the relative numbers of the heavier and lighter particles. This is illustrated by Fig. 6.48, which is a plot of the number of photoelectrons (N_{pe}) collected by PMT photon detectors as a function of particle momentum (P) in GeV/c. From the figure it can be seen that the $n = 1.030$ aerogel will permit good pion/proton discrimination up to 4 GeV/c, while the $n = 1.015$ aerogel material can be used for pion/kaon discrimination

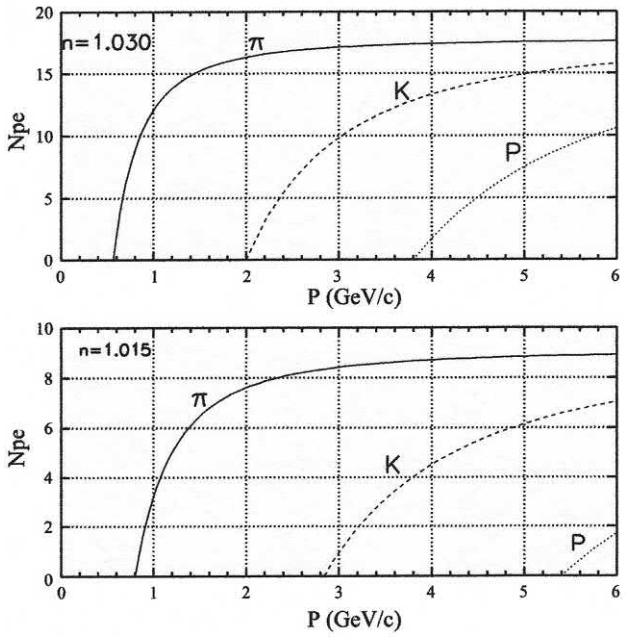

FIGURE 6.48 Particle separation using aerogel Cherenkov detectors with an index of refraction $n = 1.030$ (top) and $n = 1.015$ (bottom). Electrons (positrons) are above threshold over essentially the full momentum range. *From Asaturyan et al. (2005), reprinted with permission from Elsevier © 2005.*

in the momentum range of 1−3 GeV/c, and for pion/proton separation up to 6 GeV/c (Asaturyan et al., 2005).

As described previously in this chapter by Eq. (6.48), the number of Cherenkov photons emitted per path length of travel in the wavelength range of λ_1 and λ_2 is a function of the particle velocity β and the refractive index n of the medium or Cherenkov radiator, that is,

$$\frac{dN}{dl} = 2\pi\alpha Z^2\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\left(1-\frac{1}{\beta^2 n^2}\right) \tag{6.124}$$

where α is the fine structure constant (1/137) and Z is the charge on the particle. In most cases, $Z = 1$; and this term is often omitted from the equation. As described by Asaturyan et al. (2005) and Denisov and Stoyanova (2006), Eq. (6.124) reduces to the expression for the number of Cherenkov photons produced by a particle of charge ($Z = 1$) per particle path length (L) of travel in the wavelength region between λ_1 and λ_2 to the following:

$$N = 2\pi\alpha L\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\sin^2\theta \tag{6.125}$$

where θ is given by the well-known expression $\cos\theta = 1/\beta n$.

All Cherenkov photons are not detected by the photodetectors; and thus, the reflectivity M of the diffuse light box and the aerial fraction ε of coverage by the photodetectors must be included, as described by Carlson (1986), Poelz (1986) and Asaturyan et al. (2005) to give the expression for the average number of photons hitting the photomultiplier tubes, N_e, as

$$N_e = 2\pi\alpha L\left(\frac{1}{\lambda_1}-\frac{1}{\lambda_2}\right)\left(1-\frac{1}{\beta^2 n^2}\right)\frac{\varepsilon}{1-M(1-\varepsilon)} \tag{6.126}$$

From Eqs. (6.125) and (6.126), the number of Cherenkov photons detected is usually expressed as

$$N_e = N_0 L\sin^2\theta \tag{6.127}$$

where N_0 is the "figure-of-merit" or "quality factor", characterized by Engelfried (2011) and Lippmann (2012), Križan (2013), Beckford et al. (2014), as the figure depends on the quality and wavelength interval of the photon detection system including the efficiency of light transmission, collection and detection. Typical values of N_0 are between 50 and 100 cm^{-1} (Križan, 2013).

A gaseous carbon dioxide Cherenkov threshold detector has been designed for the measurement of 16.75 MeV gamma rays that accompany deuterium−tritium fusion (Mack et al., 2003, 2006; Caldwell et al., 2003; Kim et al., 2009a,b). The deuterium−tritium fusion reaction is discussed in Chapter 1, Volume 1, and in an earlier book (L'Annunziata, 2016). The fusion reaction generally results in the release of 17.58 MeV energy with the emission of a 14 MeV neutron and 3.5 MeV alpha particle. Alternatively, 16.75 MeV gamma rays may accompany the deuterium−tritium fusion with a branching ratio of the order of 10^{-5} γ/14 MeV neutron (Herrmann et al., 2016). Although the gamma-ray emission is less abundant, the observed high-energy gamma-ray signal in the Cherenkov detector is proportional to the observed 14 MeV fusion neutron yield and independent of neutron-induced gamma rays (Mack et al., 2003, 2006). The Cherenkov detection energy threshold is set by the pressure of the CO_2 gas; which detects the high-energy Compton electrons.

A Cherenkov detector arrangement reported by Perrino et al. (2001) provides an example of two Cherenkov detectors operated in tandem together with time-of-flight (TOF) measurements to discriminate between pions (π^+), positrons (e^+), and protons (p^+). The experimental setup consisted of a CO_2 gas detector ($n = 1.00041$) providing excellent detection for positrons, and a silica aerogel detector with a refractive index $n = 1.025$ providing (π, p) discrimination in the 1−4 GeV/c range with Cherenkov thresholds of 0.62 and 4.2 GeV/c for pions and protons, respectively. Pions and protons at 1 and 2 GeV/c are below the Cherenkov threshold in the CO_2 gas. Complementary data provided by time-of-flight measurements between two BC408 scintillation detectors separated at a 23 m distance along the particle beam enabled the tagging of protons. TOF measurements are determined by signals between detectors permitting the determination of the speed of a

particle, and with its total energy signal, the mass of the ion can be identified (Lilley, 2001).

Dual Cherenkov threshold detectors with aerogel radiators having two different refractive indices, $n = 1.015$ and 1.008 were designed by Allkofer et al. (2007, 2008) to operate in tandem to discriminate between kaons and protons in the momentum range of 4−8 GeV/c. Diffuse reflector foils coated with wavelength shifter increased the Cherenkov light yield by 50%. To discriminate between pions and kaons in the same 4−8 GeV/c momentum range, Horikawa et al. (2008) designed a threshold Cherenkov detector using perfluorobutane (C_4F_{10}) gas radiator, which has a refractive index $n = 1.00137$ at the 300 nm wavelength. In the C_4F_{10} gas, kaons are well below the threshold for the Cherenkov effect in the entire 4−8 GeV/c momentum range. Sokolov et al. (2009) designed an aerogel threshold Cherenkov detector with a thin Fresnel lens between the aerogel radiator and photomultiplier. The Fresnel lens focalizes the Cherenkov light onto a relatively small diameter photomultiplier reducing costs incurred in the use of one or more large diameter PMTs.

B. Mirror- or lens-focused RICH counters

The Ring Imaging Cherenkov (RICH) detector is designed principally for particle identification, as it can provide information on the velocity, β, and the charge of the particle, z; and complementary information provided by rigidity measurements using a magnetic tracker can provide the identity of the particle according to its mass (Pinto da Cunha et al., 2000). The possibility of precisely measuring the dimensions of a Cherenkov ring image together with instrumental design proposals and calculations for the determination of particle velocities of electrons, muons, pions, kaons, and protons may be attributed to Roberts (1960a,b). In one of his very detailed papers, Roberts (1960b) states the following:

> *A new type of Čerenkov radiation detector is proposed, in which the light emitted by a single particle traversing a radiator is imaged, by means of a lens or mirror focused at infinity, on the cathode of an image intensifier tube. The image is a ring, whose diameter measures accurately the Čerenkov cone angle, and thus the particle velocity. In addition, the coordinates of the center of the circular image accurately indicate the orientation of the particle trajectory …*

Some early designs of RICH detectors included the use of optical lenses to focus the Cherenkov photons as a ring image onto a photon-imaging plane, as described by Giese et al. (1970). Much of the pioneering work on RICH detectors was carried out by Thomas Ypsilantis and Jaques Sequinot (see Sequinot and Ypsilantis, 1977), and thorough treatments on the theory of RICH counters are available from Sequinot and Ypsilantis (1994) and Ypsilantis and Sequinot (1994). Several detector geometries and designs are reviewed by Križan (2017, 2013, 2007), Lippmann (2012), Engelfried (2011), Iijima (2010), Kerzel (2010), Ullaland (2003) and Glässel (1999).

The classic spherical-mirrored RICH detector, reviewed by Sequinot and Ypsilantis (1977) was designed to accept particles that originate from any 4π direction; and this classical RICH geometry is illustrated in Fig. 6.49. The illustration shows a particle trajectory passing through a Cherenkov radiator of refractive index n enclosed in a spherical mirror. The Cherenkov photon detector has a concentric spherical surface of smaller radius. The space between the outer surface of the photon detector and inner spherical mirror is filled with a transparent medium of a given refractive index [e.g., gas, C_4F_{10} ($n = 1.0015$), liquid, C_6F_{14} ($n = 1.276$), crystalline NaF ($n = 1.33$), or silica aerogel ($n = 1.01-1.02$)] to serve as the Cherenkov radiator (Pinto da Cunha et al., 2000). The Cherenkov radiator is chosen according to the mass and momenta of the particles to be identified, as the emission of Cherenkov radiation at an angle θ (or θ_c of Fig. 6.49) must satisfy the threshold condition $\beta > 1/n$. At the moment the particle penetrates the Cherenkov radiator, the Cherenkov radiation is emitted at an angle θ_c according to the particle velocity, β, and the refractive index (n) of the Cherenkov radiator as

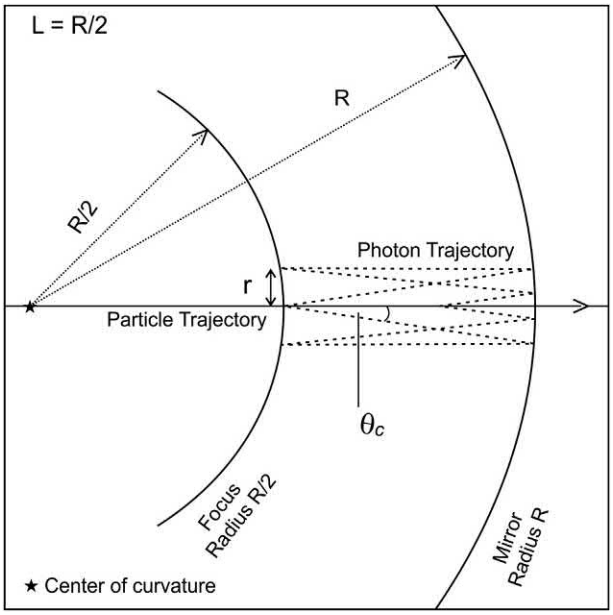

FIGURE 6.49 Working principle of a classical RICH detector. A spherical mirror surrounds a spherical photon detector. Cherenkov photon trajectories are drawn (dashed lines) in the small angle approximation surrounding the particle trajectory, which depict the emitted conical Cherenkov light and cone image (ring) reflected onto the detector surface. The radius of the light cone image is labeled r. *From Engelfried (2011), reprinted with permission from Elsevier © 2011.*

defined by Eq. (6.1) previously in this chapter, that is, cos $\theta_c = 1/\beta n$. The radiator dimensions used by Pinto da Cunha et al. (2000) were 2 cm thickness and 50 cm radius. The Cherenkov photons are reflected off the inner surface of the outer spherical mirror as a ring of light onto the conical detector surface. The ring has a radius, r, which is measured to determine the particle velocity or particle mass, if its momentum is measured. An imaging detector is used to provide an image of the ring of Cherenkov light and its coordinates relative to the vertex.

As described by Engelfried (2011), the Cherenkov photons emitted under the angle θ_c are focused (in a small angle approximation) by the spherical mirror of radius R onto a focal sphere of radius $R/2$, whereby the focal length $f = R/2$, upon which the photons form a ring of radius r (see Fig. 6.49) defined by the equation

$$r = f \tan\theta_c = \frac{R}{2}\tan\theta_c \tag{6.128}$$

The number of photons detected is defined by Eq. (6.127) described previously.

Numerous RICH detectors have been designed with mirrors to reflect and focus the Cherenkov photons onto a suitable plane of photon detectors as well as lenses to enhance images of Cherenkov rings with the objective of measuring the radius r. An example of one of several RICH detectors now in use is the COMPASS RICH-1 detector described by Agarwala et al. (2018), Abbon et al. (2010, 2011, 2015) and illustrated in Fig. 6.50. COMPASS is the acronym for Community Pentascale Project for Accelerator Science and Simulation. As illustrated in Fig. 6.50 (upper side view), an incoming nuclear particle enters the COMPASS RICH-1 detector, which is filled with gaseous C_4F_{10} radiator ($n = 1.00140$ at 150 nm). Cherenkov photons are produced along the particle path; and the ring image is condensed and reflected off a 21 m^2 wall of 116 spherical mirror elements toward a photon detector. Photon detectors are illustrated in both the upper and lower halves of the RICH detector to accommodate incoming particles either above or below a hadron beam. Ring imaging is provided by multi-anode PMTs with pixel size of $\sim 4.2 \times 4.2$ mm^2 coupled to individual telescopes of fused silica lenses and a concentrator lens to enlarge the effective active area of the photon detectors. Examples of ring images provided by multianode photomultiplier detectors are illustrated in Figs. 6.51 and 6.54. Many other RICH detector designs are used worldwide, including the HERA-B RICH detector (particle detector of the Hadron-Elektron-Ringanlage, Hamburg, Germany) reviewed by Križan (2017, 2013), Lippmann (2012), Starič (2005), Ariño et al. (2004), Gorišek (2004) and Korpar (2003), and the LHCb RICH detector (Large Hadron Collider beauty experiment at CERN) reviewed by He (2017), Papanestis and D'Ambrosio (2017), Cardinale (2016), Papanestis (2014), Kim et al. (2011), Mulheim (2011), Forty (2010) and Kerzel (2010).

For a Cherenkov radiator of given refractive index n, the radius r in the small angle approximation is a function of the particle mass m and momentum p according to the following (Engelfried, 2011):

$$r = f\sqrt{2 - \frac{2}{n}\sqrt{1 + \frac{m^2c^2}{p^2}}} \tag{6.129}$$

Thus, if the particle momentum p is known or measured (e.g., in a magnetic spectrometer, Engelfried, 2011), the particle mass m can be calculated from the radius r of the Cherenkov cone or ring; and conversely, if the particle mass is known, the particle velocity β or momentum p can be calculated. Also, as described by Lippmann (2012), with the knowledge of the Cherenkov angle θ and particle momentum p, the determination of the particle mass m is possible according to the following derivation:

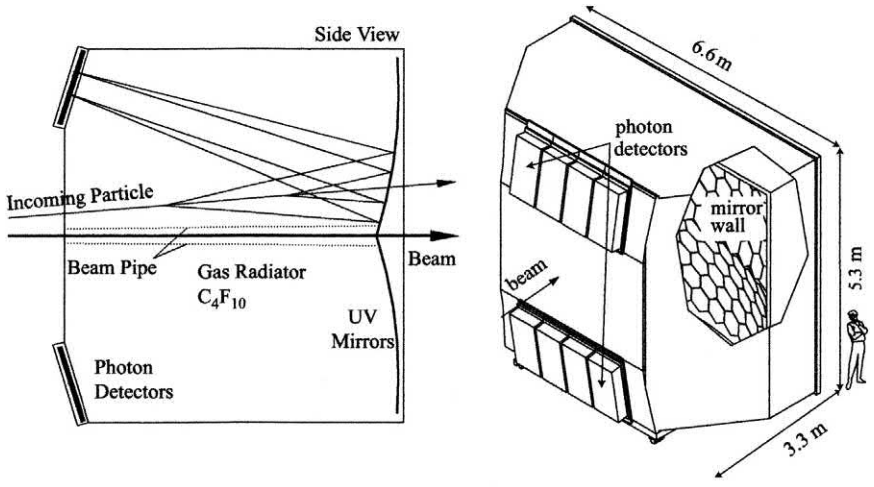

FIGURE 6.50 A scheme of the principle and an artist's view of the COMPASS RICH-1 detector. The side view (left) illustrates Cherenkov photons produced by an incoming particle inside the C_4F_{10} gas-filled detector and the focusing of the photons by mirrors onto the photon detectors for ring imaging. An exterior view (right) shows the locations of the photon detectors in the upper and lower halves of the detector and an inside view of a multifaceted photon focusing mirror wall. A sketch of a human figure is illustrated to the right to provide an idea of the magnitude of the detector. *From Abbon et al. (2011), reprinted with permission from Elsevier © 2011.*

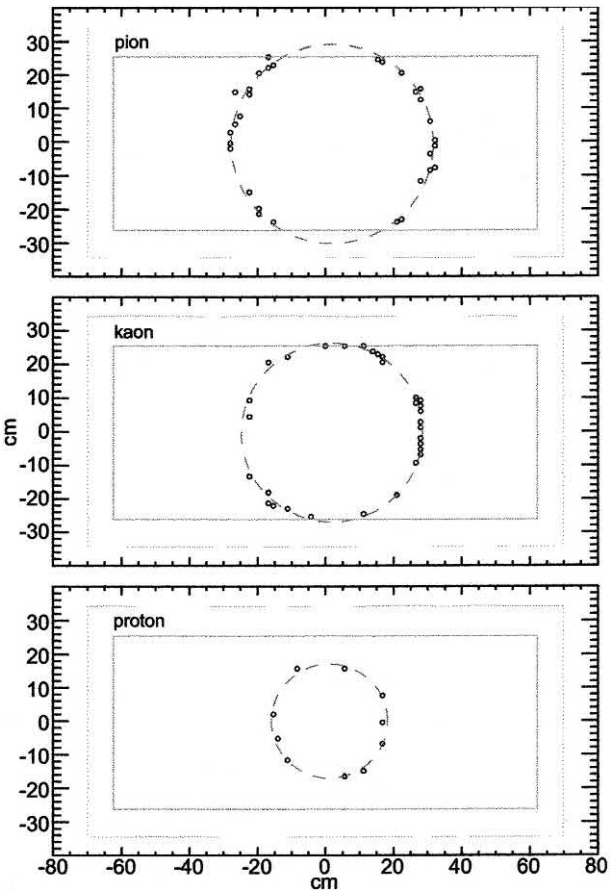

FIGURE 6.51 Sample event displays at 40 GeV/*c* pion (top), kaon (middle), and proton (bottom) rings in the RICH counter. Small circles indicate Cherenkov-photon hit PMTs. The dashed circles show the rings reconstructed from the PMT hits. *From Graf et al. (2010), reprinted with permission from Elsevier © 2010.*

Since the angle of Cherenkov photon emission θ is a function of the particle velocity and radiator refractive index n or

$$\cos\theta = \frac{1}{\beta n} \tag{6.130}$$

and the particle phase velocity β is a function of its mass and momentum according to

$$\beta = \frac{1}{\sqrt{\left(\frac{mc}{p}\right)^2 + 1}}, \tag{6.131}$$

the two Eqs. (6.130) and (6.131) can be combined to give an equation for the particle mass m as a function of its momentum and the angle of emission of the Cherenkov photons, that is,

$$m = \frac{p}{c}\sqrt{n^2\cos^2\theta - 1} \tag{6.132}$$

For a given particle momentum p and given refractive index n of the Cherenkov radiator, it can be stated that, the smaller the mass of the particle, the greater will be the Cherenkov angle θ and the greater will be the radius r of the Cherenkov ring. This is illustrated by the Cherenkov ring images for pion, kaon, and proton particles at 40 GeV/*c* momentum in Fig. 6.51, which was obtained by Graf et al. (2010) with a RICH counter filled with CO_2 gas just above atmospheric pressure as the Cherenkov radiator. The CO_2 gas has a refractive index $n = 1.00045$ at the 300 nm wavelength, which gave threshold momenta of $P = 4.5$ GeV/*c* for pions, 17 GeV/*c* for kaons, and 31 GeV/*c* for protons.

Various radiator materials of differing index of refraction (n) are selected for RICH detectors in order to discriminate between particles of differing mass and momentum. For example, Kerzel (2010) and Lippmann (2012) describe the use of three radiator substances of differing refractive index to discriminate between particles in various ranges of momentum as illustrated in Fig. 6.52. These are silica aerogel ($n = 1.03$), which is used to detect and discriminate particles in the momentum range up to $\sim$ 10 GeV/*c*, and C_4F_{10} ($n = 1.0014$) for the momentum range of $10 \leq P \leq 40$ GeV/*c*, and CF_4 ($n = 1.0005$) for particles in the range of $16 \leq P \leq 100$ GeV/*c*.

C. Proximity-focusing RICH counters

The proximity-focusing RICH detectors do not utilize mirrors or lenses to focus the Cherenkov ring image; rather the image is focused by proximity. As noted by Websdale (2008), proximity-focusing effectively means no focusing. Various proximity focusing RICH detectors are described by Šantelj et al. (2017), Torassa (2016) and Križan (2013). An example of a proximity-focusing RICH detector, used to discriminate kaons from pions with particle momentum up to 2.4 GeV/*c*, is that described by Mammoliti et al. (2011). The detector utilizes 1.5-cm-thick liquid Freon (C_6F_{14}) as the radiator and a CsI photoconverter separated by a distance of only 10 cm for Cherenkov ring imaging, illustrated in Fig. 6.53. A charged particle that exceeds its Cherenkov threshold energy in the liquid Freon ($n = 1.28$ at 180 nm wavelength) emits Cherenkov photons in the Freon in the form of a cone at an angle θ to the particle trajectory. The Cherenkov photons pass through a proximity gap filled with CH_4 at STP; and the photons are then converted into photoelectrons by a 300 nm thick CsI film deposited onto electrode pad planes of a multiwire proportional chamber (MWPC) providing a two-dimensional localization of the Cherenkov photon hits (Garibaldi et al., 2003; Cusanno et al., 2004; Iodice et al., 2005; Lippmann, 2012). An average of 12.4 photoelectrons per ring is collected with a gain of $\sim 5 \times 10^4$, which

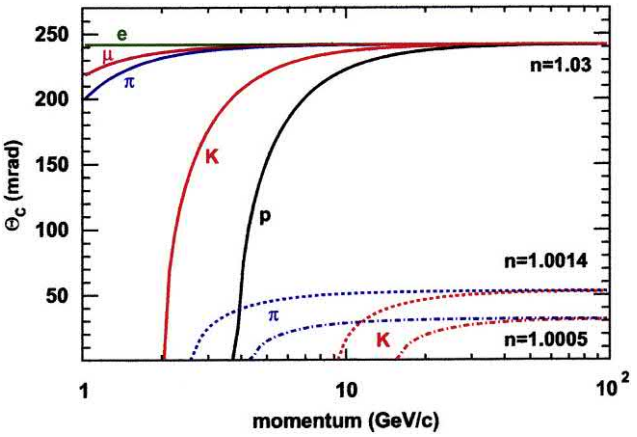

FIGURE 6.52 Cherenkov angles as a function of momentum for different particle species and for three different values of refractive index n corresponding to three radiator materials used in the LHCb RICH setup. *Lippmann (2012), reprinted with permission from Elsevier © 2012.*

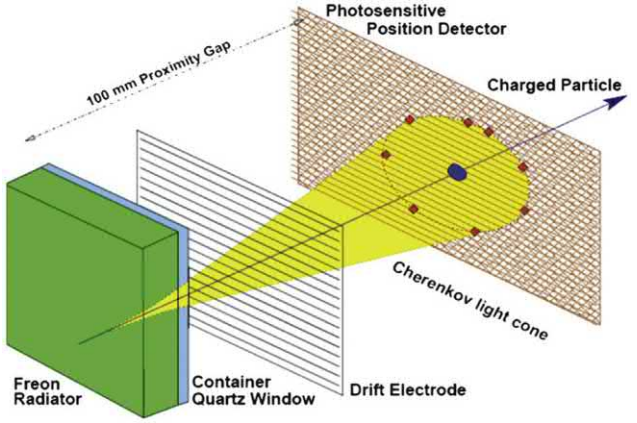

FIGURE 6.53 Artist's view of a proximity-focusing RICH counter. *From Mammoliti et al. (2011); reprinted with permission from Elsevier © 2011.*

provides the signal location for construction of the ring image (Mammoliti et al., 2011).

Among the methods used to record Cherenkov ring images is the utilization of a flat panel of numerous multianode PMTs. An example may be taken from the work of Artuso et al. (2006), which is illustrated in Fig. 6.54. Cherenkov photon hits onto individual PMTs produce the 2-dimension signal localization of the Cherenkov photons, which are reconstructed into the ring image. A schematic diagram of a typical proximity-focusing RICH counter is that described by Pestotnik et al. (2017, 2004), Torassa (2016), Korpar et al. (2005), and Križan et al. (2005) and Matsumoto et al. (2004), which is illustrated in Fig. 6.55. This RICH detector employs two $5 \times 5\,\text{cm}^2$ multiwire proportional chambers (MWPCs) to provide precise measurement of the particle track. The MWPCs are constructed of 20 μm diameter, gold-plated tungsten anode wires with 2-mm pitch equipped with 90% AR + 10% CH_4 gas flow providing a position read-out by delay lines on the x- and y-cathode strips. MWPCs are gas ionization detectors, developed by Nobel Laureate Georges Charpak and coworkers (Charpak et al., 1968, 1970; Charpak, 1969, 1970; Charpak and Sauli, 1978, 1979), contain an array or grid of uniformly spaced anode wires sandwiched between two other grids of uniformly spaced cathode wires. The two outer cathode planes are oriented at right angles to one another, and the sandwich of these grids is contained in a chamber of proportional counting gas such as an Ar + CH_4 gas mixture. Output signals provide the x- and y-coordinates of the ionizing particles entering the grid. See

L'Annunziata (1987) and Chapter 2 of Volume 1 for additional references and information on MWPCs.

As illustrated in Fig. 6.55, after passing through the first MWPC, the high-energy particles continue on to penetrate a silica aerogel Cherenkov radiator (10−25 mm thick). The refractive index ($n = 1.05$) of the aerogel provide discrimination of pions and kaons in the momenta range of 0.5−4 GeV/c. The Cherenkov photons produced in the aerogel are detected by an array of flat-panel multianode PMTs. The multichannel PMTs are connected to an analog memory board providing a readout of the PMT signals. The position sensitivity of the readout yields a Cherenkov angle resolution per photon of 10 mrad (Matsumoto et al., 2004).

The ARICH (Aerogel Ring Imaging CHerenkov) counter is a proximity-focusing RICH counter with a unique design for high-resolution Cherenkov ring imaging and particle identification. It is under development for installation in the Belle II spectrometer for the next generation B meson physics experiment with the SuperKEKB asymmetric e^+e^- collider (Super B-factory) at the High Energy Accelerator Research organization in Tsukuba, Ibaraki, Japan (Šantelj et al., 2017). An image of the location of the proximity-focusing ARICH detector within the Belle II structure is illustrated in Fig. 6.56. An introduction to the objectives of the B-factory at the KEK is provided by the writer in a previous book (L'Annunziata, 2016); and several detailed reviews on the development and principle of the ARICH detector are provided by Hataya et al. (2017), Inami (2017), Pestotnik et al. (2017), Šantelj et al. (2017), Yusa et al. (2017), and Nishida et al. (2014).

The ARICH detector is used to identify a charged particle from the angle of emission of the Cherenkov photons

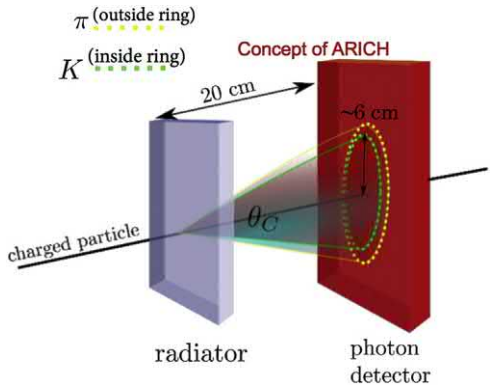

FIGURE 6.57 The concept of the ARICH. Color is visible in the electronic version of the book. *From Torassa (2016), reprinted with permission from Elsevier © 2016.*

emitted from the aerogel Cherenkov radiator, as illustrated in Fig. 6.57. A charged particle traveling through the aerogel radiator produces Cherenkov photons at an angle θ_C to the particle trajectory. Heavier particles produce Cherenkov photons in the aerogel radiator at more acute angles of emission and the resultant images of the Cherenkov rings registered by the photon detector have a smaller radius than rings produced by the lighter particles. Illustrated are two rings of ~6 cm in radius; and the inner Cherenkov ring (shorter radius) is illustrated produced by the heavier particle; and the outer ring is produced by the lighter particle. The heavier particle (e.g., kaon) will produce Cherenkov photons at a smaller angle of emission (θ_C) than the lighter particle (e.g., pion), as illustrated in Fig. 6.57.

As there is no focusing lens in the ARICH detector, the distance between the aerogel radiator and photon detector is

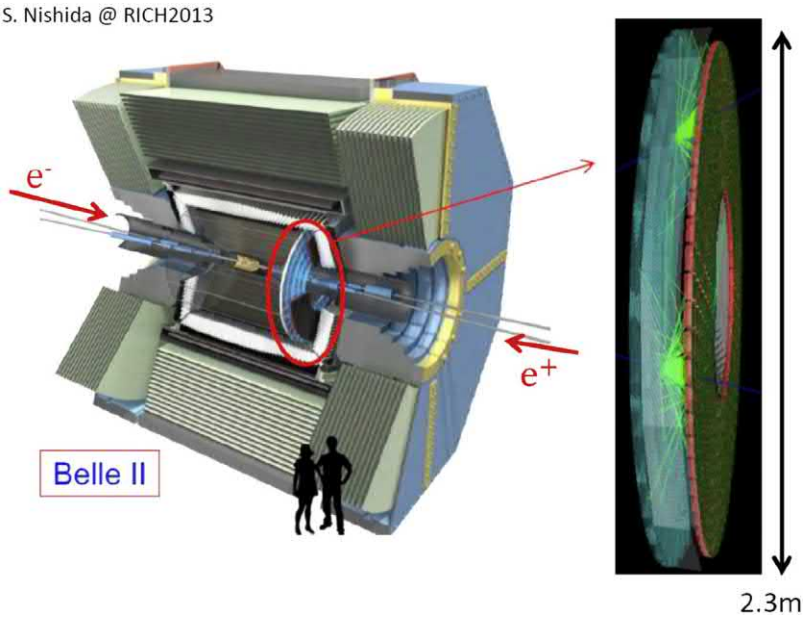

FIGURE 6.56 Left: Image of the ARICH proximity-focusing ring imaging Cherenkov detector within the Belle II structure. Two human figures are illustrated to provide a perspective of the magnitude of the Belle II structure. (2017), reprinted with permission from Elsevier © 2017.*

only 20 cm from the front surface of the aerogel to the photo detector. The ARICH detector is consequently relatively thin compared to its diameter, as illustrated in Fig. 6.58. The figure illustrates from left to right, the aerogel radiator, planar mirrors, and the photon detector consisting of an array of Hybrid Avalanche Photo Detectors (HAPDs). The numerous squares constituting the photon detector, illustrated in Fig. 6.58, are 420 HAPDs covering an area of 3.5 m^2; and the planar mirrors positioned at the outermost edge of the detector redirect photons produced from charged particles that pass near the edge that would otherwise be lost (Nishida et al., 2014). The aerogel radiator is made up of two layers of aerogel tiles with an approximate size of 18 × 18 × 2 cm with two layers of 124 tiles constituting the entire aerogel radiator area (Šantelj et al., 2017). Of the two layers of aerogel tiles, the first layer through which the particle will travel first has an index of refraction ($n_1 = 1.045$) slightly less than that of the second layer ($n_2 = 1.055$) through which the particle will travel before exiting the aerogel radiator. This arrangement yields an overlap of two Cherenkov rings produced by the two layers of aerogel resulting in an improvement in Cherenkov angle resolution, as illustrated and described further on in this chapter (see Fig. 6.61). The principle of the HAPD operation in the imaging of the Cherenkov photon rings is described by Šantelj et al. (2017).

Križan (2001) provides another excellent example of the use of position-sensitive PMTs to produce high-resolution images of Cherenkov rings. They used 2300 position-sensitive PMTs with a 2.8 m long C_4F_{10} gas radiator ($n = 1.00135$) yielding an average number of 32 Cherenkov photons per ring produced by 50 GeV/c kaons or pions and about twice that number of photons per ring when produced by overlapping e^+e^- pairs. Cherenkov photon resolutions of approx. 1 mrad provided discrimination of kaons and pions of momentum as high as 50 Gev/c. Examples of Cherenkov rings imaged by the signal outputs of position-sensitive PMTs were illustrated previously in Figs. 6.51 and 6.54.

A disadvantage of using conventional multianode PMTs for the imaging of Cherenkov photon rings is their sensitivity to high magnetic fields. Alternatives to multianode PMTs include silicon photomultipliers and hybrid photon detectors of the proximity focusing type (e.g., CsI deposited onto a cathode pad plane) for ring imaging in magnetic fields of 1.5T (Harnew, 2014; Križan, 2013; Lippmann, 2012; Pestotnik et al., 2011, 2007; Korpar et al., 2010, 2008; Dolenec et al., 2011). Silicon photomultipliers are semiconductor photosensitive devices consisting of an avalanche photodiode (APD) matrix on a silicon substrate and operating in the Geiger mode (Dolgoshein et al., 2006; Renker, 2006). The silicon photomultipliers are capable of measuring single photon events in a proximity-focusing RICH counter. They have the advantages of a low operating voltage, small dimensions, and photodetection efficiency higher than PMTs while, at the same time, insensitive to high magnetic fields; however, their main disadvantage is their relatively high dark noise count rate (Dolenec et al., 2011). To increase the detection efficiency of the silicon photomultipliers, light guides and light concentrates have been employed, and an example of a highly resolved silicon photomultiplier Cherenkov ring image produced by pion interaction with an aerogel radiator is illustrated in Fig. 6.59. The individual dots on the ring are individual photon hits.

A linear relation between Cherenkov angle θ_c and particle momentum is described by Križan (2001) to be

$$\theta_C^2 = \frac{\theta_0^2 - m^2}{p^2} \tag{6.133}$$

where $\theta_0^2 = 2(n-1)$, m is the particle mass and p is the particle momentum. The relation between the variables θ_c^2 and $1/p^2$ as defined by Eq. (6.133) is linear and thus the plot of θ_c^2 against $1/p^2$ for a particle of given mass would be a straight line. Fig. 6.60 illustrates the linear relationship between θ_c^2 and $1/p^2$ for particles of different mass, namely, protons ($m = 938.27$ MeV/c^2), kaons ($m = 493.67$ MeV/c^2), pions ($m = 139.57$ MeV/c^2) and electrons ($m = 0.511$ MeV/c^2). In Fig. 6.60, the measured ring Cherenkov angle is plotted as a function of the particle momentum, where the Cherenkov thresholds in gaseous C_4F_{10} radiator for pions, kaons, and protons are given in the figure caption. Abbon et al. (2011) points out with Fig. 6.60, that in the small

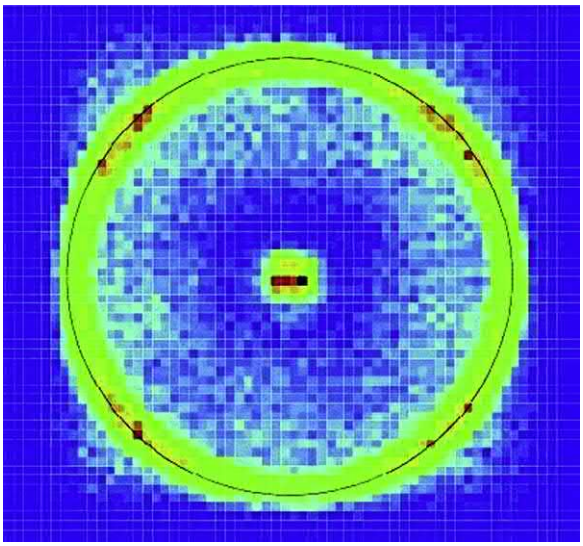

FIGURE 6.59 Cherenkov ring for hits within a 5 ns time window as recorded by an array of silicon photomultipliers described by Korpar et al. (2010) in a pion test beam *From Križan (2013), reprinted with permission from Elsevier © 2013.*

angle approximation, the relationship between the two variables θ^2 and $1/p^2$ is linear with a slope proportional to the squared mass of the corresponding particle; and the bands start at the Cherenkov threshold and have a common intercept corresponding to the maximum Cherenkov angle. Thus, measurement of the Cherenkov angle of emission in radians (rad) can be used to determine the velocity of a particle from its momentum or identify the particle from its known momentum.

A main issue in the performance of proximity focusing RICH counters is the optimization of the Cherenkov angle resolution per particle track, which is measured as

$$\sigma_{\text{track}} = \sigma_\theta / \sqrt{N_{\text{pe}}} \tag{6.134}$$

where σ_{track} is the resolution measured in mrad, σ_θ is the single photon resolution, and N_{pe} is the number of photoelectrons collected by the photon detector. Researchers have found that the proper association of nonhomogeneous Cherenkov radiators can improve the Cherenkov angle resolution per track as well as increase the number of photoelectrons collected by the photon detectors, N_{pe}, by 50% without deteriorating the angular resolution σ_θ (Pestotnik et al., 2017; Torassa, 2016; Nishida et al., 2014; Križan, 2013, 2009, 2007; Lippmann, 2012; Adachi et al., 2011, 2007; Websdale, 2008; Iijima et al., 2005; Korpar et al., 2005). As described by Križan (2009), the number of detected Cherenkov photons increases with the length of the Cherenkov radiator; however, in a proximity focusing RICH counter, the single photon resolution degrades with increased radiator length, because of the uncertainty in the point of photon emission. This is illustrated in Fig. 6.61A where it is seen that, for a homogeneous radiator of refractive index n and given length, the Cherenkov ring image resolution is a function of the radiator length. Križan (2009) indicates that for a given geometry, the optimal radiator thickness is approximately 20 mm. The limitation of resolution and radiator thickness can be overcome to a certain extent by use of a nonhomogeneous radiator, which is a radiator consisting of two or possibly three layers of aerogel of differing refractive index adjoined back-to-back, as illustrated in Fig. 6.61B and C. Such an arrangement can be made only with aerogel radiator, as silica aerogels can be fabricated over a range of refractive indices ($n = 1.005$ to 1.26), as described previously in Section VII of this chapter. As described by Križan (2009), with the appropriate selection of refractive indices of consecutive aerogel radiator layers, it is possible to achieve overlapping of the corresponding Cherenkov rings on the photon detector (see Fig. 6.61). This is a type of focusing of the Cherenkov photons by reducing the spread of the photons due to the uncertainty of the point of emission from the radiator, which may encompass any point in the radiator along the particle track, from the point of entrance of the particle to its point of exit. To achieve Cherenkov ring image focusing in this manner, the refractive indices must gradually increase from the upstream to the downstream layer. This is

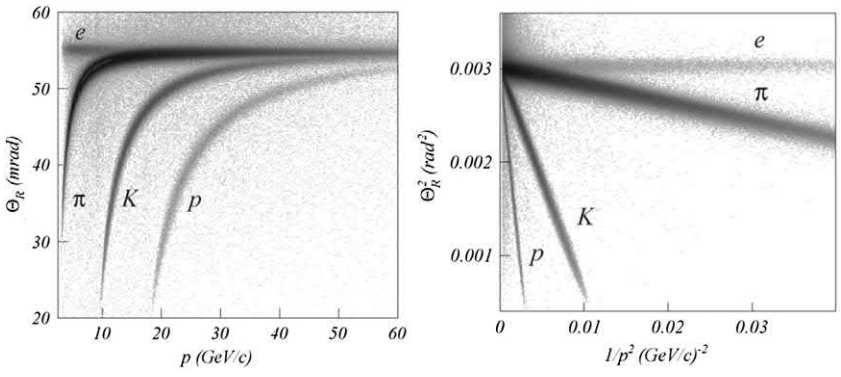

FIGURE 6.60 The measured ring Cherenkov angle θ_R versus the particle momentum p (left) with Cherenkov thresholds at ~ 2.5, 9, and 17 GeV/c for pions, kaons, and protons, respectively, and θ_R^2 versus $1/p^2$ (right) in a C_4F_{10} gaseous radiator. *From Abbon et al. (2011), reprinted with permission from Elsevier © 2011.*

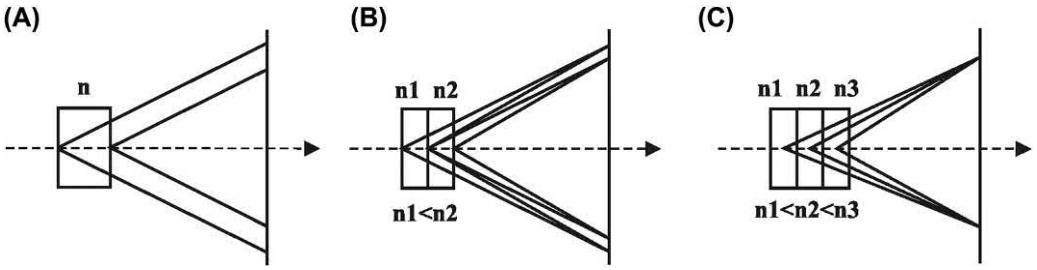

FIGURE 6.61 Effects of nonhomogeneous aerogel Cherenkov radiators (*e.g.*, dual and triple radiator combinations) that may improve ring-image resolution: (A) single radiator of refractive index n, (B) focusing dual radiator having indices of refraction $n1$ and $n2$ where $n1 < n2$ and the radiator of highest refractive index is downstream with the direction of particle and photons, and (C) focusing multiple radiator combination with the indices of refraction gradually increasing from $n1$ to $n3$ of the aerogel layers from upstream to downstream. *From Iijima et al. (2005), reprinted with permission from Elsevier © 2005.*

the technique used in the construction of the ARICH detector described previously where two aerogel radiator tiles are placed back-to-back each of only 2 centimeters thickness and with indices of refraction $n1 = 1.045$ and $n2 = 1.055$. (Šantelj et al., 2017). If the sequence of refractive indices of the layers is reversed, i.e., $n1 > n2$, from upstream to downstream, dual rings would be observed (Iijima et al., 2005; Korpar et al., 2005.

D. Time-of-propagation Cherenkov counters

A time-of-propagation (TOP) Cherenkov counter is a DIRC (Detector of Internally Reflected Cherenkov light) counter used for particle identification. The TOP counter provides a measurement of the time-of-propagation (TOP) of Cherenkov photons in a narrow (2 cm thick) quartz bar; and various designs are described by Harnew (2014), Inami (2014, 2011, 2008), Križan (2013), Matsuoka (2013), Lippmann (2012), Nishimura (2011), Starič (2011), Nishimura et al. (2010), Enari et al. (2002), Akatsu et al. (2000) and Ohshima (2000). The basic structure of the Time-of-Propagation Cherenkov counter is illustrated in Fig. 6.62. The TOP detector consists of a quartz Cherenkov radiator bar with the general approximate dimensions: 20 mm-thickness, 60 mm-width, 3150 mm-length). The time-of-propagation counter utilizes the principle of total internal reflection of Cherenkov photons produced in the quartz radiator; and it measures the position and precise arrival time of propagated photons at the radiator ends (Inami, 2014, 2011; Matsuoka, 2013). A focusing mirror is located at the back end of the bar (mirror not identified in Fig. 6.62) for focusing the Cherenkov photons. The mirror is flat at the backward end to reflect the Cherenkov light toward the forward end where the photon detector is located. The Cherenkov photons are focused horizontally onto the photon detector plane, and the time-of-propagation is measured by the photon detector. The method is based on the following principles: (1) the Cherenkov photon emission angle (θ_c), illustrated in Fig. 6.63, is a function of the particle velocity (β) according to the relation $\cos\theta_c = 1/\beta n$ where n is the refractive index of the Cherenkov radiator, (2) the time-of-propagation (TOP) of photons in a light guide with internal-total-reflection characteristics can be calculated as a function of the photon emission angle, and (3) a correlation between time-of-propagation and photon emission angle would provide information on particle identification. Notice from the example provided in Fig. 6.63, the Cherenkov photon emission angle created by the pion (π) is less acute than that created by the kaon (K) and the time-of-propagation of the Cherenkov photons derived from the pion is shorter than derived by the kaon.

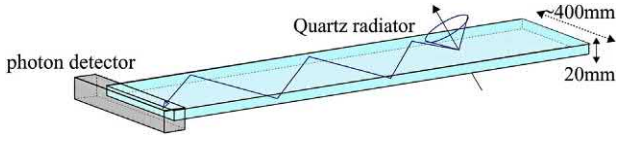

FIGURE 6.62 Schematic overview of the TOP counter. The path of a particle emitted from interaction point of the negatron-positron collider is illustrated by an arrow penetrating the quartz bar from below and producing Cherenkov photons when passing through the quartz radiator bar. The emitted Cherenkov photons are propagated inside the quartz radiator and detected by the photon detector at the bar end. The TOP counter measures the propagation time. *From Inami (2014), reprinted with permission from Elsevier © 2014.*

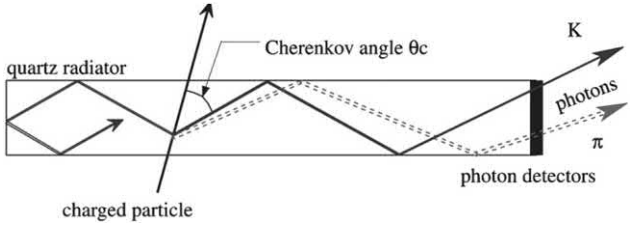

FIGURE 6.63 A side view schematic of the time-of-propagation (TOP) concept. The path length difference of Cherenkov photons emitted from a pion and a kaon within the radiator bar together with the difference in time-of-flight from the interaction point (i.e., particle origin) to the Cherenkov quartz radiator results in a difference in the Cherenkov photon arrival time at the photodetector. *From Nishimura et al. (2010), Nishimura (2011) and Iijima (2011), reprinted with permission from Elsevier © 2010.*

As noted by Inami (2011), time-of-propagation differences of 200 ps or more are found for normal incident 2 GeV/c K^+ and π^+, the time resolution for single photon detection needs about 40 ps. An additional property, that is utilized, is the time-of-flight (TOF) from the interaction point, which is the point of collision between the accelerated particles (e.g., e^+e^-) to the counter. The interaction point of the e^+e^- collider can be 1 meter away from the quartz bar. The distance from the interaction point affects the difference in the Cherenkov photons' arrival time at the photon detector additively in most cases (Inami, 2011), thereby improving the discrimination of particles (e.g. $\pi^{\pm}$ and $K^{\pm}$). Inami (2014) reports the application of the TOP counter mainly for the separation of $\pi^{\pm}$ and $K^{\pm}$ for the upgrade to the SuperKEKB/Belle II experiment at The High Energy Accelerator Research Organization (KEK) at Tsukuba, Ibaraki, Japan. In the Belle II experiment, the typical difference in the Cherenkov photon arrival times for photons produced by the $K^{\pm}$ and $\pi^{\pm}$ ranges between 150 and 200 ps; and measured with a time resolution of $\sigma \sim 40$ ps for each photon (Inami, 2014).

E. Time-of-flight Cherenkov counters

For a beam of particles of known momentum, a measurement of the time-of-flight (TOF) between a start and stop counter (*e.g.*, Cherenkov detectors) separated by several meters yields the mass of the particle (Va'vra et al., 2009; Ronzhin et al., 2010), a property key to particle identification. Numerous reviews on various designs of time-of-flight Cherenkov counters are found in the literature and current designs are reviewed by Gys et al. (2017), Harnew et al. (2016), Dey et al. (2015), Alici and ALICE Collaboration (2014), van Dijk et al. (2014), Križan (2013) and Lippmann (2012). Only the basic principles and some illustrative examples of time-of-flight Cherenkov measurements are made for particle identification.

An excellent example of the application of TOF Cherenkov counters is the utilization of proximity-focusing RICH detectors in conjunction with TOF measurements to supplement data for particle identification.

The relativistic momentum of the particle is expressed as

$$p = \gamma m v \tag{6.135}$$

where

$$\gamma = \frac{1}{\sqrt{1-\beta^2}} \tag{6.136}$$

is the relativistic Lorentz transformation factor (Airapetian et al., 2005; Lippmann, 2012), as described previously by Eq. (1.271) in Chapter 1, Volume 1, m is the particle mass, v is the particle velocity, and β is the relativistic phase velocity of the particle, that is, the velocity of the particle divided by the speed of light in a vacuum (v/c). From Eq. (6.136), Lippmann (2012) expresses the mass of the particle in terms of its momentum and phase velocity as

$$m = \frac{p}{c\beta\gamma} \tag{6.137}$$

as $\beta = v/c$; where the particle momentum may be determined by its curvature in a magnetic field and the particle velocity may be determined by time of flight and Cherenkov radiation measurements. From Eqs. (6.136) and (6.137), we can write the expression

$$\frac{mc}{p} = \frac{\sqrt{1-\beta^2}}{\beta} \tag{6.138}$$

which can be transformed to express the particle velocity β in terms if its mass m and momentum p as

$$\beta = \frac{1}{\sqrt{\left(\frac{mc}{p}\right)^2 + 1}} \tag{6.139}$$

The particle velocity β, as described by Lippmann (2012) is determined by time-of-flight (TOF) measurements of the particle flight time t over a given distance L along the particle trajectory; and β would then be expressed as

$$\beta = \frac{v}{c} = \frac{L}{tc} \tag{6.140}$$

Eqs. (6.139) and (6.140) may be used to write an equation for the particle mass m from measurements of L, t, and p, as described by Lippmann (2012) as

$$m = \frac{p}{c}\sqrt{\frac{c^2t^2}{L^2} - 1} \tag{6.141}$$

Thus, for particles of known momentum, Cherenkov detectors separated by the distance L, which can provide the start and stop signals for the measurement of t, can provide the data necessary to calculate the particle mass. In turn, Eq. (6.141) may be transposed to express the time t for a particle of mass m and momentum p to travel the distance L as

$$t = \frac{L}{c}\sqrt{1 + \left(\frac{mc}{p}\right)^2} \tag{6.142}$$

Lippmann (2012) points out that, if two particles with masses m_A and m_B carry the same momentum, their flight time difference can be calculated as

$$|t_A - t_B| = \frac{L}{c}\left|\sqrt{1 + \left(\frac{m_Ac}{p}\right)^2} - \sqrt{1 + \left(\frac{m_Bc}{p}\right)^2}\right| \tag{6.143}$$

Accurate measurements of the start and stop signals are provided by two radiation detectors. One detector is located upstream from the particle beam or trajectory and the second detector to provide the stop signal or end of the measured particle trajectory. Cherenkov photons, produced in the window of a PMT of a proximity-focusing RICH counter, have been used conveniently to provide the stop signal for TOF measurements (Iijima, 2010; Iijima et al., 2008; Križan, 2007, 2009; Adachi et al., 2007; Korpar et al., 2007). As illustrated in Fig. 6.64, Cherenkov photons, produced by a nuclear particle in the window of a microchannel plate PMT, are used to provide a stop signal for the measurement of time of flight, while the Cherenkov photons produced by the particle in passing through the aerogel detector yield ring imaging data. Thus, time-of-flight measurements supplement other particle identification methods, such as RICH counting.

An example of an arrangement where the concept of proximity-focusing RICH and TOF measurements are combined in the same detector is taken from the work of Iijima et al. (2008). The concept is illustrated in Fig. 6.65. The start signal for the measurement of time of flight of kaons and pions, illustrated in Fig. 6.65, is the interaction point (IP) and the stop signal is the signal registered by Cherenkov photons produced in the window of the PMT (referred to as a "Window Hit" in Fig. 6.65. The distance of particle travel L for the calculation of time of flight t and particle mass according to Eqs. (6.141) to (6.143) is measured in the experimental arrangement illustrated in Fig. 6.65 as $L = 1.8\text{ m} + 0.2\text{ m}$. Cherenkov photons produced by the particle passing through the aerogel detector are detected by the PMTs to yield ring image data; and the detection of a Cherenkov photon is referred to as a "Ring Hit" in Fig. 6.65. In addition to ring image, additional time-of-flight (TOF) information of the particle is obtained by

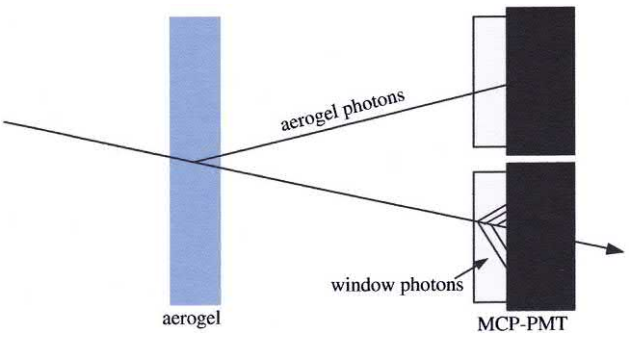

FIGURE 6.64 Schematic view of a combined proximity focusing RICH and TOF counter. Cherenkov photons produced by the charged particle in passing through the window of the microchannel plate photomultiplier tube (MCP-PMT) provide the stop signal for time of flight measurements. Cherenkov photons produced by the particle as it passes through the aerogel detector are detected by another MCP-PMT for ring imaging data. *From Križan (2009), reprinted with permission from Elsevier © 2009.*

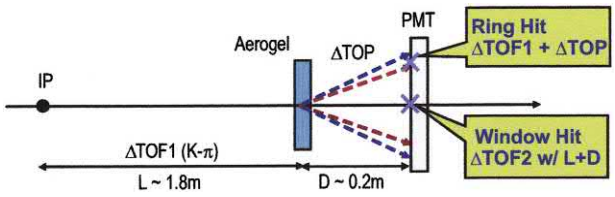

FIGURE 6.65 Concept of a RICH counter with TOF capability. *From Iijima et al. (2008), reprinted with permission of Elsevier © 2008.*

measuring TOF from the IP point to the aerogel detector (ΔTOF1 of Fig. 6.65) plus the time of propagation (TOP) of the Cherenkov photon from the aerogel radiator to the PMT (ΔTOP of Fig. 6.65). Iijima et al. (2008) measured TOF differences for 2 and 4 GeV/c kaons and pions to be 147 and 37 ps, respectively, for the "Ring Hits" and 184 and 47 ps for the "Window Hits". Such TOF measurements permit the identification of particles having momenta below the Cherenkov threshold (*i.e.*, when no Cherenkov photons are produced) in the aerogel radiator of refractive index $n = 1.03-1.05$, which is $\approx$ 1.5 GeV/c for kaons and $\approx$3 GeV/c for protons (Iijima et al., 2008).

The microchannel plate PMT photodetector is a very fast device with a reported time resolution per single photon to be $\sim$50 ps (Iijima et al., 2008). The power of TOF measurements to separate particles ($n_{\sigma_{TOF}}$) is a function of the TOF difference between the two particles ($t_A - t_B$) and the resolution of the TOF measurement (σ_{TOF}) or

$$n_{\sigma_{TOF}} = \frac{|t_A - t_B|}{\sigma_{TOF}} \tag{6.144}$$

With particle momentum $p >> mc$, Lippmann (2012) points out that the approximation

$$\sqrt{1 + (mc/p)^2} \approx 1 + (mc)^2/2p^2 \tag{6.145}$$

And from Eqs. (6.143)–(6.145), the separation power becomes

$$n_{\sigma_{TOF}} = \frac{|t_A - t_B|}{\sigma_{TOF}} = \frac{Lc}{2p^2\sigma_{TOF}}\left|m_A^2 - m_B^2\right| \tag{6.146}$$

For a given length (L) of measured particle trajectory of 3.5 m, the separation power of particles as a function of particle momentum and time resolution is illustrated in Fig. 6.66. Lippmann (2012) demonstrates from the separation power curves of Fig. 6.66, that assuming a time resolution in the range of 100–60 ps and requiring a separation power of $n_{\sigma_{TOF}} = 3$, the upper limits for the momentum are in the range of 2.1 GeV/c to 2.7 GeV/c for K/π separation and 3.5 GeV/c to 4.5 GeV/c for K/p separation.

Under development is a unique time-of-flight Cherenkov detector consisting of a panel of quartz plates (1 cm in width) as the Cherenkov radiators equipped with microchannel plate photomultipliers, described by Gys

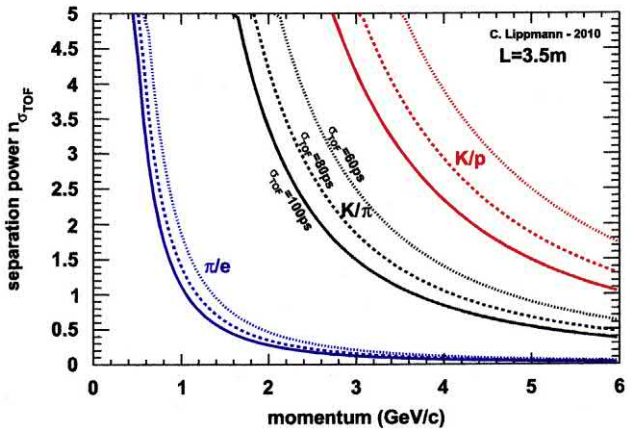

FIGURE 6.66 Particle separation with TOF measurements in three different system time resolutions ($\sigma_{TOF} = 60$, 80 and 100 ps) and for a track length $L = 3.5$ m. Infinitely good precisions on momentum and track length are assumed. Color is visible in the electronic version of the book. *From Lippmann (2012), reprinted with permission from Elsevier © 2012.*

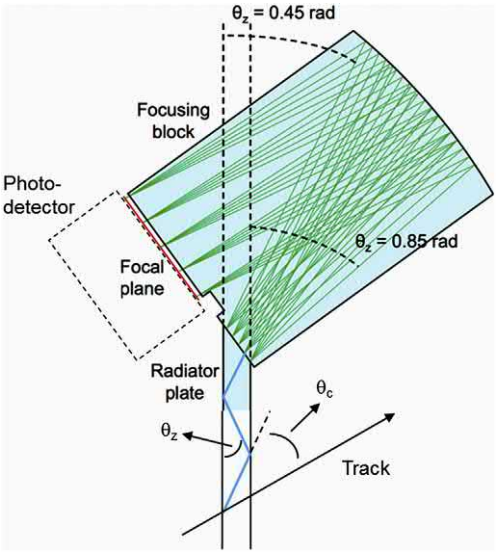

FIGURE 6.67 Schematic principle of the TORCH detector. A particle created at an interaction point of an accelerator beam at a distance of 10 m arrives at the 1-cm-thick quartz bar and passes through the bar creating Cherenkov photons. Some of the photons are reflected internally and focused onto microchannel plate photon detectors for determination of their arrival time. *Gys et al. (2017), reprinted with permission from Elsevier from © 2017.*

et al. (2017), Harnew et al. (2016), van Dijk et al. (2014), Križan (2013) and Charles and Forty (2011). The detector, known as TORCH (Timing Of internally Reflected Cherenkov photons) was designed to detect and discriminate particles following the interaction of colliding proton beams at the CERN Large Hadron Collider beauty experiment (LHCb). The detector is placed 12 m downstream of the interaction point. The detector has a specific design, which provides the Cherenkov angle (θ_C) and TOF measurements for the identification of particles of momentum up to 10 GeV/c.

The TORCH counter utilizes quartz plates of 1 cm thickness as the Cherenkov radiator. A charged particle (e.g., K/π) originating at the interaction point at distance of 10 m travels through the 1 cm quartz plate producing Cherenkov photons in the process. Some of the Cherenkov photons are trapped within the quartz plate by total internal reflection, as illustrated previously in Figs. 6.62 and 6.63. The internally trapped Cherenkov photons created in the 1-cm-thick plate is focused on to microchannel plate (MCP) photon detectors, as illustrated in Fig. 6.67, for measurement of their time of arrival. As described by Harnew et al. (2016), Cherenkov photons produced in the 1-cm thick quartz travel to the periphery of the detector by total internal reflection and their angles and arrival times are measured with the microchannel plate PMTs. The technique makes use of the measurement of the Cherenkov angle θ_c and the arrival time of the photon at the periphery of the quartz radiator bar.

Charles and Forty (2011) describe the calculations involved in the identification of kaons and muons with the TORCH. Only an abbreviated summary will be provided here; and a more detailed treatment may be obtained from Charles and Forty (2011) among other works cited previously. At the LHCb experiment, particles in the momentum range from 2 to 100 GeV/c can be identified by four methods, outlined by Charles and Forty (2011), which are summarized as follows.

(i) The first of these methods is the use of RICH detectors, independent of the TORCH detector described here. The principles of the RICH detectors were described previously in this chapter.

(ii) The second method of particle identification is by Cherenkov time-of-flight (TOF) measurement from the time that the particle is emitted from its origin, namely, the point of interaction, to its arrival at the Cherenkov detector at a distance of 12 m. Charles and Forty (2011) note that if a particle of mass m and momentum p is detected at position x and time t after travel from its origin, then the time of flight would be expressed as

$$t = \frac{x}{c}\sqrt{1+\left(\frac{m}{p}\right)^2} \approx \frac{x}{c}\left[1+\frac{1}{2}\left(\frac{m}{p}\right)^2\right] \tag{6.147}$$

and the difference in arrival times of kaons and pions would be a function of the mass difference of the two particles or

$$t_K - t_\pi = \frac{x}{c}\frac{1}{2p^2}\left[m_K^2 - m_\pi^2\right] \tag{6.148}$$

A fast response time provided by the Cherenkov detector is important for kaon identification in the

momentum range of 2−10 GeV/c. For a particle path length of 10 m, Charles and Forty (2011) calculate that a per-track time resolution of 12.5 ps and a per-photon time resolution less than 90 ps would be required.

(iii) The third method for charged particle identification, described by Charles and Forty (2011) is by the measurement of the time of propagation (TOP) or τ_γ of the Cherenkov photons over a path length d_γ. A charged particle traveling from the interaction point to the thin (10 mm) plane of the optically dense quartz detector will pass through the quartz producing Cherenkov photons emitted at an angle (θ_C) dependent on the phase velocity (β) of the particle and index of refraction (n) of the quartz radiator, where the threshold condition is

$$\cos\theta_C = \frac{1}{\beta n} \tag{6.149}$$

The Cherenkov photons propagate at the group velocity c/n_g and

$$n_g = c\frac{t_\gamma}{d_\gamma} \tag{6.150}$$

Charles and Forty (2011) point out that the relationship between n and n_g is a nonlinear function depending on the medium according to

$$n_g = n - \lambda\frac{dn}{d\lambda} \tag{6.151}$$

After solving for n from n_g, the particle phase velocity (β) and mass (m) are calculated according to

$$\beta = \frac{1}{n\cos\theta_C} \tag{6.152}$$

and

$$m = p\sqrt{n^2\cos^2\theta_C - 1} \tag{6.153}$$

(iv) A fourth approach combines the methods of particle time of flight and Cherenkov photon time of propagation described above with the utilization of the TORCH detector. A charged particle passes through the thin (10 mm) plane of quartz and the Cherenkov photons propagate via internal reflection to the periphery of the quartz radiator bar. Charles and Forty (2011) note that the arrival time of a Cherenkov photon at the edge of the plane is the sum of the time of flight of the particle track to the point of Cherenkov photon emission in the quartz, t, and the time of propagation of the Cherenkov photon in the medium (i.e., quartz), t_γ, which is calculated according to

$$t + t_\gamma = \frac{x}{c}\sqrt{1 + \left(\frac{m}{p}\right)^2} + \frac{d_\gamma n_g}{c} \tag{6.154}$$

and n_g is determined from

$$n = \frac{1}{\beta\cos\theta_C} = \frac{\sqrt{m^2 + p^2}}{p\cos\theta_C} \tag{6.155}$$

Harnew et al. (2016) underscore that the technique relies on the measurement of the Cherenkov angle θ_C and the arrival time of the Cherenkov photon at the periphery of the quartz radiator bar. The vertical dimension of the quartz detector plane is a direct measure of the angle of the Cherenkov photon path with the vertical axis (θ_Z), as described by van Dijk et al. (2014); and this track information with the photon hit provides an accurate measure of the photon path length (see Fig. 6.68). The focusing block at the edge of the detector plane can accept θ_Z values between 0.45 and 0.85 rad. The TORCH detector consists of 18 thin (10 mm) quartz modules each measuring 250 × 66 cm with their individual focusing block and photodetectors arranged in a fashion to completely surround the beam pipe of the large hadron collider up to ~ 30 m^2 time-of-flight Cherenkov detector. More detailed schematics are available from Harnew et al. (2016).

XIII. Neutrino detection and measurement

Cherenkov detectors, which utilize very large volumes of transparent material, such as water, heavy water, and ice have been designed to detect neutrinos from various sources such as solar neutrinos, atmospheric neutrinos of the cosmic ray showers, geo-neutrinos, artificially produced neutrinos arising from nuclear reactors and accelerators, and ultra−high energy (UHE) astrophysical neutrinos. Since neutrinos do not carry charge, they do not produce the Cherenkov effect. The Cherenkov photons, that are detected, are those produced by charged particles resulting from neutrino interactions such as the elastic scattering (ES) of electrons in the detector medium or via charged current (CC) or neutral current (NC) interactions of neutrinos with neutrons or protons of atomic nuclei. These neutrino interactions and the Cherenkov effect that they produce are described in detail in Chapter 1, Volume 1. Even ultra−high energy (UHE) astrophysical neutrino interactions with atomic nuclei can produce particles yielding Cherenkov radio waves, which are detected with antennas.

Very large volumes of water or ice, both naturally or artificially contained, are used as the transparent medium for the detection of Cherenkov photons produced by neutrino interactions. These detectors are designed to detect and measure neutrinos, and even discriminate between neutrinos of specific flavor, from various sources such as solar neutrinos, atmospheric neutrinos of the cosmic-ray showers, geo-neutrinos, and artificially produced neutrinos arising from nuclear reactors and accelerators.

Only a brief review of some of the methods used for the Cherenkov detection of neutrinos will be given here. More detailed information is available from the references cited and in a previous book by the writer (L'Annunziata, 2016).

A. Large light-water Cherenkov detectors

The world's largest ring-imaging water Cherenkov detector is the Super-Kamiokande detector, which is located in the Mozumi mine near the village of Higashi−Mozumi, Gifu, Japan. The detector cavity lies under the peak of Mt. Ikenoyama of 1000 m of rock or 2700 m-water-equivalent (m.w.e.) providing a shield against cosmic ray muons of energy < 1.3 TeV (Fukuda et al., 2003). The detector consists of a 50 kiloton stainless-steel water tank, 39 m in diameter and 42 m tall, illustrated in Fig. 6.69. The inner detector (ID) contains 11,129 inward-facing hemispherical PMTs each of 50 cm in diameter. Optically isolated from the inner detector are 1885 outward-facing hemispherical PMTs each of 20 cm diameter, which constitute part of the outer detector (OD). As described by Fukuda et al. (2003) neutrino interactions are identified via the Cherenkov light emitted by the charged particles that are produced in the ID. Events due to charged particles originating from events external to the inner detector are identified by the OD PMTs. The size, shape, and orientation of the Cherenkov light pattern produced by signals collected by the PMTs on the ID walls are used to identify the event as single-ring arising from electrons, single-ring arising from muons, or multiring events.

A brief history of the detector is given by Nishino et al. (2009); and current and future research are discussed by Li (2017), Kajita et al. (2016) and Nakahata (2015). The Super-Kamiokande detector has been in operation since 1996. The detector has yielded data leading to notable contributions in studies of neutrino flavor mixings and their masses (Ashie et al., 2005; Wendell, 2013; Okumura, 2015; Kajita et al., 2016), measurements of atmospheric and solar neutrinos and artificial accelerator-based neutrinos (Hosaka et al., 2006; Smy, 2013; Carminati, 2015; Renshaw, 2015;

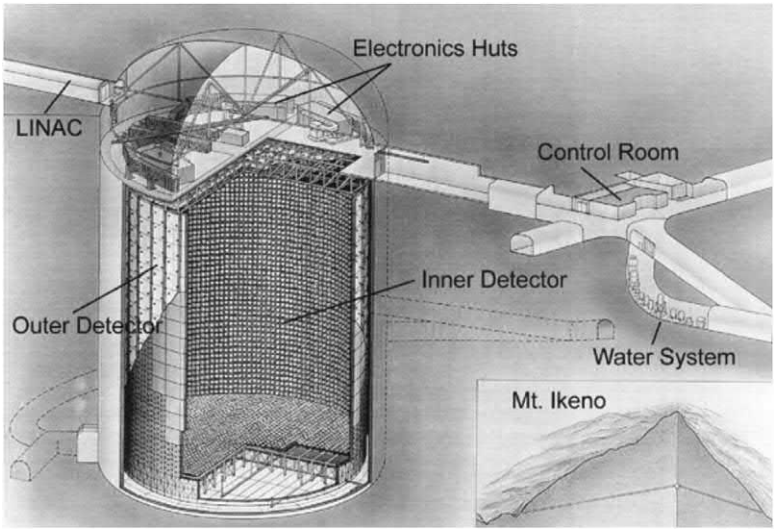

FIGURE 6.69 A sketch of the Super-Kamiokande Cherenkov detector under Mt. Ikenoyama, Japan. *From Fukuda et al. (2003) and Nishino et al. (2009), reprinted with permission from Elsevier © 2003.*

Abe et al., 2016; Desai and Liu, 2016; Sekiya, 2016; Li, 2017), and cosmic neutrinos from supernova explosions (Ikeda et al., 2007; Zhang, 2015; Himmel and Scholberg, 2016).

The Nobel Prize in Physics 2015 was awarded in one part to Takaaki Kajita of the University of Tokyo, Kashiwa, Japan for his work with the Super-Kamiokande Collaboration and in another part to Arthur B. McDonald of Queens University, Kingston, Canada for his work with the Sudbury Neutrino Observatory (SNO) Collaboration, which resulted in the words of the Nobel Committee "the discovery of neutrino oscillations, which shows that neutrinos have mass." The SNO detector is described in the next section of this chapter. From the detection and analysis of neutrinos they were able to demonstrate that neutrinos can oscillate from one flavor to another; and this would be possible only if neutrinos have mass. The Super-Kamiokande detected atmospheric neutrinos. The muon neutrinos (ν_μ) that arrived at the Super-Kamiokande detector from the atmosphere above were more numerous than the muon neutrinos that traveled through the globe and collided with the detector from below. This demonstrated that the muon neutrinos that traveled longer (i.e., through the earth) had more time to change into a neutrino of another flavor (e.g., ν_e or ν_τ). In addition, the SNO measured the solar electron neutrino (ν_e) intensity, as only electron neutrinos are produced by the Sun. Neutrinos of all three flavors (i.e., ν_e, ν_μ, and ν_τ) could also be detected by the deuterium in the SNO. As described by the Nobel Committee, the electron neutrinos were smaller in number than expected whereas the combined number of the three neutrino flavors corresponded to expectations, which indicated that the electron neutrinos had changed into a neutrino of another flavor (Rose, 2015).

The Super-Kamiokande (Super-K) is a 50 kton water detector. In the planning stage is the construction of the Hyper-Kamiokande (Hyper-K) as the next generation water detector (Li, 2017), which will consist of two identical tanks each with 520 kton of total volume and 380 kton of fiducial volume. The Hyper-K will have a fiducial volume 16 times greater than the current Super-K; and it will be equipped with 99,000 newly developed 50-cm PMTs for the inner detector and 25,000 20-cm PMTs for the outer detector with improved quantum efficiency. This will provide an instrument with greater potential for measuring atmospheric neutrinos, supernova burst neutrinos, geoneutrinos and in the search for proton decay (Nakahata, 2015; Hadley, 2016; Li, 2017).

B. Large D_2O neutrino target

A large Cherenkov detector, which utilized 1 kton of heavy water (D_2O) as the medium for the detection of solar and atmospheric neutrinos, is The Sudbury Neutrino Observatory (SNO). The SNO started collecting data in 1999. It is located at a depth of 2092 m (5890 ± 200 m.w.e) in the Vale-INCO Creighton Mine, outside Sudbury, Canada. The detector, illustrated in Fig. 6.70, consists of a 12 m diameter acrylic vessel containing D_2O target surrounded by 7 tons of H_2O shielding. The acrylic vessel housing the D_2O is surrounded by a 17.8 m diameter geodesic sphere (PSUP) illustrated in Fig. 6.70, holding 9456 inward-looking and 91 outward-looking 20 cm PMTs equipped with light concentrators to provide an effective coverage of ~54%. The volume of H_2O outside the geodesic support structure served as a cosmic-ray veto system and as a shield against natural radioactivity of the surrounding rock and construction materials (Boudjemline et al., 2010).

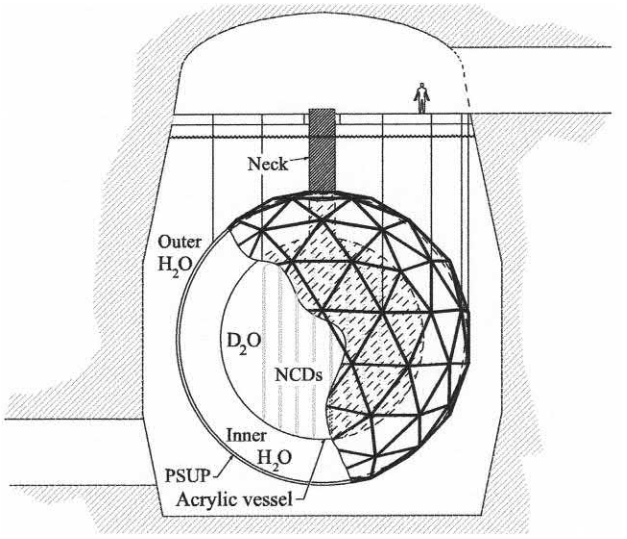

FIGURE 6.70 Layout of the SNO Cherenkov detector. The D_2O (1000 tons) was contained within an acrylic vessel. This volume could be accessed via the neck. The Neutral Current Detectors (NCDs), illustrated as vertical lines in the acrylic vessel housing the D_2O, were employed in the third phase of the experiment. The acrylic vessel was surrounded by water for shielding the radioactivity from the rock (outer H_2O) and photomultiplier tubes (inner H_2O). The photomultiplier SUPport Structure (PSUP) held the photomultiplier tubes and light concentrators. *From Boudjemline et al. (2010), reprinted with permission from Elsevier © 2010.*

The SNO detector was designed to measure the flux of neutrinos produced by ^8B decays in the Sun and to measure neutrino oscillations (Barros, 2013). As described in the previous section of this chapter, one-half of the Nobel Prize in Physics 2015 was awarded to Arthur B. McDonald of Queens University, Kingston, Canada for his work with the Sudbury Neutrino Observatory (SNO) Collaboration for the discovery of neutrino oscillation, which provides evidence that neutrinos have mass (Rose, 2015).

The current D_2O neutrino target of SNO will be replaced with a liquid scintillator in the search for neutrinoless double beta decay; and it will be renamed as SNO+,

as discussed in Chapter 6, Volume 1. The methods of neutrino detection used by SNO will be discussed here in light of the unique neutrino detection properties of heavy water.

The physics of neutrino detection in SNO are described in detail by Graham (2003), Formaggio (2009), Prior (2009), Hallin (2010) and Barros (2013). See also Chapter 1, Volume 1 of this book for an introduction to neutrino interactions with matter. A brief summary of neutrino detection in SNO will be provided here. The deuterium of the D_2O in SNO distinguishes it as a unique detector for solar neutrinos over H_2O detectors, because deuterium can be used to observe all three neutrino flavors, namely, the electron, muon, and tau neutrinos (ν_e, ν_μ, ν_τ). As described by Prior (2009), Barros (2013), and Bellerive et al. (2016), the SNO could measure the flux of ^{8}B neutrinos originating from the solar proton−proton chain via the following three distinct reactions, which are described in more detail in Chapter 1, Volume 1:

1. The charged-current reaction (CC):

$$\nu_e + d \rightarrow p + p + e^- \tag{6.156}$$

where the electron energy is well correlated with the energy of the electron neutrino. The electron neutrino ν_e is the only neutrino flavor that is able to convert the deuterium into two protons and a negatron.

2. The neutral-current reaction (NC):

$$\nu_x + d \rightarrow p + n + \nu_x \tag{6.157}$$

in which all of the neutrino flavors participate ($x = e$, μ, or τ) equally, provides a measurement of the total neutrino flux over the energy threshold of 2.2. MeV.

3. The elastic scattering (ES) reaction:

$$\nu_x + e^- \rightarrow \nu_x + e^- \tag{6.158}$$

is sensitive to all neutrino flavors, but with a reduced sensitivity to ν_μ and ν_τ. From this reaction and the anisotropic property of the Cherenkov radiation, the directional information of the neutrino can be determined. The Cherenkov light from the electron is measured for the detection of the ES and CC reactions; and the signal for the NC reaction is provided by the capture of a neutron by a nucleus.

Prior (2009) and Hallin (2010) describe the three techniques used to detect the neutrons from the NC reaction. The neutrons captured on the deuterium nucleus create a 6.26 MeV gamma ray. The gamma rays could be distinguished from the electrons by quantifying the isotropy of the Cherenkov light. Gamma rays undergo Compton scatter and consequently they create more isotropic hit patterns then electrons. A significant difference in the CC and NC flux measured was the first direct evidence for neutrino flavor transformation (Prior, 2009). In a second phase of the work, 2000 kg of NaCl was dissolved into the D_2O to enhance the neutron capture cross-section. Neutron capture on the ^{35}Cl nucleus results in a cascade of gamma-ray emissions at an 8.6 MeV threshold, which allows for a better separation of neutron capture events from other Cherenkov events. In a subsequent third phase, the NaCl was removed from the D_2O and ^{3}He counters were incorporated into the SNO detector (identified as Neutral Current Detectors, NCDs, in Fig. 6.70). The ^{3}He detectors increased the neutron capture cross-section. Another important application of the heavy-water Cherenkov detector is the detection and measurement of the high-energy muons that are created by cosmic-ray showers and atmospheric neutrino interactions. Atmospheric neutrinos are created from the decay of charged mesons (Formaggio, 2009), which are created by the interaction of primary cosmic rays with the Earth's atmosphere, as described in Chapter 1, Volume 1 and by the writer in a previous book (L'Annunziata, 2016). As described by Formaggio (2009) and Katz (2009), the atmospheric neutrino interactions are detected through the high-energy muons created via the charged-current reaction

$$\nu_\mu(\overline{\nu}_\mu) + N \rightarrow \mu^-(\mu^+) + X \tag{6.159}$$

with nuclei N of materials that surround the detector, and the overhead muons are created predominately in the Earth's upper atmosphere. Neutrino measurements from SNO are reported by Aharmim et al. (2005, 2007, 2008), Formaggio (2009), Barros (2013), and Bellerive et al. (2016).

C. Neutrino telescopes in lake and ocean floors

While the previously discussed Super-Kamiokande and SNO Cherenkov detectors for the measurement of neutrinos are very large man-made detectors, there are now in operation and in the planning, much larger detectors up to a km^3 in volume. These are based on the utilization of very huge natural bodies of water or ice as underwater detectors of neutrinos referred to as neutrino telescopes, which are reviewed by Katz (2009) Montaruli (2009a), Zornoza (2014) and Kappes (2016). Modern neutrino telescopes are derived from the original idea proposed by Markov and Zheleznykh (1961) of using a large body of water (or ice) as a detector of charged leptons (particularly muons, See Eq. 6.159) arising from charged-current (CC)

neutrino interactions with water nuclei. In their original paper Markov and Zheleznykh (1961) wrote

> *It is noteworthy that not only μ-mesons (from the reactions involving neutrinos) produced in the detector itself, but also the μ-mesons from the adjoining layers of the ground ('the cushion') are detected in the experiment … Owing to a long path of μ-mesons in the substance, the set up may collect μ-mesons from a stratum equivalent to a 500 m layer of water (the path of a μ-meson of energy 10^{11} eV) … A small neutrino interaction cross-section makes it possible to perform experiments deep underground and thus isolate the reactions (with the production of μ-mesons …) from the neutrinos coming from the lower hemisphere, i.e. passing through the earth. This experimental arrangement can in principle exclude the cosmic-ray background. All known particles with the exception of neutrinos are absorbed by scores of kilometres of the substance and thus are entirely screened by the planet … In underground experiments the relatively small background makes it possible to use large detector 'masses', which compensates to a certain degree for the weakness of high energy neutrino fluxes.*

The objective of neutrino astronomy, that is, the detection and measurement of neutrinos to observe astronomical objects and processes that are inaccessible to optical telescopes is expressed by Montaruli (2009a,b), who explains

> *… examples can be found in astronomy and history that show that whenever new instruments are pointed to the sky unexpected discoveries are possible. So the discovery of some astrophysical neutrino source not yet seen with other messengers … is possible. Neutrinos are good messengers due to their weakly interacting properties and due to the fact that, being neutral, they allow us to point back to their sources.*

Neutrino telescopes, as defined by Montaruli (2009a) are a three-dimensional array of photomultipliers (PMTs) to detect the Cherenkov light produced by charged particles with velocity in the radiator (water or ice) larger than that of light. The spacing between strings holding the Cherenkov photon sensors (PMTs) are governed by the properties of the radiator (water or ice) and the energy region of interest. Measurements of charged particles resulting from neutrino interactions with energies above 10 PeV require very large detector volumes with cubic-kilometer dimensions.

There are currently several large-scale neutrino telescopes in operation, which utilize Cherenkov photon detection and measurement, including, the BAIKAL Neutrino Telescope project in Lake Baikal in Siberia (Aynutdinov et al., 2011; Avrorin et al., 2013, 2014, 2016), ANTARES (Astronomy with a Neutrino Telescope and Abyss Environmental RESearch) in the Mediterranean Sea (Carr, 2008; Ageron et al., 2011; Aguilar et al., 2011; Brunner, 2011; Costantini, 2011; Margiotta, 2015; Spurio, 2015, 2017; De Bonis, 2016), and IceCube/AMANDA (Antarctic Muon and Neutrino Detector Array) at the South Pole (Achterberg et al., 2006; Berghaus, 2009; Montaruli, 2009b; Abbasi et al., 2010, 2011; Hultqvist, 2011; Neronov and Semikoz, 2016; Toscano and IceCube Collaboration, 2017), and the KM3NeT, which is a multi-km^3 detector in the Mediterranean Sea (Zornoza, (2014; Sapienza, 2015; Hofestädt, 2016; Margiotta, 2016). Reviews of underwater, underice, and underground measurements of neutrinos is available from Zornoza, 2014), Sapienza (2015), Hofestädt (2016), Margiotta (2016).

The BAIKAL neutrino telescope in Lake Baikal is described by Avrorin et al. (2011, 2014) and consists of an array of 10,385 PMTs enclosed in a transparent pressure sphere. Each of these constitutes an optical module (OM). The OMs are suspended in the lake on vertical cables forming a string of detectors. The telescope is configured in an arrangement of 27 clusters of strings, which are connected to the shore with individual electro-optical cables. Each of the 27 clusters is composed of eight 705 m long strings of OMs; and seven strings are arranged uniformly around a central string. Each string is comprised of 48 OMs spaced along the string by 15 m at water depths of 600−1300 m below the lake surface (see Fig. 6.71). Central strings of neighboring clusters are separated by 300 m; and the clusters are spaced over an area of 2 km^2 (Avrorin et al., 2014). The units are kept vertical in the lake bottom by buoys (Katz, 2009). The vertical units of OMs anchored on the lake bottom are distributed to cover a 2 km^2 circular area providing a 20 Mton Cherenkov H_2O detector. The detector is designed to record Cherenkov photons produced by high-energy muons resulting from charged-current reactions of high-energy neutrinos with nuclei.

The ANTARES neutrino telescope is a deep-sea neutrino telescope located at a depth of 2475 m in the Mediterranean Sea, 42 km from La Seyne sur-Mer in the South of France (Ageron et al., 2011; Costantini, 2011; Spurio, 2015; Margiotta, 2015; De Bonis, 2016). The detectors consist of 12 lines of 480 m length equipped with optical modules (OMs) anchored to the sea bed and kept vertical in the sea with buoys (see Fig. 6.72). Each line is equipped with 885 OMs. Each OM contains a 25 cm PMT housed in a 43 cm glass sphere directed at a 45 degree angle toward the sea bed. The space between the windows of the PMTs and their protective glass spheres are filled with a gel to provide their optical connection. The lines of detectors (OMs) are distributed at distances of 14.5 m from each other. As described by Aguilar et al. (2011), the main objective of ANTARES is to search for high-energy neutrinos of astrophysical origin. This is achieved by the detection of Cherenkov photons induced by the passage of relativistic particles (*e.g.*, muons) resulting from neutrino interactions in the material (sea water) surrounding the

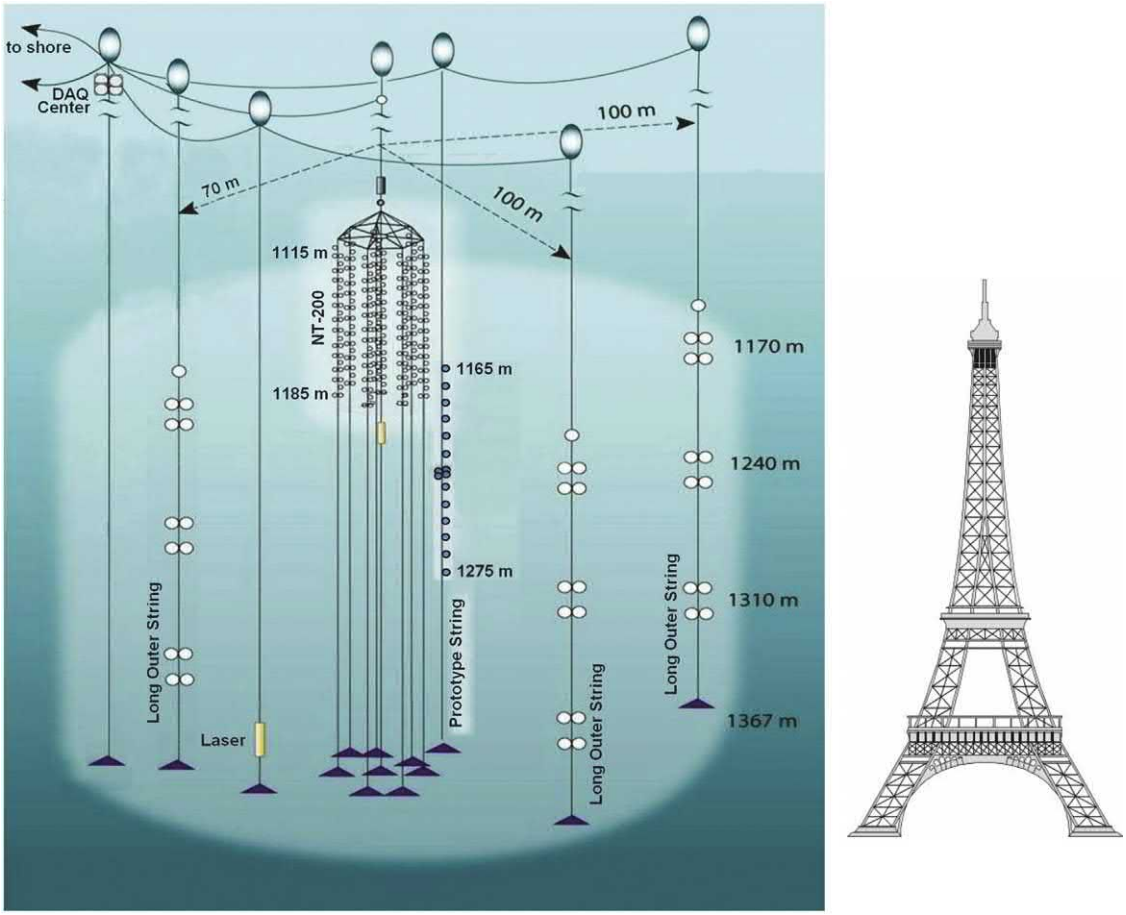

FIGURE 6.71 The BAIKAL Neutrino Telescope. A cluster of strings (one of 27 clusters encompassing 2 km^2 of lake waters) supported by buoys reach the Baikal lake floor to a depth of 1367 m. Optical modules containing PMTs for the detection of Cherenkov photons are attached to the strings (white circles). An image of the Eiffel Tower was included by the writer for a perspective of the magnitude of the detector. *Figure from Avrorin et al. (2011), reprinted with permission from Elsevier © 2011.*

detector including earth under the sea bed (see Fig. 6.73). The three-dimensional grid of PMTs or OMs is used to measure the arrival time and position of the Cherenkov photons, and their track reconstruction requires the knowledge of the relativistic arrival times of the Cherenkov photons at the PMTs (Aguilar et al., 2011; Costantini, 2011). The direction of the muon (created by a CC neutrino reaction with a nucleus; see Eq. 6.159) is reconstructed using the fact that it emits Cherenkov photons at a well-defined angle and does not suffer from multiple scattering at high energies. Thus, a simplified detector geometry is used composed of straight vertical lines and a simplified fit, which considers only direct Cherenkov photons within a narrow time window (Brunner, 2011).

The KM3NeT Neutrino Telescope is a deep-sea detector that is currently under construction at a depth between 2 and 5 km in the Mediterranean Sea; and reviews on the design, implementation and objectives of the detector are provided by Hernández-Rey (2014), Sapienza (2015), Hofestädt (2016), and Margiotta (2016). The following is a brief description of the neutrino detector design and objectives from the excellent review by Hernández-Rey (2014).

The placement of the neutrino telescope deep below the sea serves as a shield against the background of the cosmic-ray showers produced in the earth's atmosphere; and the darkness at the deep ocean water serves as an excellent medium for the detection of Cherenkov radiation produced by a charged particle, such as a muon, resulting from a high-energy neutrino CC reaction with an atomic nucleus in the sea floor or in the waters surrounding the detectors. Hernández-Rey (2014) notes that an array of photo sensors at sufficient depth in the sea can record the Cherenkov light induced by upcoming muon tracts that can originate exclusively from neutrinos that have traversed the earth and reacted with an atomic nucleus in the vicinity of the telescope array (see Fig. 6.74). High-energy neutrinos will produce high-energy muons via the CC interactions, which can travel several kilometers providing an effective detector volume for the neutrino telescope to detect and measure the

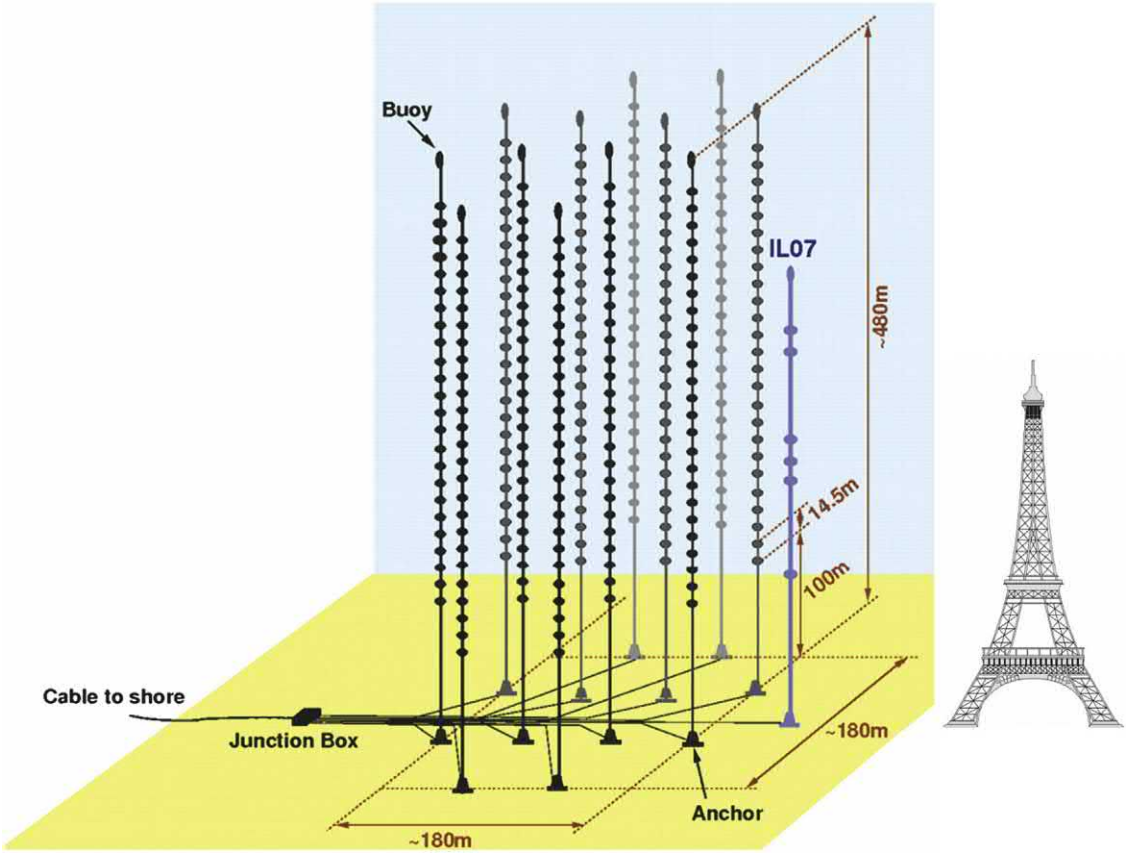

FIGURE 6.72 Schematic view of the ANTARES detector. A figure of the Eiffel Tower is inserted by the writer to give a perspective of the magnitude of the detector. *From Ageron et al. (2011), reprinted with permission from Elsevier © 2011.*

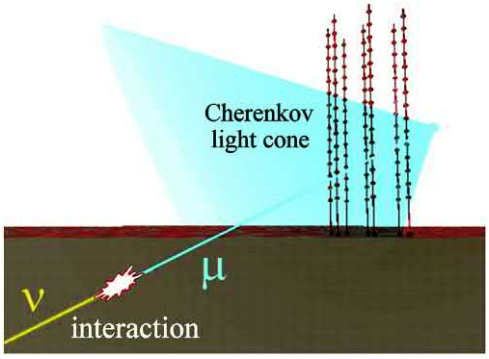

FIGURE 6.73 Principle of detection of high-energy muon neutrinos in an underwater neutrino telescope. The incoming neutrino that traversed the earth interacts with the material around the detector to create a muon. The muon produces Cherenkov light in the sea water which is then detected by a matrix of light sensors. The original spectrum of light emitted from the muon is attenuated in the water such that the dominant wavelength range detected is between 350 and 500 nm. *From Ageron et al. (2011), reprinted with permission from Elsevier © 2011.*

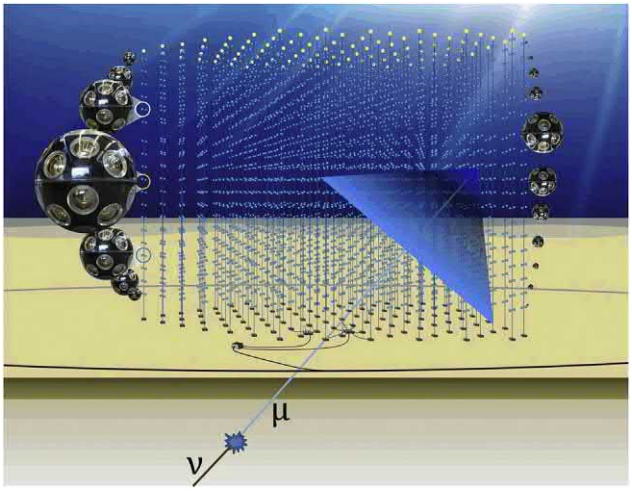

FIGURE 6.74 Artist view of a KM3NeT neutrino telescope with its array of spherical optical modules installed on long strings. The neutrino detection principle is illustrated whereby a high-energy neutrino produces a high-energy muon via a charged current reaction and the detection of the Cherenkov photons produced by the muon along its track. A Cherenkov cone is illustrated along the muon track in view of the optical modules of the neutrino telescope. On the left of the figure are enlarged illustrations of the circular optical modules each containing 31 three-inch (7.6 cm) PMTs housed in a 17-inch (43.2 cm) diameter pressure-resistant sphere. *From Margiotta (2016), reprinted with permission from Elsevier © 2016.*

resultant Cherenkov radiation. The measurement of Cherenkov photons from high-energy neutrino-to-muon interactions can yield the direction of travel of the neutrino, as the angle between the muon and its parent neutrino is low at high energies. Also, Hernández-Rey (2014) underscores that the neutrino energy, E, can be estimated within a factor of 2−3 by means of the measurement of the energy deposited in the detector by the corresponding muon track; and the showers of the cosmic radiation can provide yet better energy resolution of the order of 0.1−0.2 in log E scale.

When completed, the KM3NeT neutrino telescope will contain more than 12,000 optical modules containing PMTs installed on long strings referred to as detector units. The detector will be deployed at three sites, namely, three sites located near Toulon, France (40 km offshore and seabed at 2500 m), Capo Passero (80 km offshore and seabed at 3500 m) and Pylos, Greece (20 km offshore and seabed between 2500 and 5000 m). The optical modules are spherical in shape with a 17-inch diameter containing 31 PMTs together with the electronics for the PMT signal measurements of the Cherenkov photons and the transmission of data to shore.

Hernández-Rey (2014) notes that the main objective of the KM3NeT neutrino telescope is the measurement of astrophysical sources of neutrinos, which should provide information on the origin of cosmic rays. The primary target is Galactic sources and the primary channel for measurement is the CC interaction of the muon neutrino, as described previously; however, other neutrino sources and channels will also be targets.

D. Neutrino astronomy in Artic ice

The IceCube Neutrino Observatory is located at the South Pole. The observatory is composed of 86 instrumented strings, each holding 60 digital optical modules (DOMs) separated along each string by a distance of 17 m, which provide a total of 5160 photomultipliers. The strings supporting the DOMs are inserted into vertical drill-holes deep within the clear polar ice at depths between 1.5 and 2.5 km (Zornoza, 2014). An artist's depiction of the IceCube neutrino observatory is provided in Fig. 6.75. The drill holes are made with a special hot-water drilling technique whereby the water in the hole containing the instrumented strings of DOMs refreezes. Each DOM contains a 25 cm PMT in a glass pressure housing facing downward. The 86 strings of DOMs are separated by a distance of 125 m and distributed uniformly to provide a Cherenkov detector with PMTs extending throughout an effective volume of approximately 1 km^3 of clear ice. Toscano (2017) underscores that the one cubic kilometer of highly transparent glacial Antarctic ice provides the requirements for the detection of the faint Cherenkov photon emissions from the

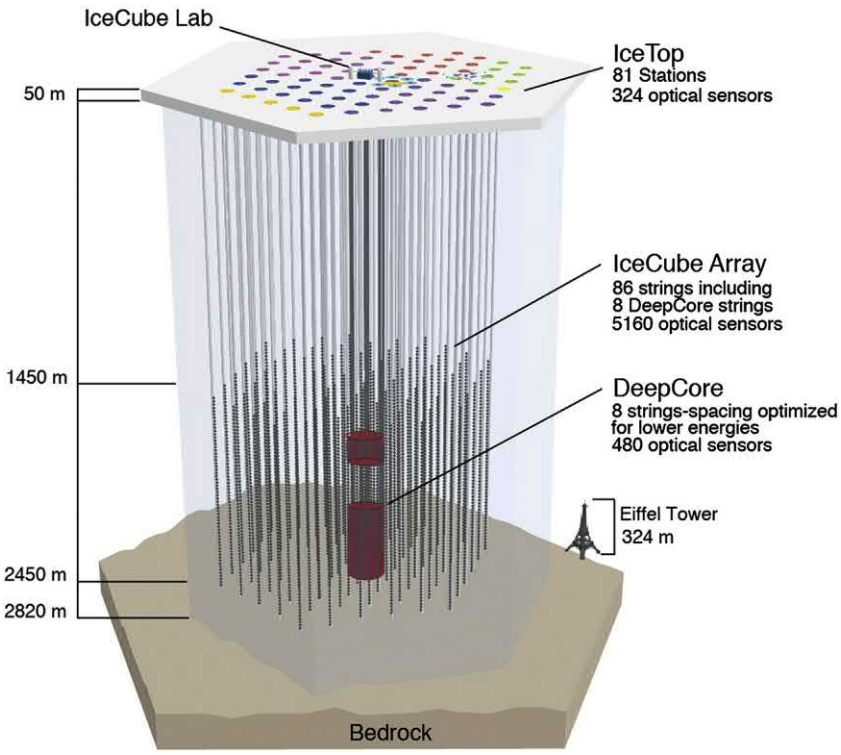

FIGURE 6.75 Artist cross-section of the IceCube detector, showing the IceTop array at the surface of the ice and the IceCube array roughly 2.5 km below. The DeepCore strings are shown in the shaded region at the middle of the IceCube detector. An image of the Eiffel Tower is provided in the lower right-hand portion of the figure to provide a perspective of the detector dimensions. *From Aartsen et al. (2016), reprinted with permission from Elsevier © 2016.*

secondary charged particles produced in neutrino interactions with the ice or the bedrock below at energies above 100 GeV. Also, a more densely instrumented DeepCore subarray (see Fig. 6.75), installed at the bottom center of IceCube, with an interstring spacing of 60 m and inter-DOM spacing of 7 m, provides a lower detection energy threshold of 10 GeV for neutrino oscillation research.

The ICECube neutrino observatory contains an additional component, called IceTop, which is a surface array of stations established for the Cherenkov detection of cosmic-ray air showers. Each IceTop station is located above each instrumented string (depicted as circular spots around the IceCube Lab in Fig. 6.75); and it consists of two tanks of clear ice monitored by two DOMs running at two different gains to achieve a dynamic detection range (Hultqvist, 2011).

The construction of IceCube was completed in 2011. Prior to its completion, measurements were carried out with a limited number of instrumented strings under the project name of AMANDA (Abbasi et al., 2010, 2011). As described by Abbasi et al. (2010), the strings of DOMs distributed in the deep ice core detect secondary muons via the CC interaction $\nu_\mu + N \rightarrow \mu + X$ (see Eq. 6.159). The muons are detected by the Cherenkov Effect, when they travel faster than the speed of light in ice, *i.e.*, $0.8c$, where c is the speed of light in a vacuum. Tamburro (2014) points out that at the altitude of IceTop, secondary cosmic-ray particles are sampled near the cosmic-ray shower maximum, which allows the precise measurement of the energy spectrum of primary cosmic rays with an energy resolution of 10% above 10^{16} eV. He also notes that events seen in coincidence by both IceTop and the deep detector (see Fig. 6.76) give clear insights into the nuclear composition of cosmic rays for energies that span PeV (10^{15} eV) to EeV (10^{18} eV). At muon energies above 1 TeV, additional Cherenkov light is detected, which arises from particles produced in the muon interactions, such as bremsstrahlung, pair production, and photonuclear reactions. The amount of Cherenkov light detected by the DOMs rises with the muon energy, which reflects also the energy of the parent neutrino. Thus, the detected light intensity can be used to determine the primary neutrino energy spectrum (Abbasi et al., 2010).

Toscano (2017) provides a summary of results from IceCube and its future expansion. Among these developments, which fall within the main goal of IceCube being the detection of astrophysical neutrinos, was the discovery in 2013 of a high-energy diffuse flux of neutrino events with energy ranging from the tens of TeV up to a few PeV of cosmic origin. This represents the first observation of astrophysical neutrinos; and the challenges presented with the current limited IceCube event sample underscores the need to overcome these challenges with a larger experimental detector volume. In this light, Toscano (2017) reports that there are plans to expand IceCube from its current 1 km^3 detector volume up to 10 km^3, dubbed IceCube-Gen2, which would include a radio Cherenkov array for ultra-high energy neutrino detection.

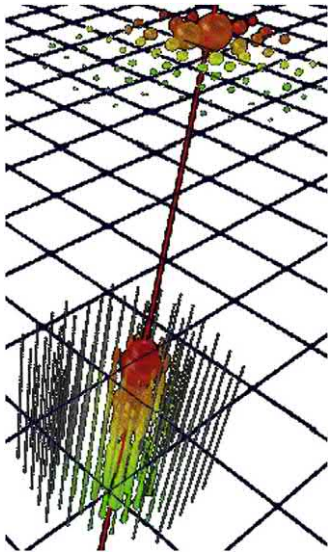

FIGURE 6.76 Cosmic ray coincident event recorded by IceCube. Triggered DOMs are indicated with colored spheres whose volume is proportional to the registered signal. Signal times are indicated with colors from red to green, red being the earliest. This event is reconstructed with an energy of 3×10^{17} eV and a zenith angle of 11.5 degrees. *For the color version of the figure, the reader is referred to the online version of the book. From Tamburro (2014), reprinted with permission from Elsevier © 2014.*

Reviews on the neutrino measurements obtained by IceCube are provided by Hussain (2014), Taboada (2014), Tamburro (2014), Neronov and Semikoz (2016), Toscano (2017), Tosi (2017), Xu (2017), and Aartsen et al. (2016, 2018).

E. Radio Cherenkov counting

There is an ongoing search for ultra-high energy (UHE) neutrinos with energies above 10^{18} eV to beyond the decade of 10^{20} eV and to find answers to their astrophysical origin. Varner (2010) underscores that protons of such high energy cannot travel far through the cosmic microwave background (CMB) without interacting, which would mean that such UHE neutrinos should be produced nearby; although there is no evidence for nearby point sources. The origin and properties of the cosmic microwave background are reviewed by the writer in a previous text (L'Annunziata, 2016). The loss or degradation of the UHE proton flux is due to the interaction of protons exceeding $\sim 4 \times 10^{19}$ eV with the cosmic microwave background photons forming a Δ^+ resonance (Gerhardt et al., 2010; Varner, 2010). The Δ^+ decay results in a chain of decays leading to ultra-high energy (UHE) neutrinos according to the GZK process; and these UHE neutrinos are also called GZK neutrinos. The GZK process is derived from the findings of Greisen (1966)

and Zatsepin and Kuz'min (1966) where UHE protons would interact with CMB photons according to the process:

$$p + \gamma \rightarrow \Delta^{+} \rightarrow n + \pi^{+} \tag{6.160}$$

where the subsequent π^{+} decay leads to a flux of UHE neutrinos according to

$$\pi^{+} \rightarrow \mu^{+} + \nu_{\mu} \tag{6.161}$$

$$\mu^{+} \rightarrow e^{+} + \nu_{e} + \overline{\nu}_{\mu} \tag{6.162}$$

UHE neutrinos, which interact in matter, produce a shower of particles. The particle shower produces ultimately a radio pulse of short duration ($\sim$1 ns) via a process known as the Askaryan Effect (Askaryan, 1962, 1965). As described by Gerhardt et al. (2010), Varner (2010) and Kravchenko (2012), the Askaryan Effect is the resultant radio emission due to the production of an excess of negative charge following the UHE neutrino interactions in matter. The particle shower that follows the interaction of a UHE neutrino with matter progresses with the Compton scattering of electrons and the annihilation of positrons resulting in a relativistic net negative charge excess of the order of magnitude of 20%–30% of the total number of charged particles in the shower. The charged particles are relativistic, and in a transparent medium such as ice or salt, they will emit Cherenkov radiation. Gerhardt et al. (2010) elucidate, that long wavelengths compared to the lateral spread of the shower add coherently; and the Cherenkov radiation is proportional to the square of the charge excess, *i.e.*, the intensity is a function of the square of the neutrino energy. In ice, the coherence yields radio waves with frequencies up to a few GHz.

Numerous detector designs have been implemented to measure the coherent Cherenkov emission at radio frequencies resulting from UHE neutrino interactions in massive transparent media. A thorough review of the numerous methods of detection of radio Cherenkov emissions is provided by Schröder (2017), and only a few examples will be described briefly here. One of these, is RICE (Radio Ice Cherenkov Experiment), described by Kravchenko (2012). The RICE experiment was installed in the South Pole with radio dipole antennas submerged deep within the ice in a 3D grid. The experiment included sensor arrays co-deployed with the IceCube experiment described previously in Part D of this section. The extension of the project was named NARC for Neutrino Array Radio Calibration. The dipole antennas are tuned to 200–500 MHz bandwidth in ice at a depth of 100–300 m below the ice surface. The RICE hardware has been modified for its implementation for the detection of radio Cherenkov emissions in boreholes of the IceCube experiment described preciously.

An illustrative example of radio Cherenkov measurements is the design of the ANITA (ANtarctic Impulsive Transient Antenna) experiment, which makes use of the entire Antarctic ice sheet as the neutrino target volume, is described by Varner (2010). The ANITA concept is illustrated in Fig. 6.77. A balloon capable of maintaining a 30- to 40-day flight with a large antenna payload at an altitude of $\sim$37 km above the Antarctic ice sheet records events in the 200–1200 MHz frequency range. At the altitude of $\sim$37 km, Allison et al., 2017 notes that the ANITA can monitor an extremely large volume of Antarctic ice equivalent to $\sim 1.6 \times 10^{6}$ km^{3}.

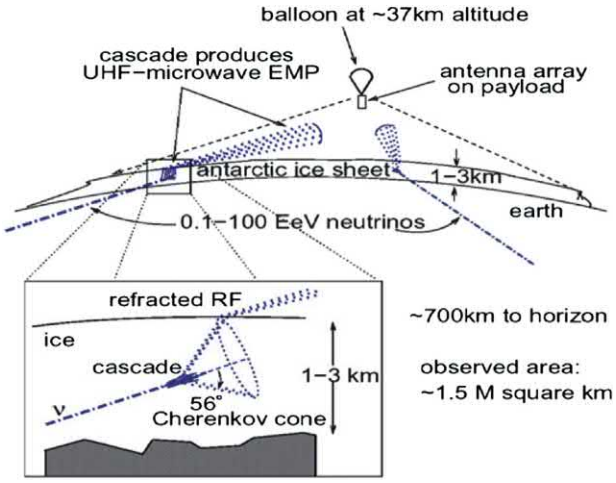

FIGURE 6.77 The ANITA concept: Antarctic ice sheet as detector and observation from a long duration balloon payload. The insert in the lower part of the figure illustrates a UHE neutrino interaction in the ice resulting in the emission of radio waves as a Cherenkov cone within a 3 km depth of the ice sheet and the refracted radiofrequency as it escapes the ice. The upper figure illustrates two conical emissions from the Antarctic ice sheet from 2 UHE (0.1–100 EeV) neutrino interactions and the antenna-equipped balloon above. *From Varner (2010) and Jones (2014), reprinted with permission from Elsevier © 2010–14.*

The ANITA balloon payload is equipped with up to 48 horn antennas, for the measurement of radio emissions at high frequencies of 200–1200 MHz. Schröder (2017) reports that at this frequency range detection is expected only for showers with favorable geometry: The Cherenkov cone of the shower must hit the antenna, which limits the detection to (i) near-horizontal air showers and (ii) neutrino-induced cascades in the overflown ice. ANITA has measured dozens of cosmic-ray air showers of energies of $\sim 10^{19}$ eV (Schoorlemmer et al., 2016; Hoover et al., 2010). For most of these high-energy air showers ANITA measured the radio signal after it was reflected off the ice rather than measure the radio signal directly (Alvarez-Muñiz et al., 2015).

An experimental design similar to ANITA is TAROGE (Taiwan Astroparticle Radiowave Observatory for Geosynchrotron Emissions) described by Chen et al. (2015) and Schröder (2017). The TAROGE experimental design is similar to that of ANITA with the exception that the radio

Cherenkov emissions are detected by an antenna receiver on a mountain top instead of a high-altitude balloon. The TAROGE receiver is designed to detect the Cherenkov radio emissions from UHE cosmic-ray showers either directly in the atmosphere or reflected off the ocean floor as well as those produced by CC interactions of neutrinos in the ocean floor.

Numerous radio Cherenkov detection designs are described in a very comprehensive review by Schröder (2017); and the reader is invited to peruse this work. Among these are the ARA (Askaryan Radio Array) described by Allison et al. (2017), which include antennas on the ice surface near the IceTop array illustrated earlier in this chapter. ARIANNA (Antarctic Ross Ice Shelf Antenna Neutrino Array) on the ross Ice Shelf at the Antarctic coast (Barwick et al., 2017), and TREND (Tianshan Radio Experiment for Neutrino Detection) in the Xianjiang Province, China, which is a radio-quiet zone permitting the design of a self-triggering detection of cosmic-ray showers. There are several other radio Cherenkov detector arrangements reviewed by Schröder (2017).

A unique detector arrangement is the Salt Sensor Array (SalSA) described by Connolly (2012). SalSa entails the deployment of an antenna array into one of many naturally occurring salt formations called diapirs that are found throughout the world. These consist of ~10 km deep salt beds originating from 100 to 200 million year old dried sea salt. As described by Connolly (2012), these salt beds have purities of ~95% and exhibit long attenuation lengths in the radio microwave frequency range. The volumes of these salt formations extend into the 10's-of-km^3, which can provide an excellent target material for UHE neutrinos. Arrays of antenna inserted vertically deep within the salt deposits can capture the radio Cherenkov signal created by particle cascades from UHE neutrino interactions in the salt. However, Schröder (2017) points out that due to the larger attenuation length of radio waves in ice, and because of the large available ice volumes at Antarctica and on Greenland, ice seems to be the medium of choice for future large-scale detectors of several 10 or 100 km^3.

Other methods, such as the Lunar Cherenkov technique described by Bray et al. (2012, 2015), McFadden et al. (2012), Mevius et al. (2012), and Schröder (2017), are aimed at detecting a nanosecond pulse of Cherenkov emissions, which are produced during UHE cosmic ray and neutrino interactions in the Moon's regolith. Earth-based radio telescopes would detect the coherent Cerenkov radiation emitted when the UHE neutrinos interact in the outer layers of the Moon. The maximum intensity of the coherent Cherenkov emission is reached at a frequency of about 3 GHz, where the radiation is concentrated in a narrow cone around the Cherenkov angle. Bray et al. (2012) describe the Parkes radio telescope, which is a single dish of 64 m diameter and 20 cm multi-beam receiver. They describe the technique used for aiming of the telescope whereby a radio pulse from a lunar Cherenkov event is expected to come from the limb of the Moon with radial polarization.

XIV. Applications in radionuclide analysis

The application of Cherenkov counting to the activity analysis of radionuclides is popular in those cases where the Cherenkov counting efficiency of the radionuclide of interest is adequate to meet particular detection limits required. Table 6.21 provides approximate Cherenkov counting efficiencies of radionuclides listed according to the E_{max} of the β particles emitted by each radionuclide. The E_{max} is listed, as the Cherenkov detection efficiency of radionuclides is a function of the beta-particle threshold energy (E_{th}) and the refractive index (n) of the medium calculated according to Eq. (6.39). For example, if water is the medium ($n = 1.333$), the Cherenkov counting efficiency would be a function of the number of β particles of $E > 262$ keV relative to the total number of β particles emitted by the radionuclide. Cherenkov counting is popular, when counting efficiencies are adequate, because of the ease of sample preparation and low expense incurred in the preparation and disposal of samples. Because water is generally the medium of counting, and fluor scintillation cocktail is not used, samples are often left in an unadulterated state suitable for subsequent tests such as chemical analysis, spectrometric analysis, chromatographic tests, or even chemical compound extraction and isolation. Some references to the application of Cherenkov counting to the analysis of specific radionuclides not already cited in this chapter are provided in the following paragraphs.

A. Phosphorus-32

Cherenkov counting of ^{32}P in aqueous extracts has become very popular, particularly because of the easy and inexpensive sample preparation techniques involved as well as the relatively high counting efficiencies obtained (L'Annunziata, 1997; L'Annunziata and Passo, 2002). As chemical quenching does not exist in pure Cherenkov counting, sample preparation techniques may be employed with little concern for the type of reagents used, and sample color may be bleached by chemicals with no quenching effect.

Cherenkov counting of ^{32}P in the dry state applied to research in the biological and physical sciences was reviewed previously in Section VI of this chapter. The popularity of Cherenkov counting of ^{32}P in aqueous media is more popular, due to obvious reasons including improved detection efficiency, as illustrated by numerous reports in the chemical, biological, and agricultural research

[a] *Where more than one β-decay transition occurs for a given radionuclide, the % intensity of each transition is provided in parenthesis.*
[b] *Counting efficiencies will vary from instrument to instrument and vial type (e.g., glass or plastic). Also, measurements made with older less efficient photomultiplier tubes provided lower counting efficiencies than can be expected from contemporary more efficiency phototubes. No attempt is made in this table to categorize the counting efficiencies according to the aforementioned governing factors that will affect slightly the counting efficiency values reported. The counting efficiencies listed are intended to provide a general idea of their orders of magnitude relative to the energies and intensities of the β-particle emissions. The counting efficiencies are values reported of nuclides in water without wavelength shifter unless otherwise noted.*
[c] *Measured with a high refractive index transparent ceramic.*
[d] *Nitrogen-16 is a high-energy beta-emitter (E_{max} = 10.4 MeV) and short-lived (half-life = 7.13 s). A Cherenkov detection efficiency is not available; however, the nuclide is detected by on-line Cherenkov counting to monitor D–T fusion following activation of ^{16}O by 14 MeV fusion neutrons via the ^{16}O(n,p)^{16}N reaction (Verzilov et al., 2006).*

(2002), Tuininga et al. (2002), Uz et al. (2002), Warshawsky et al. (2002), Wells et al. (2001), Wiebe et al. (1971), Wu et al. (2005), and Xu et al. (2007), among many others. Glass (1978) described a very simple and rapid sample preparation technique where ^{32}P- or ^{86}Rb-labelled plant material is ashed directly in glass liquid scintillation vials. An aqueous solution of 2.5 mM ANDA wavelength shifter can be added before counting to increase counting efficiencies. The addition of wavelength shifter is not necessary. Wahid et al. (1985) described a nitric-perchloric acid wet digestion procedure for the preparation of ^{32}P in plant material for Cherenkov counting. However, the writer prefers to ash the plant material at 500°C for 1 hour in a muffle furnace, because perchloric acid digestions are hazardous and tedious. The plant ash is dissolved with 2 mL of concentrated HNO_3 and transferred directly into a scintillation counting vial for Cherenkov counting. Subsequent to ashing and Cherenkov counting the analysis of total phosphorus by colorimetry via a phosphomolybdate blue complex is possible (L'Annunziata, unpublished work). Chemical analysis can be conveniently performed on samples before or after Cherenkov counting as no organic scintillation cocktails are added, which would interfere with chemical analyses. An example may be taken from the work of Palmer (1969) and Schneider (1971). These investigators determined the amounts of total phosphorus in biological samples by means of colorimetry using the phosphomolybdate blue complex method. The intensity of the blue color is proportional to the concentration of phosphorus in the sample according to Beer's law. After total phosphorus analysis, the activity of ^{32}P in the sample is determined by bleaching or decolorizing the blue complex at a high pH followed by Cherenkov counting of the colorless solution. However, the writer of this chapter prefers to carry out the Cherenkov counting of the samples before the colorimetric analysis of total phosphorus, because (1) the relative short half-life of ^{32}P ($t_{1/2}$ = 14.3 days) often warrants counting the samples without too much delay when sample activities are at their highest, and (2) bleaching of the samples to remove the blue color of the phosphomolybdate complex is not required when Cherenkov counting precedes colorimetry.

B. Strontium-89 and Strontium-90 (Yttrium-90)

The radionuclide ^{90}Sr ($t_{½}$ = 28.8 y) reaches secular equilibrium with its daughter ^{90}Y ($t_{½}$ = 64.06 hours). The ^{90}Sr is traditionally assayed in biological and radio-toxicological samples by separation and removal of strontium from other radionuclides in the sample; and this is followed by the radioassay of the parent–daughter nuclide ^{90}Sr/^{90}Y after a period of time to allow for the ingrowth of the ^{90}Y with its parent ^{90}Sr (L'Annunziata, 1971, see also a treatment of secular equilibrium between ^{90}Sr/^{90}Y in Chapters 1 and 6 of Volume 1). Alternatively, the daughter nuclide ^{90}Y may be extracted from the sample when it is at or near secular equilibrium with its parent ^{90}Sr. The ^{90}Y may then be measured; and the activity at the time of separation from its parent calculated. The analysis of ^{90}Sr(^{90}Y) may include also the analysis of the shorter-lived radionuclide ^{89}Sr ($t_{½}$ = 50.5 d) as discussed in Chapters 6 of Volume 1, because the two radioisotopes of strontium can be encountered in the same sample as fission products (L'Annunziata and Fuller, 1968).

The first reports on the application of Cherenkov counting to the analysis of ^{89}Sr and ^{90}Sr(^{90}Y) were by Buchtela and Tschurlovits (1975) from the Atominstitut in Vienna, Austria and Randolph (1975) from the US Atomic Energy Commission, Health Services Laboratory in Idaho Falls. Both papers were printed in the same journal volume. Since these pioneering papers, Cherenkov counting has become a popular method for the analysis of ^{89}Sr and ^{90}Sr(^{90}Y). Contemporary procedures may be divided into two groups, those that include the analysis of samples containing mixtures of combined ^{89}Sr–^{90}Sr(^{90}Y) and the more simplified case of samples containing only the parent/daughter radionuclides ^{90}Sr(^{90}Y). These two cases are described in this section with examples of contemporary methods.

1. Cherenkov counting of ^{89}Sr with ^{90}Sr(^{90}Y)

The Cherenkov counting of samples containing ^{89}Sr with ^{90}Sr(^{90}Y) is appealing, because both ^{89}Sr and ^{90}Y produce significant Cherenkov radiation. See Table 6.21 where ^{89}Sr and ^{90}Y are listed with Cherenkov counting efficiencies in water of ~40% and ~70%, respectively. Walter et al. (1993) demonstrated the simultaneous analysis of ^{89}Sr, ^{90}Sr(^{90}Y) by Cherenkov counting. The low Cherenkov counting efficiency of ~1% for ^{90}Sr in water facilitates the determination of ^{89}Sr in a freshly isolated ^{89}Sr–^{90}Sr mixture, that is, a ^{89}Sr–^{90}Sr mixture from which the ^{90}Y daughter is removed fresh by ion exchange, chemical precipitation, or other methods. After the chemical separation

of strontium from yttrium, Cherenkov counting of the sample is carried out at two different times and dates (t_1 and t_2). The first counting, t_1, is carried out directly after the chemical separation of strontium from yttrium, because the count rate will be derived mainly from the ^{89}Sr in the sample due to the very low ^{90}Sr Cherenkov detection efficiency (~1%). The Cherenkov photon count rate is determined again at time t_2, which is performed 3–5 days or more after the chemical separation of strontium. The period of time from t_1 and t_2 provides sufficient time for the significant ingrowth of ^{90}Y.

Banavali et al. (1992) used carbonate precipitation and extraction chromatography to isolate the radioactive strontium, which is analyzed by Cherenkov counting yielding primarily ^{89}Sr activity. After a few days to permit ingrowth of ^{90}Y, the sample is recounted by Cherenkov counting to permit the activity determination of ^{90}Y. The ^{90}Sr in the sample is calculated by the amount of ^{90}Y ingrowth from the time of radiostrontium isolation. See Chapter 1 for calculations of ingrowth of daughter nuclide with parent after the separation of radionuclides in secular equilibrium. The contribution of ^{90}Sr activity to the Cherenkov count rate of freshly prepared mixtures of ^{89}Sr–^{90}Sr cannot be ignored when the ^{90}Sr activity is higher than that of ^{89}Sr.

Chang et al. (1996) report a method utilizing Cherenkov counting and activity calculations for the analysis of mixtures of ^{89}Sr and ^{90}Sr(^{90}Y); and this method was utilized by Popov et al. (2006) to include accurate measurements of the chemical yields of strontium. The date and time of the chemical separation of strontium and yttrium are recorded as t_0. Following the chemical separation of strontium from yttrium (See Fig. 6.79), the activity of ^{89}Sr + ^{90}Sr is measured by Cherenkov counting at time t_1, for which the date and specific time is recorded. After a period of 3–5 days, the sample is counted again at time t_2, for which the date and time is also recorded. Strontium-85, which is added as a tracer to the sample before the chemical cleanup or separation of the strontium from yttrium, is analyzed by gamma-spectrometry, to determine the chemical yield of strontium.

A freshly prepared sample following chemical cleanup or isolation of stable and radioactive strontium from other elements (*i.e.*, yttrium was removed and discarded) is counted in a 15 mL aqueous solution contained in a plastic counting vial. The sample is counted in a region of 0–40 keV or other suitable counting window, which is sufficient to encompass all pulse heights produced by Cherenkov radiation. The 0–40 keV counting window is only an example where pulse height spectra are plotted on a scale calibrated to keV energy. The channel numbers illustrated in Fig. 6.78 are equivalent to approximately 0–50 keV, when the channel numbers are calibrated against beta-particle energies in keV as illustrated.

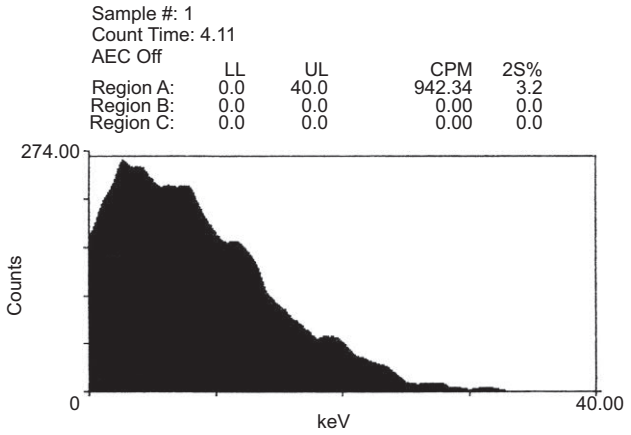

FIGURE 6.78 Cherenkov pulse height spectrum of ^{90}Sr(^{90}Y) in 10 mL H_2O in a plastic counting vial using a Packard 2750TR/LL liquid scintillation analyzer and a counting region of 0–40 keV. The sample contains 1300 DPM each of ^{90}Sr and ^{90}Y in secular equilibrium. Approximately 1% of the Cherenkov photons originate from ^{90}Sr; 71% arise from ^{90}Y. *From L'Annunziata (1997), unpublished work of the writer.*

The purified strontium samples are counted for sufficient time to provide a two sigma counting error of <2%, and the count rate, time, and date and time of ^{90}Y separation are recorded. The sample is allowed to sit for 3–5 days to permit significant ingrowth of ^{90}Y with ^{90}Sr, and the sample is then recounted in the same vial. The count rate and time of the second counting are recorded. The two count rates are used in Eqs. (6.163) to (6.167) to determine the activities of ^{89}Sr and ^{90}Sr. The equations used are found according to the derivations of Chang et al. (1996) and modified by Popov et al. (2006) as follows:

When a sample containing ^{89}Sr and ^{90}Sr is purified by separation from the ^{90}Y daughter, at time t_0, the total activity of the purified strontium is the sum of the two activities or

$$A_{t_0} = A_{^{90}Sr} + A_{^{89}Sr} \tag{6.163}$$

When the sample is counted for the first time t_1, there will have occurred during the interim of t_1-t_0 some ingrowth of ^{90}Y, and the ^{89}Sr decays slightly ($t_{1/2}$ = 50.5 days) while the ^{90}Sr will not undergo any significant decay ($t_{1/2}$ = 28.8 years). Therefore, at time t_1, when the first count rate is determined, the total activity in the sample is expressed as

$$\begin{aligned} A_{t_1} &= A_{^{90}Sr}\left[e^{-\lambda_1(t_1-t_0)}\right] + A_{^{90}Y} + A_{^{89}Sr}\left[e^{-\lambda_3(t_1-t_0)}\right] \\ &= A_{^{90}Sr}\left[e^{-\lambda_1}(t_1-t_0)\right] + A_{^{90}Sr}\left[1-e^{-\lambda_2(t_1-t_0)}\right] \\ &\quad + A_{^{89}Sr}\left[e^{-\lambda_3(t_1-t_0)}\right] \end{aligned} \tag{6.164}$$

where $A_{^{90}Sr}$, $A_{^{90}Y}$, $A_{^{89}Sr}$, λ_1, λ_2,and λ_3 are the activities in DPM and the decay constants for ^{90}Sr, ^{90}Y, and ^{89}Sr, respectively. At the time of the second counting, t_2, there

will be additional ingrowth of ^{90}Y and decay of ^{89}Sr in accord with the time difference from the time of counting and time of separation of strontium from yttrium, t_2-t_0, which is expressed as:

$$A_{t_2} = A_{^{90}Sr}\left[e^{-\lambda_1(t_2-t_0)}\right] + A_{^{90}Sr}\left[1-e^{-\lambda_2(t_2-t_0)}\right] + A_{^{89}Sr}\left[e^{-\lambda_3(t_2-t_0)}\right] \quad (6.165)$$

At time t_1, the Cherenkov count rate (CPM) C_{t_1} of the sample is expressed as

$$C_{t_1} = E_{^{90}\mathrm{Sr}}A_{^{90}\mathrm{Sr}}\left[e^{-\lambda_1(t_1-t_0)}\right] + E_{^{90}\mathrm{Y}}A_{^{90}\mathrm{Sr}}\left[1-e^{-\lambda_2(t_1-t_0)}\right] + E_{^{89}\mathrm{Sr}}A_{^{89}\mathrm{Sr}}\left[e^{-\lambda_3(t_1-t_0)}\right] + C_b \quad (6.166)$$

where $E_{^{90}Sr}$, $E_{^{90}Y}$, and $E_{^{89}Sr}$ are the counting efficiencies (CPM/DPM) of each nuclide and C_b is the background count rate.

At time t_2, the Cherenkov count rate C_{t_2} is expressed as

$$C_{t_2} = E_{^{90}\mathrm{Sr}}A_{^{90}\mathrm{Sr}}\left[e^{-\lambda_1(t_2-t_0)}\right] + E_{^{90}\mathrm{Y}}A_{^{90}\mathrm{Sr}}\left[1-e^{-\lambda_2(t_2-t_0)}\right] + E_{^{89}\mathrm{Sr}}A_{^{89}\mathrm{Sr}}\left[e^{-\lambda_3(t_2-t_0)}\right] + C_b \quad (6.167)$$

When the chemical yield of strontium, η_{Sr}, and sample volume or weight, V, are included, as reported by Popov et al. (2006), Eqs. (6.166) and (6.167) are solved to give the activities of ^{89}Sr and ^{90}Sr by the following equations

$$A_{^{89}Sr} = \frac{\dfrac{C_{t_1}-C_b}{\eta_{\mathrm{Sr}}\cdot V} - A_{^{90}\mathrm{Sr}}\cdot E_{^{90}\mathrm{Sr}}\cdot e^{-\lambda_1\cdot\Delta t_1} - A_{^{90}\mathrm{Sr}}\cdot E_{^{90}\mathrm{Y}} + A_{^{90}\mathrm{Sr}}\cdot E_{^{90}\mathrm{Y}}\cdot e^{-\lambda_2\cdot\Delta t_1}}{E_{^{89}\mathrm{Sr}}\cdot e^{-\lambda_3\cdot\Delta t_1}} \quad (6.168)$$

$$A_{^{90}Sr} = \frac{e^{-\lambda_3\cdot\Delta t_1}\cdot(C_{t_2}-C_b) - e^{-\lambda_3\cdot\Delta t_2}\cdot(C_{t_1}-C_b)}{\eta_{\mathrm{Sr}}\cdot V\{E_{^{90}\mathrm{Sr}}[e^{-\lambda_1\cdot\Delta t_2}\cdot e^{-\lambda_3\cdot\Delta t_1} - e^{-\lambda_1\cdot\Delta t_1}\cdot e^{-\lambda_3\cdot\Delta t_2}] + E_{^{90}\mathrm{Y}}[e^{-\lambda_3\cdot\Delta t_1}\cdot(1-e^{-\lambda_2\cdot\Delta t_2}) - e^{-\lambda_3\cdot\Delta t_2}\cdot(1-e^{-\lambda_2\cdot\Delta t_1})]\}} \quad (6.169)$$

where $\Delta t_1 = t_1 - t_0$ and $\Delta t_2 = t_2 - t_0$, and the chemical yield η_{Sr} is measured in % and expressed in the above equations as a decimal (e.g., 70% yield = 0.70) and the sample volume or weight V may be expressed in units of dm^3 or kg.

When ^{89}Sr is absent from the sample Chang et al. (1996) and Popov et al. (2006) show that Eq. (6.169) for the activity (DPM) of ^{90}Sr is simplified to

$$A_{^{90}Sr} = \frac{C_{t_2}-C_{t_1}}{\eta_{\mathrm{Sr}}\cdot V\cdot E_{^{90}\mathrm{Y}}[e^{-\lambda_2\cdot\Delta t_1} - e^{-\lambda_2\cdot\Delta t_2}]} \quad (6.170)$$

This method involves only the Cherenkov counting of the sample at two time intervals following the separation of radiostrontium from the radioyttrium daughter. For several standard mixtures of ^{89}Sr–^{90}Sr(^{90}Y) tested by Chang et al. (1996) a mean error of only 2.5% was reported for calculated ^{89}Sr and ^{90}Sr mixtures. Popov et al. (2006) provide also the calculations for the minimal detectable activities.

Chu et al. (1998) demonstrated the analysis of ^{89}Sr–^{90}Sr(^{90}Y) by separating the strontium from yttrium on a column of crown-ether Eichrom Sr resin (Horwitz et al., 1991, 1992; Vajda et al., 1992). The ^{90}Y and ^{89}Sr + ^{90}Sr fractions are separated and eluted from an 8-mm dia. × 40-mm long column of Eichrom Sr resin, and the two fractions are analyzed by Cherenkov counting. The ^{90}Sr activity is derived from the calculated activity of ^{90}Y, as the ^{90}S and ^{90}Y were in secular equilibrium, that is, their activities were equal prior to chemical separation. A similar analytical approach was taken by Grahek et al. (1999). A column of Eichrom Sr Spec resin was also used by Grahek and Rožmarić Mačefat (2004, 2005) to isolate strontium in liquid radioactive waste and seawater followed by successive Cherenkov counting for the determination of ^{89,90}Sr. Lazare et al. (2009) separated ^{90}Sr from other elements including yttrium by high pressure ion chromatography followed by liquid scintillation analysis; and they point to the potential of applying Cherenkov counting when ^{89}Sr is found to occur in significant levels of activity. Günther et al. (2009) isolated strontium by elution from a Chelite P chelating resin followed by Cherenkov counting immediately after isolation of strontium and after 3 days to allow for ^{90}Y ingrowth. St-Amant et al. (2011) extracted strontium using high-performance ion chromatography (HPIC) followed by Cherenkov counting immediately after the strontium purification for the quantification of ^{89}Sr followed by a second Cherenkov counting of the same sample after 10–14 days to quantify the ^{90}Sr activity based on ^{90}Y ingrowth.

Regardless of the detection method, the determination of ^{89,90}Sr requires the chemical isolation of pure strontium prior to detection and quantification. The selection of detection method, such as measurement with proportional counters, LSC with a cocktail, Cherenkov counting or a combination of LSC and Cherenkov counting, determines to what extent the isolated strontium should be purified, as

well as the conditioned methods of chemical isolation. In addition to the chemical isolation procedure, the method of detection also depends on the type of sample and the level of ^{89}Sr and ^{90}Sr activity. Consequently, there is no single methodology for isolation, but the simplest and most efficient is chosen. However, this does not mean that it is not demanding or complex. The detection and quantification of ^{89,90}Sr with proportional counters and LSC generally requires the removal of all interfering elements, both radioactive and stable. The presence of radioactive but also other stable isotopes prevents accurate quantification due to the appearance of self-adsorption with a proportional counter and due to chemical and color quenching with LSC. The advantage of Cherenkov counting is that it is not sensitive to the presence of stable isotopes and other elements (except in the case of intense coloration), which in certain circumstances permits larger quantities of strontium. It also allows for a so-called rapid determination. This takes several days, while the classic mode of determination requires almost 3 weeks. Therefore, Cherenkov counting in combination with strontium isolation procedures recently have largely relied on extraction with chromatographic separation using highly selective resins (Sr resin, Analig01Sr and Superlig620. The Analig01Sr and/or Superlig 620 is prepared by covalently bonding of ligand, most likely a variation of an 18-crown-6 (18C6) structure on silica gel (Zhang et al., 1997); and it presents the possibility of creating a methodology for the determination in very different samples. A typical example of the complexity of determination in the presence of active and stable isotopes is the determination of ^{89,90}Sr in seawater. Seawater contains 8 mg/L strontium. Consequently, sometimes it takes a couple of dozen liters of water for analysis (determination of very low activity), meaning that the fraction of strontium can contain up to several hundred milligrams of Sr. In this case, ^{89}Sr detection is hampered and the chemical isolation results in a reduction in the chemical yield of strontium. However, in Cherenkov counting the amount of stable strontium or residue of calcium does not affect the accuracy of the quantification (Grahek and Rožmarić Mačefat, 2005; Reddy et al., 2017). In developing the method of determination in seawater, Tayeb et al. (2016) encountered the problem of a reduction in the chemical yield in much smaller sample amounts. For this reason, separation was performed by using double-stacked Sr-resin cartridges illustrated in Fig. 6.79, which provided a minimal loss of Sr and improved the chemical yield by at least 25%. Strontium and yttrium were eluted from the Sr and DGA resin column with 8 mL of deionized water and 9 mL of 0.05 M HCl. This was followed by the immediate Cherenkov counting of the strontium fraction for ^{89}Sr activity determination, while ^{90}Sr was determined through ^{90}Y detection. This method has already been described in Section IX.A. and illustrated in Fig. 6.79.

The synergy between the various separation techniques and Cherenkov counting in the determination of ^{89,90}Sr in the presence of a series of radioactive isotopes can be seen in the development of an ^{89,90}Sr determination method as impurities in the production of ^{99}Tc radiopharmaceuticals, as demonstrated by Hou (2017). Technetium-99m is the principal radioisotope used in medical diagnostics and is mainly provided through a ^{99}Mo/^{99m}Tc generator. ^{99}Mo used for nuclear medical purposes is produced by the irradiation of enriched ^{235}U in a nuclear reactor and contains fission and activation products. Fig. 6.80 shows the methodology for determining low-activity ^{89,90}Sr in ^{99}Tc. After separating the radionuclide array in the anionic column, ^{89,90}Sr was isolated in the Sr columns. Cherenkov counting was applied twice to measure ^{89}Sr and ^{90}Sr. The first measurement was performed immediately after the Sr−resin column separation. The measured counts were mainly derived from the beta particle of ^{89}Sr. The ^{90}Sr in the separated strontium fraction was measured 7−10 days after the separation through Cherenkov counting of the ^{90}Y grown from the ^{90}Sr. It was shown that the contribution of

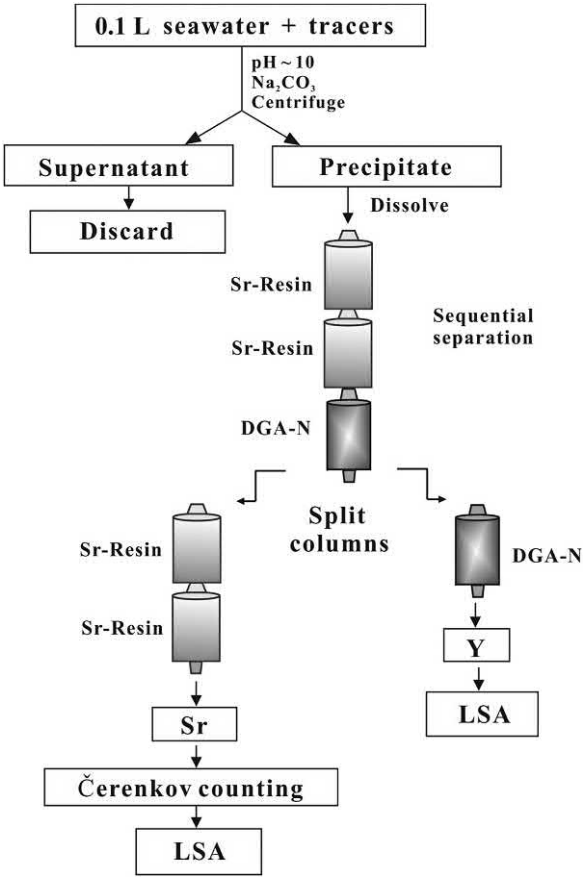

FIGURE 6.79 Flow chart of coprecipitation of 0.1 L seawater. The ^{90}Y (identified as Y in the figure may be analyzed most readily by Čerenkov counting in lieu of liquid scintillation analysis (LSA)). *From Tayeb et al. (2016), reprinted with permission from Elsevier © 2016.*

^{90}Sr (through ^{90}Y) had to be corrected if the ^{89}Sr measurement was performed more than 2 hours after separation.

Milanović and Grahek (2015) developed a method for determining ^{89,90}Sr in drinking water which includes the quantitative capture of ^{89,90}Sr in the SuperLig 620 column from a large volume of water samples and their on-column detection via Cherenkov counting. The SuperLig 620 column acts as a specific strontium separator and a sensor for Cherenkov counting. The method enables the determination of ^{89}Sr and ^{90}Sr above 30 mBq L^{-1} with good accuracy within 64 hours.

The described methods are applicable to the determination of ^{89}Sr and ^{90}Sr in a limited ratio of activity, which is usually not greater than 10, as demonstrated by Tovedal et al. (2008, 2009) and Grahek et al. (2012). When the ratio of activity is higher, the quantification of lower activity isotopes is not reliable or even impossible. However, the additional separation of yttrium and the determination of ^{90}Sr by means of ^{90}Y decay solves this problem. Tovedal et al. (2009), Holmgren et al. (2014), and Holmgren-Rondahl and Ramebäck (2018) demonstrated that the combination of Sr and Y separation in Sr resin and Cherenkov counting can reliably determine both isotopes in a ratio greater than 100:1. In the first step, strontium is separated and measured immediately after separation to determine ^{89}Sr. After a few days, the yttrium is separated from the fraction and ^{90}Sr is determined by ^{90}Y Cherenkov counting (see Fig. 6.36 in paragraph IX.A). The authors proposed this method for the analysis of fresh fallout after a nuclear explosion when the ratio between ^{89}Sr and ^{90}Sr can be 170:1.

Other strontium and yttrium isotopes, ^{91}Sr, ^{92}Sr, ^{91}Y, ^{92}Y, and ^{93}Y, produce Cherenkov radiation due to their sufficiently high beta energy, and as a consequence they interfere when determining ^{89}Sr and ^{90}Sr. Therefore, Tovedal et al. (2009) and Holmgren et al. (2014, 2016) developed a ^{89,90}Sr determination methodology that relies on double separation and a time lag to decay the isotopes ^{91}Sr ($t_{1/2}$ = 9.63 hours) and ^{92}Sr ($t_{1/2}$= 2.71 hours). However, the isotope ^{91}Sr decays to ^{91}Y with a half-life of 58.5d ($E_{\beta max}$ = 1.54 MeV) and may disturb ^{90}Sr determination through ^{90}Y decay. Zhu et al. (1990) determined ^{90}Sr and ^{91}Y in grass samples after the Chernobyl accident by extracting the yttrium from the sample and using Cherenkov counting in the selection of the ^{90}Y counting window to determine ^{90}Sr and then LSC with graphic separation to determine ^{91}Y. Grahek et al. (2012) investigated the possibility of the simultaneous determination of ^{89}Sr and ^{90}Sr in the presence of a third isotope that produces Cherenkov radiation. Changes in overall activity over time were observed and the activity of each isotope was calculated as a three-equation system with three unknowns of activity of individual isotopes in three counting time intervals. It has generally been shown that such a method of determination does not produce adequate results, but it is also shown that under certain conditions ^{91}Y can be determined. From the decay of ^{90}Y activity during its first half-life, the activity of ^{90}Y is calculated, while the activity of ^{91}Y is calculated from the difference in total activity and the activity of ^{90}Y. In experiments, ^{89}Sr was used instead of ^{91}Y due to its similar half-life and close beta energies.

2. Sequential Cherenkov counting and liquid scintillation analysis

Other methods used for the analysis of ^{89}Sr–^{90}Sr(^{90}Y) mixtures involve the sequential counting of the Cherenkov

radiation followed by liquid scintillation counting, which was first introduced by the pioneering work of Buchtela and Tschurlovits (1975) and Randolph (1975).

a. Sequential analysis without wavelength shifter

Rucker (1991) describes a sequential Cherenkov radiation and liquid scintillation analysis procedure for the analysis of ^{89}Sr–^{90}Sr(^{90}Y). The method involves purification of the sample, which includes removal of yttrium from the sample by hydroxide scavenging followed by strontium precipitation as a carbonate. The strontium carbonate is washed, dried, and weighed to calculate the percent chemical recovery of standardized strontium carrier. The precipitate is dissolved in 5 mL of 0.3 M HCl, and the aqueous solution is analyzed by Cherenkov counting without the use of any wavelength shifter to improve Cherenkov counting efficiencies, which provides a count rate primarily from the ^{89}Sr in the sample. After Cherenkov counting, scintillation fluor cocktail is added to the sample to provide a liquid scintillation count rate in one wide counting region not confined to spectral resolutions for the measurement of ^{89}Sr and ^{90}Sr. The two count rate determinations, the first Cherenkov counting and the second liquid scintillation counting, used optimized discriminator settings for the counting regions. Count ratios in each region for Cherenkov and LSC are used to correct for the fraction of the Cherenkov counts due to ^{90}Sr and the fraction of both counts (Cherenkov and LSC) due to the early ingrowth of ^{90}Y.

The following equations, derived by Rucker (1991), are provided to illustrate the basis of the method leading to the working equations:

The Cherenkov count rates, which are the first ones determined for a sample, originate primarily from ^{89}Sr (*e.g.*, Cherenkov counting efficiency 40%), with only a very small contribution from ^{90}Sr (1% counting efficiency) and the early ingrowth of ^{90}Y described by the equation

$$C_1 = {}^{89}\text{Sr cpm}_c + {}^{90}\text{Sr cpm}_c + {}^{90}\text{Y cpm}_c \qquad (6.171)$$

where C_1 is the net (background subtracted) Cherenkov count rate and cpm_c represents the Cherenkov counts per minute obtained from each nuclide. The liquid scintillation count rate comes primarily from the ^{89}Sr and ^{90}Sr of the sample with only a small contribution from the early ingrowth of ^{90}Y. The net count rate from liquid scintillation analysis, C_2, is therefore described by the following equation:

$$C_2 = {}^{89}\text{Sr cpm}_l + {}^{90}\text{Sr cpm}_l + {}^{90}\text{Y cpm}_l \qquad (6.172)$$

where cpm_l is the liquid scintillation count rate from each nuclide. Rucker (1991) then defines the count rates due to the early ingrowth of ^{90}Y, in Cherenkov counting and LSC, in terms of the ^{90}Sr count rates when the elapsed times are known from the time of chemical separation of ^{90}Y to the time of Cherenkov counting and the time of liquid scintillation counting as follows:

$$C_1 = {}^{89}\text{Sr cpm}_c + ({}^{90}\text{Sr cpm}_c)(A_1) \qquad (6.173)$$

and

$$C_2 = {}^{89}\text{Sr cpm}_l + ({}^{90}\text{Sr cpm}_l)(A_2) \qquad (6.174)$$

where

$$A_1 = 1 + (D_1)\left(1 - e^{-\lambda t_c}\right) \qquad (6.175)$$

and

$$A_2 = 1 + (D_2)\left(1 - e^{-\lambda t_l}\right) \qquad (6.176)$$

where $D_1$is the ratio of the Cherenkov counting efficiency of ^{90}Y to the Cherenkov counting efficiency of ^{90}Sr (*i.e.*, $\varepsilon^C_{^{90}\text{Y}}/\varepsilon^C_{^{90}\text{Sr}}$), t_c is the time from chemical separation of strontium from yttrium to Cherenkov counting, D_2 is the ratio of the liquid scintillation counting efficiency of ^{90}Y to the liquid scintillation counting efficiency of ^{90}Sr (*i.e.*, $\varepsilon^l_{^{90}\text{Y}}/\varepsilon^l_{^{90}\text{Sr}}$), t_l is the time from chemical separation of strontium from yttrium to liquid scintillation counting, and λ is the ^{90}Y decay constant.

The Cherenkov count rates and liquid scintillation count rates of each nuclide are demonstrated by Rucker (1991) to be related to their ratio of counting efficiencies by the two counting methods as follows:

$${}^{89}\text{Sr cpm}_c = ({}^{89}\text{Sr cpm}_l)(B_1) \qquad (6.177)$$

and

$${}^{90}\text{Sr cpm}_c = ({}^{90}\text{Sr cpm}_l)(B_2) \qquad (6.178)$$

where B_1 is the ratio of the ^{89}Sr Cherenkov counting efficiency to ^{89}Sr liquid scintillation counting efficiency (*i.e.*, $\varepsilon^C_{^{89}\text{Sr}}/\varepsilon^l_{^{89}\text{Sr}}$) and B_2 is the ratio of the ^{90}Sr Cherenkov counting efficiency to ^{90}Sr liquid scintillation counting efficiency (*i.e.*, $\varepsilon^C_{^{90}\text{Sr}}/\varepsilon^l_{^{90}\text{Sr}}$). Eqs. (6.177) and (6.178) are then incorporated into Eq. (6.173) to give

$$C_1 = ({}^{89}\text{Sr cpm}_l)(B_1) + ({}^{90}\text{Sr cpm}_l)(B_2)(A_1) \qquad (6.179)$$

The ratios of the counting efficiencies are determined experimentally by counting standards of known activity. The use of standard quench correction curves of counting efficiency versus a QIP should also be feasible. It is important to keep in mind, however, that an accurate determination of the counting efficiency of ^{90}Sr is best carried out with a freshly prepared sample, which has undergone only negligible ingrowth of daughter ^{90}Y from the time of chemical separation of parent and daughter to the time of determination of the counting efficiency of ^{90}Sr.

Rucker (1991) solved simultaneously Eqs. (6.174) and (6.179) to give

$$^{90}\text{Sr cpm}_l = \frac{[(B_1)(C_2) - C_1]}{[(B_1)(A_2) - (B_2)(A_1)]} \tag{6.180}$$

and

$$^{89}\text{Sr cpm}_l = C_2 - (A_2)(^{90}\text{Sr cpm}_l) \tag{6.181}$$

The count rates of ^{89}Sr and ^{90}Sr obtained from Eqs. (6.180) and (6.181) can then be converted to activities (DPM) by dividing by their respective liquid scintillation counting efficiencies. Using the activity conversion of Rucker (1991), the sample disintegration rates can be expressed in terms of activity units per sample volume by including the sample volume, strontium recovery rate from the chemical separation, and a conversion factor to activity units as follows:

$$^{90}\text{Sr in pCi/L} = \frac{(^{90}\text{Sr cpm}_l)}{\left[\left(\varepsilon^l_{^{90}\text{Sr}}\right)(V)(R)(2.22\ \text{DPM/pCi})\right]} \tag{6.182}$$

and

$$^{89}\text{Sr in pCi/L} = \frac{(^{89}\text{Sr cpm}_l)}{\left[\left(\varepsilon^l_{^{89}\text{Sr}}\right)(V)(R)(2.22\ \text{DPM/pCi})\right]} \tag{6.183}$$

where $\varepsilon^l_{^{90}\text{Sr}}$ and $\varepsilon^l_{^{89}\text{Sr}}$ are the liquid scintillation counting efficiencies of ^{90}Sr and ^{89}Sr, respectively, V is the sample volume in liters (L), R is the chemical recovery in decimal percent, and 2.22 DPM/pCi is the conversion factor from sample DPM to pCi.

Quantitative recoveries are reported by Rucker (1991) using various mixtures of ^{89}Sr and ^{90}Sr standards. Obviously, the analysis of ^{90}Sr activity represents also the activity of its daughter nuclide ^{90}Y, which reaches secular equilibrium as ^{90}Sr(^{90}Y) after approximately 18 days (L'Annunziata, 1971). Groska et al. (2012) used this principle to test the methods of determination of radiostrontium in milk and water samples as well as radioactive waste. Analytical methods using selective Sr resin for Sr separation and DGA resin for Y separation with liquid scintillation spectrometry and Cherenkov counting were used for ^{89,90}Sr determination. Relations for activity calculation in different counting combinations according to the recommended procedure of the IAEA for the determination of ^{89}Sr and ^{90}Sr in milk samples in emergency situations (IAEA, 2013) were used. The calculation techniques are compared in terms of the trueness and accuracy of the results and the limit of detection. Uncertainties and detection limits were calculated using the spreadsheet method. Holmgren-Rondahl and Ramebäck (2018) used a similar approach, with respect to uncertainty measurements when determining ^{90}Sr in the presence of huge ^{89}Sr activity.

b. Sequential analysis with wavelength shifter

Walter et al. (1993) describe the activity analysis of mixtures of ^{89}Sr and ^{90}Sr(^{90}Y) using Cherenkov counting with wavelength shifter followed by liquid scintillation analysis. A wavelength shifter was used during Cherenkov counting to increase the Cherenkov counting efficiencies of ^{89}Sr and ^{90}Sr.

As in the previous method, the ^{89}Sr and ^{90}Sr of the sample are separated from ^{90}Y by chemical means. The γ-ray emitters ^{85}Sr and ^{88}Y are used as tracers to measure the chemical yields in the separation procedures, because they do not cause interference in Cherenkov or liquid scintillation counting with the exception of count rate measurements of low activity samples.

Once purified, the radiostrontium samples are counted for Cherenkov radiation in 6 mL of aqueous solution in a counting region that accepts all pulse events arising from Cherenkov photons. The aqueous solution used for Cherenkov counting was doped with a 4.0 g/L concentration of the sodium salt of 1-naphthylamine-4-sulfonic acid as wavelength shifter. Walter et al. (1993) report increases in Cherenkov counting efficiency with the wavelength shifter by a factor of 1.55 for ^{89}Sr and 3.2 for ^{90}Sr compared to detection efficiencies without a shifter. Cherenkov counting efficiencies reported with wavelength shifter are ^{90}Sr 6.3%, ^{89}Sr 64%, ^{90}Y 81%, ^{85}Sr 0.3%, and ^{88}Y 0.2%. The latter two nuclides are used as tracers to determine the yields of the chemical separation of Sr and Y, respectively, from the sample.

After the Cherenkov counting of the samples, 10 mL of liquid scintillation fluor cocktail are added to the 6 mL of aqueous solution in each sample counting vial. The liquid scintillation assay was carried out without counting region limitations, and quench correction was determined with calibration curves of counting efficiency versus an external standard quench-indicating parameter. However, in the previous step of Cherenkov counting, an external standard QIP cannot be used in most cases as described previously in this chapter.

After completion of the two count rate determinations on the same sample, Walter et al. (1993) used the following equations to convert the count rates to ^{89}Sr and ^{90}Sr disintegration rates:

$$D_{89} = \frac{1}{f_\varepsilon}\left[R_C\varepsilon^L_{90} - R_L\varepsilon^C_{90}\right] \tag{6.184}$$

$$D_{90} = \frac{1}{f_\varepsilon}\left[R_L\varepsilon^C_{89} - R_C\varepsilon^L_{89}\right] \tag{6.185}$$

with

$$f_\varepsilon = \varepsilon_{90}^L \varepsilon_{89}^C - \varepsilon_{89}^L \varepsilon_{90}^C \tag{6.186}$$

where D_{89} and D_{90} are the disintegration rates (DPM) of ^{89}Sr and ^{90}Sr, R_C and R_L are the net count rates (CPM) corrected for background for the Cherenkov counting and liquid scintillation counting of a sample, respectively, ε_{89}^C and ε_{90}^C are the Cherenkov counting efficiencies for ^{89}Sr and ^{90}Sr, respectively, and ε_{89}^L and ε_{90}^L are the liquid scintillation counting efficiencies of ^{89}Sr and ^{90}Sr, respectively.

A sequential Cherenkov counting followed by dual-region liquid scintillation analysis technique described by Walter et al. (1993), permits the assay of ^{89}Sr and ^{90}Sr even after significant ingrowth of ^{90}Y up to 6.6 half-lives of ^{90}Y with average deviations of only 6.6% from the true values.

C. Strontium-90(yttrium-90) exclusive of strontium-89

The Cherenkov analysis of ^{90}Sr(^{90}Y) in the absence of ^{89}Sr may involve one of following methods of approach: (1) the chemical separation of the yttrium from other elements in the sample, when the parent-daughter nuclides ^{90}Sr/^{90}Y are in equilibrium, followed by the Cherenkov counting of ^{90}Y in aqueous media or (2) The separation of strontium from other elements in the sample followed by the Cherenkov counting of ^{90}Sr including the ingrowth of its daughter nuclide ^{90}Y. These methods will be discussed subsequently in this section.

1. Chemical separation and Cherenkov counting of ^{90}Y

The chemical separation of yttrium from other elements of the sample after secular equilibrium of the ^{90}Sr(^{90}Y) is reached, followed by the counting of the separated ^{90}Y activity, and the calculation of the ^{90}Y activity at the time of its separation from strontium was the traditional method of analysis of ^{90}Sr(^{90}Y) in secular equilibrium (L'Annunziata, 1971). Once the ^{90}Y is separated from ^{90}Sr, it will decay by its half-life of 64.06 hours. The activity of ^{90}Y at the time of chemical separation from its parent is used to determine the activity of ^{90}Sr. The time of chemical separation and the time of Cherenkov counting of the isolated ^{90}Y are recorded. The ^{90}Y decay that occurs during that period is calculated to arrive at the ^{90}Y activity at the time of chemical separation from its parent ^{90}Sr, when the parent and daughter nuclides were in secular equilibrium, that is, when the activities or DPM values of the two radionuclides were equal as discussed in Chapter 1, Volume 1.

Several examples of the application of the above technique to the analysis of ^{90}Sr are available from the literature including works by Bjornstad et al. (1992), Breban et al. (2004), Dewberry et al. (2000), Ghods et al. (1994), Jabbar et al. (2009), Laissaoui et al. (2002), Llauradó et al. (2001), Martin (1987), Mosqueda et al. (2006), Poletiko et al. (1994), Popov et al. (2009), Rao et al. (2000a,b), Shabana et al. (1996), Shawky and El-Tahawy (1999), Scarpitta et al. (1999), Suomela et al. (1993), Torres et al. (1999, 2002), and Vaca et al. (1999, 2001a,b). Some researchers elect to separate the ^{90}Sr(^{90}Y) by chemical precipitation of ^{90}Y followed by Cherenkov counting of ^{90}Y (Shawky and El-Tahawy, 1999; Jabbar et al., 2009). Several researchers have adopted the method based on that of Bjornstad et al. (1992) and Suomela et al. (1993), which involves the separation of ^{90}Sr and ^{90}Y by chemical extraction of ^{90}Y with 5%−10% HDEHP (di-2-ethyl-hexyl-phosphoric acid) in toluene (Laissaoui et al., 2002; Llauradó et al., 2001; Mosqueda et al., 2006; Torres et al., 1999, 2002; Vaca et al., 1999, 2001a,b). The ^{90}Y in the organic phase is then back-extracted with 3M HNO_3, precipitated as $Y(OH)_3$, and then redissolved in aqueous solution for Cherenkov counting of ^{90}Y. A brief description of the method used is provided below. Detailed procedures are available from the original papers.

The Swedish Radiation Protection Institute has issued a detailed procedure for the Cherenkov analysis of ^{90}Sr in food and environmental samples authored by Suomela et al. (1993). The procedure entails the following basic steps (1) ashing of the organic samples at 610°C, (2) dissolution of the ash in dilute acid, (3) the addition of yttrium carrier (10 mg of stable Y^{3+}) to facilitate extraction and chemical separation of yttrium, (4) extraction with HDEHP in toluene at low pH to remove ^{90}Y (The Sr−Y separate at this stage of the procedure. The time of the extraction is noted, because the separated ^{90}Y can be observed to decay at its half-life of 64.06 hours. The Y collects in the organic phase, and the Sr remains in the aqueous phase). (5) back-extraction of the organic phase with 3M HNO_3 to transfer the Y into the aqueous phase, (6) precipitation of yttrium from the aqueous phase as yttrium hydroxide at high pH, (7) dissolution of the yttrium hydroxide in 1 mL of conc. HNO_3, (8) dilution of the dissolved yttrium hydroxide with 14 mL of distilled water, (9) transfer of the solution to a 20-mL plastic scintillation counting vial, and finally (10) counting of the ^{90}Y in a counting region set to receive pulse events arising from Cherenkov photons. The ^{90}Sr of the sample is calculated according to the equation:

$$A_{90_{Sr}} = \frac{(R - R_0)e^{\lambda \Delta t}}{(E)(f)} \tag{6.187}$$

where $A_{^{90}Sr}$ is the activity of ^{90}Sr in becquerels or disintegrations per second (DPS), R is the gross ^{90}Y Cherenkov count rate of the sample in counts per second, R_0 is the background Cherenkov count rate, that is, count rate of a

blank counting vial in counts per second, λ is the decay constant of ^{90}Y in units of hours^{-1},

$$\lambda = 0.693/t_{1/2} = 0.693/64.06 \text{ hours} = 0.0108 \text{ h}^{-1} \quad (6.188)$$

Δt is the time interval in hours between the chemical separation of ^{90}Y and the time of counting, E is the decimal equivalent of the percent Cherenkov counting efficiency of ^{90}Y, and f is the chemical yield of the extracted yttrium.

Tayeb et al. (2015) developed a rapid method for the indirect determination of ^{90}Sr from its progeny ^{90}Y in seawater. The method consists of yttrium coprecipitation with hydrous titanium oxide (HTiO), yttrium separation in DGA-N and TDCR Cherenkov counting for ^{90}Y determination. LSA was used for quantifying yttrium recovery both through ^{90}Y and ^{90}Sr activity. The activity of ^{90}Y is calculated where Cherenkov counting efficiency was calculated as $\varepsilon_{Ch} = 0.9(\text{TDCR})^{0.75}$. The coprecipitation technique removed the excessive dominant salts of the seawater and enabled the sequential measurement of ^{90}Y. The mean chemical recovery was 88 ± 7%. The minimum detectable concentrations of ^{90}Y measured by Cherenkov counting and LSA techniques were 0.11 and 0.18 Bq L^{-1} respectively for 1 L of seawater, and 1 hour of counting time on a Hidex liquid scintillation counter. Sample preparation time was estimated to be 4 hours for a set of 10 samples.

Similarly, Yang et al. (2017) used TDCR Cherenkov counting and ^{90}Y separation from a sample matrix and interfering radionuclides through two coprecipitation steps, with hydrous titanium oxide followed by yttrium fluoride (YF_3) precipitation, to develop a rapid method for the determination of ^{90}Sr in a leaching solution for cement solidification. The performance of the method was examined using spiked samples with various activities of ^{90}Sr. The separation of Sr and Y during the coprecipitation steps was checked by X-ray fluorescence analysis by determining the Sr and Y contents in dissolved HTiO and YF_3 precipitates. Yttrium recovery was determined by UV-VIS spectrometry measuring yttrium chlorophosphonazo III complex absorbance at 673 nm in the presence of oxalic acid and Na_2EDTA. The results of ^{90}Sr determination showed a 10% deviation. The attained MDA was about 0.3 Bq L^{-1} for the 0.2 L sample and 86 ± 8% mean recovery within 1.5 hour counting time on a Hidex 300 SL counter.

Amano et al. (2016) also used TDCR Cherenkov counting after the isolation of ^{90}Y by coprecipitation with iron hydroxide and oxalic acid. The dissolved oxalate precipitate was loaded on the DGA resin, and the ^{90}Y eluate was analyzed by Cherenkov counting with a Hidex 300 SL/SLL TDCR. The MDA for this method is about 14 mBq/kg-wet. The supposed 1 kg-wet sample is treated and the chemical yield is 100%. ^{90}Sr(^{90}Y) concentration activities were determined in plant samples collected near the Fukushima Daiichi Nuclear Power Plants.

If samples are color quenched, the Cherenkov counting efficiency of ^{90}Y can be determined with a color quench correction curve of percent counting efficiency versus a sample spectrum quench indicating parameter as described by Poletiko et al. (1994) or by the SCR method employed by Vaca et al. (1998), Tarancón et al. (2002a,b), Mosqueda et al. (2007) and Todorović et al. (2017) and also expounded upon in detail in Section IV of this chapter. The Cherenkov counting efficiencies of ^{90}Y may be determined with a standard of ^{90}Sr(^{90}Y) in secular equilibrium. As described previously in this section the optimum Cherenkov counting efficiency of ^{90}Y in water is ~70%, while that of ^{90}Sr is only ~1% (see Fig. 6.78). Therefore, the use of standards of ^{90}Sr(^{90}Y) in secular equilibrium for the preparation of ^{90}Y Cherenkov color quench correction curves is convenient, as very little contribution (~1%) to the total Cherenkov count rate is made by Cherenkov photons from ^{90}Sr. Sample spectrum quench indicating parameters can be difficult to measure accurately with low activity samples. In such cases, Tarancón et al. (2002a,b) recommends the SCR method of color quench correction, as it is less dependent on the sample count rate than a sample spectrum quench indicating parameters. In most cases, the internal standard method described in Section IV of this chapter is the most reliable, as the measurement of internal standards is independent of sample activity. If wavelength shifters are used to increase Cherenkov counting efficiencies, quenching may occur as a result of the addition of wavelength shifter (Vesely et al., 2011). An alternative method for the measurement of color quench is the use of an external standard ^{152}Eu, equipped with the Quantulus 1220 analyzers, which was demonstrated by Tsroya et al. (2009, 2012, 2013a,b) as illustrated by Figs. 6.17–6.20 in Section IV.D of this chapter.

The chemical yield of yttrium is included in Eq. (6.187), as the chemical extraction of yttrium from the sample will not be complete. The method used by Suomela et al. (1993) is practical because it involves chemical titration of the sample taken from the counting vial after Cherenkov counting is completed to determine the chemical yield. The aqueous sample of yttrium is transferred from the counting vial to an Erlenmeyer flask and diluted with water to permit titration with xylenol orange indicator with 0.1M Titriplex III to a yellow color. The mL of titrant required to reach the endpoint are recorded as T_{sample}. The procedure is repeated with a standard by titrating the same volume of yttrium carrier as had been added to the sample during the chemical separation and extraction procedure for yttrium. The mL of titrant required for the standard is recorded as T_{standard}. The chemical yield f of Eq. (6.187) is calculated as

$f = T_{\text{sample}}/T_{\text{standard}}$. The yttrium chemical yield after Cherenkov counting can also be determined by atomic absorption spectrometry (AAS), ICP-OES or MS and by UV-ViS spectrophotometry, as described previously in this paragraph (Yang et al., 2017). For determination by AAS or ICP-MS/OES, an aliquot from the yttrium fraction should be taken and transferred to a flask, diluted and measured with an available instrument. The yield is usually calculated as a ratio between the determined and initial concentrations.

2. Chemical separation and Cherenkov counting of ^{90}Sr with ^{90}Y ingrowth

An alternative method of ^{90}Sr analysis is to measure the ingrowth of ^{90}Y with its parent ^{90}Sr by Cherenkov counting after the chemical separation of strontium from other elements in the sample. An advantage of this approach to ^{90}Sr analysis is that secular equilibrium between the parent–daughter nuclides ^{90}Sr(^{90}Y) need not be achieved at the time of chemical separation. It is necessary only to record the date and time of chemical separation of strontium, as this is the time that the strontium is free of its daughter nuclide ^{90}Y and daughter ingrowth begins. The chemical separation and isolation of strontium may be carried out by chemical precipitation methods (Scarpitta et al., 1999; Rao et al., 2000a,b) or by isolation of strontium on a column of Sr-specific (*e.g.*, Sr-Spec resin, Eichrom, Darien, IL, USA) ion exchange resins (Grahek et al., 2006; Harrison et al., 2011; Taylor et al., 2007; Tovedal et al., 2008; Wang et al., 2004; Wood et al., 2008). Desirable limits of detection for low activity samples will depend on the counting time and level of ingrowth of ^{90}Y. These variables were analyzed in detail by Tovedal et al. (2008), who give the general equation for the calculated ^{90}Sr activity at the time of its chemical separation as

$$A_{\text{Sr}}^{0} = \frac{R_{\text{Y}} - R_b}{\psi U(1 - e^{-\lambda_{\text{Y}} t})} \tag{6.189}$$

where R_{Y} in the count rate of ^{90}Y in CPS, R_b is background count rate in CPS, Ψ is the Cherenkov counting efficiency, U is the strontium chemical yield, λ_{Y} is the decay constant of ^{90}Y (see Eq. 6.188) and t is the time between the chemical separation of the strontium and the time of counting. Secular equilibrium is discussed in detail in Chapter 1, Volume 1, where a derivation is provided for the basic equation expressed in Eq. (6.189). The reader may compare Eq. (6.189) with those derived in Chapter 1, Volume 1.

The analysis of ^{90}Sr is usually time-consuming due to time needed to await for ^{90}Y ingrowth. There are some situations, as noted in Holmgren et al. (2016), when an acceleration of the measurement method is desirable: situations requiring rapid results in order to make urgent decisions and to maximize the throughput of samples in a limited available time span. Holmgren et al. (2016) developed a mathematical model in order to minimize the total analysis time, with the focus on the measurement of ^{90}Y during ingrowth after an initial chemical separation of ^{90}Sr and without the presence of any other yttrium/strontium isotopes. The model defines a case where the continuous ingrowth of ^{90}Y exists when determining ^{90}Sr. The model provides a tool which can be used to estimate the initial time of ingrowth, as well as individual measurement times for each consecutive sample with different detection limits and instrument backgrounds. Using the definition of the detection limit and the fact that for a given counting time the detection limit is constant and that the MDA varies depending on the instrument background, detection efficiency, sample volume, chemical yield, etc., the minimal detectable activity of ^{90}Y was expressed as follows:

$$\text{MDA}\ (^{90}\text{Y}) = \frac{1}{\Psi \cdot U \cdot V_s} \cdot \left[\left(\frac{k^2 + 2k\sqrt{2} \cdot \sqrt{R_b \cdot t_{m,n}}}{1 - e^{-\lambda_Y \cdot t_{m,n}}} \right) \cdot \lambda_Y \right] \tag{6.190}$$

where Ψ represents the counting efficiency ^{90}Y in cps/Bq, λ_Y is the decay constant of ^{90}Y, R_b is the instrument background count rate, $t_{m,n}$ is the measurement time of the sample n, U is the chemical yield of the strontium, and V_S is the sample volume in liters. When describing the MDA for ^{90}Sr, the following equation applies:

$$\text{MDA}(^{90}\text{Sr}) = \text{MDA}(^{90}\text{Y}) \cdot \frac{e^{\lambda_Y \cdot t_{cool,n}}}{1 - e^{-\lambda_Y \cdot t_{i,n}}} \tag{6.191}$$

The ingrowth time for the sample n is given by $t_{i,n}$, and $t_{cool,n}$ is the time of decay for ^{90}Y. In order to account for the ingrowth during measurement, an approximation for decay during acquisition is used. As long as the measurement time ($t_{m,n}$) is less than 0.2t½ (^{90}Y), the resulting underestimation of the ^{90}Sr activity is lower than 1% (Tovedal et al., 2008). The approximation substitutes $t_{i,n}$ with the expression $t_{i,n} + 0.5t_{m,n}$, giving the equation:

$$\text{MDA}(^{90}\text{Sr}) = \frac{\left[\frac{k^2 + 2k\sqrt{2} \cdot \sqrt{R_b t_{m,n}}}{(1 - e^{-\lambda_Y t_{m,n}})} \cdot \lambda_Y \right]}{\Psi \cdot U \cdot V_s \left[1 - e^{\lambda_Y (t_{i,n} + 0.5 t_{m,n})} \right]} \tag{6.192}$$

The ingrowth time for sample n is equal to the total analysis time ($t_{i,n} = t_{i,n\text{-}1} + t_{m,n\text{-}1} = t_{tot,n\text{-}1}$), the ingrowth time plus measurement time, for sample n-1. The results for a series of samples were obtained by solving Eq. (6.192) with regard to $t_{m,n}$ after allowing an initial ingrowth time for sample 1 (t_i,1), and then iterating the equation for all the samples in the series. The results obtained were compared with results from the standard method, obtained in a similar way and with results calculated according to a previous optimization carried out by Tovedal et al. (2008), as illustrated in Fig. 6.81.

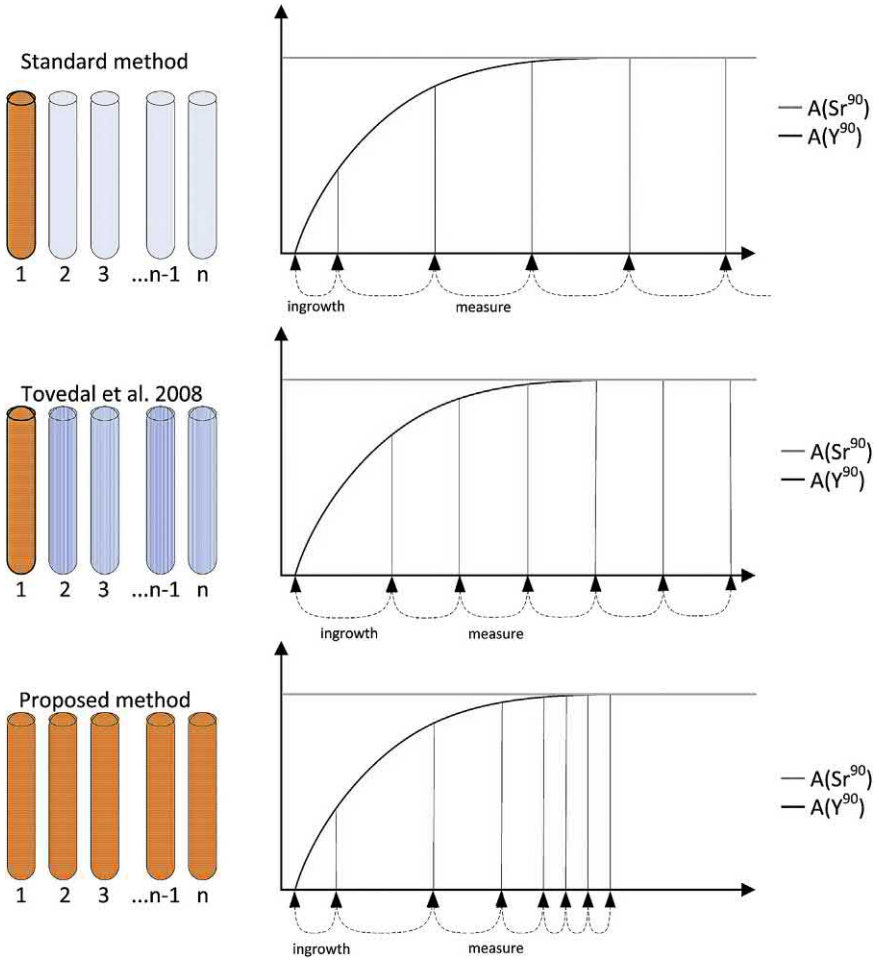

FIGURE 6.81 An illustration of the different methods. The blue (vertical lines) sample tubes represent the samples in a measurement series that were considered when determining the MDA. The orange-brown (horizontal lines) sample tubes represent the number of samples, and their individual time of ingrowth, in a measurement series when determining the MDA. The Figure also shows how the total analysis time (i.e., the time for ingrowth and measurements) is affected by the different methods. (For interpretation of the references to color in this Figure legend, the reader is referred to the electronic version of the book.) *From Holmgren et al. (2016), reprinted with permission from Elsevier © 2016.*

By using the fixed MDA and iterating the measurement time for each consecutive sample, the total analysis time will be less, as illustrated in Fig. 6.82. It was found that by optimization, the total analysis time for 10 samples can be decreased greatly from 21 to 6.5 hours when assuming an MDA of 1 Bq/L and with a background count rate of approximately 0.8 cpm.

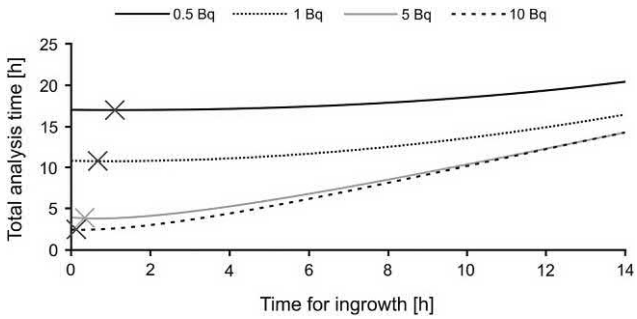

FIGURE 6.82 Change in total analysis time, for 10 samples, with varying time for ingrowth. Minima for the different MDA (Bq/L) are marked in the figure. *From Holmgren et al. (2016), reprinted with permission from Elsevier © 2016.*

Holmgren-Rondahl et al. (2017) also used the same methodology for the determination of ^{90}Sr when its daughter ^{90}Y is measured during its decay after chemical separation. It was found that the measurement times increased for each subsequent sample, since there is a longer decay time before measurement. Compared to the previous approach, the gain in total analysis time is not so significant, especially in the case when low background instruments are analyzed.

Recent works by Qiao et al. (2017), Grahek et al. (2018), and Shao et al. (2018) perform a method comparison for the determination of ^{90}Sr in different kinds of samples to identify the advantages and pitfalls in different methods. The methods differ in sample pretreatment and chemical separation, as well as the detection step, where an LSA, Cherenkov counting and proportional counter were compared. The detection limit, MDA, accuracy/precision, analytical time and robustness of the method were assessed. By comparison of every step in the method, it is shown that the Cherenkov measurement has the advantage in terms of the analytical time taken. A comparison of other parameters

shows that there is no significant difference between Cherenkov counting and other detection methods, i.e., that the advantage or disadvantage depends on the choice of method of sample preparation and chemical separation. The accuracy of determination and MDA depends on the efficiency of the detection and chemical yield, which depends on the type of sample, sample pretreatment and the chemical separation procedure. There are a number of options for combining the sample pretreatment and chemical separation procedure so that Cherenkov counting can be part of virtually any combination of these procedures. The literature thus describes a number of methods using Cherenkov counting for the quantitative determination of ^{89,90}Sr. Cherenkov detection efficiency, as one of the key parameters for accurate and reliable quantitative determination, depends on the type of available instrument. Therefore, Table 6.22 gives an overview of selected determination methods with a brief description of the separation method, the strontium isotopes that are determined by the indication of the method of determination (yttrium ingrowth or decay), the type of sample to which the method is applied, the type of instrument used for Cherenkov measurement, and the detection efficiency for each isotope for that instrument. The data was taken from the references given in the last column.

D. Yttrium-90

The analysis of ^{90}Y is noted here, because of the increased attention the nuclide is receiving in terms of its medical applications in the pure form, that is, extracted or "milked" in pure form without contamination from its parent ^{90}Sr. Goffredo et al. (2011), Šrank et al. (2010), and Dietz and Horwitz (1992), among others, underscore the therapeutic applications of ^{90}Y including the radiolabeling of antibodies for tumor therapy and the production of radiolabeled particles for the treatment of liver malignancies, among others. Although the liquid scintillation counting efficiency of ^{90}Y is 100% with the exception of samples under unusually high quench conditions, Cherenkov counting is often the method of choice for the routine analysis of this nuclide, because of the high Cherenkov counting efficiencies achieved and low cost of analysis. Cherenkov counting efficiencies of ^{90}Y reach up to ~70% in pure water and >80% with wavelength shifter under optimum conditions (see Jurkin and Wierczinski, 2008; L'Annunziata and Passo, 2002; Passo and Cook, 1994; Van Hemert et al., 2006; Walter et al., 1993; Xiques Castillio et al., 2009).

E. Other applications

In addition to the previously cited popular applications of Cherenkov counting to the analysis of ^{32}P, ^{89}Sr, ^{90}Sr/^{90}Y, and isolated ^{90}Y, numerous other, less common analytical applications are reported in the literature. Some of these are cited next.

The very first detection and measurement of ^{14}C and ^{45}Ca by Cherenkov photon counting was reported by Takiue et al. (2004) and improvements to the technique were reported by Minowa et al. (2009). The radionuclide ^{14}C and ^{45}Ca emit relatively low-energy beta particles with energy maxima (E_{max}) of 155 and 258 keV, respectively. While these energies are below the Cherenkov threshold energy of 262 keV in water medium, Takiue et al. (2004) and Minowa et al. (2009) used a high refractive index ceramic medium, which lowered the threshold energy for the production of Cherenkov photons to 70 keV. A Cherenkov photon detection efficiency of 5.0% for ^{14}C was reported by Minowa et al. (2009) with an improved ceramic Cherenkov radiator. While the detection efficiency is relatively low, it is more than adequate for the detection and measurement of ^{14}C at facilities where radionuclide sources and labeled compounds are prepared or synthesized.

A new technique, referred to as Cherenkov luminescence imaging, has appeared in the scientific literature. This method is under development in the biological and medical sciences for the in vitro and in vivo imaging of high-energy negatron emitters (*e.g.*, ^{32}P and ^{131}I) and positron emitters (*e.g.*, ^{18}F, ^{64}Cu, ^{89}Zr, and ^{124}I), among other beta emitters. Robertson et al. (2009) reported studies utilizing optical imaging of Cherenkov radiation from ^{18}F for in vivo imaging. Further reports have demonstrated the use of commercial optical instrumentation equipped with charge-coupled detectors (CCDs) for the measurement of Cherenkov radiation produced by high-energy negatron and positron emitters as a potentially new technique for in vivo radionuclide imaging (Ruggiero et al., 2010; Spinelli et al., 2010, 2011; Boschi et al., 2011; Lucignani, 2011).

Numerous radionuclides are listed in Table 6.21 together with their reported Cherenkov photon detection efficiencies and corresponding literature citations. In addition to these, the following deserve mention:

Bem et al. (1978) described the Cherenkov counting of ^{115m}Cd in blood and animal tissue with counting efficiencies of approximately 35%. Rengan and Sun (2004) also used Cherenkov counting of ^{115m}Cd to measure the sorption characteristics of chelating resins.

For studies involving the removal of ^{106}Ru from nuclear waste solutions, Carmon and Dyer (1987) report the Cherenkov counting of this radionuclide in aqueous solution in the presence of weak β emitters. The optimum Cherenkov counting efficiency of ~62% was reported. Fujii et al. (2002) describe the design of a large volume (1L) Cherenkov counting system to monitor high-energy β emitters, namely ^{89}Sr, ^{90}Y, and ^{32}P, in liquid waste with detection limits of 0.003−0.007 and 0.001−0.003 Bq/mL for 5 and 20 minutes measurements, respectively. The

ns–not specified.
p – efficiency in plastic vials (polyethylene and/or Teflon coated, see detail in reference).
g – efficiency in glass vials (normal or low potassium, see detail in reference).

Cherenkov counting of ^{90}Sr in radioactive waste can be complicated by the presences of ^{137}Cs among other radionuclides that emit high energy beta or gamma radiation. Consequently radionuclide cleanup for the extraction of ^{90}Sr on specific ion exchange resins may be needed (Torres et al., 2002), as described earlier in this chapter. Alternatively, Chitra et al. (2011) utilized gamma spectrometry for the analysis of the ^{137}Cs and Cherenkov counting for the measurement of ^{90}Sr.

^{228}Th and ^{234}Th can be analyzed via Cherenkov counting of their β-emitting daughters. Al-Masri and Blackburn (1994) and Nour et al. (2002) demonstrate the analysis of these nuclides when in secular equilibrium with their daughters. The ^{234m}Pa daughter nuclide of ^{234}Th yields a Cherenkov counting efficiency of up to 62% and the ^{212}Bi, ^{212}Pb, and ^{208}Tl daughter nuclides of ^{228}Th can be detected with a reported Cherenkov counting efficiency of up to 53%. The Cherenkov analysis of ^{234}Th can be used for the determination of uranium when ^{234}Th is in secular equilibrium with its parent ^{238}U (see Blackburn and Al-Masri, 1994; Al-Masri and Blackburn, 1994; Bower et al., 1994; Alamelu and Aggarwal, 2009; Gulin et al., 2013).

^{210}Pb has been applied to studies of container adsorption of Pb(II) by Pacer (1990); and Cherenkov counting utilized for the measurement of ^{210}Pb in air filters (Dale et al. (2002) and in lead shields (Hurtado et al., 2003) and. The analysis of ^{210}Pb by Cherenkov counting is possible only through the detection of the Cherenkov photons produced by the daughter nuclide ^{210}Bi, which reaches secular equilibrium with its parent nuclide. The Cherenkov counting efficiency of ^{210}Pb(^{210}Bi) without wavelength shifter is reported to range between 14% and 18% (Arinc et al., 2011; Salonen, 2010; Dale et al., 2002; Hurtado et al., 2003; Blais and Marshall, 1988).

Peck et al. (1998) described the measurement of ^{210}Bi by Cherenkov counting in a commercial liquid scintillation counter. The counting efficiency in water was 0.17 counts per second per Becquerel (17%). When the enhancers Triton X-100 (15% v/v) and sodium salicylate (1% m/v) are added to the solution the counting efficiency for ^{210}Bi increases from 17% to 75%. The ^{210}Po daughter of ^{210}Bi causes interference of 0.85 counts per second per Becquerel in the presence of the enhancers but not in water. When ^{210}Bi and ^{210}Po were present in secular equilibrium the total counting efficiency was 160%. When ^{210}Bi and ^{210}Po are not in secular equilibrium the ^{210}Po can be removed immediately before counting by plating onto silver foil. The use of the enhancers gives a substantial increase in counting efficiency compared to counting in water. Compared with solutions used in liquid scintillation counting, the enhancer solution is inexpensive and can be disposed of without environmental hazard.

Blackburn and Al-Masri (1993) and Al-Masri and Blackburn (1995a,b) demonstrated the analysis of ^{222}Rn and ^{226}Ra via the Cherenkov counting of their β-emitting daughters ^{214}Bi and ^{214}Pb with a Cherenkov counting efficiency of 77%. These techniques were subsequently applied to the analysis of ^{222}Rn in surface waters (Al-Masri and Blackburn, 1999).

The Cherenkov counting efficiency of ^{36}Cl is low. An optimum counting efficiency of only 6.6% can be expected due to the low E_{max} of its β particles (see Table 6.21). Nevertheless, Holst et al. (2000) elected to analyze ^{36}Cl tracer nuclide in biological studies by Cherenkov counting because analysis could be carried out without liquid scintillation cocktail, which would render the sample useless for further studies.

L'Annunziata and coworkers (see Aleissa et al., 2008) describe the first assay of isolated ^{228}Ac by Cherenkov counting and its application to the measurement of ^{228}Ra in natural waters. The activities of ^{228}Ra, determined from the Cherenkov counting of ^{228}Ac, are calculated back to the time of ^{228}Ac separation from ^{228}Ra in secular equilibrium. Optimum Cherenkov detection efficiencies of ^{228}Ac in aqueous solution contained in polyethylene plastic counting vials was reported to be in the range of 10.7%−10.9%.

Buchtela and Tschurlovits (1975) reported a Cherenkov counting efficiency of ~75% for ^{42}K in water. It has very limited use as a tracer nuclide, because of its relative short half-life of 12.36 hours. The isotope ^{40}K can be analyzed also in water with a Cherenkov detection efficiency of 55% as reported by Pullen (1986), and the Cherenkov counting technique has been applied by Rao et al. (2000a,b) to the analysis of ^{40}K in natural water samples. Because of the lack of a suitable radiotracer for K and the close chemistry of the Rb and K elements, it is at times possible to use ^{86}Rb as a tracer for potassium. L'Annunziata and coworkers (see Noor et al. 1996) and Tuininga et al. (2002), report the use of ^{86}Rb as a radiotracer with a Cherenkov counting efficiency of up to 55% in water.

XV. Advantages and disadvantages in radionuclide analysis

It is obvious that Cherenkov counting cannot compete with liquid scintillation counting as far as highest possible counting efficiency is concerned. In addition, Cherenkov counting in aqueous media cannot be used for the analysis of very low-energy beta-particle emitters. However, if very high counting efficiencies are not necessary, Cherenkov counting of relatively high-energy beta-particle emitters has the following advantages over liquid scintillation counting:

1. Samples may be counted directly in aqueous solution or in organic solvents

2. No floors, fluor cocktails, or other compounds need be added, and thus the samples to be analyzed remain unadulterated and suitable for subsequent studies or analysis.
3. A larger volume of sample may be counted in a 20-mL counting vial since fluor solution is not needed.
4. Chemical quenching is nonexistent. Solutes may change the refractive index of the medium and consequently the beta-particle energy threshold for Cherenkov production, but chemical quench per se does not occur.
5. Time and expense are saved in sample preparation. The use of expensive organic fluors or fluor cocktails, which are customarily used in liquid scintillation analysis, is avoided.
6. There is no interference from other radionuclides that cannot produce Cherenkov photons in aqueous media (e.g., ^{3}H, ^{14}C, ^{125}I) and other nuclides that do not emit beta-particles of energy equal to or in excess of the threshold energy for the production of Cherenkov photons in aqueous media ($E_{th} = 262$ keV) or radionuclides that do not yield Compton electrons of sufficient energy to create Cherenkov photons.
7. There are no chemical fluor disposal problems associated with Cherenkov counting.

XVI. Recommendations in radionuclide analysis

The following recommendations can be made to facilitate the Cherenkov analysis of radionuclides and optimize Cherenkov counting performance:

1. Always use plastic vials for Cherenkov counting unless a wavelength shifter is used. Plastic vials provide higher Cherenkov counting efficiencies and lower background than glass vials (i.e., higher FOMs). In addition, they are less expensive than glass and unbreakable.
2. Unless samples are totally colorless or have a constant quench level, prepare a color quench correction curve based on the color of the experimental samples. A color quench correction curve is preferred at all times, because even slight amounts of color could cause significant quench and loss of counting efficiency. Also, most contemporary liquid scintillation analyzers can use the sample spectrum quench-indicating parameter and a quench correction curve stored in the instrument computer for automatic conversion of Cherenkov count rate to activity, which facilitates automation and high sample throughput.
3. For samples of low Cherenkov count rates, such as in the counting of environmental samples, the liquid scintillation analyzer will require long counting times to determine a sample spectrum quench-indicating parameter [*e.g.*, SIS or SQP(I)]; error can still occur. In such cases, an internal standard method or an external standard, such as ^{152}Eu, described by Tsroya et al. (2009) and discussed in Section IV.D of this chapter, may be used to determine the Cherenkov counting efficiency.
4. Maintain the samples for counting at a constant volume in counting vials unless it can be verified through testing that there are no significant volume effects on counting efficiency over a certain range of volume changes.
5. All samples should be counted for a period of time sufficient to achieve a % 2 sigma (% 2S) error of 1% or lower to ensure accurate count determinations and good measurements of the sample spectrum quench indicating parameter.

Michael F. L'Annunziata

Michael F. L'Annunziata, Ph.D. is the Founding Editor and co-author of the Handbook of Radioactivity Analysis now in its Fourth Edition. His graduate thesis research at the University of Arizona, Tucson, AZ, USA in the 1960s, financed by the then U.S. Atomic Energy Commission, dealt with the analysis of ^{89}Sr and ^{90}Sr in the event of nuclear fallout. During 1970–71, he worked in the chemical industry (Amchem Products, Inc., Ambler, PA, USA) as ^{14}C-tracer chemist. Michael was then appointed Professor at the Postgraduate College, Chapingo, Mexico (1972–75) and Senior Research Scientist and graduate thesis advisor at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico City during (1975–77). Michael served as Scientific Officer in the Department of Research and Isotopes and Department of Technical Co-operation of the International Atomic Energy Agency (IAEA) in Vienna, Austria during 1977–91 and Head of IAEA Fellowships and Training during 1987–91. Michael F. L'Annunziata was first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as the chemical pathway and origin of the various inositol phosphate stereoisomers in soils (Ph.D. dissertation, 1970, https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum =) and in 1975 (*SSSA Journal* 39(2), 377–9), and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–6, https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733). From 1977 to 2007, he served as IAEA Expert in peaceful applications of nuclear energy in over 50 countries of the world in Europe, Asia, Africa, Latin America and the Middle East. His book entitled "Radioactivity: Introduction and History", First Edition, published by Elsevier, was on the Best Sellers List in Physics (*LibraryJournal Academic Newswire* in 2008); and his much expanded Second Edition entitled "Radioactivity: Introduction and History, From the Quantum to Quarks" published by Elsevier in 2016 (https://www.sciencedirect.com/book/9780444634894/radioactivity) was awarded an Honorary Mention in the 2017 PROSE AWARDS in the category of Chemistry & Physics.

Željko Grahek

Željko Grahek earned his undergraduate B.Sc. in chemical technology 1987 and PhD degree in analytical chemistry 1997 from the Faculty of Chemical Engineering and Technology, University of Zagreb. His research interest is focused on the development of novel separation and detection techniques for the determination of alpha and beta emitters in complex samples, optimization and automation of radionuclide determination methods, the application of Cherenkov counting in the development of rapid methods for pure beta-emitter determinations, as well as the study of radionuclide behavior in the environment. He is the

author of more than 40 papers in international scientific journals and conference proceedings. His current position is Senior Research Associate at the Ruđer Bošković Institute in Zagreb and Head of the Radioecology Laboratory in the Division of Marine and Environmental Research.

Nataša Todorović

Dr. Nataša Todorović is Full Professor of Nuclear Physics in the Department of Physics, University of Novi Sad, Serbia. Her main research fields are related to low level alpha, beta and gamma spectroscopy with applications in different research fields. She is working on the development and implementation of fast and precise LSC methods including gross alpha/beta, radon, $^{90}Sr/^{90}Y$, ^{3}H, and ^{14}C determinations. Nataša Todorović is the author of 62 papers in Current Content journals, author of two books, co-author of six contributions in books, and more than 60 contributions in other journals, books or conference proceedings. She is Coordinator of one National Project and one Bilateral Project. Nataša Todorović participated in International Projects COST Action TU1301 "NORM4Building", and is currently part of EURAMET EMPIR project MetroRADON – Metrology for Radon Monitoring (EMPIR 16ENV10), IPA projects and CEEPUS Action "Education, Training and Research in Radioecology".

Chapter outline

I. Introduction **532**
II. Absolute direct methods **532**
A. Beta–gamma coincidences 532
1. Principles of the method 533
2. Radionuclide standardization methods based on beta–gamma coincidence 535
3. Applications of the beta–gamma coincidence method in radionuclide standardization. Differentiation by type of beta counter 538
4. Applications of the beta–gamma coincidence method. Standardization of radionuclides and determination of nuclear constants 543
5. Application of the tracer method 544
6. Applications of a two-dimensional method of extrapolation 544
7. Beta–gamma coincidences. Generation of extrapolation curves 544
8. Digital systems for beta–gamma coincidence 544
B. Beta–gamma anticoincidences 544
1. Anticoincidence method with nonextending dead time 545
2. Live-timed anticoincidence counting with extending dead-time corrections 546
3. Applications of the method of anticoincidence Beta−gamma Radionuclide standardization 546
C. Beta–gamma correlations 547
1. Introduction 547
2. Theoretical description of the beta−gamma correlations method 548
3. Applications of the Beta−gamma correlations method to radionuclide standardization 549
D. Gamma–gamma coincidences 549
1. Introduction to the sum peak method 549
2. Theoretical description of the sum peak method 550
3. Dead time and pileup corrections 551
4. Applications of the sum peak method 552
III. Solid angle primary methods **555**
A. 4π proportional counting 556
B. 2π proportional counting 556
C. $4\pi\gamma$ counting 556
D. 4π windowless sandwich detectors 556
E. $4\pi\beta\gamma + 4\pi$ sum counting 557
F. Defined solid angle 557
G. Internal gas counting 559
1. Theoretical description of internal gas counting 560
2. Some experimental aspects of internal gas counting 560
3. Applications of internal gas counting to radionuclide standardization 560
H. Liquid scintillation counting 563
1. Importance of the beta spectrum in the standardization of Co-60 570
I. Calorimetric detectors 574
1. Classic calorimetry 574
2. Cryogenic calorimeter 577
IV. Relative methods **578**
A. Calibration methods based on gamma ray spectrometry 578
1. Description of the general method 578
2. Heath method 580
3. Semi-empirical methods 581
4. Monte Carlo technique 582
B. Measurement of high activity. Ionization chambers 584
1. Calibration of ionization chamber radionuclides 585
2. Applications of ionization chambers 586
3. Considerations on the calculation of ionization chamber efficiency 588
V. Reference systems **590**
A. The SIR of gammas 590
1. Measurement of short half-life gamma emitters 592
B. The SIR of betas 592
VI. Preparation of radioactive samples **595**
A. Introduction 595
B. Sample preparation for radionuclide metrology 596
1. Supports for extended samples 596
2. Dilutions in aqueous solutions 596
3. Drops deposit in the sample holder 597
4. Determination of mass 597
5. Methods for verifying and improving the quality of the source 597

I. Introduction

The activity of a radionuclide can be determined by applying different measurement procedures. The application of all these procedures depends on different parameters, particularly radionuclide decay. However, the determination of activity is often difficult due to various circumstances connected with radioactivity. The measure is not direct in the sense that an instrument cannot be applied to obtain activity directly as the weight of an object can be measured on scales or the length of a rod can be measured with a meter. Radioactive emission is a random process and, therefore, what an instrument measures is radiation emission and the activity of a radioactive sample is the average value of radioactive emission per unit of time. Furthermore, radiation measurement is indirect, so we have to consider the interaction of radiation with matter.

Finally, radioactivity measures are very sensitive but not very accurate, so that a measurement with an uncertainty of less than 1% is considered to be extremely accurate.

In this chapter we consider primary methods of radioactivity measurement (Debertin, 1996; Quinn, 1997; Pommé, 2007) and relative methods. The primary methods are based on the measurement of counts and time. Sometimes we use other complementary measurements such as corrections: geometric or other standardized radionuclides. But these measures are never comparative measures of activity. A borderline case is the tracer method in its two aspects: (CIEMAT/NIST method) based on the additional measure of the activity of a standard (^{3}H or ^{54}Mn) serving as a "sensor" for the scintillator quality of the scintillator−sample mixture and the effectiveness of the measuring geometry and the photomultiplier.

Relative methods can be comparative or interpolated. In comparative methods, a problem sample is compared with a standard sample of the same radionuclide calibrated by a primary method. In the relative method, by interpolation we obtain a calibration curve using standardized samples and obtain the activity of the sample by interpolation of a parameter linked to the activity of the sample. For example, in gamma spectrometry we use the area of the full energy peaks as a parameter, so the interpolation parameter is the energy of the emitted photons. In this chapter we will only consider the relative method by interpolation.

In Section II we study calibration methods based on the coincidence or anticoincidence of two radiations: coincidence, anticoincidence, and correlation in beta−gamma, and gamma−gamma, X−gamma and X−X coincidence, using high resolution semiconductor detectors.

Section III is devoted to primary methods based on the solid angle with which the detector sees the sample. We consider 2π and 4π solid angles, mainly in the standardization of alpha emitters, but also we consider beta and gamma emitters of low energy. Detection systems in the case of 2π solid angle are proportional counters (PCs) and in the 4πcase may be PCs, liquid scintillation counters, gas detectors or calorimeters. Defined solid angle (DSA) (below 2π) methods used in the standardization of alpha emitters are the methods with least uncertainty when they are applied properly.

In Section IV we study methods based on gamma spectrometry, for its wide application, and ionization chambers, for their ability to measure relatively high activity and high stability and reproducibility. If adequate models are developed, measures with both procedures can become primary.

Section V is devoted to the International Reference System known as SIR, on two fronts: the SIR of gammas, fully established and providing exceptional service in maintaining traceability to the international level, and the SIR of betas that started with pure beta emitters and now has been extended to nuclides decaying by electron capture.

Finally, in Section VI, we discuss the different methods of preparing quantitatively radioactive samples. We describe the procedures for preparing ultrathin films on which to deposit the radioactive solutions and methods for depositing quantitatively drops of radioactive material and methods for verifying and improving the quality of the radioactive sources.

II. Absolute direct methods

A. Beta−gamma coincidences

The $4\pi\beta-\gamma$ coincidence techniques are, among the methods of primary standardization, those that allow activity values of a sample to be obtained with lower uncertainty. The first descriptive work of such measures are due to Steyn and Haasbroek (1958), Campion (1959), Gandy (1961, 1962, 1963), Houtermans and Miguel (1962), Williams and Campion (1963), Brinkman (1961), Baerg et al. (1964), Baerg (1966), Williams and Birdseye (1966) and Grigorescu (1973), and Funck et al. (1983). These studies define the principles of the method and the required corrections.

The equations developed for this technique include both the effects of detectors and the parameters of complex radionuclide decay schemes. As counting efficiencies are not known in complex cases, correction terms are introduced for estimation purposes. The application of correction equations enables us not only to determine the sample's activity but also to obtain beta branch intensity values in decay schemes.

1. Principles of the method

a. Radionuclides with simple decay schemes

In its ideal form, the beta–gamma coincidence method only applies to the standardization of radionuclides with simple decay schemes. In this case, beta emission is followed by coincident nonconverted gamma emission. It is assumed that beta detectors only respond to beta radiation and gamma detectors to gamma radiation. In addition, the coincidence only records the simultaneous pulse emission of both detectors. For a point source with activity n_0 and detection efficiencies ε_β and ε_γ:

$$n_\beta = n_0\varepsilon_\beta \tag{7.1}$$

$$n_\gamma = n_0\varepsilon_\gamma \tag{7.2}$$

$$n_c = n_0\varepsilon_\beta\varepsilon_\gamma \tag{7.3}$$

where, n_β, n_γ, and n_c are the counting rates of beta, gamma, and coincidence channels, respectively.

When the source is extended, in which case the detection efficiencies may vary from one point to another, the total activity of the source N_0 and the counting rates, N_β, N_γ, and $N_c$are related by the expressions:

$$N_\beta = N_0\overline{\varepsilon}_\beta \tag{7.4}$$

$$N_\gamma = N_0\overline{\varepsilon}_\gamma \tag{7.5}$$

$$N_c = N_0\overline{\varepsilon_\beta\varepsilon_\gamma} \tag{7.6}$$

where $\overline{\varepsilon}_\beta$ and $\overline{\varepsilon}_\gamma$ are the average values of the basic efficiencies. If we integrate over the surface of the sample, the values obtained coincide with the counting efficiencies ε_β and ε_γ for the total sample. However, as was shown by Putman (1950), the mean value of the product $\overline{\varepsilon_\beta\varepsilon_\gamma}$ coincides with the product of the total efficiency when at least one of the detectors has the same efficiency on all points of the sample. This condition is satisfied by the gamma detectors. In the case of beta detectors based on a PC, this condition is not fulfilled. But it is true when the beta detector is a liquid scintillator. Henceforth, we will consider that the condition is met by both scintillation and PCs. Then

$$N_\beta = N_0\varepsilon_\beta \tag{7.7}$$

$$N_\gamma = N_0\varepsilon_\gamma \tag{7.8}$$

$$N_c = N_0\varepsilon_\beta\varepsilon_\gamma \tag{7.9}$$

verifying that

$$N_0 = \frac{N_\beta N_\gamma}{N_c} \tag{7.10}$$

These are the fundamental equations of beta–gamma coincidence in the ideal case. In practice, beta detectors are sensitive to gamma radiation and the above equations require correction. Furthermore, a gamma transition may have internal conversion. Thus, another correction to consider is the existence of conversion electrons.

Beta detectors sensitive to gamma radiation In most cases, beta detectors are sensitive to gamma radiation, so the above equations need to include the detection efficiency for the gamma radiation, denoted as $\varepsilon_{\beta\gamma}$. To detect a gamma photon as a beta count, the gamma photon cannot coincide with a beta particle. As the probability of not detecting a beta particle is $(1-\varepsilon_\beta)$, multiplying by $\varepsilon_{\beta\gamma}$ we obtain the probability of counting a gamma photon in the beta counter. Therefore, the above equations become the following:

$$N_\beta = N_0[\varepsilon_\beta + (1-\varepsilon_\beta)\varepsilon_{\beta\gamma}] \tag{7.11}$$

$$N_\gamma = N_0\varepsilon_\gamma \tag{7.12}$$

$$N_c = N_0\varepsilon_\beta\varepsilon_\gamma \tag{7.13}$$

and the equation to calculate the sample's activity is:

$$\frac{N_\beta N_\gamma}{N_c} = N_0\left[1 + \frac{(1-\varepsilon_\beta)}{\varepsilon_\beta}\varepsilon_{\beta\gamma}\right] \tag{7.14}$$

In the ideal case, N_0 was obtained directly from the measured quantities: N_β, N_γ, and N_c. But we now also need to know the efficiencies: ε_β and $\varepsilon_{\beta\gamma}$. To solve this equation we must relate ε_β and $\varepsilon_{\beta\gamma}$ with the measured count rates: N_β, N_γ, and N_c. The usual method is to take different values for these quantities, ε_β and $\varepsilon_{\beta\gamma}$ and extrapolate to obtain activity N_0. The general aspects of the activity calculation will be considered later when we discuss the general case of radionuclide standardization.

Converted gamma transitions Internal conversion of gamma transitions contributes to the beta channel with a count rate n_{ec} when the coincident beta particle is not detected. Therefore:

$$n_{ec} = N_0(1-\varepsilon_\beta)\varepsilon_{ce}\frac{\alpha}{1+\alpha} \tag{7.15}$$

where ε_{ce} is the probability of detecting the conversion electrons in the beta channel and α is the total internal conversion coefficient. In many cases, when the energy is relatively high, converted electrons are detected with 100% efficiency. When the energy of the converted electrons is low, detection of X-rays and Auger electrons can compensate for the low energy of converted electrons and high counting efficiencies are obtained. In this case $\alpha\varepsilon_{ec}$ should be replaced by:

$$\sum_i \alpha_i\left[\varepsilon_i + (1-\varepsilon_i)\varepsilon(X,A)_i\right] \tag{7.16}$$

where α_i is the internal conversion coefficient of the i-shell, ε_i is the beta detector efficiency for conversion electrons of

the i-shell, and $\varepsilon(X,A)$ is the probability of detecting at least one X-ray or Auger electron in the beta counter following conversion electron emission from the i-shell.

As internal conversion electron transitions compete with gamma photon emissions, converted electrons can reduce gamma−photon counts. The counting rates for the detection of gamma photons and for the coincidence channel are, respectively:

$$N_\gamma = N_0 \frac{\varepsilon_\gamma}{1+\alpha} \tag{7.17}$$

$$N_c = N_0 \frac{\varepsilon_\beta \varepsilon_\gamma}{1+\alpha} \tag{7.18}$$

where ε_γ is the intrinsic efficiency for gamma−ray detection. It is assumed that X-rays, arising from internal conversion, are excluded from detection in the gamma channel by appropriate energy discrimination.

Beta counter sensitivity to gamma radiation A gamma ray detected by the beta counter will only be counted if the respective beta particle is not detected. Thus:

$$n_{\beta\,\gamma} = N_0(1-\varepsilon_\beta)\frac{\varepsilon_{\beta\,\gamma}}{1+\alpha} \tag{7.19}$$

where $\varepsilon_{\beta\,\gamma}$ is the intrinsic efficiency of the beta counter for gamma photons. On the other hand, accidental coincidences occur due to the presence of gamma−ray cascades and Compton scattering. The probability of such coincidences, which we denote as ε_c, increases the number of coincidences in:

$$n_c = N_0(1-\varepsilon_\beta)\varepsilon_c \tag{7.20}$$

The value of ε_c is reduced significantly if the gamma channel is discriminated.

Gamma detector sensitivity to beta radiation The interaction of beta particles in the gamma detector is not probable and easily avoided in PCs by inserting absorbent material between the sample and the gamma detector. When liquid scintillation counters are used, the walls of the vial prevent beta particles from reaching the gamma detector. When beta particle energy is high, Bremsstrahlung occurs and interacts with the gamma radiation detector. Campion (1959) studied this problem and concluded that errors due to this process are practically negligible and disappear when beta detector efficiency approaches 100%. On the other hand, the problem can be entirely avoided by appropriate adjustment of the γ-detector threshold.

Beta−gamma angular correlation The angular correlation factor for beta−gamma coincidences was studied by Campion (1959), concluding that the correlation is expected in the case of forbidden beta transitions. The asymmetry factor was energy dependent and decreasing with beta energy. However, the correlation effect is small and cancels when the beta detector efficiency is equal to unity.

General expressions for single beta−gamma transitions The general equations for a decay scheme involving a single $\beta-\gamma$ transition are:

$$N_\beta = N_0\left[\varepsilon_\beta + (1-\varepsilon_\beta)\left(\frac{\alpha\varepsilon_{ce} + \varepsilon_{\beta\,\gamma}}{1+\alpha}\right)\right] \tag{7.21}$$

$$N_\gamma = N_0 \frac{\varepsilon_\gamma}{1+\alpha} \tag{7.22}$$

$$N_c = N_0\left[\frac{\varepsilon_\beta \varepsilon_\gamma}{1+\alpha} + (1-\varepsilon_\beta)\varepsilon_c\right] \tag{7.23}$$

where ε_{ec} is the efficiency for the internal conversion electrons.

b. Radionuclides with complex decay schemes

When the decay scheme has several beta and gamma branches, the equations for beta, gamma, and coincidence counting rates are more complicated (Baerg, 1973; Smith, 1978, 1987; Smith and Stuart, 1975). When the decay scheme has n branches with intensity a_i and at least one of the branches has one or more associated gamma transitions:

$$N_\beta = N_0 \sum_i a_i\left[\varepsilon_{\beta_i} + \left(1-\varepsilon_{\beta_i}\right)\left(\frac{\alpha\varepsilon_{ce} + \varepsilon_{\beta\gamma}}{1+\alpha}\right)_i\right] \tag{7.24}$$

$$N_\gamma = N_0 \sum_i a_i \varepsilon_{\gamma i} \tag{7.25}$$

$$N_c = N_0 \sum_i a_i\left[\varepsilon_{\beta i}\varepsilon_{\gamma i} + \left(1-\varepsilon_{\beta_i}\right)\varepsilon_{ci}\right] \tag{7.26}$$

where the summations extended over the n branches. The subscript i refers to the i-beta branch. a_i is the fractional branching ratio, ε_{β_i} is the β-detection efficiency of the i-beta branch, α is the total internal conversion coefficient associated with this β-branch, $(\varepsilon_{ce})_i$ is the β-detector efficiency for these internal conversion electrons associated with the i-branch, and ε_{ci} is the efficiency of the detector for i-rays associated with branch i, and $\varepsilon_{\gamma i} = \left(\frac{\varepsilon_\gamma}{1+\alpha}\right)_i$ is the efficiency of the γ-detector for γ-rays associated with branch i.

If we define C_i as the ratio of beta inefficiencies (Grigorescu, 1973):

$$C_i = \frac{1-\varepsilon_{\beta i}}{1-\varepsilon_{\beta s}} \tag{7.27}$$

where $\varepsilon_{\beta i}$ is the beta efficiency of the i-beta branch and $\varepsilon_{\beta S}$is the β-detector efficiency for any one arbitrarily selected β-group.

From Eqs. (7.24)–(7.26) we have:

$$\frac{N_\beta N_\gamma}{N_c} = N_0\left[1+(1-K)\left(\frac{1-N_c/N_\gamma}{N_c/N_\gamma}\right)\right] \tag{7.28}$$

or

$$N_\beta = N_0[1+k(1-N_c/N_\gamma)] \tag{7.29}$$

with

$$K = \frac{\sum a_i C_i\left\{1-[(\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma})/(1+\alpha)]_i\right\}}{\sum a_i\varepsilon_{\gamma i}C_i(1-\varepsilon_{ci}/\varepsilon_{\gamma i})}\sum a_i\varepsilon_{\gamma i} \tag{7.30}$$

In general, the graph of the function (7.28) is linear provided C_i changes just slightly with N_c/N_γ.

The best fit of the graph corresponds to:

$$\frac{\varepsilon_{\gamma 1}(1-\varepsilon_{c1}/\varepsilon_{\gamma 1})}{\left(1-\dfrac{\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma}}{1+\alpha}\right)_1} = \ldots = \frac{\varepsilon_{\gamma i}(1-\varepsilon_{ci}/\varepsilon_{\gamma i})}{\left(1-\dfrac{\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma}}{1+\alpha}\right)_i}$$

$$\ldots = \frac{\varepsilon_{\gamma s}(1-\varepsilon_{cs}/\varepsilon_{\gamma s})}{\left(1-\dfrac{\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma}}{1+\alpha}\right)_s} = E \tag{7.31}$$

where E is constant for a given setting (for good counting statistics E should be as large as possible).

In this case K is independent of C_i and reduced to:

$$K = \sum a_i\frac{\left(1-\dfrac{\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma}}{1+\alpha}\right)_i}{1-\varepsilon_{ci}/\varepsilon_{\gamma i}}$$

$$= \sum a_i\left[1-\left(\frac{\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma}}{1+\alpha}\right)_i+\frac{\varepsilon_{ci}}{E}\right]$$

$$= 1-\sum a_i\left[\left(\frac{\alpha\varepsilon_{ce}+\varepsilon_{\beta\gamma}}{1+\alpha}\right)_i-\frac{\varepsilon_{ci}}{E}\right] \tag{7.32}$$

In this equation, K represents the correction of gamma sensitivity for the beta detector. In practice, we can use less restrictive conditions:

$$\varepsilon'_{\gamma 1} = \ldots = \varepsilon'_{\gamma i} = \ldots = \varepsilon'_{\gamma s} \tag{7.33}$$

where

$$\varepsilon'_{\gamma i} = \varepsilon_{\gamma i}(1+\alpha)_i \tag{7.34}$$

Let us consider some nuclides as examples:

^{198}Au has the efficiencies ε_{412} and ε_{676} for the gamma rays of 412 and 676 keV, respectively. Condition (7.33) becomes:

$$\varepsilon_{412} = \varepsilon_{412}+\varepsilon_{676}(1-\varepsilon_{412})$$

To ensure compliance with this equality, the second term of the equation must be negligible compared to the first. This is achieved by setting a very narrow window in the 412 keV peak. The ε_{676} efficiency thus becomes negligible and also the term $\varepsilon_{676}(1-\varepsilon_{412})$.

For ^{131}I we have:

$$\varepsilon_{365} = \varepsilon_{637} = \varepsilon_{732} = 0.54\varepsilon_{503}$$

The last term of the equality is negligible because the abundance of 503 keV gammas is very small. In this case a discrimination level of 330 keV is sufficient to ensure compliance with equality.

Eq. (7.28) enables us to obtain the sample's activity from the count rates without recourse to data from the decay scheme. The procedure is a primary standardization method for the radionuclides for which the equation may be applicable. We simply determine the constant K for a given detection system and each radionuclide, by appropriate variation of the N_c/N_γ parameter.

2. Radionuclide standardization methods based on beta–gamma coincidence

a. Bidimensional extrapolation

Smith and Stuart (1975) developed a new coincidence technique applying two-dimensional extrapolation. They showed that, for some radionuclides, the beta count rate could be expressed as a function of at least two observed beta efficiencies, and that the absolute rate of disintegration could be obtained by simultaneous extrapolation to 100% for two or more dimensions. This reduces the systematic uncertainties in the efficiency extrapolation, as the shape of the extrapolation function is unknown, the extrapolation should coincide. In the two-dimensional case, for example, the two extrapolations must agree at the same point. They applied their procedure to the absolute standardization of ^{57}Co and ^{134}Cs.

b. Tracer method

The efficiency tracing technique was proposed by Campion et al. (1960). The experimental procedures are well established and the sources of uncertainties in the experiment were discussed by Williams and Goodier (1967). By applying this method, the accuracy of the measurement of specific activity for low-energy beta emitters is greatly improved. However, the type B uncertainty introduced by the extrapolation cannot be avoided. The final uncertainty of the specific activity of the low-energy pure beta emitter is still of the order of 1%–4% (Barnes et al., 1971; Baerg and Bowes, 1960; Merritt et al., 1960; Steyn, 1973; Lowenthal and Wyllie, 1973).

The tracer technique can be described as follows: we prepare a series of samples containing the nuclide emitting

only beta particles (pure beta emitter) with a suitable beta–gamma emitter (tracer). A varying amount of carrier is added to the samples so that they present variable surface density. We measure beta detection efficiency ε_β relative to the tracer in a $4\pi\beta - \gamma$coincidence system. After this measurement, the tracer is left to decay. Then we count the samples in the same detector to determine the count rate due to the pure beta emitter, the half-life of which is much longer. This count rate is drawn against the measured efficiency of the tracer. The line obtained is extrapolated to 100% efficiency to determine pure beta emitter activity. In general, all corrections that involve the factor $(1-\varepsilon_\beta)$ can be neglected, both in the counting rate $4\pi\beta$ and in the efficiency determination, as they only add a linear term and these magnitudes are zero for 100% efficiency. As the beta–gamma nuclide is only required for a measure of efficiency and then disintegrates, its activity does not need to be known.

When a long half-life tracer is used, we need to know the activity of the tracer in each sample. Therefore, the contribution of the tracer to the total beta count rate of each sample is determined from the efficiency and amount of activity added. This is then subtracted to obtain the pure beta emitter activity. Alternatively, the total beta count rate of each source drawn against the efficiency of the tracer can be extrapolated to 100% efficiency to obtain the sum of the decay rates (activities) of both nuclides. These decay rates are subtracted from the total decay rate to obtain the activity of the pure beta emitter.

c. Dead time and resolving time corrections

Numerous studies have been published concerning corrections for dead time and resolution time in the past. The most prominent are, in chronological order, Campion (1959), Gandy (1961, 1962), Bryant (1963), and Grigorescu (1973). Other less precise equations are due to Brinkman (1961) and Haywood (1961). These equations correspond to the expression:

$$N_c = PC + C_i$$

where N_c is the net counting rate of coincidences, C is the true coincidence rate in the coincidences channel, C_i is the accidental coincidence rate, and P is the probability of both beta and gamma channels being free in an arbitrary time. In the equations, in addition to the beta, gamma, and coincidence counting rates, N_β, N_γ, and N_c, the dead time θ is introduced in all three channels, together with the resolving time τ. Grigorescu (1973) provides tables of C_i, P, and N_c showing the Campion, Gandy, Bryant, and Grigorescu equations.

Dead time We will describe two models of dead time in the behavior of counting systems: nonparalyzable dead time and paralyzable dead time. In nonparalyzable models, the system responds to the arrival of an event with the creation of a fixed dead time during which the system does not respond to the arrival of new events and, furthermore, counts the pulse generated by the dead time.

In paralyzable systems, the system responds to the arrival of an event with a dead time during which the arrival of another event will lengthen the initial dead time but not result in counting the new event which is lost. So it will only count the initial event.

Nonparalyzable dead time If we designate the rate of incident events (or rate of interactions) as n, the rate of counted events as m and the dead time as τ, in the case of nonparalyzable systems, the relation between these three magnitudes is obtained from the number of lost events. The rate of lost events is on the one hand equal to $n - m$. On the other hand, if we take into account that the total dead time per unit of time is $m\tau$, then the number of counts lost per unit of time is $nm\tau$. So:

$$n - m = nm\tau$$

and

$$n = \frac{m}{1 - m\tau}$$

This expression has been applied in Example 8.13, Chapter 8 of this book.

In the case of a nonparalyzable model, successive events between intervals must be considered.

The Poisson distribution treats all intervals as independent. If the average rate of events per unit of time is n, the probability of not counting any event in a time interval t, during which nt events are generated, is on average:

$$P_0 = \frac{(nt)^0}{0!}e^{-nt} = e^{-nt}$$

The probability of an event occurring in time $dt$is simply ndt. The combined probability that no event occurs during time t and an event in time $t + dt$ is $ne^{-nt}dt$. Therefore, the probability dP_t of the duration of a particular interval being between t and $t + dt$ is:

$$dP_t = ne^{-nt}dt$$

If we have a large number N of intervals, the number of intervals greater than t_1 but less than t_2 is:

$$P = \int_{t_1}^{t_2} ne^{-nt}dt = e^{-nt_1} - e^{-nt_2}$$

If we want to obtain the number of intervals greater than that of τ, we will integrate between $t_1 = \tau$ and $t_2 = \infty$. The result is:

$$P = e^{-n\tau}$$

The rate of occurrence of such intervals is obtained by multiplying by n. Therefore, in a paralyzable model:

$$m = ne^{-n\tau}$$

This expression has a maximum in:

$$\frac{dm}{dn} = e^{-n\tau} - n\tau e^{-n\tau} = 0$$

This happens when

$$m = \frac{1}{\tau}\, e^{-1} = \frac{1}{\tau e}$$

Suppose that a nonparalyzable counter has counted a maximum of 50,000 accounts per second: the dead time will be:

$$\tau = \frac{1}{50000 \times e} = 7.36 \times 10^{-6} s = 7.36 \mu s$$

We will emphasize that when $n << 1/\tau$ (small dead time)

Nonparalyzable model $m = \frac{n}{1+n\tau} \approx n(1 - n\tau)$

Paralyzable model $m = e^{-n\tau} \approx n(1 - n\tau)$

d. Efficiency variation

Both in coincidence and anticoincidence techniques, we have to use a method called efficiency variation or extrapolation. This requires having different values of the beta count rate for different values of N_c/N_γin order to carry out the extrapolation of that relationship to the value of 1. This has been carried out with one of the following five methods:

1. Self-absorption variation
2. Foil-absorption variation
3. Threshold level variation
4. Wet extrapolation
5. Ink-jet printing (Sato et al., 2008)

The self-absorption method was the first to be used. It consists of incorporating increasing amounts of inactive carrier to increase self-absorption and thus decrease the detection efficiency of beta particles.

The method of interposing foils is possibly the most common. Beta efficiency is changed by using absorbers on one or both sides of the source. The absorbers are made of collodion film coated with a thin gold layer ($\approx$20 $\mu g cm^{-2}$) or aluminized MYLAR of different thickness.

Threshold level variation is especially useful since it is nondestructive and avoids other sources of error (e.g., sampling and foiling) that may obscure the results. Other advantages arise with electron capture and internal conversion processes. Threshold level variation is applied in the case of PCs operating at higher than atmospheric pressure, while the foil-absorption method is used with PCs working at atmospheric pressure.

Wet extrapolation was proposed by Zajic (1987). It uses absorption change during the drying of water droplets added to the surface of the source. A wet source is inserted into the PC and measured, while detection efficiency in the PC increases as the water evaporates. This method enables a smooth decrease of source self-absorption and can be reproduced using the same source. Sochorova et al. (2008) applied this procedure to the standardization of ^{54}Mn, ^{139}Ce, ^{88}Y, and ^{57}Co.

Sato et al. (2008) varied the counting efficiency of the sources by adding aqueous black pigment ink (Epson ICBK24), which is electrically conductive. The ink is sprayed on the sources with an ink-jet printer (Mastermind MMP-13100BT, the OEM product "DTG digital, the KIOSK" is available outside of Japan, http://www.dtgdigital.com). This printer has a flat motorized table and the printing position and pattern can be computer controlled. Adobe illustrator and a Macintosh computer were used for drawing a figure (filled rectangle) over the source. Ink was sprayed twice on the source with 40% color density scale with black-pigment ink; the sources were again measured by $4\pi\beta-\gamma$ coincidence. Overpainting of a single source can be repeated several times to obtain varying thicknesses of ink, so several data points can be obtained from one source to develop the $4\pi\beta-\gamma$ efficiency curve.

e. Biparametric extrapolation

Smith and Stuart (1975) presented an extension of the $4\pi\beta-\gamma$ coincidence technique. They showed that, for some radionuclides, the beta count rate could be expressed as a function of at least two observed β-efficiencies, and that the absolute disintegration rate could be obtained by simultaneous extrapolation to 100% efficiency in two or more dimensions. As examples of this generalization of the extrapolation technique, they described measurements of two nuclides, ^{57}Co measured with a PC as the β detector and ^{134}Cs, measured with a liquid scintillator, as the β detector.

Koskinas et al. (2002), Fig. 7.1, determined the activity of a solution of ^{152}Eu by a biparametric extrapolation curve obtained from two selected γ-windows. ^{152}Eu decays 27% by β^-emission and 73% by electron capture and β^+ emission. Both branches are followed by γ-ray emission. Measurements were carried out in a 4πPC–HPGe detection system. The efficiencies were changed by external absorbers. Calibration was performed by selecting two γ-ray windows: 334 keV following β^- decay and 1408 keV following the electron capture and β^+ processes.

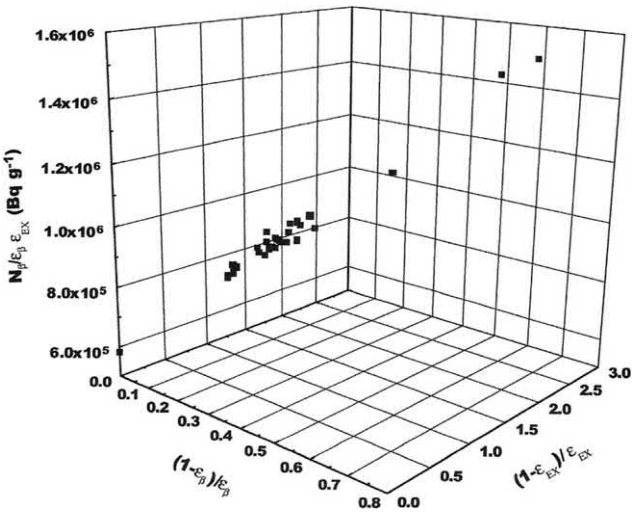

FIGURE 7.1 The biparametric extrapolation curve. *From Koskinass et al. (2002), reprinted with permission of Elsevier Science © 2002.*

The disintegration rate N_0 was determined by changing the efficiency value, using external absorbers over and below the radioactive source made of conducting collodion films previously coated with a 40 μgcm^{-2} gold layer. Activity was determined by simultaneous extrapolation to zero of inefficiency parameters. $\left(1-N_{ci}/N_{\gamma i}\right)/\left(N_{ci}/N_{\gamma i}\right)$

Chylinski and Radoszewski (1992) used a two-parametric method with coincidence and anticoincidence $4\pi(LS)-\gamma$ counting to standardize ^{22}Na. The electronic circuit contained a two-stage coincidence system. The first-stage coincidence unit formed the β-counting channel. Two scintillation counters with NaI(Tl) crystals working in sum mode formed the γ-counting channel. The second-stage coincidence and anticoincidence units were connected to the output of these two counting channels. The extrapolation curves as a function of the ratio $(1-\varepsilon_\beta)/\varepsilon_\beta$ were obtained by changing the high voltage on the photomultipliers.

Chylinski (1992) presents a new version of the tracer technique for measuring EC nuclides. Both the coincidence and anticoincidence methods were used simultaneously in the experiment. He presents the results of ^{134}Cs and ^{55}Fe activity measurements when traced by ^{139}Ce and ^{54}Mn. In this new version of the tracer technique, dependence on the amount of pure beta emitter relative to the tracer amount in the source is eliminated.

Chylinski and Radoszewski (1996) presented the basic relationships, as well as experimental results, for a generalized tracer method, with a multiparameter coincidence and anticoincidence system, for absolute activity measurements of pure beta-emitters. A liquid scintillation counter, with two photomultipliers working in coincidence, was used for beta particle detection and two NaI(Tl) crystals for gamma-ray detection.

A double extrapolation procedure was applied: first, extrapolation as a function of tracer counting efficiency and second, extrapolation as a function of emitter to tracer concentration ratio in the mixed radioactive solution. The second extrapolation procedure minimizes the count uncertainty involved in the first procedure.

The experimental results were illustrated by ^{63}Ni and ^{147}Pm activity measurements with the same tracer: ^{60}Co. The uncertainties obtained were within a 1% limit for a 0.99 confidence level.

Chylinski et al. (2000) measured 12 radionuclides: ^{133}Ba, ^{90}Sr, ^{99}Mo, ^{85}Sr, ^{65}Zn, ^{139}Ce, ^{192}Ir, ^{60}Co, ^{241}Am, ^{152}Eu, ^{169}Yb. They used a multidetection scintillation head for $4\pi(LS)-\gamma$ coincidence and anticoincidence with double-parametric registration.

Chylinski et al. (2002) applied a multimethod of radionuclide standardization with a "triangular scheme" of disintegration. The system is based on the multiparametric coincidence and anticoincidence methods. They presented considerations and experimental data of ^{51}Cr-activity measurement using the above methods.

3. Applications of the beta–gamma coincidence method in radionuclide standardization. Differentiation by type of beta counter

Radionuclide standardization procedures have improved significantly in the last 10 years. International comparisons and the SIR system have effectively contributed to this improvement. In the case of beta–gamma coincidence, uncertainties have been reduced and the number of radionuclides that can be measured by the beta–gamma coincidence method has increased. Below is a list of the most important studies on the subject published in the last decade.

a. Beta–gamma coincidence with proportional counter

^{18}F. Primary activity standardizations were performed on solutions of ^{18}F, using $4\pi\beta-\gamma$ coincidence counting by means of a PC, with efficiency variation achieved by the use of absorbers, and liquid scintillation counting (LSC) according to the CIEMAT/NIST method. A β^+-emission probability of 96.86% was used for both methods (Schrader et al., 2007). Combined relative standard uncertainty (k = 1) (Square root of the sum of quadratic components) was 0.40% and 0.30%, respectively. Sahagia et al. (2014a,b) apply the $4\pi\beta-\gamma$ coincidence method, using positron annihilation quanta and extrapolation of efficiency. Uncertainty was 0.58%.

^{22}Na. Nähle et al. (2008) apply two procedures based on variation of detector source distance. Zero distance extrapolation enables us to obtain the efficiency of the sum

peak and therefore the activity of the sample. Dias et al. (2010) use a PC coupled to a single or pair of NaI(Tl) scintillation crystals. They use Monte Carlo codes to calculate the extrapolation curve of coincidences.

^{31}Si. Koskinas and Dias (1993) measured the gamma-ray probability per decay of Si-31. A $4\pi\beta-\gamma$ coincidence method and the efficiency tracing technique were applied using ^{24}Na as the tracer. A calibrated HPGe spectrometer was used to count the gamma rays.

^{42}K. Simoes et al. (2001) measured the gamma-ray emission probabilities per decay of ^{42}K transitions. The activity of samples was measured in a $4\pi\beta$(PC)$-\gamma$ coincidence system and the gamma-ray measurements were performed in an HPGe spectrometer. The intensity of the 1524 keV gamma ray obtained was (0.1813 ± 0.0014).

^{54}Mn. Havelka et al. (2006) determined the activity of ^{54}Mn and ^{65}Zn by $4\pi\beta$(PC)$-\gamma$ coincidence counting with efficiency variation performed by altering the self-absorption in the sources and by the computer discrimination method. Sochorová et al. (2008) used a wet extrapolation method (absorption change during the drying of a water droplet onto the source surface) to standardize electron capture radionuclides (^{54}Mn, ^{139}Ce, ^{88}Y, ^{57}Co). Havelka (2012) improve the optimal setting of coincidence parameters for EC-β^+ radionuclides. A new procedure based on the coincidence to total PC ratio, a multigamma window combined with subwindows fractions and a source test for PC detection efficiency were introduced.

^{56}Co, ^{57}Co. Havelka and Sochorova (2008) presented a system of digital coincidences for the calibration of these radionuclides. The system consists of a PC and an HPGe detector for the gamma channel (Havelka et al., 2002, 2004, 2006). The Software Coincidence Counting (SCC) uses the conventional method of altering the sample's self-absorption and the computer discriminator method. It also used a conventional PC and two NaI(Tl) detectors. The extrapolation method uses the sample's self-absorption for the efficiency variation by adding extra mass to the sample. The differences between the coincidence results from the conventional method and SCC do not exceed 0.4% and 0.1% for ^{56}Co and ^{57}Co, respectively, which are smaller than the respective uncertainties. Koskinas et al. (2010) standardized ^{57}Co with two $4\pi\beta$(PC)$-\gamma$ coincidence systems. The first coupled the PC to a pair of NaI(Tl) detectors, the second used a HPGe detector.

^{59}Fe. Koskinas et al. (2016) standardized ^{59}Fe using a $4\pi\beta$(PC)$-\gamma$ coincidence system. The experimental setup consisted of a thin window gas flow PC coupled to a NaI(Tl) scintillator and a HPGe detector. The beta efficiency was changed using Collodion films and aluminum foils as external absorbers. Zhang et al. (2016) standardize ^{59}Fe and ^{60}Co using $4\pi\beta$(PC)$-\gamma$ (NaI(Tl)) digital coincidence counting (DCC) and efficiency extrapolation.

^{60}Co. Havelka et al. (2004) described a new procedure to obtain the resolving time and the accidental coincidence corrections. In this procedure a true coincidence resolving time rate is calculated from the records of time and amplitude data of individual pulses. Kawada et al. (2012) present a simple and versatile data acquisition system for software coincidence and pulse-height discrimination in $4\pi\beta-\gamma$ coincidence experiments. They apply this system to ^{60}Co, ^{134}Cs, and ^{152}Eu. Zhang et al. (2016) developed DCC with two NaI(Tl) gamma detectors and a $4\pi\beta$ PC. Kossert et al. (2018) measured the activity of ^{60}Co using four methods: $4\pi\beta-\gamma$ coincidence counting and LSC. The agreement between the different methods shows that the atomic exchange effect and screening corrections in the beta spectrum calculation are correct for a good agreement between liquid scintillation measurements.

^{72}Ga. It is an interesting nuclide because of its high gamma energy. It emits intense gamma rays at 630, 834, 2202, 2491, and 2508 keV. These energies fill the range from 1369 to 2754 keV, of interest in gamma-ray spectrometry. The drawback is that this nuclide has a short half-life of 14.10 hours, which makes it of local interest (Koskinas et al., 2006b).

^{99m}Tc. Sahagia (2006) calibrated this radionuclide using the 4π(PC)$-\beta$ coincidence method. She used three different procedures, all based on beta−gamma coincidences. The first is based on the coincidence between the conversion electrons (119.5−142.6) keV and X-rays. The second used the coincidence between the conversion electrons of 2.13 keV, measured by the PC, and the gamma rays of 140.5 keV. In the third procedure, she counted the whole spectrum of radiations detected in the PC and the γ-rays. The latter was described by Goodier and Williams (1966) and then by Ayres and Hirshfield (1982) with an uncertainty of 0.95%. They measured the total spectrum in the PC, obtaining general and specific equations for ^{99m}Tc. The conclusions from comparing the three procedures are as follows. The first is highly efficient, as it involves short-range extrapolation. The disadvantage of this method is the high Compton background under the X-ray peak. The second method has the advantage of a low slope of extrapolation. The third is simple and has a high count rate, but a greater extrapolation interval, with a steep slope.

^{134}Cs. García-Toraño et al. (2002a) calibrated this radionuclide through three methods: liquid scintillation, $4\pi\beta-\gamma$, and $4\pi\gamma$. They applied the CIEMAT/NIST LSC method. For coincidence measurements, they used a conventional system with two gamma windows: from 550 to 650 keV and from 750 to 850 keV. The main difference with the Grigorescu (1973) approach is that it suggests a narrower window for the 605 keV photon or the use of a discrimination level of more than 700 keV. In the approach established in this chapter the following relationship is approximately fulfilled:

$$\varepsilon_{800} = 0.13\varepsilon_{1365} + 0.87\varepsilon_{800} = 0.42\varepsilon_{1038} + 0.12\varepsilon_{1168}$$

For $4\pi\gamma$ calibration, they used a NaI(Tl) well crystal; and the Monte Carlo method was applied using the PENELOPE program (Salvat et al., 2006). The results obtained with the three methods were consistent within 0.65%.

Kawada et al. (2012) constructed a powerful and versatile bidimensional data acquisition system and carried out $4\pi\beta(\text{PC})-4\pi\gamma$ measurements of ^{60}Co, ^{134}Cs, and ^{152}Eu as examples.

To vary the mass, Sochorová and Auerbach (2014) use the wet efficiency extrapolation method to standardize the ^{134}Cs. The most significant item on the list of uncertainties is the uncertainty of extrapolation. Preparation of samples with lower self-absorption will be the subject of further research.

^{152}Eu. This radionuclide was calibrated by Grigorescu et al. (2002) and Park et al. (2002) in the context of an international comparison organized by the BIPM. ^{152}Eu is a gamma-ray emitter that is important in radionuclide metrology for the calibration of gamma spectrometers in both energy and efficiency. The solution was prepared in ampoules by the PTB. Solutions were measured at the BIPM in the SIR ionization chambers and then sent to participating laboratories. The work was carried out in the IFIN-HH Radionuclide Metrology Laboratory, where the solution was calibrated using an extrapolation method in conjunction with beta efficiency by applying the foil absorption procedure to modify the beta efficiency of the samples. They used a measurement system consisting of a PC $4\pi\beta$ and a crystal of NaI(Tl). There was no more than 0.5% impurity in the samples. They used a gamma window from 180 to 1500 keV. Dead time was 10 μs. The uncertainty obtained was 0.24% and was mainly due to the component of the extrapolation procedure.

Koskinas et al. (2002) calibrated the ^{152}Eu solution applying the $4\pi\beta-\gamma$ coincidence technique. They used a P-10 gas-filled PC operating at 0.1 MPa, coupled with an HPGe gamma detector. They used two discrimination windows for the gamma channel, one linked to the beta (344 keV) and the other to electron capture events (1408 keV), to determine the efficiencies for beta particles, X-rays, and Auger electrons in the proportional counter. The activity of the samples was determined using two-parameter extrapolation (Cox and Isham, 1977; Smith, 1987) obtained for the two windows.

Johansson et al. (2003b) apply six direct methods for the standardization of ^{152}Eu: two methods using the same equipment are $4\pi\beta(\text{PC})-\gamma$ coincidence counting and $4\pi\beta(\text{PC})-\gamma$ sum counting. The equipment was a pressurized PC (Ar-CH_4) for counting electrons and low energy photons and a 15 × 15 cm NaI(Tl) well crystal for counting gamma rays.

Havelka and Sochorová (2010) standardize ^{152}Eu and ^{152}Sb using a new SCC system. They demonstrate the advantages of the software coincidence system in setting and checking the optimal counting parameters. Havelka (2012) improves the SCC system for the standardization of EC-β^+ radionuclides.

Dias et al. (2013) developed a Monte Carlo simulation code ESQUEMA to be used as a benchmark for radionuclide standardization. ^{152}Eu was standardized by $4\pi\beta(\text{PC})-\gamma$ coincidence system and compared to Monte Carlo simulation.

^{182}Ta. Koskinas et al. (2008) applied the $4\pi\beta-\gamma$ method and extrapolation technique for the calibration of ^{182}Ta. They used a PC and a 76 mm × 76 mm NaI(Tl) detector. Beta efficiency was varied with collodion films previously coated with 20 μg/cm^2 of gold, and aluminum foil was applied to both sides of the sample. To obtain the coincidence events, two windows were used for the gamma channel, the first from 40 to 300 keV and the second from 1000 to 1300 keV.

^{241}Am. A very interesting application (Koskinas et al., 2006a) is the calibration of a solution of ^{241}Amusing a $4\pi\alpha-\gamma$ coincidence system. The PC, which detects the alpha particles, has P-10 gas, operates at 0.1 MPa, and has an aluminum window of 0.1 mm on the external wall to minimize gamma ray attenuation. Two extrapolation techniques (foil absorbers and threshold level variation) are applied to determine activity. Alpha efficiency variation is performed using two methods: the first uses external absorber collodion films coated with 20 μg cm^{-2} of gold, and the second uses electronic discrimination, changing the threshold of the alpha spectrum. The results of the two methods are comparable: 295.31 ± 1.06 and 296.44 ± 1.07 kBq g^{-1} and consistent within experimental uncertainty (Table 7.1).

b. Beta−gamma coincidence with a liquid scintillation counter (4π(LS)ex-γ)

^{139}Ce, ^{125}I, ^{192}Ir, ^{65}Zn. The beta−gamma coincidence technique $4\pi(\text{LS})\text{ex}-\gamma$, based on a beta liquid scintillation detector, has been successfully applied to the standardization of these radionuclides by Van Wyngaardt and Simpson (2006a). The four radionuclides were measured by the liquid scintillation extrapolation method. The last three radionuclides (^{125}I, ^{192}Ir, and ^{65}Zn) were part of a BIPM intercomparison. These four EC nuclides were standardized using variations of the coincidence extrapolation technique. The advantages of using liquid scintillation in the 4π channel are: absence of self-absorption (allowing measurement of Auger electrons with relatively high efficiency), relatively simple sample preparation, and highly reproducible sample geometry. This last advantage generated good reproducibility of the counting efficiency of

X-rays and Auger electrons, and consistent results between the counted samples. This technique was applied previously to ^{201}Tl (Simpson and Meyer, 1994b). In the case of ^{139}Ce, the counting system consisted of two photomultipliers in coincidence, which detected the light produced by the scintillator sample, and a crystal of NaI(Tl) to detect gamma rays.

The expression used to calibrate the radioactive sample is obtained as described below. First, the count rate, $N_S = N_0[f + (1-f)PP_S + (1-f)(1-P)\varepsilon_{AX}]$, from the liquid scintillation coincidence system is given by:

$$N_S = N_0[f + (1-f)PP_S + (1-f)(1-P)\varepsilon_{AX}] \quad (7.35)$$

where N_0 is the activity of the sample, f is the emission probability for the converted electrons, ε_{AX} is the detection efficiency of the emissions subsequent to EC (X-rays and Auger electrons), P is the probability that the gamma rays interact with the scintillator solution, and P_S is the detection probability of Compton electrons together with the particles emitted in the electron capture process giving a sum pulse. The conversion electrons are detected with 100% efficiency.

The gamma counting rate given by the NaI(Tl) detector is:

$$N_\gamma = N_0[(1-f)(1-P)\varepsilon_\gamma] \quad (7.36)$$

where ε_γ is the detection efficiency of events in the full-energy peak. The coincidence rate is:

$$N_C = N_0[(1-f)(1-P)\varepsilon_{AX}\varepsilon_\gamma] \quad (7.37)$$

from Eqs. (7.36) and (7.37) we have:

$$\frac{N_C}{N_\gamma} = \varepsilon_{AX} \quad (7.38)$$

Eq. (7.35) can be expressed as:

$$\frac{N_S N_\gamma}{N_C} = N_0(1-f)(1-P) + N_0[f + (1-f)PP_S]\frac{N_\gamma}{N_C} \quad (7.39)$$

When $N_\gamma/N_C \to 1$ and $P_S \to 1$, Eq. (7.39) becomes:

$$\frac{N_S N_\gamma}{N_C} \to N_0 \quad (7.40)$$

When N_γ/N_C is varied, we expect that P_S changes due to the low energy of the Compton electron spectrum. If the variation of P_S is linear, so will be the variation with respect to N_γ/N_C. Fig. 7.2 shows the extrapolation curves for three gamma windows. The points designated as Photopeak correspond to a window that covers the full-energy peak for gamma rays of 166 keV. The points designated as (K X-ray peak to end of photopeak) correspond to a window that extends from the X-ray peak to the full energy absorption peak. Finally, the points marked as "Iodine escape peak and photopeak" correspond to a window that includes the escape peak and the full energy absorption peak. The lines fitting the data sets were obtained with a third-order polynomial, with the second-order coefficient equal to zero.

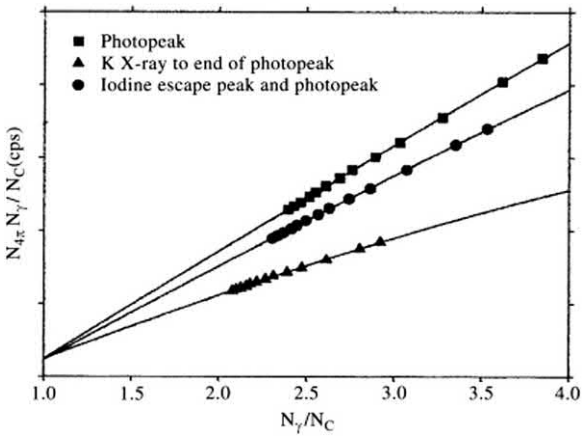

FIGURE 7.2 Extrapolation curves for three gamma windows. *From Van Wyngaardt and Simpson (2006a,b), reprinted with permission from Elsevier Science © 2006.*

Standardization of ^{192}Ir is more problematic because of the complexity of the spectrum; a method similar to that of ^{139}Ce has been used.

^{65}Zn can be standardized with the coincidence data without extrapolation (Simpson and Morris, 2004a). However, the extrapolation gives excellent results.

^{125}I is calibrated by applying the extrapolation technique using the equations of Simpson and Meyer (1989) (Table 7.2).

^{60}Co. Dias et al. (2008) have developed a $4\pi\beta-\gamma$ coincidence detector using plastic scintillators for beta detection in 4π geometry. The gamma detector used was a NaI(Tl) crystal. The new system improved the efficiency of the old PC, which was 60%, and obtained an efficiency of 77% for the new beta detector based on plastic scintillators.

c. beta–gamma coincidence with plastic scintillation sheets

A $4\pi\beta(PS)-4\pi\gamma$ coincidence counting with plastic scintillation was described by Nedjadi et al. (2010). This technique is very useful for standardizing the activity of short-lived radionuclides used in nuclear medicine. The technique is less cumbersome than the usual $4\pi(PC)-\gamma$. The Swiss National Metrological Institute (IRA-METAS) has set up this new coincidence system. They standardize ^{18}F. A similar system was already used to standardize ^{18}F by Yamada et al. (2008). In this technique, the beta detector is composed of two thin plastic scintillators sandwiching the source, coupled to a photomultiplier tube. The beta detector with the source is inserted into a large well type NaI(Tl) scintillator detector for γ-ray detection. Table 7.3

4. Applications of the beta–gamma coincidence method. Standardization of radionuclides and determination of nuclear constants

^{65}Zn. In 2006, an exercise called International EUROMET action 721, was organized in order to obtain more reliable decay data in the decay of ^{65}Zn (Bé, 2006; Bé et al., 2010). Nine laboratories participated by sending their activity measurement results and the intensity [50.22 (11)%] of the 1115 keV gamma ray. Except for two participants, who individually used an ionization chamber method and LSC, all the laboratories measured the activity by means of the $4\pi\beta-\gamma$ coincidence method. In the context of this project, we should highlight the contribution of Kossert et al. (2006a,b). The result of the activity measurement was combined with gamma spectroscopy measurements to investigate photon emission probabilities. The half-life of ^{65}Zn was measured, with improved accuracy, by a 4π ionization chamber, which was also used to measure secondary activity. In addition, a new secondary calibration procedure using LSC was tested. In general, the combined relative uncertainty was found to be 0.2% and 0.4% for $4\pi\beta-\gamma$ coincidence counting and LSC, respectively. The activity measured by LSC proved to be only 0.05% lower than that obtained by the coincidence method. The results obtained with the ionization chamber were even better and the relative standard deviation was estimated at 0.3%. These results confirm the excellent long-term stability of the ionization chamber.

5. Application of the tracer method

^{35}S, ^{63}Ni, and **^{185}W.** Yan et al. (2002) measured the activity of these pure beta-emitting radionuclides using ^{60}Co and ^{134}Cs as tracers. The uncertainties of the final results for the three pure beta emitters were 0.5% at the 99.7% confidence level. Beta theory was applied to calculate Fermi relations between the beta spectra of the five radionuclides. The authors reinvestigate the influence of spectral shapes and the value of the maximum energy of the nuclide tracers in the activity of pure beta emitter samples. They also investigate the type B uncertainty introduced by the upper limit of the region of adjustment (for radionuclides with low counting efficiency), by the power of the polynomial fit (for the tracer ^{60}Co), the lower limit for the region of adjustment (due to self-absorption), and by the gate setting for gamma rays (when ^{134}Cs is used as a tracer).

^{89}Sr. Razdolescu et al. (2002) calibrated ^{89}Sr using two methods. The first was the TDCR technique, using a liquid scintillation system. The second was the efficiency tracing technique using ^{60}Co as a tracer and a $4\pi\beta-\gamma$ coincidence system. The activity of the samples was determined by a general curve extrapolation procedure using data from various sources. The results obtained with both methods agreed within their combined uncertainties. Csete et al. (2002) calibrated a solution of ^{89}Sr at the National Office of Measurement (OHM) using two different methods. The first was the conventional $4\pi\beta$ method of counting with two gas flow PCs operating with methane gas (Szörenyi and Vágvölgyi, 1984). The second method of measurement was $4\pi\beta-\gamma$ using ^{22}Na as a tracer. The beta efficiency for each of these techniques was 100%. The agreement between the results of the methods was 0.5%.

6. Applications of a two-dimensional method of extrapolation

^{166m}Ho, ^{58}Co, and **^{88}Y.** Yuan et al. (2002) applied the $4\pi\beta-\gamma$ coincidence method to the standardization of these radionuclides. In the case of nuclides ^{88}Y and ^{166m}Ho, three gamma windows were established to study systematic error caused by the use of different gamma ray windows. To eliminate the effect of the large difference in the efficiencies of the counter between electron capture events and positron decay, a two-dimensional extrapolation method was applied in the case of ^{58}Co. The results of the measurements of the three radionuclides have been used to link to the SIR of the BIPM through two APMP (Asia–Pacific Metrology Program) regional comparisons.

7. Beta–gamma coincidences. Generation of extrapolation curves

^{54}Mn. Sato et al. (2008) used a novel technique to vary the efficiency of radioactive counting samples to be measured in a $4\pi\beta-\gamma$ system by varying the beta efficiency as follows. They covered the radioactive sample with varying amounts of an electrically conductive pigment used in inkjet printers. This method can be used to prepare samples needed to generate multiple extrapolation curves.

8. Digital systems for beta–gamma coincidence

For years, the traditional method of data collection for counting with the $4\pi\beta-\gamma$ coincidence technique used analog electronics. Modules used have been single-channel analyzers, linear gates, units of dead time and delay, time-amplitude converters, and multichannel analyzers. The high cost of the acquisition and maintenance of these systems has led to the search for more robust and flexible counting systems. The National Physical Laboratory (NPL) and the Australian Nuclear Science and Technology Organization (ANSTO) collaborated in the development of a digital coincidence system (DCC) to be used in $4\pi\beta-\gamma$ systems (Keightley and Watt, 2002). This chapter presents a system overview and a good analysis of its advantages. Details of these coincidence systems were published previously (Buckman et al., 1998; Butcher et al., 2000), followed by a comprehensive review by Keightley and Park (2007).

^{152}Eu and **^{88}Y**. Park et al. (2002) measured the activities of these radionuclides by the DCC technique and compared the results with those obtained with traditional coincidence techniques. ^{152}Eu activity was determined by extrapolation of the efficiency functions obtained with three gamma gates. The result obtained with the DCC system showed good agreement, to within a 2%, with the result obtained with the traditional method. The uncertainty for DCC was 0.19% and 0.21% for the conventional method. ^{88}Y activity was obtained by the DCC method and the reliability of the results was tested within the inter-Asia Pacific Metrology Program (APMP).

B. Beta–gamma anticoincidences

In anticoincidence counting techniques, only gamma events not coincident with beta events are counted. The coincidence rate is obtained as the difference between total and noncoincidence counting rates. This method has certain advantages for removing instrumental effects, particularly in the case of nuclides with excited gamma states. There are two methods for measuring anticoincidence: the first is based on nonextending dead time and the second measures live time with extending dead time circuits. The anticoincidence system based on nonextending dead time was the first to be employed. However, the one based on live time is now the most commonly used, and involves the simplest electronics (Tables 7.4 and 7.5).

1. Anticoincidence method with nonextending dead time

This method was introduced by Bryant (1962, 1967) and only requires correction for dead time and background, avoiding correction for accidental coincidences. In the case of coincident beta–gamma radiation, only gamma signals that precede or follow the signals in the beta channel in minimum time T are accepted as anticoincidence gamma events. This is achieved by delaying the gamma signal by a fixed time T and closing an anticoincidence gate on the gamma channel for a fixed time $2T$ after each beta signal. By choosing an appropriate T, we assure that we never count accidental anticoincidences.

According to Bryant (1962), the expression for the rate of disintegrations N_0 is given, in the case of correlated beta–gamma anticoincidences, with the expression:

$$N_0 = \frac{\left(\frac{N_\beta}{1-N_\beta T_\beta} - B_\beta\right)\left(\frac{N_\gamma}{1-N_\gamma T_\gamma} - B_\gamma\right)}{\frac{N_\gamma}{1-N_\gamma T_\gamma} - \frac{N_{\gamma A}}{1-N_\beta(T_\beta+2T)} - (B_\gamma - B_{\gamma A})} \quad (7.41)$$

where N_β and N_γ are the count rates in the beta and gamma channel, respectively; $N_{\gamma A}$ is the count rate of the gamma anticoincidences, T_β and T_γ are the beta and gamma dead time, and $2T$ is the time that the gate has to remain closed. B_β, B_γ, and $B_{\gamma A}$ are the background rates of the beta, gamma, and anticoincidence channels, respectively.

The anticoincidence method has advantages in the case of delayed gamma emission (Bryant, 1967), as in isomeric states with a short half-life. In this case, the anticoincidence gate has to remain closed for a time τ in addition to the time $2T$, as mentioned earlier. In this instance no signal from the daughter nuclide, in the counting channel (channel B), can pass through the gate to be accepted as an anticoincidence, unless at least one time T before and after at least one signal in the time $T+\tau$ on the parent radiation channel (channel A). If $T+\tau$ is equal to m half-lives of the state that produces the delayed radiation, the probability that a coincidence was recorded as an anticoincidence is 2^{-m}. Choosing m properly, the ratio of incorrectly recorded anticoincidence signals can be as small as desired.

The anticoincidence rate can be corrected for dead time, if we know the proportion of time that the gate is open and the time that the channel counting the daughter nuclide radiation is active. The anticoincidence rate corrected for dead time (not for background) is:

$$N_{CA} = \frac{N_R(1+N_A T_A)}{\exp[-N_A(2T+\tau)] - N_R T_B(1+N_A T_A)} \quad (7.42)$$

where N_R is the anticoincidence rate not corrected for dead time, N_A is the count rate in the channel counting parent radiation corrected by dead time, T_A is the dead time in the channel counting parent radiation, T_B is the dead time of the channel counting daughter radiation, $2T+\tau$ is the time, after the end of a period of dead time, in the parent radiation channel, during which the anticoincidence gate remains closed.

The probability of the anticoincidence gate being open is the product of the probability that channel A is alive and has been alive for at least one time period of $2T+\tau$. These probabilities are, respectively, $1/(1+N_A T_A)$ and $\exp[-N_A(2T+\tau)]$.

De Carlos and Granados (1973) introduced the Shared Dead Time (SDT) concept and method, and the principle on which the instrumentation is based. The basic idea of the SDT concept is to prevent the situation in which one channel is open while the other is blocked. They impose on both channels the same occupation time intervals by simultaneous blockade. The overlapping process disappears and the three dead times of the three channels have a unique dead time, at the expense of a greater loss of counts.

2. Live-timed anticoincidence counting with extending dead-time corrections

Anticoincidence counting using live-timed extending dead-time corrections (Baerg et al., 1976) removes all corrections due to instrumental effects. The method consists of first delaying the gamma signal with respect to the beta signal for an amount greater than any beta−gamma jitter and possible delay of beta pulses; then combining the beta and gamma logic signals so that one logical pulse triggers the extending dead time generator circuit. The extending dead time, τ, is adjustable and must have a value greater than the beta−gamma "jitter" and the delay (for example, $\tau \geq 2\,\mu s$). The output pulses of this circuit are applied as gate signals for simultaneously closing a channel with a live time clock and beta and gamma channels. A small delay (≈ 5 ns) in the gate allows the beta and gamma pulses that initiated the extending dead time to reach their counting channel and be recorded before the gates close.

This system ensures that only the gamma events not correlated with the events of the beta channel are counted in the gamma channel. This is a consequence of the extending nature of dead time; no other pulse (beta or gamma) can be detected in the time interval τ that precedes the observed pulse. It can also be shown that any beta event correlated with a gamma event can be registered because the gamma signal ensures that the channel will already be blocked by a signal on the gate initiated by a correlated beta event.

The live time clock, controlled by the gate triggered by the same impulses that control the beta and gamma channel count, cumulatively measures the time intervals of the combined $\beta-\gamma$ series. The counts accumulated in each channel are divided by the accumulated live time results in the correct count rate for the respective channel. The anticoincidence technique does not require corrections for the effects of resolving time or by dead time or by the $\beta-\gamma$ jitter effects. It only requires knowledge of the background rate and application of the corrections for isomeric state decay.

3. Applications of the method of anticoincidence Beta−gamma Radionuclide standardization

a. Applications of nonextending anticoincidence dead time

^{170}Tm. Chylinski et al. (1972) described the electronics and presented the measurement method using a $4\pi\beta-\gamma$ anticoincidence system that enables the absolute measurement of radioactive solutions. The systematic error is less than 0.1%, showing that the system works in an efficient and stable way. Comparing the results of measuring the radioactive concentration of a solution of ^{170}Tmusing the anticoincidence and coincidence methods shows the advantages of the presented method. The difference between the results of the two methods is 0.4%.

^{60}Co, ^{110m}Ag − ^{110}Ag, ^{134}Cs. Kawada et al. (1970) used a $4\pi\beta-\gamma$ system with a Ge(Li) detector and an anticoincidence system for measuring radionuclides with complex decay schemes without resorting to corrections for the decay scheme. They used the full gamma spectrum in both the gamma and anticoincidence channel. They applied the method to the standardization of ^{60}Co, ^{134}Cs, and ^{110m}Ag − ^{110}Ag, and compared the results with those obtained by other methods. The use of anticoincidence instead of the coincidence procedure has advantages in $4\pi\beta-\gamma$ systems with particular reference to accuracy and precision.

b. Applications of live-timed anticoincidence counting with extending dead time

^{241}Am, ^{124}Sb, and **^{131}I.** Da Silva et al. (2008a) described a coincidence and anticoincidence system that is composed of a cell for LSC, instead of a PC detector, and a 3" × 3" NaI(Tl) crystal. Live time measurements with an extended dead time device in the anticoincidence system were used to eliminate dead time corrections. ^{241}Am, ^{124}Sb, and ^{131}I were measured to test the system. Extrapolation curves were obtained by electronic discrimination in the liquid scintillation detector. The results are consistent with those obtained with a high pressure PC.

^{60}Co and **^{210}Pb.** Fitzgerald and Schultz (2008) use a photomultiplier tube to detect the scintillations of the liquid scintillator and a well-type NaI(Tl) crystal for gamma emission. The beta efficiency was varied by a discriminator. Three windows are used for the gamma channel: G1 for the Compton region, G2 for the full-energy peak, and G3 for the sum peak. The live time and the sum dead time were 100 μs. The containers were hemispheres containing 4 mL of HiSafe-3 LS-cocktail for ^{60}Co and 4 mL of PCS LS scintillation cocktail for ^{210}Pb.

^{60}Co, ^{137}Cs, and **^{166m}Ho.** Lu and Wang (2003) describe a system in which gamma radiation is measured with an HPGe detector and the β-counter is a PC. The Combined Standard Uncertainties for each of the aforementioned radionuclides were 0.24%, 0.33%, and 0.44%, respectively. Compared with the coincidence system, the ^{60}Co and ^{137}Cs results were satisfactory. For ^{166m}Ho, results from other methods have greater uncertainty due to the complexity of the nuclide's decay scheme. However, the anticoincidence technique has some shortcomings. First, the anticoincidence system is linked to the decay scheme, which introduces some uncertainties due to the lack of precision of the decay scheme data. Moreover, the anticoincidence channel uncertainty may be higher due to the low count rate.

^{51}Cr, ^{55}Fe, and **^{67}Ga.** Da Silva et al. (2008b) calibrated these radionuclides by anticoincidence counting using a live time clock with extending dead time. The chapter discusses the difficulties of the method and the uncertainties of the measurement results. Finally, they compare these results with those obtained using other methods of measurement. **^{67}Ga.** Santry et al. (1987) applied the live time technique with anticoincidence for the absolute standardization of ^{67}Ga. In contrast to the coincidence method, no dead time corrections, resolving time or effects due to e$-\gamma$-time jitter, are required in this case. This was achieved by extending the system dead time by several times the longest half-life. It was only necessary to apply background and decay corrections.

^{210}Pb. Laureano-Perez et al. (2007) standardized ^{210}Pb in solution by applying the CIEMAT/NIST method, using tritium as a tracer. As a confirmatory method they used high-resolution gamma spectrometry (HPGe), and $2\pi\alpha$ spectrometry with a Si barrier detector to determine the activity of ^{210}Po. From this activity they determined the activity of ^{210}Pb. They assumed that the sample of ^{210}Pb was in equilibrium. This procedure had been applied previously by Lucas (1998).

^{99}Tc. Lucas (1998) obtained the activity concentration of ^{99}Tc by applying an anticoincidence system with live time to a $4\pi\beta$(LS)$-\gamma$ counter. He used ^{60}Co as a tracer. He also applied the CIEMAT/NIST LSC method. In this case, he examined the influence of the shape factor of the second forbidden nonunique beta transition. Three gamma channels were used in the anticoincidence technique and the SD of the obtained activity ranged from 0.35% to 0.39%, according to the channel used.

^{134}Cs. Da Silva et al. (2018b) standardized ^{134}Cs applying three methods: $4\pi\beta-\gamma$ live-timed anticoincidence counting, $4\pi\beta-\gamma$ coincidence counting, and CIEMAT/NIST liquid scintillation methods. The standardization was made in order to reduce the uncertainty in ^{134}Cs. The agreement between the results of the three methods was excellent.

^{68}(Ge + Ga) and ^{18}F. Da Silva et al. (2018a) standardize ^{68}(Ge + Ga) using three methods: $4\pi\beta-\gamma$ live-timed anticoincidence counting, $4\pi\beta-\gamma$ coincidence counting, and the TDCR method. The results obtained were consistent. The difference between the calibration factors of ^{68}(Ge + Ga) and ^{18}F was lower than 0.3%, demonstrating that ^{68}(Ge + Ga) can be used as a substitute for ^{18}F in quality control tests in radiation measurement equipment used in nuclear medicine.

^{106}Ru/Rh. Da Silva et al. (2017) standardized ^{106}Ru/Rh. The high β produced by the decay of ^{106}Ru to ^{106}Pd is used in radiotherapy for treating eye cancer. ^{106}Ru can be standardized directly by coincidence or anticoincidence counting; however, as it is in equilibrium with ^{106}Rh, the activity of ^{106}Ru can be obtained by the activity of ^{106}Rh. The results of both procedures were quite satisfactory.

C. Beta–gamma correlations

1. Introduction

In a pioneer paper, Friedlander (1964), following Goldansky and Podgoretsky (1955), proposed applying correlation techniques to radionuclide standardization. The author suggested that the correlation method had two major advantages over the conventional $4\pi\beta-\gamma$ method: the application of small corrections to the count rate for the elimination of accidental coincidences, and statistical accuracy that was independent from the total number of observed coincidences. Williams and Sara (1968) examined these potential benefits in the case of absolute measurements using the $4\pi\beta-\gamma$ technique to perform the calibrations with the maximum precision. To this end, they directly compared the two methods. These authors found that correction of the total count rate is higher with the correlation method than the traditional method. Their conclusions were that the correlation method used to observe coincident events shows no advantage over the traditional method. The statistical accuracy is at most equal to the traditional method and dependence on the count rate is higher. Later, Lewis et al. (1973) applied the correlation method to radionuclide standardization in which there is a long half-life level. This is an excellent study; and they applied it to the standardization of ^{75}Se, ^{67}Ga, and ^{85}Sr, as well as the detection and estimation of "after pulses" in LSC.

The measurement of activity using correlation techniques can be applied to radionuclides with delayed states without detailed knowledge of the decay scheme and, therefore, is superior to the conventional coincidence method. In the case of coincidences without delay, the conventional method is better than correlation except when the exact form of the covariance by dead time is known. When this occurs, the correlation method has advantages

over conventional counting since no corrections are required for resolving time. Müller (1975) also gave a good theoretical explanation of the correlation in $4\pi\beta-\gamma$ counters.

We consider two situations: one of which uses two detectors to obtain the correlation. Such is the case when applied to ^{85}Sr. In the other case, only one detector is used for the correlation. Hence, the radionuclide has a typical decay scheme. The first excited level is a prompt gamma emission. The second excited level has a measurable half-life with highly converted delayed gamma emission. ^{67}Ga and ^{75}Se are good examples.

2. Theoretical description of the beta–gamma correlations method

The basic idea of correlation counting is to determine the counting rate of genetically correlated event pairs by statistical analysis of the events without coincidence, and therefore, without the problems related to timing effects. The method is based on the fact that radioactivity is a process described by Poisson statistics. The distribution of the number of events occurring in a well-defined time interval of length T is accumulated with a large number of successive measurements.

In general, the method involves determining the number of events n_i, occurring in an interval T, for a number of intervals N and calculating the moments of the distribution of the number of events per interval.

For example, the average number of events per interval is:

$$m = \frac{\sum_i n_i}{N} \tag{7.43}$$

and the second moment about the mean (i.e., the variance) is:

$$V = \frac{\sum_i n_i^2}{N} - \frac{\left(\sum_i n_i\right)^2}{N^2} \tag{7.44}$$

If events are radioactive decays, detected by a counter with zero dead time, the events follow the Poisson distribution and then, for a sufficiently large N, the average number of events per interval $\overline{n}$ can be obtained from m and V. In this simple case, the variance does not provide additional information, as the expected value is:

$$E[V] = m \tag{7.45}$$

but in more complex cases, the correlation method has considerable advantages. We will discuss two situations in which the correlation method gives good results (Lewis et al., 1973).

Situation 1. When the intermediate state has a significant half-life, covariance depends on the decay constant λ and T (length of the intervals, not to be confused with the half-life). The number of parent–daughter pairs c_i recorded in the i interval, ignoring the effects of dead time, are distributed according to a Poisson distribution and the covariance estimate is the mean value c of c_i.

$$c = N_0 T \varepsilon_p \varepsilon_d \left(1 - \frac{1 - e^{-\lambda T}}{\lambda T}\right) = N_0 T \varepsilon_p \varepsilon_d f(\lambda, t) \tag{7.46}$$

When $\lambda T \to \infty$, parent and daughter are simultaneous, and $f(\lambda, T) \to 1$. For small λT, we have $f(\lambda, T) \approx \lambda T/2$, which is reasonable.

In deriving the covariance modified by dead time, we have to deduce the probability of losing a parent event correlated with the loss of the respective correlated daughter. In this case, the probability should be modified and written as $g(\lambda, \tau_p, \tau_d) c_i (c_i - 1) \Theta_c$, where

$$g(\lambda, \tau_p, \tau_d) = 1 - \exp[-\lambda(\tau' - \tau_c)] \frac{1 - \exp(-2\lambda\tau_c)}{2\lambda\tau_c} \tag{7.47}$$

and τ' is the longer of τ_p and τ_d

Expectation values are given by:

$$X' \approx X[1 - (2p\Theta_p + 2d\Theta_d - c\Theta_c g(\lambda, \tau_p, \tau_d))] \tag{7.48}$$

which again is sufficiently accurate for dead time losses of a few percent.

Situation 2. When we have a nuclide whose decay scheme shows an excited long-term state that is preceded by an excited state that decays instantly and parent and daughter events are indistinguishable, both radiations are detected in the same detector. One example is a beta decay followed by an internal converted γ-transition. If we measure $n_i = p_i + d_i$ (parent + daughter), the quantity n_i does not follow a Poisson distribution. Setting $p_i = x_i + c_i$ and $d_i + y_i + c_i$, where x_i and y_i are uncorrelated events, we have:

$$E(V) = n + 2c \tag{7.49}$$

here

$$c = N_0 T \varepsilon_p \varepsilon_d \left[\left(1 - \frac{\tau}{T}\right) - \frac{1 - \exp[-\lambda(T - \tau)]}{\lambda T}\right] \exp(-\lambda t) \tag{7.50}$$

and substituting

$$f(\lambda, T, \tau) = \left[\left(1 - \frac{\tau}{T}\right) - \frac{1 - \exp[-\lambda(T - \tau)]}{\lambda T}\right] \exp(-\lambda t) \tag{7.51}$$

we have

$$c = N_0 T \varepsilon_P \varepsilon_d f(\lambda, T, \tau) \tag{7.52}$$

as a fraction of the daughter events is lost in the dead time of the parent. The MSD is deduced by substituting $n_i = n + \delta x_i + \delta y_i + 2\delta c_i$ in Eqs. (7.44) and (7.45). When $N \gg 1$, we have:

$$\sigma_V^2 \approx \frac{2V^2 + V + 12c}{N} \tag{7.53}$$

The mean count and the variance can be obtained from the same data and the magnitude $2c$(equal to $V - n$) can be extracted directly with an MSD of $(4c + 2V^2)/N$.

The expression for a_i, being $a_i\Theta$ the probability of losing one event of $n_i$due to rate effects, must be modified as follows:

$$a_i = n_i(n_i - 1) - 2c_i - h(\lambda, \tau)(n_i - c_i - 1)q_i - h^*(\lambda, \tau)q_i c_i \tag{7.54}$$

The term $2c_i$ takes into account the fact that the components of any pair cannot annihilate each other. Factors $h(\lambda, \tau)\Theta$ and $h^*(\lambda, \tau)\Theta$ represent the probability that if a parent whose daughter was lost originally in its dead time is lost, the daughter may now be recorded outside the dead time in which its parent is lost. In the i^{th} interval there are q_i of these parent events and:

$$h(\lambda.\tau) = \frac{\varepsilon_d[1 - \exp(-h\lambda t) - \lambda\tau \exp(-\lambda\tau)]}{\lambda\tau(1 - \exp(-\lambda\tau))} \tag{7.55}$$

And

$$h^*(\lambda\tau) = \frac{\varepsilon_d \exp(-\lambda\tau)[1 - \exp(-\lambda\tau)]^2}{2\lambda\tau} \tag{7.56}$$

The mean count observed for small dead time losses is:

$$n' \approx n - n^2\Theta(1 - \delta_1) \tag{7.57}$$

$$n' \approx n - n^2\Theta + h(\lambda, \tau)(n - c)q\Theta + h^*(\lambda, \tau)qc\Theta \tag{7.58}$$

This expression can be an approximation of

$$n' = n\left(1 + \frac{n\Theta}{1 + \delta_1}\right)^{-1} \tag{7.59}$$

which is exact for $\delta = 0$.

The expected value of the observed variance, for small dead time losses, is:

$$V' = V - 3V\Theta(n - h(\lambda, \tau)q) - 2c\Theta(n + h(\lambda, \tau)q) - 5qc\Theta[h(\lambda, \tau) - h^*(\lambda\tau)] \tag{7.60}$$

3. Applications of the Beta–gamma correlations method to radionuclide standardization

^{75}Se. Smith and Woods (1994) standardized a solution containing ^{75}Se. They measured the radionuclide's activity simultaneously by coincidence and by correlation, as part of the international comparison organized by the BIPM in 1992. The correlation measurement provided an explicit correction to take into account the isomeric state of the daughter (^{75}As) and enable a direct measurement of the half-life of the isomeric level (16.23 ± 0.33 ms). The half-life was obtained by measuring the fraction of correlated pairs (c/n) as a function of the time $T$of the correlation range. Three similar sources were measured in the same conditions in the range of 1–150 ms. It is shown that (c/n) must be proportional to $f(\lambda_m, T, \tau)$, for constant conditions. A least squares nonlinear fitting was applied to the function

$$\frac{c}{n} = Bf(\lambda_m, T, \tau) \tag{7.61}$$

where B and λ_m are unknown parameters, and gave $\chi^2 = 1.01$with the half-life of 16.23±0.33 ms. Data points were weighted according to their variances.

Janssen (1990) presented a data acquisition system based on a VMEbus. This system was developed to determine the activity of radioactive samples using the correlation count method. The paper provides a detailed description of the components of the data acquisition system and the method's principles. By way of example, Janssen describes the measurement of a sample of ^{75}Se using a pressurized PC and a NaI(Tl) detector working in coincidence. He describes the system's operation. The correlation method has been used to experimentally determine the fraction of pairs of genetically correlated events in the PC.

Hwang et al. (1996) presented a data acquisition system to carry out experiments for correlation counting. All beta–gamma signals are recorded simultaneously in a static random access memory (SRAM). The coincidence resolving time and the multiple gamma gates are selected by a computer program and the efficiency functions are obtained by computer discrimination. The method applies well to the activity determination of radionuclides with intermediate levels with relatively long half-lives.

They applied the procedure to ^{75}Se. The fraction of delayed events was studied through a system with a pressurized PC and a NaI(Tl) detector. The measurement time of each sample was 9000 s, which was sufficient not only to achieve the efficiencies of electron capture detection, but also to obtain the variation of efficiency curves for the fraction of pairs of correlated events in the PC. These fractions were obtained by sequentially extracting the data in 2×10^5 intervals of 45 minutes duration for each level of discrimination assigned to the pulse amplitude spectrum from the PC. The results were compared with others obtained previously.

D. Gamma–gamma coincidences

1. Introduction to the sum peak method

Radiation coincidence has been used for the primary standardization of radionuclides. In all cases, a pair of detectors

is used to record the interaction of two coincident radiations: $\beta-\gamma$, $\gamma-\gamma$, $X-(X,\gamma)$, etc. and the detector counts are used to determine the activity of the sample using coincidence or anticoincidence counting.

The sum peak method is based on the same coincidence principles but requires a single X- or gamma ray detector and its associated electronics. In this method, activity is determined from the gamma spectrum using the count rates of the full-energy single peaks, the sum peak due to the coincidence of two gamma rays, and the total counting rate of the spectrum.

The advantage of the sum peak method lies in the simplicity of both the technique and the detector system. The sum peak method requires a gamma detector and the electronics chain for spectrometry, while the coincidence method requires two detectors with their time modules. The sum peak method has another advantage when compared with the relative measurement technique used in gamma spectrometry. The measure requires an accurate calibration curve (counting efficiency vs. energy) for a given source-detector geometry. Therefore, it is influenced by the experimental conditions regarding source-detector geometry, photon energy, and sample activity.

The sum peak method was initially developed by Brinkman and Aten (1963, 1965) and Brinkman et al. (1963a,b, 1965). They measured nuclides ^{60}Co, ^{46}Sc, ^{22}Naand ^{18}F with a NaI(Tl) well detector, correcting for the effect of the angular correlation between the two coincident gamma cascade photons. ^{60}Co and ^{46}Scare nuclides that decay by β^-emission and two coincident gamma photons. They canceled the angular correlation by placing the source on the detector surface. They also obtained 2π geometry. For ^{22}Na, a $\beta^+-\gamma$, the radioactive source was placed on the surface detector well, thus obtaining the sample's activity without measuring the angular correlation between annihilation photons and gamma ray emission. They also measured the sample inside the well and determined the effect of the angular correlation of annihilation radiation and gamma rays.

From the ^{22}Na spectrum they obtained the count rates of annihilation peaks, gamma peaks and sum peak, and the detection efficiency of annihilation radiation and gamma rays. They determined the count rates in the peaks of annihilation gamma and sum spectrum and the result was then used to correct the angular correlation of ^{18}F, a pure positron emitter. Accuracy was between 2% and 5%.

Another sum peak method, using NaI(Tl) crystals, was developed by Zajic (1986). The detection system comprised two NaI(Tl) crystals and the respective temporal electronics. In this case both coincidence and anticoincidence were used. The summation method with two detectors was first used by Hutchinson et al. (1973). However, Zajic improved the method's accuracy by correcting for dead time, pulse pileup and random coincidences. ^{88}Y and^{207}Bi were measured in 4π geometry and therefore do not require correction for angular correlation. The estimated total uncertainties were 1.4% and 2.4% for ^{88}Y and ^{207}Bi, respectively.

The application of Ge detectors for the sum peak method was carried out by Martin and Taylor (1992) to standardize ^{125}I. They took dead time and pileup into consideration but failed to correct for angular correlation. The measure was carried out by diluting several samples with different dilution activity. The activity concentration of the initial solution was obtained by extrapolation of the samples with different concentrations to zero mass. The resulting uncertainty was under 2%.

Asano et al. (1996) measured ^{60}Cowith a Ge detector applying a theoretical correction for angular correlation. The radioactive source was placed 8.7 cm away from the detector surface. Angular correlation correction was performed applying a Monte Carlo simulation using the correlation functions of the gamma ray cascade. As the angular correlation correction increases with source detector distance, in this case the correction was 9%. They did not mention corrections for dead time, pileup pulse, and accidental coincidences. The uncertainty achieved was estimated at around 1%.

Kim et al. (2003) conducted a detailed study of the sum peak method and applied it to ^{60}Co, using sources with activities between 25 and 350 kBq. The radiation detector used was an HPGe crystal and the samples were placed at distances ranging from 0.5 to 8 cm. The high count rate generated problems due to increased dead time, pulse pileup, and accidental coincidences in the sum peak. A greater distance between the source and detector reduces these problems. However, a greater distance between the source and the detector implies a significant decrease in count rate at the peak sum. Therefore, the angular correlation and the corrections associated with the high count rates are inevitable problems in this type of measurement. Correction for the angular correlation was carried out applying a Monte Carlo simulation. Pulse pileup was corrected by extrapolation varying amplifier time.

2. Theoretical description of the sum peak method

We only consider the case of two coincident photons, both with 100% decay. Other more complex cases such as emission of less than 100% or positron emission can be found in the references cited above.

If we denote sample activity as N_0, and N_1 and N_2 are the counting rates in the full-energy gamma peaks, expressed in the same units of time as activity, we have:

$$N_1 = N_0\varepsilon_1^p\left[1-\varepsilon_2^t\overline{W}(0)\right]L_p \tag{7.62}$$

$$N_2 = N_0\varepsilon_1^p\left[1-\varepsilon_1^t\overline{W}(0)\right]L_p \tag{7.63}$$

where ε_1^p and ε_2^p are the efficiencies of the full-energy peak, and ε_1^t and ε_2^t are the total efficiencies. Subscripts 1, 2 denote the corresponding gamma ray. On the other hand, $\overline{W}(0)$ and L_p are the correction factors for angular correlation and pileup pulses, respectively. The count rate at the sum peak due to the coincidence of the two photons is denoted by N_{12} and the total counting rate by N_t. Therefore:

$$N_{12} = n_0\varepsilon_1^p\varepsilon_2^p\overline{W}(0)L_p + G \tag{7.64}$$

$$N_t = \left[\varepsilon_1^t + \varepsilon_2^t - \varepsilon_1^t\varepsilon_2^t\overline{W}(0)\right] \tag{7.65}$$

where G is the correction factor for pileup pulses. In the last equation, it is assumed that the total loss of counts by pulse pileup is negligible. Strictly speaking, the definition of $\overline{W}(0)$ in the above equations is slightly different. We should distinguish between factor ε^p for the full-energy peaks for the partial absorption factorε^t. Usually they have the same value for any combination of the two detectors for gamma rays, as was shown by Kim et al. (2002). From the above equations, it follows that the activity of the sample is given by:

$$N_0 = \left[\frac{N_1N_2}{(N_{12}-G)L_p} + N_t\right]\overline{W}(0) \tag{7.66}$$

The probability of counting coincident gamma ray cascade depends on detection efficiency, detection geometry, and the angular correlation $\overline{W}(\theta)$ of cascade gamma rays. Rose (1953) and Camp and Van Lehn (1969) calculated angular correlation $\overline{W}(\theta)$ to estimate the effect of finite angular resolution on coincidence counting with finite size detectors.

In the case of a single HPGe detector, without a collimator, $\theta = 0$ and $\beta^{\max}$ (the maximum incidence angle of the gamma-ray) cover the detector face. In the case of ^{60}Co, Kim et al. (2002) estimated $\overline{W}(0)$ and found that the effective angular correlation factor ranged from 1 to 1.1, when the distance between the source and the detector is from 0 to 5 cm. For distances from 5 to 25 cm, the angular correlation factor remained constant and equal to 1.1. The main radionuclides standardized by the sum peak method are shown in Table 7.6.

3. Dead time and pileup corrections

The random nature of the temporal emission of gamma radiation and the finite processing time of the pulses produced give rise to two important phenomena in gamma radiation detection: dead time and pulse pileup. In the processing of pulses generated by gamma radiation, the detector system is insensitive to the reception of new gamma rays for a finite time called dead time. Dead time produces a loss of pulses from the incident gamma rays and therefore affects the total counts to be recorded by the spectrometer. Moreover, consecutive gamma ray pulses can pile up due to finite resolution time. This pileup can distort

the gamma spectrum in a region and increase or decrease the number of counts of a peak.

Dead time is usually corrected by an ADC working in a live time mode. Piled-up pulse losses are described by effective dead time τ_P (Debertin and Helmer, 1988) defined as the time interval between two consecutive pulses that cause the loss of a count in the gamma peak. Consideration of pileup requires a definition of the effective resolution time of coincidence τ_R (Knoll, 1989) as the time interval between two consecutive pulses that produce a gain in the peak sum counts. Therefore, the correction factors due to these effects are:

$$L_P = 1 - \tau_P N \tag{7.67}$$

and

$$G = 2\tau_R N_1 N_2 \tag{7.68}$$

where N_1 and $N_2$are defined in (7.62) and (7.63) and N is the detector count rate. It is assumed that all nonregistered counts that were below the lower level or above the upper level discriminators can be neglected. Pulse width and magnitudes τ_P and τ_R are closely related. The pulse formed by (CR)−(RC)^2 in the amplifier is expressed analytically by the following equation:

$$V(t) = \frac{1}{2}\left(\frac{t}{\tau}\right)\exp\left(-\frac{t}{\tau}\right) \tag{7.69}$$

where $V(t)$ is the pulse height, in time t, and τ is the time constant RC from circuit (CR)−(RC)^2. The preamplifier output signal is assumed to be a step function and pole-zero cancellation was complete. Parameters τ_P and τ_R depend on τ and the pileup can be reduced by decreasing τ. The activity measured for τ without correction for pileup is

$$N(\tau) = \left[\frac{N_1(\tau)N_2(\tau)}{N_{12}(\tau)} + T(\tau)\right]W(0) \tag{7.70}$$

where $N_1(\tau)$, $N_2(\tau)$, and $T(\tau)$ are measured with the time constant τ. In this expression $N_0(\tau)$ is similar to N_0, but does not include pileup corrections. Both are the same when the time constant is zero, i.e., $N_0 = N_0(0)$. The value of $N_0(0)$ is obtained in practice by obtaining $N_0(\tau)$ for different values of τ and extrapolating to $\tau = 0$.

4. Applications of the sum peak method

^{125}I. The sum peak method was applied by Harper et al. (1963) and Eldridge and Crowther (1964) to calibrate ^{125}I. This radionuclide decays by electron capture to the state of 35 keV of ^{125m}Te, which in turn decays to the ground state by gamma emission or electron conversion. The emission of conversion electrons and the subsequent atomic rearrangement produces K X-ray emission of 27.4 and 31 keV. The spectrum has two peaks, the first of which corresponds to 2K X-rays, but the proximity of their energies does not permit their resolution. The second peak is the sum peak and corresponds to coincidence of gamma and K X-rays. Given the low energy photons, the Compton effect is negligible in the case of NaI(Tl) detectors. The activity is given by:

$$N_0 = \frac{P_1 P_2}{(P_1 + P_2)^2}\frac{(A_\mathrm{I} + 2A_\mathrm{II})^2}{A_\mathrm{II}} \tag{7.71}$$

where P_1 is the probability per decay of K X-ray emission in electron capture. ($P_1 = P_K\omega_K$), and P_2 is the sum of the probabilities for the 35 keV gamma ray and the K X-ray emitted in internal conversion ($P_2 = (1+\alpha_K\omega_K)/(1+\alpha_T)$). A_I and A_II are the areas of the first and second peaks of the spectrum expressed as counts per second.

Horrocks and Klein (1975) analyzed the decay scheme of ^{125}I and calculated the emission probabilities of each of the various decay pathways. They deduced an equation for calculating the decay rate by the coincidence method from the probability of disintegration. While the Eldridge and Crowther (1964) equation is accurate in 1% with this method, the authors argue that we can calculate the activity of any radionuclide by measuring the single and sum peaks.

Eddiss and Abrams (1981) established a technique for determining the activity of ^{125}I using a multisample gamma counter. They extended the method and deduced an equation to calculate the uncertainty of the measured activities. The validity of the equation was tested and they found that it was satisfactory. They described a technique for selecting appropriate counting conditions.

Dias and Koskinas (1995) described a new method for correcting accidental coincidences (summing pileup) when determining the activity of ^{125}I by applying the Eldridge and Crowther equation (1964). The results were compared with those obtained with the X−(X,γ) coincidence method. The corrections were estimated using a Monte Carlo code. Other predictions were made for other detection efficiencies and electronic shaping times. They used two 3" ×3" NaI(Tl) crystals.

Two of the seven calibration techniques employed for standardization of ^{125}I by Pommé et al. (2005a,b) were based on the sum peak method with a single detector, applying the Eldridge and Crowther equation (1964). The measurements were performed with two detectors sensitive to photons from 35 keV gamma rays and X-rays of 27.4 and 31 keV, but insensitive to other radiations (electrons and low-energy X-rays). NaI(Tl) and CsI(Tl) detectors were applied with good resolution to separate the peaks with only a small overlap. The 6"× 6" NaI(Tl) detector with a well had a total efficiency of 75.7%. The uncertainty of the measurement with the NaI(Tl) detector was 0.3% (1 σ). The CsI(Tl) detector was a 4π counting sandwich spectrometer and consisted of two CsI(T1) crystals, 55 mm in

diameter and 25 mm high (Denecke, 1994). To stop the electrons emitted in the process of atomic deexcitation, a spherical cavity between the two is covered with 0.12-mm-thick absorbent polyethylene. The low-energy radiation was removed with a low-energy discriminator, set at around 14 keV.

De Felice and Mytebery (1995) describe an intercomparison for measuring the absolute activity of ^{125}I by the sum peak method by the Primary Standard Laboratories for Ionizing Radiation of Italy (ENEA) and (INP) in Albania. Radioactive sources were prepared by ENEA from a solution of ^{125}I. The sources were measured at ENEA and INP. The results were perfectly consistent. The deviation of the ENEA and INP results was 0.5% with a total uncertainty of both results of 0.3% (1 σ). The paper describes the instrumentation and experimental procedures used in this comparison by both these institutions.

Capogni et al. (2006) applied the sum peak method (Eldridge and Crowther, 1964) for the absolute measurement of ^{125}I activity. They experimentally determined the dependence of the count rate corrections for the random sum of counts and the effects of dead time for different count rates in various experimental conditions. They used two NaI(Tl) crystals of different volumes. The crystal was connected to a system for recording pulses with different characteristics, with a live time correction circuit with or without rejection of pile-up pulses (with or without pile-up rejection live time correction circuits) (PUR/LTC). They proposed a theoretical model to explain the different behavior found experimentally. They show that the dependence of the count rate will be drastically reduced by use of PUR/LTC.

With the introduction of germanium detectors, peaks can be obtained with a better resolution. Thus the first peak of the spectrum of ^{125}I obtained with a NaI(Tl) crystal comprises three peaks: two X-ray K_α (27.38 keV) and K_β (30.97 keV), and gamma emission (35.5 keV). For well detectors we obtain peaks in the spectrum of given energies. When using a flat crystal, however, we also obtain the escape peaks for the X-ray energy of 17.5 and 21.1 keV. Therefore, in the case of a germanium detector plane the number of peaks in the spectrum is five in the first peak of the NaI(Tl). The second peak obtained with a NaI(Tl) crystal is broken down into five peaks, in the case of a well crystal, corresponding to coincidences $K_\alpha + K_\alpha$: (54.76 keV), $K_\alpha + K_\beta$ (58.35 keV), $K_\beta + K_\beta$ (61.9 keV), $K_\alpha + \gamma$ (62.87 keV), and $K_\beta + \gamma$ (66.5 keV). The peaks of 61.9 and 62.87 keV are difficult to separate. In the case of a flat crystal we obtain the coincidences of X-rays of ^{125}Te with the escape of X-rays of germanium, i.e., escape peaks corresponding to $K_\alpha + K_\alpha +$ escape Ge (44.9 keV) and $K_\alpha + K_\beta +$ escape Ge (48.5 keV). A spectrum of ^{125}I obtained with a plane Ge detector can be seen in Da Silva et al. (2006), and a spectrum of the same radionuclide obtained with a well crystal is presented in the study by Wang et al. (2001). In this study, the equation to compute the activity of a sample from the peaks of the spectrum without having to resort to nuclear or atomic constants is obtained.

Da Silva et al. (2006) standardized ^{125}I with a germanium plane detector. The equation used to determine the activity of the sample was the same as that estimated by Brinkman et al. (1977) for ^{123}I:

$$N_0 = T + \frac{N_\gamma N_X}{N_{X\gamma}} - \frac{N_{XX} N_\gamma^2}{N_{X\gamma}^2} \tag{7.72}$$

where $N_X =$ Single X, $N_{XX} =$ coincidence XX, $N_{X\gamma} =$ coincidence X-γ

Da Silva et al. (2006) applied the sum peak method to standardize ^{125}I. ^{54}Mn and ^{125}I were standardized in the intercomparison organized by the BIPM, while the ^{203}Hg was part of the traceability of the National Laboratory for Ionizing Radiation Metrology (LNMRI)/Brazil. The activity of ^{125}I was obtained applying the Eldridge and Crowther (1964) equation and Brinkman et al. (1977) equation to spectra obtained using a germanium detector. As the expression of Brinkman does not use atomic data, uncertainties obtained with this method are inferior to those obtained with the Eldridge and Crowther equation (1964). Radioactive sources were placed on the surface of the 3″ × 3″ NaI(Tl) and germanium detectors, and into the well of the 5″ × 5″ NaI(Tl) well crystal. All samples were measured once at 10^4 s each, so that counting statistical uncertainty was less than 0.1%. They obtained five spectra of each sample and the calculation was performed using the MAESTRO program (2002) incorporated into a multichannel analyzer.

Wang et al. (2001) obtain the following equation for well Ge detector:

$$N_0 = T + \frac{N_\gamma N_{\alpha\beta}}{N_{\beta\gamma}(N_{\alpha\alpha} + N_{\alpha\beta})}\left[N_\alpha + N_\beta - N_\gamma\left(\frac{N_{\alpha\beta}}{2N_{\beta\gamma}} + \frac{N_6}{N_{\beta\gamma}} - \frac{2N_{\alpha\alpha}}{N_{\alpha\beta}}\right)\right] \tag{7.73}$$

where N_α, N_β, and N_γ are the counting rates at the single peaks. $N_{\alpha\alpha}$, $N_{\alpha\beta}$, $N_{\alpha\gamma}$, $N_{\beta\beta}$, and $N_{\beta\gamma}$ are the sum picks and $N_6 = N_{\beta\beta} + N_{\alpha\gamma}$. The energy of $E_{\alpha\alpha} = 62.0$ keV and $E_{\alpha\gamma} = 62.8$ keV, consequently the two peaks overlap.

The equations of Eldridge and Crowther (1964), Brinkmann et al. (1977), and Wang et al. (2001) can be deduced from a general procedure described in the paper by Grau Carles and Grau Malonda (2011). Given the generality of the method, the resulting new possibilities, and the fact that new research can be done, we will describe this

method and its consequences in some detail. This paper also analyzes the Eldridge and Crowther (1964) equation and concludes that counting efficiencies are average efficiencies taking both the full-energy peak and the Compton contribution into account which is not negligible for Ge detectors.

The method is based on the following set of equations, valid for an ^{125}I spectrum obtained with a Ge-well detector. The basic equations are the following.

If N_0 designates the activity of a ^{125}I sample, and N_α, N_β and N_γ the counting rates at the single peaks we have the following expression:

$$N_\alpha = N_0[P_{1\alpha}\varepsilon_\alpha(1-t_1)+P_{2\alpha}\varepsilon_\alpha(1-t_2)] \tag{7.74}$$

where $P_{1\alpha}$ and $P_{2\alpha}$ are the probabilities for the K_α X-ray in EC and IC emission, respectively; ε_α is the photoelectric detection efficiency of K_α X-ray, and t_1 and t_2 are the total emission detection efficiencies for EC and IC plus gamma, respectively. This equation is obvious if we recall that $N_0P_{1\alpha}\varepsilon_\alpha$ is the number of K_α X-photons detected by the detector. These photons do not all go to the N_α peak. Those coincident with other radiations such as $K_\alpha X$ and $K_\beta X$, from IC, more gamma photons emitted in the gamma decay go to the $N_{\alpha\alpha}$, $N_{\alpha\beta}$, and $N_{\alpha\gamma}$ peaks, respectively. On the other hand, neither do the X-rays that have not interacted by the photoelectric effect go to the N_α peak. Hence, the term $(1-t_2)$ takes into account the probability of noncoincidence. Similarly, $K_\alpha X$ photons emitted in IC are $N_0P_{2\alpha}\varepsilon_\alpha$ and those that coincide in their interaction with the $K_\alpha X$ photons emitted in the EC do not go to N_α peak. Hence, the term $(1-t_1)$ takes into account the probability of noncoincidence. For the N_β peak we have:

$$N_\beta = N_0[P_{1\beta}\varepsilon_\beta(1-t_1)+P_{2\beta}\varepsilon_\beta(1-t_2)] \tag{7.75}$$

where $P_{1\beta}$ and $P_{2\beta}$ are the K_β X-ray emission probabilities due to EC and IC, respectively, and ε_β is the efficiency of photoelectric detection of K_β X-rays. On the other hand, we have:

$$N_\gamma = N_0P_\gamma\varepsilon_\gamma(1t_1) \tag{7.76}$$

where P_γ and ε_γ are the gamma emission probabilities and photoelectric detection efficiency, respectively.

For the sum-peaks $N_{\alpha\alpha}$, $N_{\alpha\beta}$, $N_{\alpha\gamma}$, $N_{\beta\beta}$, and $N_{\beta\gamma}$ we have:

$$N_{\alpha\alpha} = N_0P_{1\alpha}P_{2\alpha}\varepsilon_\alpha^2 \tag{7.77}$$

$$N_{\alpha\beta} = N_0(P_{1\alpha}P_{2\beta}+P_{1\beta}P_{2\alpha})\varepsilon_\alpha\varepsilon_\beta \tag{7.78}$$

$$N_{\alpha\gamma} = N_0P_{1\alpha}P_\gamma\varepsilon_\gamma \tag{7.79}$$

$$N_{\beta\beta} = N_0P_{1\beta}P_{2\beta}\varepsilon_\beta^2 \tag{7.80}$$

$$N_{\beta\gamma} = N_0P_{1\beta}P_\gamma\varepsilon_\beta\varepsilon_\gamma \tag{7.81}$$

The total count rate of the total spectrum is:

$$T = N_0(t_1+t_2-t_1t_2) = N_0[1-(1-t_1)(1-t_2)] \tag{7.82}$$

and

$$t_1 = N_0P_{1\alpha}t_{1\alpha}+N_0P_{1\beta}t_{1\beta} \tag{7.83}$$

and

$$t_2 = N_0P_{2\alpha}t_{2\alpha}+N_0P_{2\beta}t_{2\beta} \tag{7.84}$$

To these equations we must add the equation of symmetry:

$$P_{1\alpha}P_{2\beta} = P_{1\beta}P_{2\alpha} \tag{7.85}$$

This equation enables the writing of Eq. (7.78) in two ways:

$$N_{\alpha\beta} = 2N_0P_{1\alpha}P_{2\beta}\varepsilon_\alpha\varepsilon_\beta \tag{7.86}$$

and

$$N_{\alpha\beta} = 2N_0P_{1\beta}P_{2\alpha}\varepsilon_\alpha\varepsilon_\beta \tag{7.87}$$

These equations are the same as those of Wang et al. (2001). The important point to keep in mind is that Eqs. (7.74) and (7.75) are not independent, as shown in the Appendix of Grau Carles and Grau Malonda (2011). The fact that they are not independent indicates that instead of Eqs. (7.74) and (7.75), any linear combination of both can be used, that is:

$$N_\alpha + \lambda N_\beta$$

Where λ can take any rational value. In Grau Carles and Grau Malonda (2011) we have taken four par values, which are: $\lambda = 0$ (only Eq. 7.74 is taken for N_α), $\lambda = 1$ (the sum $N_\alpha + N_\beta$ is taken), $\lambda = -1$ (the difference $N_\alpha - N_\beta$is taken), and $1/\lambda = 0$ (only Eq. 7.75 is taken). We have deduced 24 valid equations to calculate the activity of ^{125}I. In the paper, the discrepancies between the activities of each equation and the result of Wang et al. (2001) are shown, as are the standard deviations of the activity of each equation. Six of these typical deviations are lower than that of Wang et al. (2001). For example, the equation for $\lambda = 0$:

$$N_0 = T + \frac{N_\alpha N_\gamma N_{\alpha\beta}}{2N_{\alpha\alpha}N_{\beta\gamma}} - \frac{N_\gamma^2 N_{\alpha\beta}^2}{4N_{\alpha\alpha}N_{\beta\gamma}^2} \tag{7.88}$$

The first question that arises is how to obtain an equation that minimizes the standard deviation. It must take into account that the calculations are based on the experimental values published by Wang et al. (2001). Other experimental values could make other equations most accurate.

Ferreira Filho et al. (2018) standardized ^{152}Eu, a radionuclide with a complex decay scheme using a method similar to that proposed by Grau Carles and Grau Malonda (2011).

^{57}Co. Iwahara et al. (2009b) applied the sum peak method with a germanium detector for the calibration of

^{57}Co. The main features of the ^{57}Co.decay scheme are that it decays by electron capture, followed by gamma rays of three different energies; and it has a level with a half-life of 98 seconds. The equation used to compute the activity of a sample is very similar to the classic equation:

$$N_0 = T + \frac{N_X N_1}{N_{X1}} \tag{7.89}$$

where N_X is the count rate of the peak of 6.39 and 6.40 keV X-rays, N_1 is the counting rate of 14.41 keV gamma-ray, and N_{X1} is the peak area due to coincidence of 6.40 keV X-ray and 14.41 keV gamma ray.

$$N_0 = T + \frac{N_X N_2}{N_{X2}} \tag{7.90}$$

where N_2 is the area in counts per second of the 122.06 keV gamma ray peak and N_{X2} is the peak area corresponding to the coincidences of the 6.40 keV X-ray and the 122.06 keV gamma ray.

^{51}Cr. The work of De Almeida et al. (2007) consisted of two parts; in one part ^{51}Cr activity was determined by three methods: $4\pi\beta-\gamma$ coincidence and anticoincidence and sum peak. On the other hand, he determined the probability of 320 keV gamma ray emissions, comparing this result with those obtained in other studies. Their consistency confirmed the reliability of these measurements. For the sum peak method, he used a coaxial germanium detector with a volume of 260 cm^{3}and an energy resolution of 1.9−1332.5 keV. The Brinkman and Aten (1963) equation was applied for the activity calculation.

^{60}Co. Sutherland and Buchanan (1967) found that the Eldridge and Crowther (1964) equation is only valid for the sum peak method when the detector has the same response in all parts of the source. This condition is satisfied when we use a solid detector and the source surface is made as pointed as possible, or counting the larger samples in a well detector.

Oderkerk and Brinkman (1990) based their study on the experimental fact that, when applying the sum peak equation (Brinkman et al., 1963a; Binkman et al., 1963b) to the activity of extended sources, the result is less than that obtained with point sources. This effect is not due to absorption in the extended source, but the detector does not have the same efficiency for all sample points. In their study, they derive expressions to calculate the size of the effect.

Kawano and Ebihara (1990) determined the activity of a ^{60}Co point source (12 mm diameter in a thin plastic disk) and a volume source of the same radionuclide (10−100 mL in a polyethylene bottle) by the sum peak technique. The sum peak equation (Brinkman et al., 1963a,b) gives the exact decay rate for different positions of the point source in front of the detector. However, when the volume of the solution is increased, the deviation from the true activity value also grows. Extended sources should be treated as amalgams of many point sources.

Kawano and Ebihara (1991) applied the sum peak method (Brinkman et al., 1963a,b) to determine the activity of two small samples of ^{60}Co (30−350 kBq) in lead containers of various thicknesses (3, 6, 9, 15, 21.27, and 33 mm) using a NaI(Tl) detector. The results showed that the sum peak method was effective for samples of 30 kBq in the case of containers with a thickness of 15 mm and less. However, for those with thicknesses of 21, 27, and 33 mm, the decay rates were understated and the deviations from the true activity increased rapidly by increasing the thickness of the containers. We suspect that underestimation of the activity was the result of overestimating the total area under the peak caused by the interference of the 2614 keV gamma rays emitted naturally by the ^{208}Tl radionuclide of the thorium series.

Kawano and Ebihara (1992) applied the sum peak method to the decay rate of extended sources comprising two ^{60}Co point sources. They concluded that when the detector has equal efficiency for both point sources we can determine the activity, and when efficiency is different, activity is underestimated. They examined the uncertainty in the extended sources and found that the theoretical results perfectly matched those of the experiment. The work is based on the theory of Brinkman et al. (1963a,b).

^{152}Eu. Ferreira Filho et al. (2018) standardized a solution of ^{152}Eu by coincidence sum peak for 121.8 keV peak with respective characteristics X-rays. A high-purity germanium detector (HPGe) was used in this paper. ^{152}Eu has a very complex decay scheme. It disintegrates into ^{152}Sm by electron capture (72.1%) and positron emission (0.027%) and into ^{152}Ga by beta minus emission (27.9%). The daughter nucleus ^{152}Sm has 19 excited levels and the ^{152}Gd has 15. Novkovic et al. (2007a, 2016) describe a theoretical method for obtaining the count rate equations describing coincidence summing. This method was later named the Direct Matrices Multiplication (DMM) method (Novković et al., 2012). Nadderd et al. (2012, 2013) and Jordanov et al. (2016) present a new matrix method for deriving these counting rate equations. The spectra were analyzed with MAESTRO software determining the areas of each multiplet region. They use the fundamental equation and new definitions (Grau Carles and Grau Malonda, 2011) to obtain the activity of the sample.

III. Solid angle primary methods

One of the oldest techniques used today is the determination of a sample's activity by calculating the solid angle with which the sample sees the detector. The technique is based on the solid angle obtained by placing an opening in front of the detector and calculating the solid angle subtended by the sample. The conditions for the method's success are correct scattering and absorption between the source and detector, including backscattering of the sample

holder. This is true for alpha particles and low energy gamma or X-rays, less than 80 keV.

A. 4π proportional counting

A special case in counting geometry is to use a solid angle 4π. For beta counting, one can implement a windowless counter with maximum efficiency by mounting two gas counters facing each other (each of them subtending an angle 2π), with the source placed between the counters. Intrinsic efficiency can be kept very close to 100% by adjusting the operating voltage, amplifier, and discrimination level, so that any charged particle that leaves the sample is counted. Departures from 100% efficiency can be attributed to absorption by the source and support.

There are obvious advantages to this method. First, as efficiency is practically 1, all the corrections for scattering and absorption out of the sample are removed. This technique is therefore very suitable for counting electrons. Second, when radionuclides with complex beta−gamma decay schemes are counted, due to the high efficiency, all the corrections for the detector response to gamma or X radiation are minimized, provided that this radiation is coincident with the primary radiation.

If the counter is a PC, it is continuously filled with methane gas, or more frequently by P10 gas (a mixture of 90% argon and 10% methane) and pressurized to multiples of an atmospheric pressure of 0.1−2 MPa. Electronegative gas impurities such as water or oxygen should be avoided in the counter. Gas flow is maintained through a bubbler and pressure must remain constant in the counter (Denecke et al., 1998).

In the past, this procedure was the preferred method for calibrating nuclides such as ^{32}P, ^{35}S, ^{131}I, and ^{241}Am, when uncertainties between 1% and 2% were considered to be an excellent result GHFin international comparisons. Recently, the method has been applied to the determination of the activity of alpha emitters (Schötzig et al., 2000; Johansson et al., 2003a), pure beta emitters (Hult et al., 2000; Alzitzoglou et al., 2002; Csete et al., 2002; Da Cruz et al., 2004), as well as X-ray or weak gamma ray emitters (Lowenthal et al., 1982). One of the main difficulties of this method is the determination of nonefficiency and its uncertainty. A direct method for determining both is the Monte Carlo simulation method (Roteta and García-Toraño, 2006) or experimental tests (Johansson et al., 2002).

It is currently of interest, moreover, as it is part of the device to calibrate radionuclides using the $4\pi\beta-\gamma$ technique, which was discussed above.

High pressure 4π counters can be used to measure the activity of nuclides decaying by EC to increase intrinsic efficiency for low energy photons.

B. 2π proportional counting

In 2π geometry, only half of the particles emitted by the sample will be measured. This is not the case in general due to the backscatter phenomenon. The measurement of electron emitters is therefore not recommended, reserving the counter for measuring alpha emitters. Backscatter corrections are also required in this case, but they are much smaller than with electron emitters. These corrections can be determined theoretically (Williams, 1940; Crawford, 1949; White, 1970; Lucas and Hutchinson, 1976) or through simulations (Ferrero et al., 1990; Martín Sánchez et al., 2000; Jurado Vargas and Fernandez Timon, 2004; Jurado Vargas et al., 2004; Jurado Vargas and Fernandez Timon, 2005).

C. 4πγ counting

Gamma ray detectors with geometry close to 4π [a large-well NaI(Tl)] have proved to be very interesting, particularly in the metrology of radionuclides with complex decay schemes incorporating transitions with coincident photons, due to the sum properties of such detectors. For a few coincident gamma rays, the efficiency approaches 100% and the uncertainties are very small, often independent of precise knowledge of the values of the decay scheme parameters (Winkler and Pavlik, 1983; Ballaux, 1983; Pavlik and Winkler, 1983; Vatine and Chauvenet, 1987; Schötzig, 1992; Decombaz and Laedermann, 1996; García-Toraño et al., 2002b; Johansson et al., 2003b; García-Toraño and Roteta, 2004; Spring et al., 2006; Nedjadi et al., 2007).

Another form of calibration is sandwiching a source between two NaI(Tl) detectors. Such a system has been used for the calibration of radioactive samples for the determination of nuclear decay data (Plch et al., 1973b; Plch and Zderadièka, 1974; Dragoun et al., 1976; Plch et al., 1976; Plch et al., 1979; Plch et al., 1991), or also sandwiching the samples between two CsI(Tl) detectors (Denecke, 1987, 1994; Pommé et al., 2005a,b).

The radioactive sample is usually deposited on a thin plastic film and placed between the two detectors. These have holes to accommodate the sample and prevent contamination.

D. 4π windowless sandwich detectors

Plch et al. (1973a) constructed a nonwindow 4π counter with two NaI(Tl) detectors with a diameter of 4.4 cm and a height of 2 cm. Gamma detection efficiency was 97% between 20 and 160 keV. The instrument has been used for the calibration and determination of nuclear data (Plch and Zderadièka, 1974; Plch et al., 1973b, 1976; 1979; Dragoun, 1976). Denecke (1987, 1994) developed the first detector with no window in the IRMM. This detector consisted of

two CsI(Tl) crystals, 51 mm in diameter and 25 mm thick. The radioactive source was deposited on a thin plastic sheet, which in turn was sandwiched between the faces of the two crystals. The detector presented 100% efficiency for charged particles over 19 keV and efficiencies of 98% for photons from 10 to 200 keV. The detector is of interest in the calibration of radionuclides with complex decay schemes (Reher et al., 1992; Johanson et al., 2003b) as well as for pure beta emitters (Hult et al., 2000, Alzitzoglou et al., 2002), pure alpha (Johanson et al., 2003a), and pure electron capture nuclides (Pomme et al., 2005a, b)

E. $4\pi\beta\gamma + 4\pi$ sum counting

The efficiency of a NaI(Tl) well detector for X- and gamma ray photons can be supplemented with the signals produced by charged particles or low energy photons in an additional detector (Yu et al., 1990). This additional detector may be a pressure PC (Johansson et al., 2003b; Li et al., 2005) or two thin plastic scintillators (Kawada et al., 2004; Yamada et al., 2006) placing the sample in the hole of the NaI(Tl) detector. The detection system can also include a Ge detector (Xie et al., 2005). In this method, we gain in particle detector efficiency while reducing the efficiency of the photon detector due to the detector material. As both detectors, because of their high geometry, can record signals from the same decay, these signals have to be subtracted to avoid double counting. This method has been successfully applied to the standardization of radionuclides with complex decay schemes such as ^{152}Eu and ^{192}Ir, as well as nuclides with simpler schemes such as ^{241}Am, where the reduced nonefficiency for alpha particles is compensated by the detector's efficiency for X- and gamma rays.

F. Defined solid angle

The calibration method for DSA is one of the most accurate standardization methods for alpha-emitting radionuclides. It requires the control of a number of parameters. First, it requires a careful mechanical design and careful execution of the different parts of the system: precise determination of distances and calculation of the solid angle subtended by the detector.

Standardization of alpha-emitting radionuclides using the DSA technique is based on determination of the count rate of alpha particles emitted by a sample and interacting with the detector in a solid angle Ω subtended by the detector and the radioactive sample. The first publication about the technique was by Jaffey (1954) and a review of this technique, focusing on the main sources of uncertainty, was provided by Bambynek (1967). The uncertainties achievable with this method are of the order of 0.1%.

The problem of calculating the solid angle has been addressed in numerous publications such as Williams et al. (1968), Gardner and Carnesale (1969), Gardner and Verghese (1971), Verghese et al., (1972), Chatelier and Launois (1972), Green et al. (1974), Kaplanis (1982), Haitjema (1987), Gardner et al. (1980, Cook (1980), Hosseini-Ashrafi and Spyrou (1992), Ruby (1994), Selim and Abbas (1994), Pommé 2004, Pommé et al. (1995, 2003), Tryka (1997), Prata (2003, 2004), García-Toraño et al. (2008), Conway (2006, 2007, 2008, 2010), and Friot (2015).

The radioactive solution is deposited on a flat support and centered on the symmetry axis parallel to the diaphragm and the detector. Although the accuracy of the DSA method is excellent, taking the solid angle calculations into account, nonetheless, the uncertainties may be high due to sample imperfections, and the nonhomogeneous radioactive distribution or eccentricity of radioactive sample activity compared to the detector's symmetry axis.

Digital autoradiography is the most obvious method for obtaining accurate information about the distribution of activity on the substrate. One way of knowing this distribution is pixelated autoradiography, calculating the respective solid angle for each pixel and calculating a normalized sum for all pixels, using the local activity factor. This method can be applied to a Monte Carlo simulation to calculate solid angle (Briesmeister, 2000). An alternative method that integrates the actual source activity distribution into the solid angle calculation and requires less computing time is due to Sibbens et al. (2003). We can use an algorithm based on numerical integration (Pomé et al., 2003), which is faster than the Monte Carlo technique, and also makes use of the measuring device's axial symmetry. The sample is divided into concentric rings whose points correspond to a common solid angle. This reduces computation time without affecting activity measurement accuracy. As the relative amount of activity in the rings is used as weight factor, the total geometric factor of the source is given by the ratio of the sum of the products of the geometric factor for the intensity of each element and the sum of element intensities.

The procedure for the determination of activity in a particular case is clearly described by García-Toraño et al. (2008). Distribution of activity in the sample was determined by autoradiography of the sources using a Kodak Biomax MS film. The film was then scanned with a digital scanner with 24,002 $\times$ 400 dpi optical resolution for the array of optical densities. Then they used the characteristic curve of the film to make it an array of intensities. The curve linking the optical densities of the radiation intensities was measured by exposing the film to a collimated ^{241}Am source. Distribution of activity in the source was represented by an array of 100 $\times$ 100 elements. As the maximum source diameter is 2.5 cm, each pixel

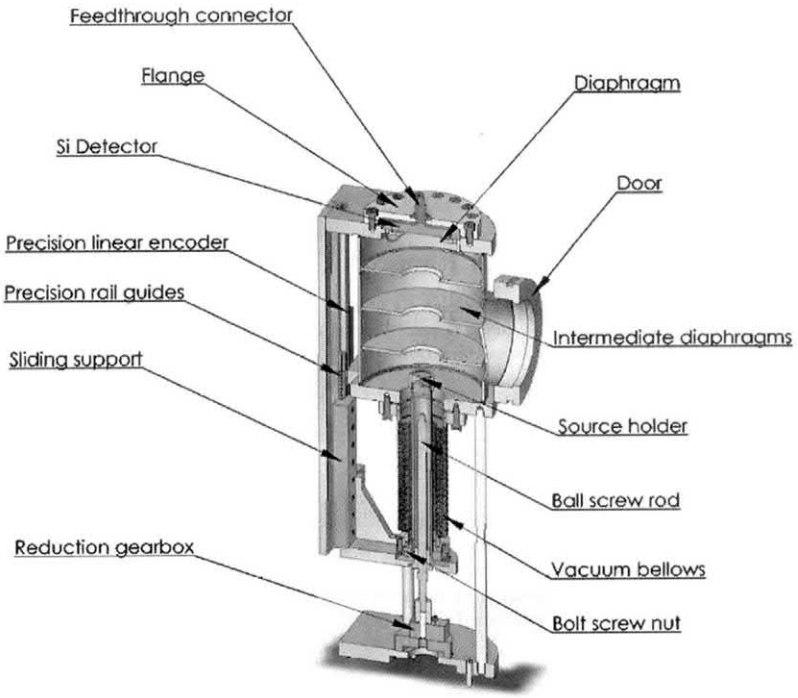

FIGURE 7.3 Diagram of the counter showing the main components. Alpha particles are detected with a 2000 mm^2 Si detector. Diameter of the main diaphragm, source-detector and activity distribution of the source define the geometry of the measurement. Source to detector distance can be continuously varied between 80 and 190 mm. *From García Toraño et al. (2008), reprinted with permission of Elsevier Science © 2008.*

corresponds to a $0.25 \times 0.25\ mm^2$ area. They used a Si detector with a 2000 mm^2 active area. The sensitive area was obtained with an aperture with a radius of 24.9 mm. This enables changing the detector without changing the geometry. Source detector distance can be adjusted from 8 to 19 cm. Fig. 7.3 shows the measuring device with its main components.

Calculation of the geometric factor depends on the distribution of radioactive material at the source. Fig. 7.4 shows a point source located at a distance Z from the detector of radius R. The geometric factor $G_C = \Omega_C/4\pi$ is given by the expression:

$$G_C = \frac{1}{2}\left[1 - \frac{Z}{D}\right] = \frac{1}{2}\left[\frac{R^2}{D(D+Z)}\right] \tag{7.91}$$

When the source is not in the common axis (Fig. 7.4) but moved away from this, Jaffey (1954) proposed the following expression:

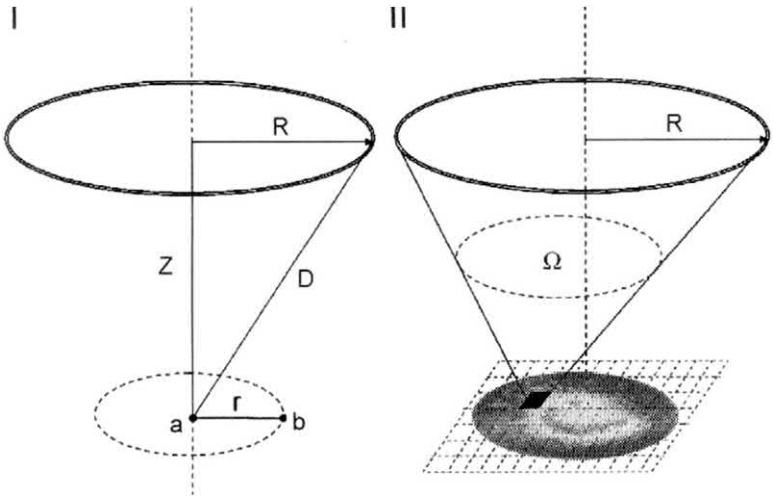

FIGURE 7.4 (I) Schematic representation of a measured setup composed by a circular detector and a point source in the axis (A) or off the axis (B). (II) Real sources are characterized by numerical arrays whose elements correspond to radiation intensities. The overall solid angle for the source is obtained as the weight mean of all elements. *From García Toraño et al. (2008), reprinted with permission of Elsevier Science © 2008.*

$$G = G_C + \frac{1}{2}\sum_{n=1}^{\infty}\frac{2n+1}{2n}\left(\frac{Z}{D}P_{2n}\left(\frac{Z}{D}\right) - P_{2n+1}\left(\frac{Z}{D}\right)\right)P_{2n}(0)\left(\frac{r^2}{D^2}\right)^n \tag{7.92}$$

where P_n are the Legendre polynomials. This expression is valid for $r/R < 1$. Usually, three or four terms are sufficient for the precision required in practice. Other authors have published analytical expressions to calculate the solid angle for circular sources (Ruby and Rechen, 1968; Ruby, 1994; Pommé, 2004; Conway, 2006). These equations require that radioactive sources be circular and homogeneous.

García-Toraño et al. (2008) applied expression (7.91) to all elements of the radiative zone (Fig. 7.4). A random mesh of 100 elements is generated for each element and the solid angle is calculated for each. The total geometric factor is obtained by a weighted average of the point values obtained:

$$G = \frac{\sum_{i,j} I_{i,j} G_{i,j}}{\sum_{i,j} I_{i,j}} \tag{7.93}$$

where $G_{i,j}$ and $I_{i,j}$ are geometric factors and intensity of the corresponding element of the array, respectively.

The background count rate for alpha emitters is very low ($\approx 10^{-3}\text{s}^{-1}$) and can be easily removed from the source spectrum. Satellite peaks accompanying some of the alpha peaks in alpha spectra are due to contamination by recoiling nuclei and can be avoided by covering the sample with VYNS foil (Nylandsted Larsen et al., 1984). Any impurities in the enriched material can be identified with alpha spectrometry or high-resolution gamma spectrometry.

Several mathematical methods have been developed to calculate the solid angle. They include analytical methods (Ruffle, 1967; Rubby and Rechen, 1968; Gardner and Verghese, 1971; Bellusco et al., 1974; Gardner et al., 1980; Selim and Abbas, 1994; Ruby, 1994; Abbas, 2001; Galiano and Rodrigues, 2006; Conwey, 2006); series expansions (Lerch and Spernol, 1966; Vega Carrillo, 1996; Pommé, 2004); numerical integration for axial symmetry (Zhihua and Xinmiao, 1992; Pommé et al., 1995; Tryka, 1997), rectangular window (Gotoh and Yagi, 1971); elliptical window (Conway, 2006); two disks and no parallel samples (Obložinsky and Ribanský, 1971); double diaphragm (Aguiar and Galiano, 2004); the Monte Carlo simulation method (Williams, 1966; Cox, 1969; Carchon et al., 1975; Wielopolski, 1977; Stavroulaki and Kaplanis, 1979); and solid angle calculations including the geometric distribution of sample activity (Pommé et al., 2003; Sibbens et al., 2003).

Setups for alpha-particle counting at a DSA have been described in the literature by several institutes, including IRMM (formerly CBNM) (Denecke et al., 1999; Pommé and Sibbens, 2008); LRL (Robinson, 1960); NIST (Hutchinson et al., 1968); ANL (Flynn et al., 1972); LNE-LNHB (Blanchis, 1983; Blanchis,1984), CIEMAT (García-Toraño and Aceña Barrenechea, 1989; García-Toraño et al., 2008), and PTB (Schötzig and Schönfeld, 2000). New setups have recently been constructed in TAEK (Turkey) (Seferinoğlu and Yeltepe, 2015) and NPL (UK) (Arnic et al., 2016) inspired by the IRMM model. Specifically for the standardization of the activity concentration of ^{222}Rn gas, DSA counters were built in which the gas could be condensed on a cold plate and measured in an ion-implanted planar silicon detector in vacuum conditions (Picolo, 1996; Dersch, 2004); Spring et al., 2006). The specific activity of ^{226}Ra in soil has been measured in the frame of proficiency test organized by IAEA and IRMM (Dirican et al., 2012)

Pommé (2015a,b) investigates the main uncertainty components of counting at a defined angle. He arrives at the following conclusions: Radioactive solutions can be standardized with 0.1% for alpha emitters and 1% for X-ray emitters, including the uncertainty from weighing the dispensed amounts in the sources. The activity of each specific source can be measured with better accuracy. Repeatability of the activity measurement of a source can be achieved within 0.01%, depending also on counting statistics. The technique is extremely well suited for half-life measurements, either by specific activity measurement of long-lived nuclides or decay curve analysis of intermediately long-lived nuclides, provided that dead time compensation and interfering signals are well under control. Statistical uncertainty can be a dominant factor, depending on source activity and measurement time.

Ferreira Filho et al. (2018) applied this method to obtain the equations for ^{152}Eu to standardize this radionuclide. They used a matrix technique for complex decay schemes.

G. Internal gas counting

Calibration of gaseous radionuclides can be performed by the internal gas counting technique (Kits et al., 1967; Spernol, 1967). A known amount of radioactive gas is mixed with the counting gas in a set of cylindrical PCs. This procedure eliminates the problem of self-absorption in the gas and is therefore well suited for measuring radionuclides that emit low energy beta radiation, such as tritium. To eliminate the end effects of the PCs, the commonly applied technique is differential counting with counters of different lengths. Other factors to consider are wall effects and loss of low energy signals, which have

been addressed by extrapolation methods, Monte Carlo simulations (Mori et al., 1998) and analytical calculation (Stanga et al., 2002). More details on this technique are presented in Unterweger (2007).

1. Theoretical description of internal gas counting

According to Kits et al. (1967), the specific activity of the radioactive sample measured by an X counter can be calculated using the equation:

$$a = \frac{V}{m}\frac{N_X - B_X}{\frac{1}{4}d^2 L_X(1 - N_X\tau)}\frac{1}{(1-p_X)(1-p_W)(1-p_d)} \tag{7.94}$$

where a is the sample specific activity ($s^{-1}g^{-1}$), V is the volume (cm^3), m is the mass of the sample (g), N_X is the counting rate of the counter X (s^{-1}), B_X is the count rate of the background (s^{-1}), τ is the dead time (s), d is the cathode diameter (cm), L_X is the length of the counter cathode (cm), and p_X, p_w, and p_d are the probabilities that a particle is not detected due to end effect, wall effect, or discrimination, respectively. We define p_X as the probability that a particle is not detected in a counter of L_X length and that the pulse formed by the particle due to the end effects has amplitude below the level of discrimination.

Because of the extreme effect, the counter of length L_X acts as a counter without an end effect with an effective length of:

$$L'_X = L_X - L_0 \tag{7.95}$$

where L_0 is the counter length without sensitivity. The effective length of the counter can be expressed as:

$$L'_X = L_X(1 - p_X) \tag{7.96}$$

therefore

$$p_x = \frac{L_0}{L_X} \tag{7.97}$$

Taking into account the difference between the count rates of the two counters called L and S, the length corresponding to the difference of their volumes will be:

$$L_{L-S} = L_L(1-p_L) - L_S(1-p_s)$$

$$= L_L\left(1 - \frac{L_0}{L_L}\right) - L_S\left(1 - \frac{L_0}{L_S}\right) = L_L - L_S \tag{7.98}$$

so the correction for end effects was eliminated. The specific activity of a sample measured by two counters will be:

$$a = \frac{V}{m}\frac{\frac{N_L - B_L}{1 - N_L\tau} - \frac{N_S - B_S}{1 - N_S\tau}}{\frac{1}{4}d^2(L_L - L_S)}\frac{1}{(1-p_W)(1-p_d)} \tag{7.99}$$

2. Some experimental aspects of internal gas counting

The volumes of the cylinders formed by the cathode are calculated from the mass of distilled water that fills the cathode between two flat glass plates applied to the cathode ends. The mass is determined by weighing at 20°C. All measurements were performed without the shielding of the counters as this would have complicated the device.

To correct for dead time, as this is small, we apply the method of measuring two sources separately and together. In this case we take two counters filled with active gas; and we measure the count rates with parallel connections of the two counters. The mean value found was 16.7 μs.

The correction for the wall effect is determined by breaking down 5 weighted amounts of $Na_2^{14}CO_3$ and adding methane to the carbon dioxide to obtain different pressures in the range of 0.592−0.955 atm, after which the differential count rate is measured. A straight line is then drawn through the experimental points by means of the least-squares method.

The dependence of the count rate on discrimination voltage, measured at an operating voltage of 3750 V, shows a relative increase of 0.55%, 0.69%, and 0.91% for the long, medium, and short counters, respectively, by extrapolating the conventional voltage of 5 V to zero. This shows that, in the case of two counters, correction for discrimination is unnecessary.

3. Applications of internal gas counting to radionuclide standardization

^{85}Kr. Mori et al. (1992) directly measured the radioactivity of ^{85}Kr with a position-sensitivity proportional counter (PSPC) method, excluding the influence of the wall effect. The standard deviation of the activity was 0.80%. The result was compared with the measurement obtained with a diffusion-in long PC, obtaining good agreement (0.5%). The use of logarithmic amplifiers was very useful for distinguishing the signals of beta rays and noise and for minimizing errors.

Makepeace et al. (1994) conducted an intercomparison of internal gas counting of ^{85}Kr and ^{3}H under the auspices of EUROMET, European Collaboration in Measurement Standards. A sample of ^{85}Kr mixed with inactive krypton

was measured by three laboratories while a sample of ^{3}H, mixed with nitrogen, was measured in four laboratories. The laboratories involved were the NPL, Teddington (England), Laboratoire Primaire de Métrologie des Rayonnements Ionizants (LPRI), Saclay (France) and Physikalisch-Technische Bundesanstalt (PTB) Baunschweig (Germany). In each case, the values were within the uncertainties of the measurements. The paper describes the techniques, results and conclusions of each of the laboratories.

Stanga et al. (2002) presented analytical calculations of losses in an internal gas PC. The results were checked by internal gas counting and the method of measurement developed in LNHB-Saclay. The experimental results with a sample of ^{85}Kr were compared with those obtained by an analytical calculation method. Consistency was excellent. Extrapolation experimental methods, commonly used in internal gas counting, were consistent with the analytical calculations.

Philips et al. (2010) participated in the key-comparison of the BIPM for primary standardization of ^{85}Kr using internal gas proportional counting (IGPC). The activity supplied for the intercomparison was relatively high, 40 MBq, and two-stage dilution was necessary to obtain an appropriate level for gas counting. A new gas-handling ring was built. The dilutions introduced significant uncertainties in the measurements so that it was necessary to resort to other activity measurement methods to confirm the internal gas counting results. The combined uncertainties for the three methods were compared, obtaining: 1.10% for IGPC, 0.63% for HPGe and 1.06% for NaI(Tl) ($k = 1$).

Yunoki et al. (2010) participated in the key-comparison of the BIPM for ^{85}Kr primary calibration using internal gas proportional counting (IGPC). Absolute measurement was performed with a set of PCs of different lengths. The original gas ampoule was diluted 2×10^5 times to achieve a concentration of appropriate activity. Therefore, a new method of dilution based on a large-volume balloon was introduced. The estimated relative uncertainty was 1.25% ($k = 1$).

Schlosser et al. (2017) described the PCs and a $\beta-\gamma$ coincidence system. Typical limits of detection (LD) are 8 mBq m^{-3} for ^{85}Kr and 4 mBq m^{-3} for ^{133}Xe for the PCs and for similar xenon volumes the (LD) for ^{133}Xe in the $\beta-\gamma$ system is about 4 times lower.

^{3}H. Mann et al. (1964) performed a calibration of the NBS tritium standards that had been calibrated by calorimetric methods in 1954–55. The recalibration described in the paper uses length-compensated internal gas counters. The new activity values were 1.96% lower than the previous ones. But this difference also involved uncertainties in the half-life and mean beta ray energy of ^{3}H. A value of 0.92 was obtained for the combined rate of evaporation and reaction with Zn, for HTO and H_2O.

Spernol and Denecke (1964) described a method for the measurement of tritiated water with 0.1%–0.2% reproducibility and 0.3%–0.4% absolute accuracy. The first two parts of the work describe the preparation of the counting gas and the counters used. The measurement procedure and systematic errors are examined in detail in the third part.

Hadzisehovic et al. (1973) presented the results of the specific activity of tritiated water measures by internal gas counting. Two reducing agents, uranium and zinc, were used to convert water to gas. The absolute disintegration rate per unit volume of the counter was determined by the compensation method using three gas PCs. Depending on the procedure for determining the mass of radioactive hydrogen, two methods were used to obtain the specific activity of water. Both methods gave the same results within 1%. The total uncertainty in determining specific activity was ±1%.

Mori et al. (1987) described a new principle using a PC with a resistive anode partially resistive and sensitive to the position for measurement of ^{3}H gas. The new method eliminated the influence of end effects and could define the effective counting volume. The paper describes the process of preparing the anode and its characteristics.

Unterweger et al. (1980) described the recalibration of SRM 4926 and SRM 4927 tritiated water according to the standards that had been measured by the method of internal-gas proportional counting. The paper concludes that the half-life of tritium must be corrected to 1243 ± 0.05 years.

Makepeace et al. (1996) performed an intercomparison of internal gas counting of tritiated water under the auspices of EUROMET, European Collaboration in Measurement Standards. The laboratories involved were the NPL, Teddington (England), the National Institute for Satandards and Technology (NIST), Gaithersburg (US) and the Physikalisch Technische Bundesanstalt (PTB), Baunschweig (Germany). The samples were measured by internal gas proportional counting after reducing the tritiated water to produce gas HT. Consistent results were obtained within the uncertainties. However, the NPL value was significantly higher than the others to the level 1σ. This means that it must carry out an investigation on the effect of the use of a molecular sieve to collect the gas, as this is the most significant difference between the systems used by NPL and the PTB and NIST.

Stanga et al. (2006) calibrated tritiated water by two methods: a method based on liquid scintillation, using the technique of triple-to-double coincidence ratio (TDCR), and the other method, internal gas proportional counting, in conjunction with a generator of tritium gas by water chemistry reduction. The uncertainties of both methods were less than 0.6% and both measurement results were consistent within this uncertainty, indicating that both methods were suitable for standardization of tritiated water.

Stanga et al. (2005) standardized tritiated water by internal gas proportional counting following its chemical reduction, by means of a tritium gas generator, to produce tritiated hydrogen. They describe a new tritium gas generator in detail together with the method of measurement based on the internal gas counting. The method had new and improved features and offers the advantage of being simpler and easier to operate than other tritium generators available. The tritium generator had the following new features: (1) it performed the water reduction at a lower temperature (450°C) than the other generators which need 600°C; (2) the reduction yield was always unitary. Also, it had a simple and compact construction by using the same components for water degassing and water reduction. Its simple disassembly and reassembly allowed for easy maintenance.

Bonicalzi et al. (2016) use a single compound (methane) for dual tritium and radiocarbon measurements in environmental applications. They present an optimized methane percentage, detector fill pressure, and analyze energy windows to maximize measurement sensibility while minimizing count time. The optimized method uses 9-atm fill of P35 (35% methane, 65% argon) and the window for tritium from 1.5 to 10.3 keV. This method optimizes tritium-counting efficiency and minimizes radiocarbon beta-decay interference.

^{14}C. Mann et al. (1961) determined the half-life of ^{14}C by internal gas counting with an uncertainty lower than other previous determinations. Carbon dioxide was released by the action of perchloric acid on barium carbonate containing ^{14}C, approximately 44% of isotopic abundance. The technical difficulties of the work are due to absorption problems, whose solution is described in detail in the paper. The value obtained for the half-life was 576.0 ± 50 years. The currently accepted value is 573.0 ± 40 years.

Watt et al. (1961) measured the specific activity of pure samples of carbon dioxide containing 45% and 2% of ^{14}C per atom. Using mass spectrometry and gas internal count by counting with a PC, they obtained a half-life of 578.0 ± 65 years. This is far from the accepted value of 573.0 ± 40 years, but excellent when compared with previously obtained values. The paper describes the various corrections applied subsequently which served as the basis for modern measures.

^{127}Xe. Rodrigues et al. (2014) standardize ^{127}Xe using three differential internal PCs. Detection efficiency is not very independent from the decay scheme; and this enables the activity of this standard to be used for the determination of gamma ray emission intensities. ^{127}Xe is useful in the quality control of remote radio-xenon monitoring stations, with the advantage of a longer half-life than ^{131m}Xe or ^{133}Xe.

^{131m}Xe. The work of Garfinkel et al. (1973) presented the changes in the gas-counting system of National Bureau of Standards. They describe the preparation of various standards of radioactive gas. The system was successful in the standardization of ^{131m}Xe. The gamma ray of 164 keV is well converted and the same value for the count rate was obtained with two levels of discrimination. Standards of ^{131m}Xe were prepared by first doing a separation by isotope separator and then by measuring with the internal gas counting system. The method of five levels of discrimination was successfully applied to gaseous radionuclides: ^{3}H, ^{14}C (as CO_2), ^{39}Ar, and ^{85}Kr, all with a continuous beta ray spectrum. However, ^{37}Ar, a nuclide decaying by pure electron capture, did not yield satisfactory results. It took a series of corrections in relation to L and M electron-capture for standardization.

^{133}Xe. The work of Picolo et al. (1998) presented the results of an international comparison of ^{133}Xe conducted under the auspices of EUROMET (project Nr. 304). The project was divided into two stages. In the first, sealed glass ampoules containing 40 MBq of ^{133}Xe were measured. The following laboratories participated in the comparison: BIPM, LPRI, NIST and NPL. LPRI, NIST, and NPL participated in the second measurement, the activity concentration of ^{133}Xe mixed with nitrogen. Activity concentration was about 50 MBq/mol. The paper describes the experimental techniques used, the results obtained and the conclusions of the participating laboratories.

Positron emitters. The intense use of the Positron Emission Tomography (PET) technique for clinical diagnostic purposes has led to the proliferation of cyclotron facilities to produce positron emitters such as ^{11}C, ^{13}N, ^{15}O, and ^{18}F. To meet the requirements of radiation protection, the operators of the cyclotron are required to use one of the air measurement techniques for monitoring. Marouli et al. (2007) report that it is required to have a primary standard for positron emitters in gas to ensure that the measures are sufficiently precise. The basis of the primary standard is a system of internal gas counting established at NPL for the calibration of β^- emitters. Therefore, they have to establish the difference between the system's response to positrons and electrons. This paper describes the energy deposited by positrons compared with electrons in the gas volume of the counter. They used the calculation code PENELOPE to study the energy deposited by the abovementioned radionuclides in P10 gas. It was found that positrons deposited between 1.5 and 2.5 times more energy than electrons in the gas, depending on the maximum energy of the spectrum, affecting the lower limit of concentration detectable of positron counters.

The work of Marouli et al. (2007, 2008) describes the need for a UK primary standard and monitor calibration service for positron emitting radionuclides in gases by the users of cyclotron facilities to enable them to calibrate radioactivity-in-air monitors and thus ensure the accuracy and traceability of measurements of any airborne

radioactivity releases arising from the production of these radionuclides. A system of gas flow PCs, already established at the NPL for the standardization of β^--emitting gases, was used as the basis of the primary standard. They focus on initial problems encountered in the use of the system for measuring positron emitters.

Marouli et al. (2010) developed a method involving internal gas proportional counting and the PENELOPE calculation code to determine Monte Carlo corrections for lost of counts. The work focuses on the calibration of ^{11}C, but the method can be applied to other positron emitters. The results were compared with measurements of ^{11}C in aqueous solution carried out by a reentrant ionization chamber calibrated with reference to absolute counting techniques.

Zimmerman (2013) analyzes the current status and future needs for standards of radionuclides used in PET. Marganiec-Galazka et al. (2018) carry out the activity determination of ^{68}Ge/^{68}Ga by means of $4\pi\beta(\check{C})-\gamma$ coincidence counting. Measurements were made by means of a new PTB-custom-built $4\pi\beta(LS)-\gamma$ coincidence counting system, where a liquid scintillator detector in the beta channel can also be used as a Cherenkov counter, and a NaI(Tl) crystal detects annihilation radiation.

H. Liquid scintillation counting

Liquid scintillation is also a 4π measurement technique. In general, the efficiency of alpha emitters is 100% (Havelka, 2018). In the case of high-energy beta radionuclides, extrapolation can be applied to obtain the activity of the sample. Such is the case of ^{131}I, ^{32}P, ^{60}Co radionuclides (Steyn, 1956). Due to ionization quenching, extrapolation is difficult to apply to radionuclides with emission of low- or medium-energy beta particles. Several papers have been published to calculate the counting efficiency for beta emitters with maximum energy below 200 keV (Horrocks and Studier, 1961; Lukens, 1961; Gibson and Gale, 1968; Horrocks, 1976). Van Wyngaardt and Simpson (2006a) obtained the absolute activity of these radionuclides decaying by electron capture: ^{139}Ce, ^{131}I, ^{192}Ir, and ^{65}Zn by LSC, using the extrapolation technique. This technique was previously applied to the standardization of ^{204}Tl by Simpson and Meyer (1994b).

In 1961, in a pioneering study, Horrocks and Studier (1961) proposed the idea that the relationship between the computed counting efficiencies for two photomultipliers in coincidence and a single photomultiplier is connected to counting efficiency. If the relationship is extrapolated to 1, the counting efficiency will be 100% and the extrapolated count rate will coincide with the sample's activity expressed in the same time units. Although the idea and procedure are correct, the difficulty of obtaining the real count rate with a single photomultiplier, due to interference from electronic noise, limits its applicability to the radionuclides with energy of beta emissions above 100 keV.

It immediately suggests that the procedure proposed by Horrocks and Studier (1961) should be applied to a three-photomultiplier detector system, using the counting efficiencies for two and three photomultipliers, as coincidences virtually eliminate electronic noise. The main difficulty was that the quantum yield of the photomultiplier was very small, which meant a high uncertainty in the determination of activity.

The development of a photomultiplier with high quantum performances radically changed the situation so that Schwerdtel (1968) made the first detection system with three photomultipliers. Subsequently, Pochwalski et al. (1988) built a much more elaborate triple and double coincidence system in order to directly obtain the activity of a radioactive specimen.

In 1980, Grau Malonda (1982a), in his doctoral thesis, presented the first models for calculating the counting efficiency of radionuclides with different decay schemes: pure beta, beta-gamma, pure electron capture, electron capture-gamma emitters, and pure positron emitters. The paper compares the efficiency curves versus the chemical quenching, experimental and calculated, for the following radionuclides: ^{14}C, ^{35}S, ^{99}Tc, ^{185}W, ^{36}Cl, ^{204}Tl, ^{89}Sr, ^{32}P, ^{203}Hg, ^{60}Co, ^{90}Sr+^{90}Y, ^{55}Fe, ^{85}Sr, ^{125}I, ^{139}Ce, ^{137}Cs, ^{65}Zn, and ^{22}Na. Discrepancies between experimental and theoretical values were below 5%. Note that, at that time, many of the commercial calibration solutions had uncertainties of around 3%. In international comparisons, uncertainties of 1% were classified as excellent.

The first publications about the tracer method, which was then called the CIEMAT/NIST method, were by Grau Malonda and Garcia-Toraño (1982), on pure beta radionuclides, and Grau Malonda (1982b) on nuclides decaying by electron capture. These papers outline the foundation for subsequent models for calculating the efficiency of LSC.

The first computer program to calculate the efficiency of beta emitters was the EFFY program (García-Toraño and Grau Malonda, 1981), followed by EFFY2 (García-Toraño and Grau Malonda, 1985). The first program to calculate the efficiency of nuclides decaying by electron capture was VIASKL (Los Arcos et al., 1987).

In 1985, collaboration began between CIEMAT and the NBS (now NIST) in order to study the application of computational models to the standardization of radionuclides by LSC. This collaboration was extremely fruitful and complementary. The NIST calibration solutions were the best in the world and, in particular, Dr. Coursey was the most experienced investigator in the preparation of samples for liquid scintillation. The term "CIEMAT/NIST" method is due to the fact that both institutions supported the method's development, with a significant reduction in the

uncertainties associated with the standardization of radionuclides.

In 1986, Dr. Coursey received the results of ^{3}H and ^{14}C obtained with the three-tube system developed by Pochwalski and Radoszewski (1979) and Pochwalski et al. (1988). It was easy to prepare a calculation model for systems with three photomultipliers, based on the earlier developed two-photomultiplier model. In the summer of 1986, the calculations were ready and a submission was prepared (Grau Malonda and Coursey, 1988), sending the results to Dr. Radoszewski. The Polish team presented a paper (Broda et al., 1988) based on a binomial model. A code for this model was never published.

In 1990, Grau Malonda (1990) showed that despite the different statistical assumptions applied, both models should lead to identical results for monoenergetic electrons. Discrepancies in the counting efficiencies calculated with both models for ^{3}H and ^{14}C presented in the works of Grau Malonda and Coursey (1988) and Broda et al. (1988) were due to the fact that, in the latter, an infinite series is truncated and introduces a truncation error, whereas Grau Malonda and Coursey (1988) apply an accurate equation. The expressions used in this type of calculation were derived in the book by Grau Malonda (1999).

Later, Grau Carles and Grau Malonda (1989) studied the problem of the form of response curve (counting efficiency as a function of the triple/double relationship) for nuclides decaying by electron capture. As Fig. 7.5 shows, for a free parameter value we can have up to three values of counting efficiency. This ambiguity is resolved by a three-dimensional representation (ε −T/D−λ) counting efficiency (ε), T/D ratio, and the free parameter (λ) (Fig. 7.6.). On the other hand, they show that the extrapolation method for LSC cannot give linear responses enabling extrapolation so the results are not good for nuclides decaying by electron capture.

In recent years, major efforts have been made to solve these problems, both experimentally and theoretically, considering two different lines: the CIEMAT/NIST method and the TDCR method. The principles and applications of both methods are described masterfully in Chapter 6, Volume 1 of this book.

As the method can be applied to measure relatively low activities, it has been used for the measurement of the natural radioactivity of some radionuclides such as ^{40}K, ^{10}Be, and ^{87}Rb obtaining their half-lives with uncertainties lower than other procedures (Grau Malonda and Grau Carles, 2002; Kossert, 2003; Kossert and Günther, 2004; Grau Carles and Kossert, 2006, 2007; Schwarz et al., 2011).

As the uncertainty of ^{54}Mn is lower than that of ^{3}H, the former is a good candidate as a tracer. In particular, for nuclides decaying by electron capture, Günther (1998) made the proposal, which was later tested by Kossert and Grau Carles (2006), to use ^{54}Mn as a tracer instead ^{3}H, confirming a reduction of dependence, if ^{54}Mn is used to standardize ^{55}Fe and ^{65}Zn.

While the CIEMAT/NIST method uses commercial liquid scintillation counters, the TDCR method requires the use of special counters equipped with three photomultipliers. A good example of a counter of this type was described by Cassette and Vatin (1992). The system with three photomultipliers allows for double coincidences (AB, AC, BC, and the possible sums of these coincidences, and the triple coincidence (ABC), from which counting

efficiency can be obtained. Tables 7.7A and 7.8A show the equations for calculating efficiencies in double and triple coincidences, assuming a similar response for the three photomultipliers.

When the responses of the photomultipliers are different, the expressions to calculate counting efficiencies are given in Tables 7.7B and 7.8B. A detailed deduction for these equations and others more, in the case of four photomultipliers, is given in Grau Malonda (1999).

For photomultipliers with the same response, the ratio of triple-to-double efficiencies, when double coincidences are added, is:

$$\frac{\varepsilon_T}{\varepsilon_D} = \int_0^{Em} S(E)(1 - \exp(-EQ(E)/3\lambda))^3 dE \times \left[\int_0^{Em} S(E)\left[3(1 - \exp(-EQ(E)/3\lambda))^2 - 2(1 - \exp(-EQ(E)/3\lambda))^3\right] dE \right]^{-1} \quad (7.100)$$

where E is the electron energy, $S(E)$ is the normalized energy spectrum, $Q(E)$ is the ionization quench function and λ is the free parameter.

It is experimentally found that the CIEMAT/NIST method enables the standardization of radionuclides decaying by low beta energy emission, with a high level of accuracy. However, the calibration of radionuclides decaying by electron capture is less accurate. In some cases we have uncertainties of about 2% for ^{125}I. Some authors advocate the use of two tracers, tritium for nuclear beta decay, and ^{54}Mn for nuclides decaying by EC. From a practical point of view this is acceptable, but it is not acceptable from a fundamental point of view. When a procedure gives excellent results for some radionuclides and worse results for others, this indicates that the procedure requires further investigation.

A great effort has been made to develop computation programs to obtain the count efficiency of radionuclides dissolved in liquid scintillation or in water. The main programs published in relation to the EC are the following: CAPMULT, counting efficiency for electron capture by a KLMN four-shell model (Galiano Casas et al., 1995); EMI, counting efficiency for electron capture, electron capture-gamma, and isomeric transitions (Grau Carles et al., 1994c); EMI2, counting efficiency for electron capture by a KL1L2L3M model (Grau Malonda et al., 1999); EMILIA, LS counting efficiency for electron-capture and capture-gamma emitters (Grau Carles, 2006a,b); CHEREN, Cherenkov counting efficiency (Grau Carles and Grau Malonda, 1998); CHEREN2, Cherenkov counting efficiency by an anisotropy detection model (Grau Carles and Grau Malonda, 2006b); SRLOG, the simultaneous standardization of 90Sr+90Y+89Sr mixtures (Grau Carles, 1994b); MLOG, the simultaneous standardization of multi-nuclide mixtures (Grau Carles, 1996); MICELLE, the micelle size effect on LS counting efficiency (Grau Carles, 2007); study of a Monte Carlo rearrangement model for the activity determination of electron-capture nuclides by means of LSC (Kossert and Grau Carles, 2008).

The application of these computation programs has generated different lines of research: A New Linear Spectrum Unfolding Method Applied to Radionuclide Mixtures in Liquid Scintillation Spectrometry (Grau Carles, 1994a);

TABLE 7.8B Counting efficiency equations for counting systems with three different photomultipliers. $\overline{n}_1 = EQ(E)/3\lambda_1$; $\overline{n}_2 = EQ(E)/3\lambda_2$; $\overline{n}_3 = EQ(E)/3\lambda_3$.

Beta shape factor determinations by the cutoff yield method (Grau Carles, 2005); Precision measurement of the RAE shape factor (Grau Carles and Grau Malonda, 1996); Radionuclide standardization by Cherenkov counting (Grau Carles and Grau Malonda, 1995); The anisotropy coefficient in Cherenkov counting (Grau Malonda and Grau Carles, 1998); Synergic quenching effects of water and carbon tetrachloride in liquid scintillation gel samples (Grau Carles, 2006a,b); Alpha/beta separation in liquid scintillation gel samples (Grau Carles and Grau Malonda, 1994); Inelastic scattering and stopping power of low energy electrons (0.001−10 keV) in toluene (Garcia et al., 2004); Computational aspects in modeling the interaction of low-energy X-rays with liquid scintillators (Grau Carles and Grau Malonda, 2006a); The ionization quench factor in liquid-scintillation counting standardizations (Grau Malonda and Grau Carles, 1999); Half-life determination of ^{40}K by LSC (Grau Malonda and Grau Carles, 2002); Half-life measurements of ^{87}Rb by LSC (Kossert, 2003); LSC measurements of the half-life of ^{40}K (Kossert and Günther, 2004); Ionization quenching in LSC (Grau Carles et al., 2004); The photoionization-reduced energy in LSC (Grau Carles et al., 2006); Improved method for the calculation of the counting efficiency of electron-capture nuclides in liquid scintillation samples (Kossert and Grau Carles, 2010); and Extension of the TDCR model to compute counting efficiencies for radionuclides with complex decay schemes (Kossert et al., 2014a,b).

The TDCR method gives excellent results for the standardization of nuclides decaying by EC and worse results for low-energy pure beta-ray-emitting radionuclides. Again, we believe that more research is needed to improve the method.

Grau Malonda and Grau Carles (2008), Grau Malonda et al. (2006) studied the influence on ionization quenching of the Auger electron coincidence due to EC and IC in the decay of ^{125}I. Clearly, when two low-energy electrons coincide, ionization quench should increase. In this study the authors quantified this effect and concluded that the correction could affect up to 1%. However, the uncertainty in this case is 2%. Therefore, this process cannot completely correct uncertainty.

An extraordinary improvement in the calculation of counting efficiency of nuclides decaying by electron capture has been achieved with the new MICELLE2 code (Grau Carles, 2007), following a new procedure to calculate stochastic activity. Kossert and Grau Carles (2010) analyze the main advantages of more realistic treatment of the emission of electrons and atomic rearrangement process subsequent to electron capture. They also analyze the energy deposition in the micelles. A new version of the MICELLE2 code enables the calculation of counting efficiency in the case of nuclides with complex decay schemes. Kossert and Grau Carles (2010) explore the following nuclides using the CIEMAT/NIST method: ^{55}Fe, ^{54}Mn, ^{64}Cu, ^{65}Zn, ^{88}Y, ^{109}Cd, and ^{123}I. All of them are first standardized by other methods, some of them in international comparisons, and then their activities were obtained from calculation using the improved MICELLE2 code. In the paper, discrepancies between experimental and calculated activities, for each nuclide, and the different parameters used in the calculation are presented. The TDCR method was also applied to the following nuclides: ^{55}Fe and ^{89}Sr. An analysis of this paper clearly shows the advantages of the stochastic code and the improvements due to a better and more detailed atomic rearrangement model.

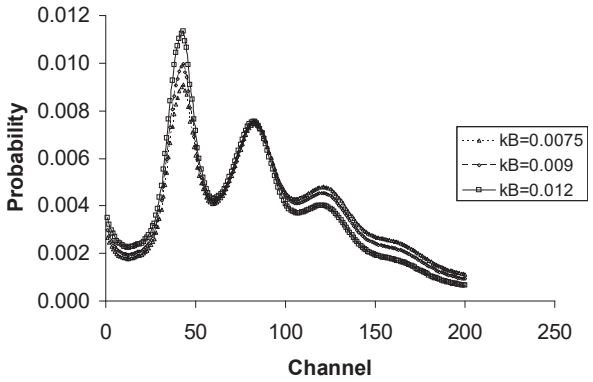

FIGURE 7.7 ^{55}Fe spectra for three different values of kB. *From Grau Carles and Grau Malonda (1989), reprinted with permission of CIEMAT.*

In a later paper, Grau Carles and Grau Malonda (2010) introduce a new methodology for studying these problems. They study theoretically calculated differential spectra. The procedure used to calculate the spectral response is based on obtaining the spectrum of "monos" for each photomultiplier. Thus, they place a lamp emitting photons of sufficient energy to produce a photoelectron in the photocathode of the photomultiplier. The response of the photomultiplier, in this case, a pulse amplitude spectrum as shown by Houtermans (1973), enables, by deconvolution, a spectrum similar to the experimental one. The Houtermans idea with the CIEMAT/NIST method enables calculation of the spectral response for any radionuclide. This procedure could be used to examine the discrepancies between theoretical and calculated spectra from the variation of any parameter. Fig. 7.7 shows the spectral response of a single photomultiplier for ^{55}Fe and different values of the kB parameter. It is sufficient to compare the experimental and theoretical spectra of ^{55}Fe to obtain the most suitable experimental value of kB.

Determination of the activity of radionuclide mixtures (pure beta ray emitters, pure electron capture or both) is a problem of interest, but complicated. Initially, these problems were solved in the case of beta emitters with very different energies. ^{32}P, ^{14}C, and ^{3}H were the most common mixtures (Altzitzoglou, 2004). They were measured by placing different counting windows, two or three, depending on the number of radionuclides. Grau Carles et al. (1993a) showed that in mixtures of radionuclides such as ^{14}C and ^{35}S, with relatively close maximum beta energies of 156.5 and 167.5 keV, respectively, the activity of each nuclide could be determined by working with the pulse height spectra. In this case, separation was possible because the beta spectra of these nuclides have different shapes due to the Coulomb effect of the nucleus on the beta particles emitted. The decomposition procedure (Grau Carles, 1994a, 1996) requires the availability of experimental spectra with parameters of well-defined chemical quench. The possibility of calculating the spectra theoretically facilitates the calculation of mixtures and decomposed mixtures that cannot now be obtained.

Application of the CIEMAT/NIST method to ^{125}I produces discrepancies of about 2% compared to other methods. Grau Carles and Grau Malonda (2010) note a possible cause. When calculating the efficiency of any beta nuclide by the CIEMAT/NIST method, we take the full energy spectrum, from zero to the maximum energy of the nuclide. However, experimentally, a discrimination level is placed in each of the photomultipliers to eliminate electronic noise. If the level of discrimination is a bit high, it cuts the experimental spectrum, reducing the number of counts and distorting the experimental measurement. On the other hand, if the level of discrimination is a little low, accidental coincidences are counted, due to the noise of the photomultipliers. This artificially increases the count number and falsifies the measurement. It is necessary to resort to calculation of the spectra to clarify the situation and correct any of the two discriminator effects.

As shown by Grau Carles and Grau Malonda (2010), it is possible to calculate the spectrum of a nuclide and determine the influence of asymmetry in the response of the photomultiplier in the case of the TDCR method. Tables 7.9A and 7.9B present expressions for calculating the statistical factor in the case of two photomultipliers when photomultiplier responses are similar and different, respectively. Tables 7.10A and 7.10B show the equations for three photomultipliers.

A problem that requires further analysis is the correction of ionization quench. This factor depends on the expression used for its calculation. There are two expressions: Birks (1964) and Voltz (1969). It also depends on the stopping power of the particle energies from zero to its maximum energy. Stopping power values vary from one table to another and none reaches zero (Garcia et al., 2004; Zhenyu et al., 2009), so the type of extrapolation applied has to be known. Finally there is the kB used. In most studies only the value of kB is given. In this case, it is impossible to know the ionization quench function obtained. Another issue related to the ionization quench is a basic one. It is usually taken as axiomatic that the ionization quench must be zero for zero energy of the particles, and this assumption gives good results in practice. However, according to the equations, if quenching is zero, the stopping power must be infinite and this is not true for the stopping powers known. There is also the question of whether the stopping power is a quantity applicable to energies below 1 eV.

Cassette and Do (2008) describe a new calibration method for LSC based on a virtual tracer source (Compton virtual source) created inside the liquid scintillator by Compton interaction of gamma rays emitted by an external collimated source of ^{241}Am. The procedure is similar to the CIEMAT/NIST method, but using Compton electrons instead of the tritium standard. Compton electrons

From Grau Carles and Grau Malonda (2010), reprinted with permission of CIEMAT.

operating in coincidence in a liquid scintillation counter with three photomultipliers while the Compton scattered photons are detected in a germanium detector and the pulses are carried to coincide with the signals of the three tubes added two by two. This method is called Compton Efficiency Tracing (CET).

Cassette et al. (2010) take advantage of the international comparison of ^{3}H to measure the activity of the nuclide by the usual TDCR method and CET method. The CET method is less sensitive than TDCR to the kB parameter in determining the correction factor of ionization quenching. This first experiment reveals no significant bias of the method due to the variability of the scintillators. Even if the counting efficiency varies from 0.4 for Hionic-Fluor to about 0.6 for Ultima Gold LLT, the activity obtained is correct. This shows that the CET method is less sensitive to scintillator composition than the TDCR method. The way to obtain the Compton electron spectrum shows that the cross-section interaction of these scintillators can be quite different for energies near 60 keV; and this difference is probably higher for lower energies, causing more variability for X-rays emitted after electron capture or internal conversion. More experimentation on this point is therefore required. The paper concludes with a discussion of the advantages and disadvantages of using the CET method as an international system for radionuclides, which are pure beta low-energy emitters.

Bobin et al. (2010b) described the first step in developing a digital platform dedicated to the primary standardization of radionuclides. They measured ^{241}Am and ^{3}H. In the case of ^{241}Am, they measured the activity for resolving times of the order of 24, 40, 72, and 120 ns and always obtained the same activity. In contrast, when they measured ^{3}H, with values of time resolution from 40 to 500 ns, the count rate when the system of three photomultipliers works with a sum of double coincidences varies by 4%. The authors found no explanation for this change in the count number. The only thing that they affirm is that it cannot be accidental. On the other hand, they say that when they switch from Ultima Gold to toluene, the count increase is much smaller.

We interpret the count increase when resolution time grows. In the scintillation process two components of light are found, fast and slow. The fast component is attributed mainly to emission from singlet states, induced by charged particles. The origin of the slow component is less clear and several hypotheses have attributed the emission delay to ion−electron recombination, intermolecular triplet−singlet transition, or triplet−triplet interaction. As the fast component has a half-life of 1.5 ns, in that time its contribution to light emission will be negligible. Thus, increases in light for resolution times above 40 ns should be due to the slow component. Moreover, the concentration of excited molecules due to the fast component will be huge compared to the concentration of excited molecules of the slow component. Consequently, ionization quenching, which is linked to elevated concentrations of excited molecules, will be seen in the fast component phase and be negligible in the slow component.

The explanation of why the count increase is higher with Ultima Gold than with toluene is simple. Scintillation fluids are binary systems in which solvent excitation energy is transferred to a primary scintillator (solute). Singlet excited states S_1 transfer their energy to singlet states F_1 of the primary scintillator. For typical concentrations of liquid scintillation, this reaction is fast enough to not alter the kinetics of light emission. However, if oxygen or air is present, there is highly efficient quenching of triplet states T_1; they reduce the intensity of delayed emission and change the law of decay. It is known experimentally that toluene is a liquid with an extraordinary avidity for air. If no special precautions are taken, bubbling noble gases, for example, the toluene scintillator is air saturated and, therefore, significantly reduces the emission of triplet states, so the impact of resolution time on light emission is reduced.

The constancy of the number of counts with resolution time of a certain value, as in the case of alpha emitters such as ^{241}Am, is due to the high efficiency of alpha emitters, about 100%. Therefore, the number of counts cannot increase when all the particles emitted by the radionuclide are counted. In the case of tritium, the situation is different, as there are beta particles not counted. Fast emission does not produce enough light to be detected. However, the increase in light due to slow emission makes them detectable (Tables 7.11 and 7.12).

1. Importance of the beta spectrum in the standardization of Co-60

Since the creation of the calculation models on which both the CIEMAT-NIST method (Grau Malonda and Garcia Toraño, 1982; Grau Malonda, 1999) and the TDCR (Grau Malonda and Coursey, 1988; Broda et al., 1988) are based, the importance of the calculation of the beta spectra in both methods for the determination of the primary activity has been emphasized. The inappropriate use of the beta spectrum can lead to discrepancies in activity concentrations when counting efficiency varies. Recent studies with ^{63}Ni (Kossert and Mougeot, 2015) resolved the aforementioned discrepancies when the effects of atomic shielding and the effects of the exchange were taken into account in the calculation of the beta spectrum (Mougeort and Bisch, 2014).

The agreement between the determinations of activity of ^{241}Pu through CIEMAT-NIST and TDCR was improved by Kossert et al. (2011a) using the experimental determination of the beta spectrum by metallic cryogenic detectors (Loidl et al., 2010). Since then the quality of experimental beta spectra has been improved (Loidl et al., 2014) and improvements have been made in the theoretical calculation of the beta spectrum (Mougeot et al., 2012; Mougeot and Bisch, 2014).

Kossert et al. (2018) have applied the measures $4\pi\beta(LS)-\gamma$ and $4\pi\beta(PC)-\gamma$ to determine the activity of a sample of ^{60}Co. At the same time they tried to obtain the activity of the sample through the CIEMAT-NIST and TDCR methods. The measurements using these two methods depend on the calculation model applied to the beta spectrum and the value adopted from the kB. They observed that corrections for atomic shielding and exchange (Mougeot et al., 2012; Mougeot and Bisch, 2014; Mougeot, 2015; Mougeot, 2016) significantly improve the activities obtained by these methods compared to those of coincidence. Finally, by appropriately varying the value of the kB, they obtain so many per 1000 agreements for the activities measured by the four methods. This result is very important and indisputable as it confirms the application of these corrections of calculation of the beta spectrum to the CIEMAT-NIST and TDCR methods in the extent of the activity of the ^{63}Ni, already advanced by Kossert and Mougeot (2015), and for ^{241}Pu, taking advantage of cryogenic spectrometry (Loidl et al., 2010, 2014).

Given the importance of the results obtained in the work of Kossert et al. (2018). Fig. 7.8 reproduces the relative deviations between the activity concentrations for the ^{60}Co with two liquid scintillation measurement methods compared to the reference value obtained with the $\beta-\gamma$ coincidence methods.

An improved calculation of electron capture transitions has recently been published. Overlap and exchange effects are corrected using Bacall's and Vatai's approaches. Shake-up, shake-off, and inner hole effects are approximately corrected (Mougeot, 2018).

I. Calorimetric detectors

1. Classic calorimetry

Calorimetric methods have been used in radionuclide standardization from the beginning of the last century, after the discovery of radioactivity. Historically it is interesting to note that the radium emission rate of RaE (^{210}Bi) by Ellis and Wooster (1925a, 1925b) led Pauli to postulate the existence of the neutrino. A clear and comprehensive review of the application of calorimetric methods to activity measurements from 1903 to 1958 is available on the Encyclopedic Dictionary of Physics (Mann, 1962). Subsequent reviews were made by Gunn (1964, 1970, 1976) and Mann (1973). Special mention should be made of the Ramthun (1973) review, summarizing the basic types and forms of calorimeter and their application to activity measurement. It is the best source for the metrological aspects of calorimetry applied to radioactivity measurements.

Calorimetric methods have been used for the preparation of standard samples of ^{35}S (Selinger et al., 1958), and beta emitters Collé (2007). An isothermal calorimeter was used by Lowental and Hicks (1966) to standardize sources of alpha and beta emitters. Other developments in the measurement of radioactivity by calorimetric methods have been described by Ramthun (1973). A recent review of modern methods of measurement by classical calorimeters was made by Collé and Zimmerman (2011). This excellent description of the state of classical calorimetry provides details of companies that currently manufacture calorimeters as well as recent results at NIST obtained with calorimeters.

The "radiobalance" designed by Callander (1910) was the first precision calorimeter applied to radionuclide standardization. Mann (1954) developed a version of this isothermal microcalorimeter based on the Peltier effect. This calorimeter was used in the NBS (now NIST) for 40 years for radium comparison (Coursey et al., 2002), as well as primary standardization; ^{63}Ni (Barnes et al., 1971; Collé

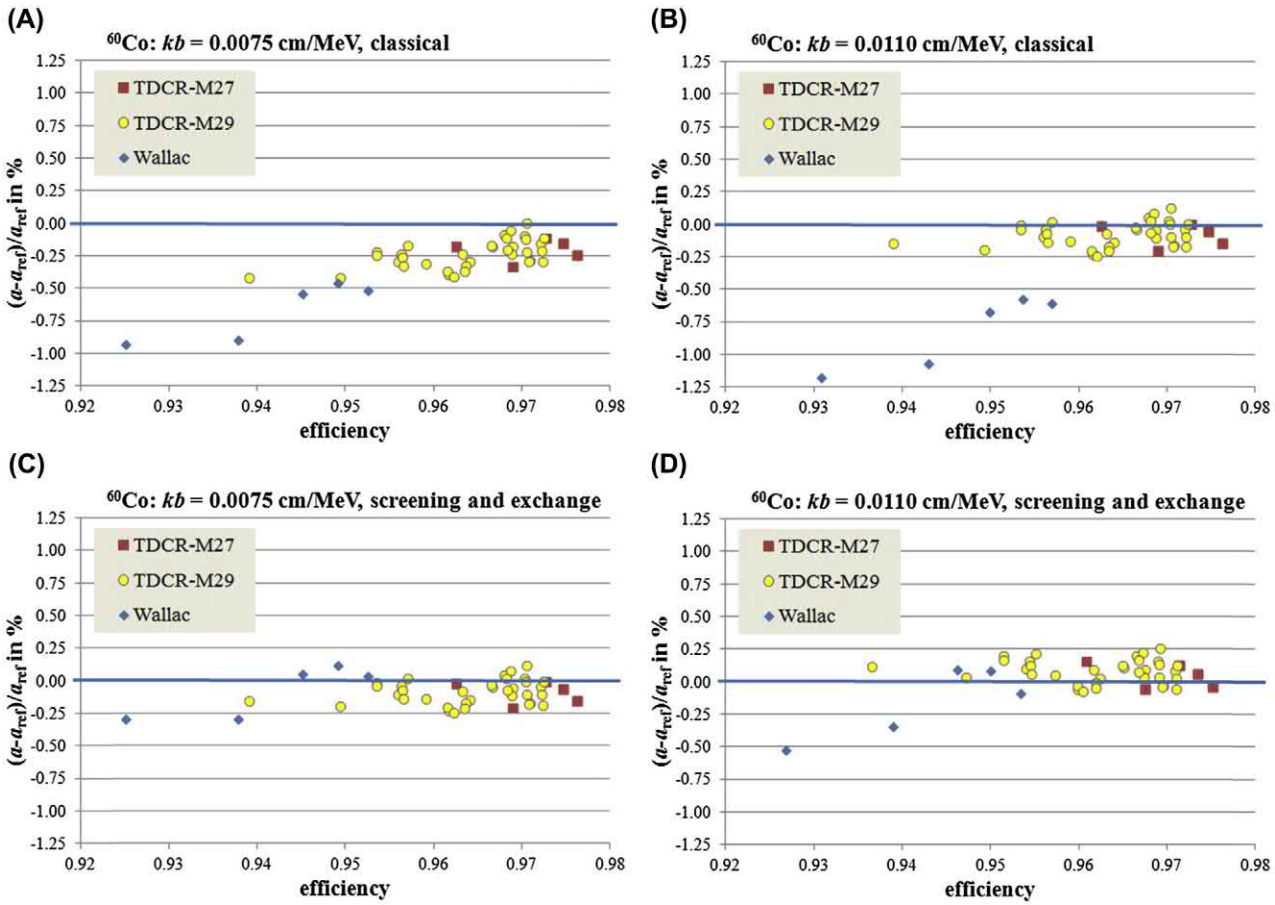

FIGURE 7.8 Relative deviation between the activity concentrations determined from individual ^{60}Co LS samples and a reference value. The reference value (a = 143.571 kBq (G^{-1}) was determined as the weighted mean of the two coincidence counting methods and is represented by the horizontal line at 0. The LS data were analyzed with the following configurations: (A) classical beta spectrum and kB = 0.0075 cm MeV^{-1}, (B) classical beta spectrum and kB = 0.0110 cm MeV^{-1}, (C) beta spectrum taking atomic exchange effect and screening correction into account and kB = 0.0075 cm MeV^{-1}, and (D) beta spectrum as in (C) and kB = 0.0110 cm MeV^{-1}. *From Kossert et al. (2008), reprinted with permission of Elsevier Science © 2008.*

and Zimmerman, 1996). Calorimeters have been used in different applications to obtain nuclear parameters including the following: the measurement of ^{3}H half-life (Jenks et al., 1950), ^{14}C (Jenks and Sweeton, 1952), ^{210}Po (Eichelberger et al., 1954), ^{147}Pm (Wheelwright et al., 1965), and ^{226}Ra (Holden, 1990); the measurement of ^{239}Pu alpha energy (Stout and Jones, 1947), Average energies in the beta decay of ^{3}H (Jenks and Sweeton, 1952; Pillinger et al., 1961), ^{14}C (Jenks and Sweeton, 1952), and ^{147}Pm (Wheelwright et al., 1965); the measurement of the degree of nuclear fuel burned (Krillovich et al., 1976; Hofmann and Wertenbach, 1973); the analysis of tritium in nuclear materials for military use (Meniere and Ganivet, 1972) and fusion technology (Anderson, 1992). Recently, calorimetry has been used to establish standards for brachytherapy in the GBq range (Collé and Zimmerman, 2001, 2011; Collé, 2002; Collé et al., 1999).

Ramthun (1973) clearly described three basic forms of the calorimeter: heat flow, isothermal, and adiabatic. Although the methods described are idealized and most of today's calorimeters incorporate more than one of these basic forms, the classification is very educational. Fig. 7.9 is taken from Ramthun (1973).

The flow of heat between two bodies at different temperatures T_c and T_e is given by the expression:

$$\frac{dQ}{dt} = -k(T_c - T_e) \tag{7.101}$$

In the case of calorimeters, T_c and T_e are the calorimeter and the environment temperatures and k depends on the different shape of surface and environment. In general, this magnitude must remain constant in a calorimeter. In the adiabatic calorimeter, kdQ/dt must be equal to zero. Since no material satisfies this condition, T_c and T_e must be equal.

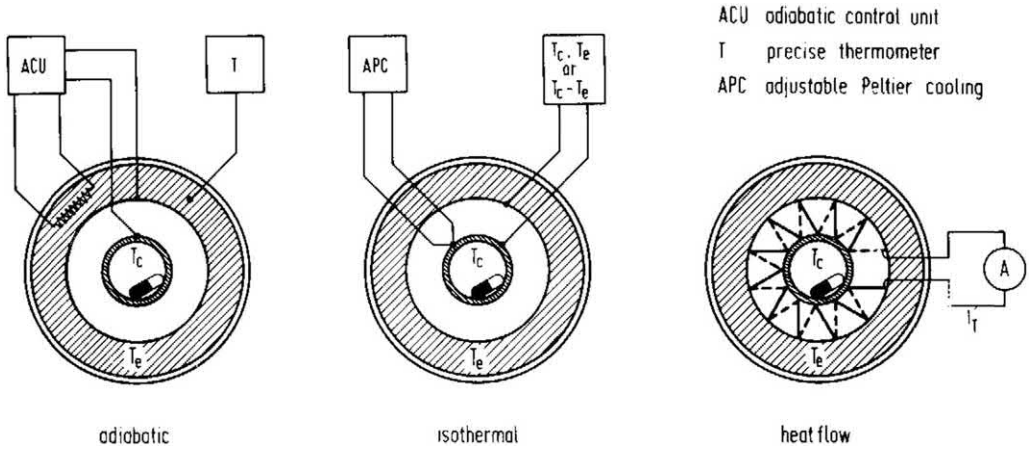

FIGURE 7.9 Principle types of calorimeters. *From Ramthun (1973), reprinted with permission of Elsevier Science © 1973.*

In this case, the calorimeter temperature must rise linearly with time t according to the expression:

$$T_c(t) = T_c(0) + \frac{Pt}{C} \tag{7.102}$$

in which heat power P remains constant. In this expression, C is the heat capacity that must be known to calculate the slope:

$$\frac{dT_c}{dy} = \frac{P}{C} \tag{7.103}$$

The isothermal calorimeter is represented by the Bunsen ice-calorimeter or the Peltier compensation calorimeter. In general, these calorimeters are rather semi-isothermal or near-isothermal. The temperature T_e of the jacked surrounding remains constant. When a heat source is inserted into the calorimeter, the temperature rises to a constant value. The heat source power is obtained from this temperature difference. The constant is determined by calibration with an electrical heater. When the time constant $\tau = k/C$ is so large that it can not reach steady state within a reasonable time, other methods can be applied to determine power P. If it is possible to cool the calorimeter casing before the measurement, when $T_c = T_e$ temperature and time values can be taken, drawing the tangent to the curve and calculated from the slope, knowing the heat capacity C, the thermal power:

$$P = C\left(\frac{dT}{dt}\right)_{T_c=T_e} \tag{7.104}$$

Another possibility is to calculate the slope of the curve at any point by the expression:

$$P = C\left(\frac{dT}{dt}\right) + k(T_c - T_e) \tag{7.105}$$

Another very ingenious process known as radiobalance is due to Mann (1954). It consists of calculating the power from the Peltier current needed to compensate P. A diagram is shown in Fig. 7.10 which shows a schematic device of this radiobalance with which the standards of radium and tritium were measured for years.

Calorimetry possibilities have not been fully implemented by most laboratories. There is a wide field of calibration samples of very high activity in which calorimetry is not replaceable by any other method of measurement. In the future, fusion reactors due to the use of very large quantities of tritium, calorimetry will play a major role in the standardization of intense sources of this radionuclide.

In the field of medical applications, calorimetry has progressed considerably in recent years. In the US, calorimetry has been applied to the determination of absorbed

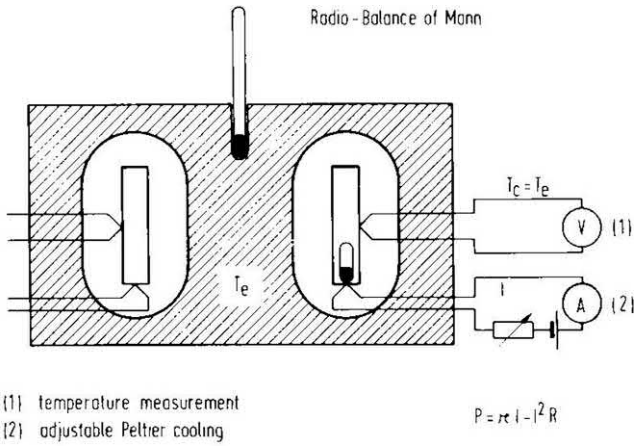

FIGURE 7.10 Schematic diagram of the radio-balance of Mann (NBS). *From Ramthun (1973), reprinted with permission of Elsevier Science © 1973.*

dose in the standard of water for ^{60}Co, which is the basis of calibration of linear accelerators for medical use. Measurements are performed in a water calorimeter developed by Domen (1980) at the National Bureau of Standards (now NIST). The latest medical application is the treatment of prostate cancer using brachytherapy. In the US, it is estimated that approximately 220,000 men are diagnosed with prostate cancer every year. Brachytherapy for prostate cancer involves the implantation of ^{125}I or ^{103}Pd sources for about a year. The sources, in general, are cylinders 4 mm in length and 0.8 mm in diameter, encapsulated in Ti. One of the main keys to the treatment's success is accurate determination of source activity. Stump et al. (2005) described the design, construction, and characterization of a cryogenic calorimeter operating at 8 K specifically designed to allow an absolute standardization of the power deposited by this type of brachytherapy source.

2. Cryogenic calorimeter

A calorimeter or bolometer has three parts: absorber or thermal mass that contains the event or incident power absorbed and thermalized energy, a fully matched thermostat measuring the increase of temperature of the absorbent, and a thermally weak link to a heat sink that measures the absorber's temperature increments and a link that takes absorbent temperature to the established value, in the absence of a signal. The absorber is characterized by its heat capacity C, the thermal link by its conductivity G, and the heat sink by its temperature T_0.

The same configuration can be used to measure stationary input power P, with $\Delta P = P/G$. In this case the device is usually called a bolometer. These detectors have been used for many years to measure infrared radiation and the theory is well developed.

In the last 10 years, cryogenic calorimeters have been considerably developed and have some promising outstanding features: high resolution, nearly 100% efficiency, and a low energy detection threshold. The most recent applications are in alpha spectrometry (Leblanc et al., 2006; Ranitzsch et al., 2011), methods for absolute measurement of activity (Fig. 7.11) (Loidl et al., 2004, 2008), determination of form factors in beta decay (Loidl et al., 2010), determination of atomic and nuclear data of ^{55}Fe (Loidl et al., 2006), and absolute measurement of samples of ^{55}Fe and its spectrum Fig. 7.12 (Loidl et al., 2004; Loidl et al., 2008; Leblanc et al., 1998, 2002).

To date, the calorimeters that have been applied most to radioactive measurements are the Metallic Magnetic Calorimeter (MMC) operating at temperatures below 100 mK (Fleischman et al., 2003, 2004; Enss et al., 2000; Lausberg, 2008). These detectors consist of a gold absorber attached by ultrasonic welding to a magnetic temperature sensor. The sensor is a small piece of metal doped with a small

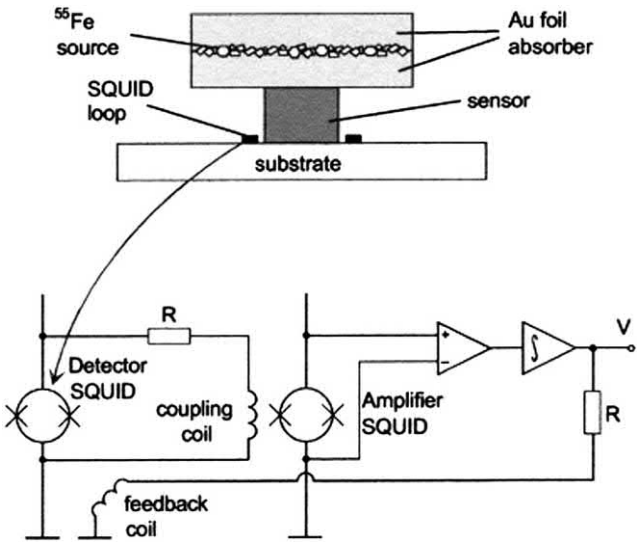

FIGURE 7.11 Schematic cross-sectional view of the detector used in the present work, the magnetic sensor is placed inside the loop of the detector SQUID. (2004), reprinted with permission of Elsevier Science © 2004.*

concentration of paramagnetic ions. The sensor can be a gold disc 50 μm in diameter and a thickness of 25 μm doped with 900 ppm (mass) of Er^{3+}. When the sensor is exposed to a magnetic field, it presents a magnetic moment the magnitude of which varies strongly with temperature.

The energy deposited by a particle or a photon interacts with the absorbing metal and is thermalized. Thermal equilibrium is rapidly established between the absorber and

the sensor due to metal contact. With the Au:Er sensor, energy transfer from the conduction electron to the spins of the Er ions leads to variation in the sensor's magnetic moment. Thermalization time of the electron system and its coupling to the spin system is less than 1 μs for temperatures between 25 and 50 mK. The thermal relaxation time of the detector is several milliseconds, depending on the strength of its coupling to the heat bath.

SQUIDs (Superconducting Quantum Interference Devices) are well adapted for reading magnetic calorimeters. The sensor is placed directly in a loop of a DC-SQUID for optimal coupling of the magnetic flux of the SQUID sensor. The best noise reduction was obtained using a second SQUID as a first stage of amplification to the signal of the SQUID detector.

A SQUID is a device that converts the magnetic flux in tension; made by thin films, which should be well matched to measure small changes in the magnetic moment of the MMC thermometer. After the interaction of each particle, the detector returns to its initial temperature via a connection to a heat bath. Therefore, the detector does not integrate incident power but determines the energy of each particle individually. The pulse shape of the individual signals can be approximated by a first order exponential with a rise time of one to a few microseconds, essentially due to the heat diffusion time within the detector and an exponential decrease, of around 1 millisecond, which corresponds to the detector's return to its equilibrium temperature.

The temperature increase is inversely proportional to the heat capacity of the detector, which decreases with temperature. Therefore, at very low temperatures the amplitude of the signal is relatively large, while the thermal noise is very small. Metallic magnetic calorimeters operate at temperatures below 50 mK, giving a high signal to noise ratio.

IV. Relative methods

A. Calibration methods based on gamma ray spectrometry

The gamma spectrometry technique is often used for the qualitative and quantitative analysis of gamma emitting radionuclides (Helmer et al., 1994; Noguchi et al., 1981, Debertin and Helmer, 1988; Helmer et al., 1994, 1995; Gilmore, 2008). Many radionuclides undergo gamma deexcitation after beta or alpha decay. On the other hand, detector manufacture has improved considerably; first came the scintillation detectors that led to the construction of large volume and highly efficient detectors, and they were followed by the semiconductor detectors that generate high-resolution spectra.

Activity determination of a sample by gamma spectrometry is based on the efficiency curve of the full-energy peak as a function of energy. In practice, this efficiency curve can be obtained experimentally using a calibrated set of samples or a multigamma sample. In the first case, one attempts to use radionuclides with single spectra and half-lives of more than 30 days. The most used are ^{22}Na, ^{54}Mn, ^{60}Co, ^{85}Sr, ^{88}Y, ^{137}Cs, ^{139}Ce, and ^{203}Hg. The most used multigamma samples are ^{152}Eu, ^{226}Ra, and ^{56}Co. In this case, we must know the intensities of different gamma lines with reasonable accuracy (Gehrke et al., 1977; Helmer et al., 2003, 2004) to obtain an accurate calibration curve. The US National Institute for Standards and Technology (NIST) issues a mixture of ^{125}Sb, ^{154}Eu, and ^{155}Eu (Coursey et al., 1982), which covers the energy range from 27 to 1274 keV. The German Physikalisch-Technische Bundesanstalt (PTB) has a sample mixture of eight nuclides: ^{7}Be, ^{54}Mn, ^{57}Co, ^{65}Zn, ^{88}Y, ^{133}Ba, ^{137}Cs, and ^{139}Ce.

1. Description of the general method

Although the efficiency curve initially refers to the efficiency of the full-energy peak or peak efficiency, the total efficiency, defined as the ratio of the number of registered counts on the spectrum and the number of photons emitted by the source in the same unit of time, is also important both for obtaining the peak efficiency curve and for determining the activity of the sample from the efficiency curve.

Total efficiency can be obtained by calculation and experimentally. The photons emitted in a specific element of solid angle $d\Omega$ see a thickness x of the material depending on the angle of emission. The probability of an interaction along a pathway x is $1 - e^{-\mu x}$, where μ is an attenuation coefficient, dependent of the energy. The expression of the total efficiency is:

$$\varepsilon_t = \frac{1}{4\pi}\int (1 - e^{-\mu x}) d\Omega \tag{7.106}$$

Integration is carried out on the solid angle subtended from the source by the detector. Vergors et al. (1958) gave the equation for a cylindrical detector with radius R and height t when the source is a point located on the cylinder axis at a distance d.

$$\varepsilon_t = \frac{1}{2}\int_0^{\theta_1}\left[1 - \exp\left(-\frac{\mu t}{\cos\theta}\right)\right]\sin\theta d\theta$$
$$+\frac{1}{2}\int_{\theta_1}^{\theta_2}\left[1 - \exp\left(-\frac{\mu R}{\sin\theta} + \frac{\mu d}{\cos\theta}\right)\right]\sin\theta d\theta \tag{7.107}$$

where

$$\theta_1 = \tan^{-1}\left[\frac{R}{d+t}\right] \tag{7.108}$$

$$\theta_2 = \tan^{-1}\left[\frac{R}{t}\right]$$

where θ_1 is the maximum angle at which a direct photon can pass through the detector's output base. The angles between θ_1 and θ_2 correspond to photons entering through the detector face and leaving through the lateral surface of the cylinder. The integral has to be calculated by numerical integration. Vergors et al. (1958) also deduced the corresponding expressions for sources in the form of discs centered on the cylinder axis detector.

Germanium coaxial detectors have a nonsensitive radiation core that reduces total efficiency. Griffiths (1971) and Atwater (1972) extended the above equation to take this core into account. However, when the total efficiency correction is applied to the correction of sum events, the above expression does not give satisfactory results.

The way to obtain total efficiency with greater precision is to use an experimental method. In this case, one must take into account the photons scattered by the materials surrounding the detector. Radionuclides that are considered suitable for their monoenergetic nature are: ^{241}Am (59.5 keV), ^{109}Cd (88.0 keV), ^{139}Ce (165.9 keV), ^{51}Cr (320.1 keV), ^{7}Be (477.6 keV), ^{85}Sr (514.0 keV), ^{137}Cs (661.7 keV), and ^{54}Mn (834.8 keV). Total efficiency is given by the expression:

$$\varepsilon_t = \frac{N_t}{A_0 p} \tag{7.109}$$

where N_t is the total count rate of the extrapolated spectrum to 0 keV, A_0 is the activity of the sample, and p is the probability of gamma photon emission. For radionuclides emitting two or more close energy photons, p would be the sum of the individual emission probabilities, assigning total efficiency to a mean energy $\overline{E}$. For example, ^{60}Co emits two gamma photons of energy $E_1 = 1173.24$ keV and $E_3 = 1332.50$ keV; the average energy is $\overline{E} = 1253$ keV. Other interesting mean energies are as follows: ^{55}Fe (6.0 keV), ^{93m}Nb (17 keV), ^{125}I (28 keV), and ^{57}Co (124 keV). Total efficiency for higher energy nuclides is obtained from two nuclides with well-separated energies. Total efficiency $\varepsilon_t(E_1)$ for one energy can be interpolated from other measured values. Then we can subtract the respective number of total counts $A_0 p_1 \varepsilon_1(E_1)$ and obtain:

$$\varepsilon_t(E_2) = \frac{N_t - A_0 p_1 \varepsilon_t(E_1)}{A_0 p_2} \tag{7.110}$$

When the source-detector distance is small, the above expression should be modified to take the reduction of N_t due to coincidence summing into account. This effect is discussed later. In the case of radionuclides with high beta energies, we should correct N_t by the contribution of bremsstrahlung from beta particles.

a. Extended sources

So far we have considered point sources, but sources are more often extended. We assume that the ratio of solid angles Ω_A of an extended source and a point source Ω_p can be approximated, in the first order, by the ratio of total efficiencies

$$\frac{\varepsilon_A(d)}{\varepsilon_P(d)} = \frac{\Omega_A(d)}{\Omega_P(d)} \tag{7.111}$$

We assume that the source is circular and centered on the axis of the cylindrical detector. We use $\Omega_P(r,d)$ to denote the solid angle subtended by the detector to a point in the source at a distance r from its center. We can write $\Omega_P(r,d)$ as an integral over the detector area. This integral must be calculated numerically. Instead of a disc, Gardner and Verghese (1971) used a polygon for which analytical expression can be obtained. Integration on the surface of the source gives:

$$\Omega_A(d) = \frac{2}{R_S^2}\int_0^{R_S} \Omega_P(R,d) r dr \tag{7.112}$$

Gardner and Verghese (1971) calculate this integral using numerical integration by Simpson's method and generating a table based on values of $\Omega_a(d)$ as a function of R_S/d and R_D/d where R_D is the radius of the detector. An approximation for the series is:

$$\Omega_A(d) = \frac{1}{2}\left[1 - \left(1 + \frac{R_D^2}{d^2}\right)^{-1/2} - \frac{3}{8}\frac{R_S^2}{d^4}\left(1 + \frac{R_D^2}{d^2}\right)^{-5/2}\right] \tag{7.113}$$

which converges successfully for $R_S/d < 0.5$. One way to solve the problem experimentally is based on first measuring a centered point source, that is, with $r = 0$, and then measuring the sample for different r values. The curves obtained for different energies can be described by the equation:

$$\varepsilon_P(r,d) = \varepsilon_P(0,d) e^{-c(d) r^2} \tag{7.114}$$

where parameter $c(d)$ depends on the energy and distance (Kushelevski and Alfassi, 1975). We can also write:

$$\varepsilon_P(r,d) = \varepsilon_P(0,d)\frac{d^2}{r^2 + d^2} \tag{7.115}$$

where $d = d_S + d_C + d_e(E)$ is the effective distance from the center of the sample, d_S is the distance from source-to-detector endcap, d_C is the distance from the endcap of the detector to the surface, d_e is the distance to the effective interaction depth, $d_e(E)$ is linked to the linear attenuation coefficient of the material $\mu(E)$ and is expected to be around $1/\mu(E)$. The best option is to consider $d_e(E)$ as a parameter to be determined. Notea (1971, Clisler et al. (1971), Cline (1979), Gunnink and Niday (1972, 1976)

introduced an effective interaction radius $r(E)$ so that the effective distance was

$$d = \left[(d_C + d_S + d_e(E))^2 + r_e^2(E)\right]^{1/2} \tag{7.116}$$

The efficiency of large circular sources, with uniformly distributed activity, is given by the expression:

$$\varepsilon_A(d) = \frac{2}{R_S^2}\int_0^{R_S} \varepsilon_P(r,d) r dr \tag{7.117}$$

which, as a function of $\varepsilon_P(0,d)$, is:

$$\varepsilon_A(d) = \varepsilon_P(0,d)\frac{d^2}{R_S^2}\log\left(1+\frac{R_S^2}{d^2}\right) \tag{7.118}$$

Janssen and Waltz (1987) compared the results obtained with the above equation with experimental values for circular sources with uniformly distributed activity and radii of up to 7 cm. The sources were placed directly on the detector surface with their center in the detector axis. The experimental and calculated results differed by less than 5%.

The correlation in Ge detectors has been studied by McCallum and Coote (1975).

2. Heath method

The Heath (1964) method was a very popular gamma-emitting radionuclide procedure in the 1960s−1970s. Its popularity was due, first, to its easy implementation and management and, secondly, because it enabled the calibration of a wide range of radionuclides. Its use in radionuclide production facilities was widespread. We must remember that the popularity of NaI(Tl) detectors was then at its peak.

This is a method that combines a theoretical calculation of total counting efficiency and an experimental determination of the peak-to-total ratio. The theoretical calculation method can be based on an analytical calculation of numerical integration or a Monte Carlo method. The uncertainties achieved with this method were 3%−5%. At that time the analytical method gave better results than Monte Carlo, but as computer speed grew, the Monte Carlo method became more attractive, because it obtained sufficient accuracy, increasing the number of events, and could be applied to solve more complex problems from a geometric perspective.

The key point for calculations is the computation of solid angles for different geometries. In this regard, there has been considerable activity both in the analytical calculation and in the use of the Monte Carlo method. The most interesting references, using the analytical method for calculating solid angles, are the following: Abbas (2001, 2006), Aguiar et al. (2006), Aguiar (2008), Belluscio et al. (1974), Brysk (1977), Conway (2010), Cook (1980), Galiano and Rodrigues (2006), Gardner and Carnesale (1969), Gardner and Verghese (1971), Gotoh and Yagi (1971), Green et al. (1974), Haitjema (1987), Li and Uren (1997), Obložinsky and Ribanský (1971), Pommé (2004, 2007), Pommé et al. (2003), Prata (2003, 2004), Sibbens et al. (2003), Timus et al. (2007), Tryka (1997), Verghese et al. (1972), Williams et al. (1968), Wu Zhihua and Wei Xinmiao (1992). The most interesting references of the Monte Carlo method for calculating the solid angle in very different situations, are the following: Williams (1966), Cox (1969), Carchon et al. (1975), Wielopolski (1977), Stavroulaki and Kaplanis (1979), Kaplanis (1982), Nicolaou et al. (1986), and Hosseini-Ashrafi and Spyrou (1992).

a. Description of the method

Counting efficiency is obtained from total efficiency, which is in turn obtained from intrinsic efficiency. Thus, we first describe the theoretical calculation of intrinsic efficiency. Intrinsic efficiency is defined as the ratio between the number of counted photons and the emitted photons reaching the detector, namely:

$$\text{Intrinsic efficiency} = \frac{\text{Number of counted photons}}{\text{Number of photons entered in detector}}$$

While total counting efficiency is:

$$\text{Total efficiency} = \frac{\text{Number of counted photons}}{\text{Number of photons emitted by the source}}$$

The analytical expression for calculating the intrinsic efficiency of an isotropic point source located centrally to the d distance of a NaI(Tl) cylindrical detector of length L and radius R is:

$$\varepsilon_{\text{int}} = \frac{1}{(1-\cos\theta_0)}\left\{\int_0^{\theta_1} 1-\exp\left(-\frac{\mu(E)L}{\cos\theta}\right)\sin\theta d\theta + \int_{\theta_1}^{\theta_0}\left[1-\exp\left(-\frac{\mu(E)L}{\sin\theta}-\frac{\mu(E)d}{\cos\theta}\right)\sin\theta d\theta\right]\right\} \tag{7.119}$$

where

$$\tan\theta_0 = \frac{R}{d} \quad \tan\theta_1 = \frac{R}{d+L} \tag{7.120}$$

$\mu(E)$ is the attenuation coefficient of the NaI(Tl) detector to photons with E energy.

Total efficiency is calculated with a similar expression:

$$\varepsilon_{total} = \frac{1}{2}\left\{ \int_0^{\theta_1} 1 - \exp\left(-\frac{\mu(E)L}{\cos\theta}\right)\sin\theta d\theta \right.$$

$$\left. + \int_{\theta_1}^{\theta_0}\left[1 - \exp\left(-\frac{\mu(E)L}{\sin\theta} - \frac{\mu(E)d}{\cos\theta}\right)\sin\theta d\theta\right]\right\} \quad (7.121)$$

Vergos et al. (1958) carried out calculations for 32 detectors of different sizes, for detector-source distance values of 0−100 cm and photon energies from 10 keV to 10 MeV. They calculated absolute detection efficiency, defined as the probability that a photon emitted by the source interacts with the detector with the loss of a finite amount of energy.

The other parameter for a monoenergetic gamma emitter is the peak-to-total ratio, which is obtained experimentally and defined by the expression:

$$P = \frac{N_P}{N_T} = \frac{\varepsilon_P}{\varepsilon_T} \quad (7.122)$$

where N_P is the count rate at the peak, N_T is the total count rate in the total spectrum, ε_P is the photoelectric efficiency or, more correctly, full-energy peak efficiency, and ε_T is the total efficiency of the gamma spectrum. Heath (1964) used the count rates obtained directly from the gamma spectra for a number of radionuclides: ^{47}Sc, ^{139}Ce, ^{51}Cr, ^{7}Be, ^{85}Sr, ^{137}Cs, ^{22}Na, ^{54}Mn, ^{65}Zn, ^{60}Co, ^{29}Al, ^{24}Na, and ^{37}S. The use of gamma spectra enables us to work with nonmonoenegéticos nuclides as long as we are able to separate the spectra from the peaks and their respective Compton continuums. Heath (1964) describes how to perform these operations and obtain the peak area of total absorption with excellent precision.

Another way to obtain the peak-to-total ratio curve, $P(E)$, is by using standardized monoenergetic gamma radionuclides and experimentally obtaining the efficiencies ε_P and ε_T.

Both total efficiency and the peak-to-total ratio are a function of the energy and distance between source and detector. Heath presented curves of the efficiency values for different energies between 25 keV and 4 MeV and distances between 0 and 50 cm. The peak-to-total ratio curve varies very little with the distance between source and detector. The curves for distances of 3 and 10 cm coincide at low energy ($E_\gamma < 350$ keV) and high energy ($E_\gamma >$ 1300keV) and the greatest divergence of both curves (discrepancy) is 2% for 835 keV, less than the method's uncertainty.

b. Precautions

Application of Heath's method is very simple. The critical point is to know the source-detector distance. This requires placing the sample into a sample holder with well-defined distance from the detector and also to know the distance from the NaI(Tl) crystal to the outside of the capsule in which it is contained. This distance is obtained by making detector gammagraphy. The distance usually varies from 3 to 10 mm.

Another important point is how to obtain the area of the full-energy peaks. Heath (1964) developed several programs to accurately calculate the area of these peaks.

3. Semi-empirical methods

Semi-empirical methods using analytical expressions and numerical integration to calculate full-energy peak counting efficiencies were very popular at the onset of gamma models. They enabled rapid calculation of total efficiency, while Monte Carlo methods require more computational time and less accuracy. However, when computer speed and storage capacity increased, the Monte Carlo method prevailed.

In the case of point sources, we must mention the work of Abbas (2001, 2006), and Peterman et al. (1972), which follow analytic equations for calculating full-energy peak efficiency for both NaI(Tl) and HPGe detectors. They determine photon attenuation by calculating the attenuation along the path of the photon in the source. They compared experimental results with those calculated by this method and concluded that discrepancies are less than 2.5%.

The real advance in the application of this and the Monte Carlo method was the work of Moens et al. (1981), by introducing the efficiency transfer factor. It is interesting, so we summarize the arguments. To obtain a full-energy peak count, a gamma photon emitted by the source must meet the following three conditions:

1. It must interact with the active area of the detector without undergoing energy degradation in the source or adjacent materials.
2. It must not interact with the detector material in any way other than coherent scattering.
3. The interacting photon should deposit all its energy in the detector material, giving rise to one full-energy peak count.

The direct calculation of full-energy peak efficiency requires very complex calculations. However, total efficiency is easy to calculate. If $\overline{\Omega}$ is the effective solid angle for which conditions (1) and (2) are met, total efficiency is

$$\varepsilon_t = \frac{\overline{\Omega}}{4\pi} \tag{7.123}$$

where ε_t is the total efficiency related to ε_P, the efficiency of the full-energy peak, which consists of different contributions:

$$\varepsilon_P = \alpha_P^f + \alpha_P^c + \alpha_P^P \tag{7.124}$$

where ε_P^f, ε_P^c, ε_P^P are the fractions of ε_P for the photoelectric effect, multiple Compton interactions, and pair production, respectively.

Similarly, we define an effective solid angle for each of the above quantities $\overline{\Omega}_f$, $\overline{\Omega}_c$, $\overline{\Omega}_P$, describing the probability that the emitted gamma photon interacts by the photoelectric effect, Compton interaction or pair production, respectively. Thus we can write:

$$\varepsilon_P = \frac{1}{4\pi}\left(\overline{\Omega}_f + \overline{\Omega}_c\kappa + \overline{\Omega}_P\nu\right) \tag{7.125}$$

where κ and ν take into account the fact that only a fraction of the Compton and pair interactions leads to one full-energy peak count.

It can be shown that:

$$\frac{\overline{\Omega}}{\mu_t} = \frac{\overline{\Omega}_f}{\mu_f} = \frac{\overline{\Omega}_c}{\mu_c} = \frac{\overline{\Omega}_P}{\mu_P} \tag{7.126}$$

where μ_t is the linear coefficient of total absorption of the detector material for energy E_γ; μ_f, μ_c, μ_P are the absorption coefficients for photoelectric effect, Compton interaction, and pair production, respectively. So we have:

$$\varepsilon_P = \frac{1}{4\pi}\left(\frac{\mu_f + \mu_c\kappa + \mu_P\nu}{\mu_f}\right)\overline{\Omega} = \frac{1}{4\pi}\frac{P}{T}\overline{\Omega} = \frac{P}{T}\varepsilon_t \tag{7.127}$$

where P/T is the virtual peak-to-total ratio for the bare detector, without any interaction with the surrounding material.

When we know ε_t, we have to calculate the P/T ratio. The values of κ and ν are unknown and can only be approximated using the Monte Carlo method. The P/T ratio cannot be obtained experimentally. The usual peak-to-total ratio used in the Heath method does not apply here. The total area of the gamma spectrum contributes, with degraded energy, the gamma rays that have experienced incoherent scattering in the materials surrounding the detector. The experimental peak-to-total ratio is therefore dependent on the sample and the counting efficiency. It is assumed that the "virtual" P/T ratio is independent of the sample, the geometry and the counting rate. It is therefore an intrinsic characteristic of the detector used.

The semi-empirical determination of the curve ε_P for a sample and a given geometry is obtained as follows:

1. Determination of the experimental curve ε_P in terms of E_γ for point sources positioned for long distance (denoted as the subindex *ref*) from the detector;
2. Calculation of $\overline{\Omega}$ for a reference experimental setup and also for a given detector-source distance. In this way, we can construct a curve ε_P as a function of E_γ.
3. The efficiency of one of the configurations considered (x) and for one energy is calculated by the equation:

$$\varepsilon_{P,x} = \varepsilon_{P,ref}\frac{\overline{\Omega}_x}{\overline{\Omega}_{ref}} \tag{7.128}$$

The only hypothesis applied is the constancy of the virtual peak-to-total ratio. Experimental results have shown that this assumption is justified. This principle has been successfully used by Moens et al. (1981), Moens and Hoste (1983), Mihaljević et al. (1993), Wang et al. (1993), Wang et al. (1995), Wang et al. (1997), Piton et al. (2000), Vidmar (2005).

Knowledge of the total efficiency and the peak-to-total ratio is not sufficient, in the case of extended sources, to calculate the correction factors due to coincidence summing. If the sample is viewed as a collection of point sources embedded in the matrix, the variation in the efficiency of these sources in the volume of the source must also be considered, as noted by Debertin and Schötzig (1979) and Korun and Martincic (1995). In other words, correction factors cannot be calculated as if the sample were a point source.

Blaauw and Gelsema (2003) and Gelsema (2001) developed a method to solve the problem. They introduced the concept of "LS curve": (linear-to-square curve) or "third curve" in gamma spectrometry. Blaauw and Gelsema (2003) obtained the LS curve experimentally using standardized sources. Subsequently, Vidmar and Korum (2006) and Vidmar et al. (2011) used a direct calculation method to obtain the LS curve.

4. Monte Carlo technique

The application of the Monte Carlo technique to calculate the full-energy peak efficiency applied to gamma ray detectors and X-ray has a long history. The first studies were by Wainio and Knoll (1966) and De Castro Faria and Levesque (1967), who applied the Monte Carlo technique to germanium and silicon detectors. Other computation codes were developed, to be applied to coaxial detectors, by Aubin et al. (1969), Lal and Iyengar (1970), Gaggero (1971), Grosswendt and Waibel (1975). The new generation of calculation codes added attenuation at the source and more complex geometries as well as detectors. Examples of these codes are: Nakamura and Suzuki (1975), Birattari and Salomone (1980), Rieppo (1981), Nakamura and Suzuki (1983), Cesana and Terranian (1989), Sima (1990), Herold and Kouzes (1991), Laborie et al. (2000), Sima and Arnold (1996). Comparison of experimental and computed calibrations gave discrepancies of 5%−10%.

In these preliminary calculations, there are four sources of uncertainty. There was a statistical limitation due to the

large number of photons that are needed and the relatively slow calculation capacity of computers at that time. A second limitation was the knowledge of the interaction probability of electrons and photons and angular distribution. Thirdly, the information about the physical dimensions of the detector and its position was inadequate. Finally, the fourth limitation was that charge collection was not uniform throughout the detector volume due to imperfections in the crystal and nonuniform electric field. Given these limitations, an accuracy of 5%−10% for the results of the Monte Carlo method was very reasonable.

Some investigators developed the Monte Carlo method and applied it to several detectors to compare and generalize the results: Liye et al. (2006), Keyser (2004).

There are two ways to use the Monte Carlo method for the calculation of efficiencies. The first is simply to scale the Monte Carlo results to minimize the differences between calculated and measured efficiencies. The Monte Carlo method thus becomes an effective method of interpolation for a limited range of energies. The second method is to use the initial Monte Carlo results to adjust the physical parameters of the detector, producing a better agreement with the efficiency measurements and thus enabling more accurate interpolation for a wider range of energies. Examples of this second procedure were found in the following: Ashrafi et al. (1999), Vidmar and Likar (2002). Using the GEANT 3.21 program (Brun et al., 1987) with the values of the constructor for the radius of the crystal, dead layer thickness, central hole radius, distance between the crystal and the detector housing, they minimize the weighted sum of the squares of the differences in measured and calculated efficiencies. Hardy et al. (2002), Helmer et al. (2003), Huy et al. (2007), Lyie et al. (2006), Boson et al. (2008), Budja et al. (2009) fit two parameters: front-dead-layer value and dead-layer thickness.

There are also methods that combine semi-empirical calculations with Monte Carlo simulation: Gunnink and Nidal (1976), Gunnink (1990), Sima (1996), Jehouani et al. (2000), and Agrafiotis et al. (2011). They combine the semi-empirical method to derive the effective volume of a given energy before using the Monte Carlo simulation to calculate geometric correction factors for the transfer. The method used by Bernasconi and Capote (1994) is based on the use of a Monte Carlo simulation to quantify the difference between two geometries and determine how these differences influence absolute efficiency (Abbas, 2001, 2006).

There have been many studies aimed at improving and optimizing the data provided by manufacturers of semiconductor detectors: Birattary and Salomone (1980), Mohanty et al. (2008), Luis et al. (2010), Padilla Cabal et al. (2010). Hernandez and El-Daoushy (2003) also considered the case of incomplete charge collection.

New procedures to obtain detection efficiency with good accuracy for point samples have been developed: Ludington and Helmer (2000), Ewa et al. (2001), Hardy et al. (2002), Helmer et al. (2004), Dryak and Kovar (2006), Peyres and García-Toraño (2007), and Vidmar and Kanicsh (2010).

For years, attempts have been made to introduce the decay scheme to calculate the contributions of individual gamma photons and also correct for coincidence summing: Debertin and Schötzig (1979), Morel et al. (1983), Schima and Hopes (1983), Decombaz et al. (1992), Blaauw (1993) Laedermann and Décombaz (2000), Berlizov and Tryshyn (2005), Nedjadi et al. (2007), Novcovic et al. (2007b), Sima and Arnold (2008), Vidmar and Kanisch (2010, 2012). An interesting package to be included in such codes is NUCLËIDE by Bé et al. (2004). This package is already included in the ETNA code, Lepy et al. (2006).

In the case of low activity samples that require a high sample volume and the best counting efficiency, some computer codes have been developed for measuring Marinelli containers: Lippert (1983), Debertin and Jianping (1989), Rodenas et al. (2000, 2003, 2007), Jurado Vargas et al. (2002), and Blaauw and Gelsema (2003).

Calculation codes can be classified into two types (Vidmar et al., 2010a): general and specialized. Among the specialized, the most used are: ANGLE (Jovanovic et al., 1997, 2010); DETEFF 4.2 (Cornejo and Jurado Vargas 2008); EFFTRAN (Vidmar 2005); ETNA (Piton et al., 2000; Lepy et al., 2006; Radu et al., 2009); GAMEFF (Bernaconi and Capote, 1994); GESPECOR 4.2 (Sima and Arnold, 2002; Arnold and Sima, 2004a, 2004b); MAR (Bertolo et al., 1992); EGSnrc (Kawrakow and Rogers, 2006); ESOL (Wang et al., 1993, 1995); TRUECOINC (Sudár, 2002); and SWELL (Wang et al., 1999). The most used general codes are: EGS4 (Nelson et al., 1985a); GEANT (Brun et al., 1987); GEANT-4 (Agostinelli et al., 2003; Hurtado et al., 2004, Nemes et al. (2016)); MCNP (Briesmeister, 2000; X-5 Monte Carlo Team, 2003, Marques Salgado et al., 2006; Mowlavi et al., 2005; McKinney et al., 2006; and Huy, 2010, 2011), PENELOPE (Salvat et al., 2003, 2006; 2008; Jurado Vargas and Guerra; 2006; Karfopoulos and Anagnostakis, 2010); EXTSANGLE (Mihaljević et al., 1993); and TRIPOLI-4 (Both et al., 2003).

International comparisons are made of different calculation codes. Lépy et al. (2001), in EUROMET Project 428, examined the results of the transfer of efficiencies for a Ge detector when efficiencies for point sources are known. The main conclusion is that the discrepancies between calculated and experimental results can reach 10%, although some discrepancies are of the order of 2−3%. Moreover, it was concluded that data on the geometry of the detector supplied by manufacturers are insufficient for accurate efficiency estimates. A comparison organized by the IAEA to review the codes applied in the measurement of low activities has also been carried out (Los Arcos et al., 2005).

Vidmar et al. (2008) made a comparison exercise of Monte Carlo codes, used in gamma spectrometry, to calculate full-energy peak and total efficiency. They compare the results of GEANT3 codes (Brun et al., 1987), GEANT4 (Agostinelli et al., 2003), PENELOPE (Salvat et al., 2003, 2006, 2008), MCNPX (McKinney et al., 2006), GESPECOR (Sima et al., 2001), EGS4 (Nelson et al., 1985a, b; Kawrakow and Rogers, 2006), TRIPOLI-4 (Both et al., 2003), that revealed striking differences between the results of the different codes. Vidmar et al. (2010a) compared four Monte Carlo codes (GEANT3, PENELOPE, MCNP, and EGS4) and five packages devoted to determining gamma spectrometry efficiency (ANGLE, DETEFF, GESPECOR, ETNA, and EFFTRAN). They calculated the factors for transfer of efficiencies (TE) for well-defined parameters of the detector and the energies typically found in environmental measures. The discrepancies between the results of different codes are below 2%.

Kanisch et al. (2009) compared five procedures for correcting for coincidence summing Andreev et al. (1972), Semkow et al. (1990), Novkovic et al. (2007a, 2007b). Vidmar et al. (2011), presented the EFFTRAN efficiency-transfer code.

Several papers have been published related to volume and environmental samples taking into account matrix effects: De Bruin et al. (1979), Sima (1996), Sima and Dovlet (1997), Vidmar et al. (2010b).

Finally, the same program based on the Monte Carlo method was applied to the analysis of several detectors with different characteristics. Lyie et al. (2006) applied the Monte Carlo method to three HPGe detectors: a coaxial n-type, a p-type coaxial, and four BEGe detectors. The deviations obtained in all cases were below 5%.

B. Measurement of high activity. Ionization chambers

Ionization chambers have been used for the measurement of radioactivity for over a century, and many of the basic studies are more than 50 years old. Ionization chambers can work in pulse or current modes. Here we consider the measures of radioactivity emitting gamma or X-ray by current ionization chambers.

The most extensive, modern, well-documented, and extremely clear summary of this type of ionization chambers, with a complete list of references up to 1997, is the monograph by Schrader (1997). Details of the construction techniques for measuring ion beam current, linearity and saturation, and the current correction are not considered in this section. We recommend this monograph and Chapter 2, Volume 1 of this book. We analyze the measurement techniques and the latest applications. The type of chamber we consider here is known as a reentrant cylindrical chamber, usually working under pressure.

The main features of these chambers are: high efficiency for gamma radiation, stability over time, sensitivity over a wide range of gamma activities, and linearity of response.

Once calibrated, the ionization chamber is used to maintain the unity of activity. This is particularly important for radionuclides with short half-lives, since the chamber can be recalibrated at intervals that are much longer than the specimen's half-life and maintain the value of an activity standard beyond its half-life. For example, the radionuclides used in PET are calibrated using an ionization chamber.

Activity concentration of a standard radioactive solution of a particular radionuclide is deduced from the activities of several sources prepared from the same stock solution and standardized primarily by primary procedures. This radioactive solution is called "standard reference material", since the activity concentration (Bq/g) is known and chemical parameters should remain constant. From this standard solution, we can obtain other standards with the same concentration or we can make dilutions. These liquid samples are stored as aqueous solutions in glass ampoules closed to the flame. The measure of a number of ampoules with the ionization chamber also enables control of the weighing procedures.

Some precautions must be taken into account to achieve the maximum accuracy level of the ionization chamber. Sample chamber geometry must be kept constant to compare the results of the measurements. Solutions without radioactive impurities or with very small, known amounts have to be used. Usually the impurities in the solution must be detected and measured by highly selective measurement systems, for example, Ge detectors. Once we know the rates and the respective calibration factors, a factor to obtain the result in terms of activity has to be applied to the ionization chamber reading.

Chamber and measuring system stability is verified by repeated measurements of a reference source with a long half-life, usually ^{226}Ra in equilibrium with its descendants. The measurements of the sample, background, and reference source are carried out alternately in a cycle that checks the stability of the system and the reproducibility of the measurement conditions. Taking into account the radioactive decay of radionuclides, the ratio of the currents in a given reference time should remain constant for all measurements. Ionization chambers are relatively simple to operate and the checks required are cheap and give results with good reproducibility and accuracy. Ionization chambers with direct activity readings, called radionuclide calibrators, are the instruments most suitable for testing radiopharmaceuticals.

It is helpful to give some definitions and discuss some simple relations, provided that the measurement conditions remain stable during the measurements. The ionization current I of the chamber, from a source with a single radionuclide N is proportional to its activity A:

$$I = \varepsilon_N A \tag{7.129}$$

The factor of proportionality is called the efficiency ε_N of the radionuclide. In the above equation, the measured current I_m should be corrected by the background current I_b, determined in identical conditions as the sample. Therefore, $I = I_m - I_b$. With many current measurement instruments, we can adjust the reading of the instrument R by an internal (or external) instrument setting. This is done by an amplifier instrument. This property can be described by an instrument constant g in the equation above:

$$R = gI = g\varepsilon_N A \tag{7.130}$$

An instrument can be set to show activity, reading $R_N = A$, for a defined radionuclide N, directly in units of Bq or its multiples (kBq, MBq). The adjustment condition requires $g_N\varepsilon_N = 1$ and, therefore:

$$A = R_N = \left(\frac{1}{\varepsilon_N}\right) I \tag{7.131}$$

This technique is usually applied to instruments such as calibrators for the quantitative testing of radiopharmaceuticals. Golas (1998) and Oropesa et al. (2002) measured ^{131}I, ^{201}Tl and ^{99m}Tc. Kossert and Thieme (2007) measured ^{99m}Tc. Sahagia et al. (2002) measured ^{186}Re and ^{188}Re. Tauhata et al. (2008) and Yuan et al. (2006) measured ^{188}Re. Yuan et al. (2008) measured ^{67}Ga. Dos Santos et al. (2004, 2006) implemented a national metrology network of radionuclides used in nuclear medicine. Other authors present the improvements in the calibration of calibrators for nuclear medicine: Paton Walsh et al. (1996) and Oropesa et al. (2008) apply it to brachytherapy sources, Cessna et al. (2008) in the case of ^{18}F in plastic syringe. Colle (2000) assayed intravascular brachytherapy sources. Szörényi et al. (1998) monitored the radionuclides used in nuclear medicine. Colle (2001) calibrated ^{32}P "hot-wall" angioplasty-balloon-catheter sources. Collé et al. (1999) and Collé (2000, 2001, 2002) calibrated radionuclides for brachytherapy. Schrader et al. (2007, 2008) calibrated a radionuclide calibrator. Kumar et al. (2010) calibrated brachytherapy sources. Olšovcová (2010) simulated the activity measurement of ^{131}I, ^{111}In and ^{153}Sm in a calibrator. Razdolescu et al. (2002) and Oropesa et al. (2003) measured ^{60}Co and ^{188}Re. Santos et al. (2009) measured syringes. Schultz et al. (2006) measured nuclear pharmacy and clinics in the US. These instruments have an ionization chamber coupled to a current meter with fixed instrument settings adjusted for each radionuclide that can be measured in the chamber. The settings have been established by measuring activity standards or transferred by the manufacturer from calibrated reference instruments. The most important works on this topic are Zimmerman and Cessna (1999, 2000), Zimmerman et al. (2001a, 2004), and Yuan et al. (2008). Lee et al. (2012) calibrate a KRISS reference ionization chamber for key comparison of ^{99m}Tc measurements.

1. Calibration of ionization chamber radionuclides

Ionization chambers are often used in relative procedures for comparison with activity standards. In many applications it is useful to compare currents:

$$\frac{I_i}{I} = \frac{\varepsilon_{Ni} A_i}{\varepsilon_N A} \tag{7.132}$$

where i is the index that specifies a particular sample. The comparison is made between samples with the same geometry. When we measure under appropriate conditions, the efficiency ratio is equal to one and, therefore, the unknown activity is derived from the activity standard.

In general, the basic equations for the indirect calibration of the ionization chamber for a radionuclide N against a reference source (index r) are:

$$\frac{R}{R_r} = \frac{\varepsilon_N}{\varepsilon_r}\frac{A}{A_r} \tag{7.133}$$

where R and R_r are the instrument readings on the source to be measured and the reference source, respectively, while A and A_r are the respective activity values. The radionuclide activity to be standardized is given by:

$$A = \frac{\varepsilon_r}{\varepsilon_n} A_r \frac{R}{R_r} = \left[\frac{\varepsilon_r}{\varepsilon_n} A_{r0}\right] \exp[-\lambda_r (t_m - t_{r0})] \frac{R}{R_r} = A_e \frac{R}{R_{r0}} \tag{7.134}$$

in which the "equivalent activity" is given by:

$$A_e = \frac{\varepsilon_r A_{r0}}{\varepsilon_N} \tag{7.135}$$

and

$$R_r = R_{r0} \exp[-\lambda_r (t_m - t_{r0})] \tag{7.136}$$

in these expressions, A_{r0} is the source activity reference at time t_{r0}.

The expressions given here refer to samples of pure radionuclides. When the sample contains impurities in small quantities, a different treatment is required. If we denote with the subscript N the components of the main radionuclide and the impurities by subscript k, the response of the ionization chamber is:

$$R = \varepsilon_N A_N + \sum_k \varepsilon_k A_k = \varepsilon_N A_N \left(1 + \sum_k \varepsilon_k A_k / \varepsilon_N A_N\right) \tag{7.137}$$

Activity values A_l $(i = N, k)$ must be corrected by decay each time that we measure R. To calculate A_N from R one must know the values of A_k or A_k/A_N and the respective efficiencies ε_i $(i = N, k)$. The efficiencies ε_i are determined by direct calibration with a standard sample or by calculation by means of the efficiency versus energy curve of the chamber.

The detection of impurities in the sample is usually performed by Ge detectors which identify the impurity and determine its activity. The efficiency of an ionization chamber for a specific radionuclide is given by the sum of the contributions of gamma components:

$$\varepsilon_N = \sum_i p_i(E_i)\varepsilon_i(E_i) \tag{7.138}$$

where $p_i(E_i)$ is the probability of photon emission with energy E_i per decay and $\varepsilon_i(E_i)$ is the efficiency of the ionization chamber for gamma photons with energy E_i.

Simulating the response of the chamber, using the Monte Carlo technique, as a function of energy is of great interest. The code EGS4 (Electron Gamma Shower) (Nelson et al., 1985a, b) was the first step to obtain the calibration curve of an ionization chamber. Suzuki et al. (1998) studied the response of three types of ionization chambers filled with argon or nitrogen. They found an excellent agreement between calculated and experimental results. They also applied the calculation code to evaluate the corrections required in changing the source conditions such as displacement of the position of the source. Gostely and Laedermann (2000) applied the GEANT code (Agostinelli et al., 2003) to obtain the chamber's response in the 40 keV to 2 MeV energy range; the calculations were compared with experimental results in terms of equivalent activity. The chamber used experimentally was of the well type at high pressure IG11 from the twentieth Century, similar to the BIPM SIR. The radionuclides measured were: ^{125}I, ^{133}Ba, ^{109}Cd, ^{57}Co, ^{99m}Tc, ^{123}I, ^{131}I, ^{51}Cr, ^{137}Cs, ^{22}Na, ^{60}Co, and ^{88}Y. Agreement between the experimental and calculated values was excellent. Olsovcová and Havelka (2006) applied the Monte Carlo method to obtain the activity of radiopharmaceuticals. The ionization chamber was a calibrator or activity meter, a well-type chamber at high argon pressure, called a Bqmeter; and they found a good agreement between experimental and calculated values for the chamber's response function for vertical or horizontal displacement of the source. In normal ampoule applications, uncertainties in the activity values obtained were very small. In the case of measures of syringes (two) and needles (four), the results were also excellent.

2. Applications of ionization chambers

a. SIR reference system

The most important application of ionization chambers is the SIR reference system (Système International de Référence), designed to complement and extend the measures of international comparisons organized by the BIPM. The SIR system consists of two reentrant ionization chambers with current meters and data storage. The two chambers are identical [Twentieth Century, IG/N20 (Rytz, 1983a,b)] filled with nitrogen at a pressure of 2 MPa, shielded with 5 cm thick lead bricks. The background current and leakage of the system is about 33 fA. The current of the samples is measured relative to the reference sample of ^{226}Ra. Five sources of this radionuclide containing about 0.003−0.3 mg were chosen, in order to have a wide range of measurement. The sources were carefully compared and the ratios are known to be approximately 2×10^{-4}. To verify that the sources are close to equilibrium, two additional sources containing old radium are used. Since the date of purchase, 1983, they have been measured monthly to check the equilibrium of the radium and its descendants. The reproducibility and repeatability of the two chamber systems are compared with reference sources; and the data show that current ratios are stable. Sample-detector geometry tests have also been carried out. The impact of the thickness of the vials containing the samples to be measured in terms of energy has also been studied. There is evidence that the uncertainty of 1.35 MeV of ^{60}Co was 0.05% and for 60 keV of ^{241}Am was 0.1%, for uncertainties of (1σ).

It is possible to estimate the correction factors of the chambers with standardized solutions of monoenergetic gamma emitters. The K_R factor of the chamber, for the source of ^{226}Ra, for a gamma emitter of energy E and gamma emission probability for decay P_γ is given by:

$$K_R = P_\gamma A \frac{R_R}{R} \tag{7.139}$$

where R is the ionization chamber reading for the monoenergetic sample, R_R is the reading for the source of ^{226}Ra and A the activity of the sample.

If one has a curve fitted to $1/K_R$ as a function of energy E, it is possible to calculate the effective factor for a radionuclide emitting n photons of different energy and probability per decay. The activity of the radionuclide is given by:

$$A = \frac{R}{R_R} \sum_{i=2}^{n} \left(\frac{K_R}{P_\gamma}\right) \tag{7.140}$$

where the sum is carried out for all the i photons. K_R values for each of the gamma photons are obtained from the calibration curve $1/K_R$ as a function of E.

In the case of SIR measurements, equivalent activity A_e (Rytz, 1983b) is given by the equation:

$$A_e = A_s F_i \left[R + \frac{(R-1)f}{I_S - f}\right] \exp[-\lambda_S(t_m - t_S) \times]\exp[\lambda_{Ra}(t_m - t_0)] \quad (7.141)$$

This activity is related to the current produced by the stronger reference source (number 5) (0.308 mg Ra element). In this equation, the meaning of different magnitudes is: A_S is the activity of the source of the laboratories participating in the established reference time t_S, F_i is the reference source ratio related to the 0.308 mg Ra source, $R = I_{Ra}/I_S$ is the ratio of the ionization currents of the reference source and the source from the participant laboratory, f is the background and leakage current, λ_{Ra} and λ_S are the decay constants of ^{226}Ra ($T_{1/2} = 1600 \pm 7$ y) and the submitted radionuclide, and t_m is the time of measurement (midrun) at BIPM, t_0 is the reference time for the reference sources (1976-01-01).

The measurements were carried out in cycles consisting of a background run, 10 readings with the reference source, 10 with the sample to be measured, and again 10 with the reference source. The A_e determination was performed by a computer program taking into account the parameters measured, the corrections for decay, and the corrections for impurities. The final result A_e, expressed in Bq, with its components of uncertainty and sample parameters were tabulated. The lower limits of activity and levels of impurities acceptable to the SIR are presented in a report by Rytz (1983a).

The response curve of the chamber is steady and growing from 200 keV to 2 MeV. Below 200 keV, the curve presents a maximum close to 60 keV and falls then to energies close to 15 keV. Because there are no accurate calibration points in the entire interval from 1333 to 1836 keV, the shape of the curve can only be described by mathematical expressions deduced from fitting procedures. A suitable procedure was proposed by Dryak and Dvorak (1986). Michotte (2002) obtained the efficiency curve with extraordinarily low uncertainty, less than 1%.

b. Measurement of half-lives

Ionization chambers are characterized by excellent stability and reproducibility of measures which have been widely used to measure the half-lives of these nuclides: ^{159}Yb, Delgado et al. (2001); ^{198}Au, Chen et al. (2011); ^{18}F, García-Toraño et al. (2010); ^{106}Cd, Kossert et al. (2006a); ^{99m}Tc, Kossert and Thieme (2007); ^{65}Zn, Luca et al. (2003) and Kossert et al. (2006b); ^{90}Y, Kossert and Schrader (2004); ^{124}Sb, Paepen et al. (2010); ^{82}Sr, Pibida et al. (2009); ^{68}Ge/^{68}Ga, Schönfeld et al. (1994a); ^{177}Lu and ^{188}Re, Schötzig et al. (2001); ^{153}Sm, Schötzig et al. (1999); ^{152}Eu, Da Silva et al. (2002); ^{152}Eu and ^{153}Eu, Siegert et al. (1998); ^{152}Eu and ^{154}Eu, Wood and Lucas (1986); ^{201}Tl, Simpson and Meyer (1994b); ^{24}Na, ^{42}K, ^{76}As and ^{198}Au, Unterweger and Lindstrom (2004); ^{54}Mn, Van Ammel et al. (2010); ^{109}Cd, Van Ammel et al. (2011); ^{64}Cu, Wanke et al. (2010); ^{125}I, ^{54}Mn and ^{203}Hg, Da Silva et al. (2006); ^{90}Sr, Woods and Lucas (1996); ^{152}Eu and ^{154}Eu, Woods and Lucas (1986); ^{133}Xe, Woods et al. (1975); ^{137}Cs, Woods (1990).

Schrader (2004, 2010) provides an analysis of radionuclides of which the half-lives were measured in the PTB in the last 30 years. Unterweger (2002) presents the half-life measurements made at NIST of the following radionuclides: ^{60}Co, ^{137}Cs, ^{85}Kr, ^{133}Ba, ^{207}Bi, ^{152}Eu, ^{154}Eu, ^{155}Eu. Gostely (1992) measured the half-life of ^{137}Cs. Fitzgerald (2010) describes an automated ionization chamber (remotely and automatically handling radioactive sources) that can increase sample measurement frequency and include a shield that reduces the background; improving half-life measurements, which enables the measurement of large numbers of sources and minimizes exposure to radiation.

c. Comparison with primary standards

To ensure the quality of the measurements made in hospitals, there have been national campaigns for comparisons with primary standards. Such is the case of ^{99m}Tc and ^{131}I in Polish hospitals, Broda et al. (2010); ^{131}I, ^{123}I and ^{99m}Tc in Brazilian hospitals, Iwahara et al. (2001, 2002); ^{131}I in Indian hospitals, Joseph et al. (2003); ^{131}I and ^{99m}Tc in Korean hospitals, Kim et al. (2005); ^{89}Sr in British hospitals, Woods et al. (2006); and ^{131}I, ^{123}I, ^{99m}Tc, ^{67}Ga, and ^{201}Tl in Brazilian hospitals, Tauhata et al. (2008). Schrader (2000) provided measures of 19 radionuclides standardized by the PTB, obtaining efficiency values for the following ionization chambers: Centronic IG12/A20, Vinten ISOCAL IV and a calibrator for nuclear medicine. He provided criteria for transferring calibration factors from one chamber to another. Schrader and Svec (2004) compared three ionization chambers by measuring the activity of 23 radionuclides calibrated by the PTB. The calibrated chambers were: IG11 from BIPM, ISOCA from NPL, and IG12 from PTB. Woods et al. (1992) calibrated ^{192}Ir brachytherapy sources for UK hospitals.

The calibration of ionization chambers for measurement by relative methods requires the absolute standardization of the radionuclides to be measured in the chamber. The nuclides most often used in calibration are: ^{192}Ir, Anuradha et al. (2005); ^{223}Ra, Bergeron et al. (2010); ^{89}Sr, Coursey et al. (1998); ^{152}Eu, Da Silva et al. (2002); ^{125}I, ^{54}Mn and

^{203}Hg, Da Silva et al. (2006); ^{169}Yb, Delgado et al. (2001); ^{166m}Ho, Hino et al. (2000); ^{192}Ir, Hino and Ohgali (1998); ^{153m}Sm, Lépy et al. (2006); ^{22}Na, Nähle et al. (2008); ^{18}F, Nedjadi et al. (2010) and Yamada et al. (2008); ^{131}I, Oropesa Verdecia and Kossert (2009) and Sahagia et al. (2008); ^{18}F, ^{186}Re and ^{188}Re, Sahagia et al. (2002); ^{64}Cu, Wanke et al. (2010): ^{125}I, Woods and Lucas (1975); ^{69}Ga, Yuan et al. (2008); ^{188}Re, Yuan et al. (2006); ^{166m}Ho, ^{58}Co and ^{88}Y, Yuan et al. (2002); ^{188}W/^{188}Re, Zimmerman et al. (2002); ^{166}Ho, Cessna et al. (2004); ^{153}Sm, Lepy et al. (2006); ^{65}Zn, Sahagia et al. (2004). Simpson (2002) presented the calibration of 20 radionuclides and discussed the applicability of the CIEMAT/NIST method to standardize samples for the SIR system.

International comparisons have been made for some nuclides: ^{133}Xe, Picolo et al. (1998); ^{192}Ir, Ratel (1998); ^{121}I, Sahagia et al. (2008), together with comparisons for the SIR system. Hino (2002) calibrated the following radionuclides: ^{58}Co, ^{88}Y, and ^{166m}Ho. Michotte et al. (2006), based on measurements obtained for the SIR, obtained the photon emission intensities of the following radionuclides: ^{65}Zn and ^{201}Tl. Michotte (2000), applying an interactive method, obtained the efficiency of the chamber as a function of energy using a few monoenergetic gamma emitters and also examined the influence of radiochemical impurities on SIR measurements. Olšovcová et al. (2010) presented a comparison of ^{131}I in clinics of nuclear medicine in eight countries: Brazil, Cuba, Czech Republic, India, Iran, Republic of Korea, Romania, and Turkey. Zimmerman et al. (2008) analyzed the results of an international comparison organized by the IAEA for the traceability of ^{131}I. Zimmerman and Palm (2010) presented the international comparison results of ^{57}Co.

Calibrations of ionization chambers for measurement of radon have been carried out by Paul et al. (2000); Lee et al. (2004a,b); Venoso et al. (2009); Beck et al. (2009) and Janik et al. (2009).

3. Considerations on the calculation of ionization chamber efficiency

Several investigators, Gray (1949), Dale (1961,a,b), Heydorn (1967), Oncescu and Rebigan (1968), and Bensch and Ledermann (1969), found that variations in the response of ionization chambers are related to the k value, the specific gamma emission constant of radionuclides (NCRP, 1985). At least, in the ideal case of a chamber with walls of material equivalent to air, Dale et al. (1961) observed that the 1383A-type chamber used in the NPL does not have air wall conditions, so there was a deviation in its response. The experimental representation of current per mCi against the value of k is almost a straight line not passing through the origin, as is shown in Fig. 7.13. If we represent the current per mCi divided by the value of k versus k, the nonlinearity is clearer. The 1383A ionization chamber has a 1/8-inch brass inner lining in which gamma radiation interacts. Dale (1961) first calculated secondary electron production due to the interaction of gamma rays: $E_\gamma(e^\sigma a + e^\tau a)$ He then computed the absorption of secondary electrons by brass, to finally obtain the corrected curve of secondary electrons as a function of energy as is shown in Fig. 7.14. In this curve, the ordinate is in arbitrary units, to pass it to $\mathrm{pA}/3.7 \times 10^7 \mathrm{photon/s}$. Dale used the measurement of the chamber slopes for two nuclides ^{24}Na and ^{60}Co. From the values of the curve, we can calculate the slope of the chamber for any gamma-emitting radionuclides with uncertainties below 3%, if we know the decay scheme data with low uncertainty. In the 1960s and 1970s this method was extremely useful in the direct calibration of radionuclides.

Suzuki et al. (1998) applied the Monte Carlo code EGSA4 to three types of ionization chambers at high pressure: Centronic IG11/A10 (1 MPa, Argon, 2.54 cm diameter reentrant well), Centronic IG12/A20 (2 MPa, Argon, 2.54 cm reentrant diameter well) and Centronic IG12/N20 (2 MPa, Nitrogen, 5.08 cm diameter reentrant well). These chambers were built by the Centronics company based on a design by Shape and Wade (1951), NCRP (1985). Eleven radionuclides of standard solutions were measured to compare the experimental with the calculated curve. They also analyzed the effect of displacement of the measured sample. In all cases, the calculations are in good agreement with the experimental results. Simoes et al. (2010) applied the Monte Carlo MCNPX method to obtain the response of the Curiementor 2 ionization chamber.

Gostely and Laedermann (2000) applied the GEANT Monte Carlo code to the calibration of the Centronics IG11 ionization chamber. The equipment used is similar to the BIPM and fully described earlier by Rytz (1983b).

Gostely and Laedermann (2000) used 12 calibrated standards: ^{125}I, ^{133}Ba, ^{109}Cd, ^{57}Co, ^{99m}Tc, ^{125}I, ^{123}I, ^{51}Cr, ^{137}Cs, ^{22}Na, ^{60}Co, and ^{88}Y. These sources cover the energy range between 40 keV and 2 MeV. Agreement between calculated and experimental efficiencies is complete. They studied the effect of the displacement of sources as well as the Bremsstrahlung effect of high energy beta emitters. They also analyzed the effects of the distribution of emission points of annihilation radiation from a positron emitter and applied the results to the case of ^{18}F.

Calculation programs for the Monte Carlo method have been applied by some investigators to obtain the absolute activity of radioactive sources of different nuclides. De Vismes and Amiot (2003) applied the PENELOPE program to the Vinten 671 chamber using a limited number of radionuclides (^{133}Ba, ^{99m}Tc, ^{60}Co) and obtained excellent calibration for other energies. The discrepancy between the experimental and calculated values of a large number of samples is less than 0.5%. Amiot (2004) calculated the calibration factor, using the PENELOPE code, for the nuclides: ^{18}F, ^{99m}Tc, ^{111}In, and ^{123}I. Kryeziu et al. (2007) calculated the calibration factors and volume correction of the following radionuclides: ^{90}Y, ^{125}I, ^{131}I, and ^{177}Lu; they also used the PENELOPE code.

Olsovcová (2004, 2010) applied the MCNP 4C code (Briesmeister, 2000) to the CMI chamber with excellent results for vials and syringes. Olšovcová (2010) applied Monte Carlo code MCNP 4C to the following radionuclides: ^{123}I, ^{111}In, ^{153}Sm in syringes. Olšovcová Havelka et al. (2006) applied Monte Carlo code MCNP 4C to the Bqmeter chamber (BQM Consortium) to obtain the calibration curve for various types of syringes and the calibration and geometry correction factors of a radionuclide calibrator. Olšovcová et al. (2010) conducted a national comparison of ^{131}I measurements among nuclear medicine clinics in eight countries.

Sato et al. (2006) calculated the response for standard ionization chambers: TPA MkII (argon), IG12/A20, IG11/A20, IG11/N20, in the APMP area (Asia−Pacific Metrology Program) using the EGS4 Monte Carlo code. Lin and Chu (2006) introduced corrections to the INER chamber applying the Monte Carlo method.

Švec and Schrader (2000, 2002), calculated the efficiency and deviation from experimental results, for a large number of nuclides (28) calibrated by the PTB. Uritani et al. (1994) estimated the activity of ^{192}Ir in metal samples by analytical computation. Grau Malonda et al. (1982)

applied the Monte Carlo method to the activity determination of metal mercury samples with ^{203}Hg in cylindrical containers measured with a 1383A ionization chamber. Büermann et al. (1994) standardized ^{192}Ir metal samples using self-absorption corrections.

V. Reference systems

A. The SIR of gammas

The International Reference System (Système International de Référence) (SIR) for activity measurements of radionuclides that emit gamma radiation was established in 1976. Each National Metrology Institute (NMI) can request a standard ampoule (3.6 g) which is filled with radionuclide in an aqueous solution, from the Bureau International des Poids et Mesures (BIPM). A different standard ampoule is used for radioactive gases. The NMI completes a submission form detailing the standardization method used to determine the absolute activity of the radionuclide and the full uncertainty budget for the evaluation of uncertainty. The ampoules are sent to BIPM where they are compared with the standard sources of ^{226}Ra using pressurized ionization chambers. Details of the SIR method, experimental set-up and determination of equivalent activity are given in Ratel (2005, 2007) and Woods et al. (2000).

The SIR enables national laboratories to check the reliability of their activity measurements at any time. This is achieved by determination of the equivalent activity of the radionuclide and comparing the results with the key comparison reference value (KCRV) determined from the results of primary standardizations.

Each NMI that submits ampoules to SIR has measured the activity of the radionuclide by primary standardization methods or a secondary method such as a calibrated ionization chamber. In this case, the traceability of the calibration must be identified to ensure that all corrections have been taken into account.

The details of the submitted solution are: chemical composition, solvent concentration, carrier concentration, density (g/cm^3) and relative activity of the impurity, if any (Rytz, 1983a). The typical BIPM method for evaluating the activity of impurities is the use of a spectrometer with a calibrated Ge(Li) detector as described in Michotte (2000, 2001). The Consultative Committee for Ionizing Radiation CCRI (II) agreed that this approach will continue in accordance with the protocol described in Michotte (2002), when an NMI makes a request or when discrepancies appear. All submissions to the SIR since it was established in 1976 are recorded in a database known as the "master file".

The SIR for gamma is based on two reentrant ionization chambers filled with nitrogen to 2.0 MPa. These chambers are coupled to an electronic system capable of measuring currents as low as a few hundred femtoamperes with high precision (some parts of 10^4). Until recently, one of the chambers was used only for verification purposes, while the other, more sensitive, chamber was used for NMI measurements.

The idea of SIR was to have a reliable, stable, and precise system, as simple as possible (Rytz, 1983b). Relative measurements seemed a more convenient way to achieve the proposed goal, provided that we use a sufficiently stable reference. This is achieved with five sources of radium that have a half-life of $T_{1/2} = 1600$ y, $u = 7$ y. Thus, comparisons in the SIR are reduced to comparing two similar ionization currents. One current is produced in the chamber by the NMI ampoule and the other current is induced by one of the five radium sources. Consequently, the SIR feature is the use of the five sources of ^{226}Ra. These are made of radium sulfate in double-walled sealed platinum-iridium cylinders of identical geometrical sizes (Rytz, 1978). The ratio between the activities of two successive sources of radium is about three, so that the dynamic range in activity covered by the five sources is approximately 81 times, for a total activity of the five sources of 16.4 MBq. To reduce experimental systematic effects, the same measurement conditions are used for samples and radium sources. This is accomplished by choosing the source of radium which gives the closest ionization current to the sample.

As the ionization current is proportional to the activity of the sample, it is useful to define the equivalent activity of a radionuclide as the activity that produces a current equal to that produced by the radium source of highest activity in the ionization chamber. Given the disintegration of the sample, designated by s, and the source of radium, designated as Ra, given the dates of reference t_r and t_0, and the date of measurement t_m, common to the radium source and the sample, the equivalent activity value (Rytz, 1983b) can be expressed as:

$$\frac{A_e e^{-\lambda_{Ra}(t_m - t_0)}}{A_S e^{-\lambda_s(t_m - t_r)}} = \frac{F_j(I_{Ra} - I_f)}{I_s - I_f} \tag{7.142}$$

A normalization coefficient F_j, with $j = 1$ to 4, has been introduced in this equation, to convert the measured current, obtained with the radium source used to adapt the sample current, to the current that would have been produced by the radium source with highest activity.

In order to fulfill the condition of long-term stability required by the SIR system, the stability of sources and ionization chambers is checked regularly. At the same time as the measurements of the samples sent by the laboratories, the five sources of radium are measured each month to obtain the current ratios $r_j = I_{j+1}/I_j$ for values of

$j = 1-4$, so as to determine the ratio between the currents due to the source of highest activity and each of the other sources.

This enables the determination of the efficiency of the ionization chamber as a function of energy. When a radionuclide decays with emission of several gamma rays of different energies, each of these gamma rays contributes to the total current of the chamber. Normally, the chamber responds differently to different excitations caused by these photons. Thus, each radionuclide has a particular energy signature represented by its decay scheme and the detection efficiency can be defined for each radionuclide. So, for a radionuclide emission characterized by several energies E_i, and emission probabilityp_i, the detection efficiency is given by:

$$\varepsilon_{\text{rad}} = \sum_{i=1}^{n} p_i(E_i)\varepsilon_i(E_i) \tag{7.143}$$

where photon efficiency $\varepsilon(E_i)$ is a smooth function that depends on the energy of the gamma line measured: Rytz (1983b) assumed that efficiency could be broken down into a linear part, dependent on energy, and a small amount $\delta(E_i)$, that represents a deviation of the energy, following an idea presented by Schrader and Weiss (1983).

The efficiency curve is a function of energy. It was first established experimentally in a region where the curve is almost linear. They used monoenergetic radionuclides such as ^{54}Mn ($E = 834.838$keV, $u = 0.005$keV) and ^{60}Co with two lines relatively close in energy ($E_1 = 1173.240$keV, $u = 0.003$keV and $E_2 = 1332.508$keV, $u = 0.004$keV) with similar emission probabilities (99.85% and 99.9988%, respectively). So we can use a mean energy value with a fictitious emission probability equal to the sum of emission probabilities. When some values of f_i were known, it was possible to draw a provisional curve and extend the validity region of the curve by selecting particular values of factor f_l for energy level l:

$$f_l = \frac{\dfrac{10^5}{6}\dfrac{1}{A_e} - \sum_{i=1, i\neq l}^{n} E_i p_i(E_i) f_i}{E_l p_l(E_l)} \tag{7.144}$$

The curve has been extended from $E = 2751.77$ keV for ^{24}Na, and toward lower energies with ^{153}Gd ($E = 97.43103$ keV). Attempts have been made with radionuclides with lower energy, such as ^{125}I ($E_\gamma = 35.4919$ keV), but the results are not sufficiently reliable because of the influence of the glass ampoule thickness.

Different ways of approximating analytical curves to the response curve of the chamber have been tested. We emphasize the excellent work of Michotte et al. (2006). They applied polynomial exponentials to adjust SIR experimental data by nonlinear least squares minimization.

In the process followed for approving the results of the NMI by the BIPM, the key comparison reference value is obtained from the average of all results submitted to the SIR with the following provisions (Michotte et al., 2010):

a. Only primary standardized solutions are accepted, with the exception of radioactive gas standards, for which results from transfer instrument measurements are directly traceable to a primary measurement in the laboratory;
b. Each NMI or other laboratory only has one result (normally the most recent result if more than one ampoule is submitted);
c. Any outliers are identified using a reduced Chi-squared test.
d. Exclusions must be approved by the CCRI (II).

A long list of radionuclides (60) has been subjected to SIR. See the BIPM website for information about comparisons (http://www.bipm.org/en/scientific/ionizing/radionuclide/sir/). By clicking on the nuclide of interest one can obtain information on the comparison or comparisons that have been made with the nuclide. For example, if you enter http://iopscience.iop.org/0026-1394/47/1A/06001, which corresponds to the action of 2010 on ^{22}Na we obtain the abstract of the nuclide. Clicking again on the final report contained in the abstract, the final report on the action of SIR is obtained. This report provides details of the participants, the method or methods of calibration, characteristic details of the provided solution, results of the measurements, a table of degrees of equivalence and uncertainty (uncertainty budgets) of the different calibration methods applied to the primary radionuclide.

After many years of measuring a large number of ampoules, the SIR has become a repository of many reliable results. Calibration of ionization chambers by relative methods requires the absolute calibration of radionuclides that are later going to be measured in the chamber. The nuclides most often used in standardization are: ^{192}Ir, Anuradha et al. (2005); ^{223}Ra, Bergeron et al. (2010); ^{89}Sr, Coursey et al. (1998); ^{152}Eu, Da Silva et al. (2002); ^{125}I, ^{54}Mn and ^{203}Hg, Da Silva et al. (2006); ^{169}Yb, Delgado et al. (2001); ^{166m}Ho, Hino et al. (2000); ^{192}Ir, Hino and Ohgali (1998); ^{153}Sm, Lépy et al. (2006); ^{22}Na, Nähle et al. (2008); ^{18}F, Nedjadi et al. (2010); Yamada et al. (2008) and Roteta et al. (2006); ^{131}I, Oropesa Verdecia and Kossert (2009) and Sahagia et al. (2008); ^{186}Re/^{188}Re, Sahagia et al. (2002); ^{64}Cu, Wanke et al. (2010); ^{125}I, Woods and Lucas (1975); ^{69}Ga, Yuan et al. (2008); ^{188}Re, Yuan et al. (2006); ^{166m}Ho, ^{58}Co and ^{88}Y, Yuan et al. (2002); ^{188}W/^{188}Re, Zimmerman et al. (2002); ^{166}Ho Cessna et al. (2004); ^{153}Sm, Lépy et al. (2006); ^{133}Ba, Simpson and van Wyngaardt (2008); ^{65}Zn, Sahagia et al. (2004). Simpson (2002) presents the calibration of 20 radionuclides and

discusses the applicability of the CIEMAT/NIST method to the standardization of samples for the SIR system.

The SIR system is therefore a means of coordinating the calibration results of the NMIs and checks the validity of primary radionuclide standardization methods.

1. Measurement of short half-life gamma emitters

Radionuclides with a short half-life can only be linked to the SIR of the BIPM if the laboratory is close to the Sèvres laboratory. In 2003, the CCRI (II), aware of the constant increase in the use of such radionuclides and the need for all countries to compare their measurement results, decided to establish a Transfer Instrument Working Group (TIWG) to study the possibility of extending the scope of the SIR.

After lengthy discussions it was decided that the BIPM could only achieve this through the use of a transfer instrument (TI) circulated among the participants of the comparison. This equipment should be related to the original SIR so that measurements obtained with this procedure should be able to be compared with those obtained with the original procedure. A 76 mm × 76 mm NaI(Tl) crystal with a well of 2 mm diameter hole was chosen as the TI. The goal was to count all events that exceed a threshold level. The detector was accompanied by a source consisting of a mixture of ^{93m}Nb ($T_{1/2}$ = 16.12a) and ^{94}Nb ($T_{1/2}$ = 20300a) produced by the IRMM. This sample had two aims: the ^{94}Nb enables verification and correction of stability and the ^{93m}Nb, which emits 17 keV X-rays, sets the threshold level. The ^{94}Nb fulfills the same role as the usual radium in the SIR system. Furthermore, it has to define an equivalent activity in the same terms as in the traditional SIR system. The IT system was assembled at the BIPM and preliminary experiments were carried out. The LNE-LNHB prepared a solution of ^{99m}Tc high activity that was first measured in the SIR chamber and then, after decaying several half-lives, when activity had declined, it was measured in the NaI(Tl). The activity was low enough that there were no dead time distortions. These consecutive measurements enabled the determination of the linking factor, defined as the ratio between equivalent activity in the SIR and the transfer instrument.

B. The SIR of betas

The success of the SIR for gamma emitters led to extending the procedure to pure beta decay, alpha decay and pure electron capture decay. For pure beta emitters the liquid scintillation technique and in particular the CIEMAT/NIST method seems to be the most appropriate procedure. To test this procedure several comparisons have been organized by the CCRI (II), using the CIEMAT/NIST method, for the following nuclides: ^{14}C, ^{90}Sr, ^{89}Sr, ^{90}Y, and alpha emitters ^{238}Pu and ^{241}Am. These tests have been successful and, therefore, present no difficulty to be included in the SIR.

The CIEMAT/NIST method permits the compensation for LSC long-term anomalous effects; in particular, the effect of permanent photomultiplier fatigue. This effect can modify the counting rate. Grau Malonda (1982a) applied the CIEMAT/NIST method to C-14 standardization using tritium as a tracer when the photomultiplier response presented a big degradation. Calibration curves of H-3 and C-14 presented important anomalies, but the activity of C-14 samples was accurate.

Rodríguez-Barquero and Los Arcos (2004a) measured samples of H-3, C-14 and Ni-63 over a long period of time: 4, 2.4 and 2.3 years, respectively. In this work, they prove that the counting rates vary over time; but C-14 and Ni-63 activities obtained with the CIEMAT/NIST method, when the calibration curves prepared in times close to the activity measurement, gave discrepancies of −0.5% and −0.4% for Ni-63 and the C-14, respectively. Rodríguez-Barquero and Los Arcos (2004a) conclude in their work: "This behavior confirms the reliability of the CIEMAT/NIST method as a monitoring tool for the determination of activity concentration on the long term with no need for additional checking procedures or stability curves".

For ^{204}Tl, a beta emitter with a small branch of EC, the measurement was sensitive to the chemical preparation, a problem expected in other radionuclides. Another objective is to extend the SIR to nuclides decaying by pure electron capture, such as ^{55}Fe and ^{165}Er, which are not now covered by the SIR. They emit photons with too low energy (below 50 keV). It has been shown repeatedly that ^{3}H ($T_{1/2}$= 12.312 y, and E_{max} = 18.591 keV) is an excellent tracer for the standardization of beta emitters by the CIEMAT/NIST method and has been proposed to be used as a monitor. However, its half-life is relatively short. A nuclide of longer half-life is ^{14}C; but its use requires special care. It could lose activity, producing carbon dioxide that escapes from the sample. ^{63}Ni seems to be a better candidate in view of its half-life (100 years) and maximum energy (65.9 keV), lower than ^{14}C.

In 2007, at the ESIR WG (Extended SIR Working Group) meeting, CIEMAT, PTB, and LNE-LNHB proposed different methods and procedures for the SIR extension. The PTB method (Kossert, 2006) is very similar to the CIEMAT/NIST method. The method presented by the LNE-LNHB (Cassette and Do, 2008) is based on the application of a Compton spectrometer to the scintillation detector, with the creation, in the liquid scintillator, of an internal and virtual reference source, which is measured by the Compton effect. CIEMAT introduced a new scintillator and applied the CIEMAT/NIST method. CIEMAT presented results showing good stability for the proposed XAN6040 scintillator. We describe each of the proposals in detail.

Kossert (2006) described a secondary method based on the efficiency curve of tritium as a tracer and the efficiency curve of the radionuclide to be studied. The procedure is as follows. In a first stage we have the efficiency curve (efficiency against quench parameter QIP) of tritium and the efficiency curve of the nuclide to be studied, i.e., $\varepsilon_{\text{tracer}}(\text{QIP})$ and $\varepsilon_{\text{nuclide}}(\text{QIP})$. For both measures a set of samples with different quenching are prepared. We measure efficiency and quench parameter QIP. As both curves have a common element, the QIP, we obtained from these curves a new curve $\varepsilon_{\text{nuclide}}(\varepsilon_{\text{tracer}})$ that links the efficiency of the studied nuclide and the tracer. In a second stage, which may be several years later, the operation is repeated and we prepare a set of tracer samples with a different quench, so you get a new curve $\varepsilon_{\text{tracer}}(\text{QIP})$ and from the measurement of the radionuclide under study we obtain the parameter QIP. With this parameter we determine the new efficiency of the tracer; and with the new efficiency of the tracer, we enter the curve $\varepsilon_{\text{nuclide}}(\varepsilon_{\text{tracer}})$ and we determine the efficiency of the nuclide. The activity of the sample under study is obtained applying the equation $A_{\text{nuclide}} = N_{\text{nuclide}}/\varepsilon_{\text{nuclide}}$. Kossert (2006) presented Fig. 7.15, which clarifies the description given. The composition of the sample and the geometry of the measurement must be very similar for all measures; and the time between the preparation of tracer sample and the nuclide under study should be short. Moreover, the time between the first and second measurements of the sample under study can be very long, many years. This method enables us to correct for gain variations of the measuring equipment, but cannot correct the count variations in the sample by absorption or microprecipitation, as the QIP is only sensitive to the liquid scintillator and not to the radionuclide incorporated to the liquid scintillator.

Cassette and Do (2008), Cassette et al. (2010) and Jean-Baptiste et al. (2014) described a new calibration method based on liquid scintillation using a virtual source, which acts as a tracer, created inside the scintillator by Compton interaction. When a sample is placed in the liquid scintillation counter, it is irradiated by an external and collimated source of ^{241}Am emitting 59.4 keV gamma rays. A gamma detector is placed in the bottom of the optic cell of the liquid scintillation counter with its axis normal to the beam of gamma photons. The gamma detector measures part of the gamma photons scattered in the liquid scintillator by coherent or incoherent Compton scattering. For incoherent photons, the spectrum is centered around the scattering at 90 degrees, which corresponds to an average energy of 53.2 keV. The Compton spectrum is separated from the coherent scattering spectrum using a detector with good resolution, for example a Ge detector. The Compton spectrum analyzer is selected by an SCA (single-channel analyzer) and this signal is used to validate the acquisition of the photomultiplier of the liquid scintillation counter. All pulses created by gamma-ray interaction in the liquid scintillator are viewed by the liquid scintillation counter, but only those pulses in coincidence with the SCA signal are selected. The coincidence system rejects all light pulses generated by the sample's disintegration in the liquid scintillator. The energy spectrum of Compton electrons from the source is deduced from the experimental spectrum of Compton scattered photons by applying the principle of conservation of energy to the Compton effect. This spectrum is used to calculate the free parameter of each

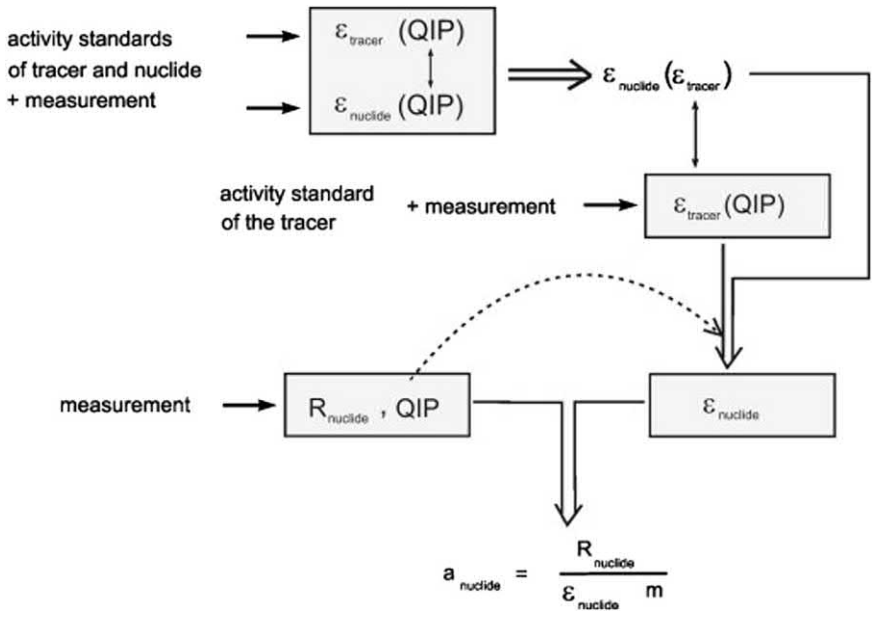

FIGURE 7.15 Illustration of the secondary standard measurement procedure. *R* denotes the counting rate, QIP the quench indicating parameter, ε the counting efficiency, a_{nuclide} is the solution activity concentration and *m* is the source mass. *From Kossert (2006), reprinted with permission of Elsevier Science © 2006.*

photomultiplier, from the experimental values of the relationship triple-to-double. Then the gamma source is removed and the sample is measured using the traditional TDCR method. This procedure has the advantage of allowing the direct determination of the nonlinearity of the response of the liquid scintillation at low energies due to ionization quench. However, it is not possible to determine the stability of the sample measured or correct for counting variation in the sample by absorption or microprecipitation of the radionuclide.

Rodriguez Barquero and Los Arcos (2000) measured the stability of ^{110m}Ag samples for liquid scintillation with four comercial scintillators: Insta-Gel Plus, Ultima-Gold, HiSafe II and HiSafe III. Ultima-Gold samples were completely unstable for 2 months, Insta-Gel Plus and HiSafe II reached stabiltity after 30 days and only HiSafe III samples were stable for the full term of 2 months. Samples were prepared with 15 mL of liquid scintillator and four carrier levels: 0.0, 1.5, 3.0, and 6.0 μg of $AgNO_3$.

Rodriguez Barquero and Los Arcos (2010) presented a systematic study of five scintillators, four commercial: Ultima-Gold, Optiphase, HiSafe II, and Optiphase HiSafe III, and one homemade reference scintillator, XAN6040, useful to stabilize up to 19 radionuclides (Rodríguez Barquero and Los Arcos, 2005). They determined the density and the elemental composition of these liquid scintillators. The density at 16°C is higher by 0.4% than the density at 20°C. However, the discrepancy among different batches of commercial scintillators can reach up to 4%, all having the same nominal composition. Several laboratories analyzed the weight percentages of H, C, O, N, P, Na, S, and B of all the laboratories. The elemental composition of commercial scintillators presented discrepancies with the nominal values from 2% and up to 260% depending on the element and the scintillator.

Rodríguez Barquero and Los Arcos (2005, 2007) introduced a new liquid scintillator of known composition called XAN6040 with the goal of becoming the typical scintillator of the SIR for betas. The tests carried out at CIEMAT focused on stability and reproducibility of the cocktail, which gave excellent results. The composition of the XAN6040 liquid scintillator is given in the patents of Rodriguez Barquero and Los Arcos (2003, 2004b,c,d).

Los Arcos and Rodríguez Barquero (2013) proposed a method of "cross-efficiency" for the extension of the Systeme International de Référence (SIR) for radionuclides emitting nongamma radiation. The method is based on the so-called "universal reference curve" described by Cassette and Tartes (2014). This curve represents the efficiency of the radionuclide of interest as a function of the efficiency of a tracer radionuclide for various quench values. This method is the one initially proposed by Kossert (2006), with the difference that Los Arcos and Rodríguez Barquero (2013) affirm that the curve is independent of the counter and the scintillator, while Kossert (2006) recommended a similar scintillation composition for all measurements.

Using three different counters and two different scintillation cocktails, Los Arcos and Rodríguez Barquero conclude that the curve is universal for the following radionuclides: ^{55}Fe, ^{63}Ni, ^{14}C, ^{60}Co, and ^{90}Sr−^{90}Y. They obtain curves that do not depend on the counter or the scintillator used.

In 2011, an intercomparison exercise was proposed in the framework of the Working Group of the CCRI (II) for the extension of the SIR in order to verify the method. The BIPM sent ^{63}Ni calibrated samples to eight laboratories. Three different cocktails were used: Ultima Gold, Hionic-Fluor and Bio Fluor, and three different counters: Beckman LS 6000 TA, Packard TriCarb 2900 TR and Wallac Guardian 1440. The results were presented to the ICRM 2011, but were not published in the Proceedings. The presentation concluded that the results appeared to be independent of the counter and the scintillator and that the uncertainties were of the order of 1−2%.

Cassette and Tartés (2014) affirm: However, after a precise analysis of the data at the LNBH, we thought that this conclusion cannot be withstanding critical scrutiny. From these contradictory results, we wish to verify the influence of the scintillator cocktail and of the counter in the cross-efficiency curve, as it is the key point of the method for the use as an extension of the SIR to radionuclides emitting no gamma rays.

Cassette and Tartés (2014) prepared sets of samples using three different LS cocktails: Ultima Gold, Hionic-Fluor, and Picofluor 15 from PerkinElmer in glass vials with low potassium. No additive was added to stabilize the sources; but the stability was checked by measuring them at different times. They used two quenchers: nitromethane, as a chemical quencher and tartrazine, as a quencher by color. They prepared a total of 120 samples, which were calibrated by the TDCR method and then measured in three different commercial LS counters: Wallace Quantulus 1220, Packard TriCab 2900 TR and Wallac Guardian 1440. The results corresponding to the cross-efficiency curve are shown in Fig. 7.16. These authors conclude: (1) Quenching curves depend on the scintillator and this dependence varies with the radionuclide. (2) Quenching curves depend on the counter. (3) Quenching curves depend on whether the quencher is chemical or color. (4) Quenching curves depend on the volume of the source and the nature of the vial.

Actually, conclusions (3) and (4) are known from the beginning of the application of the LS to the calibration of radionuclides.

The points in question are (1) and (2): according to Los Arcos and Rodríguez Barquero (2013), quenching curves are universal and independent of the scintillator and the counter.

VI. Preparation of radioactive samples

A. Introduction

Radioactive sample preparation is a very broad subject. Here we only discuss the methods of preparing samples for radionuclide metrology. For additional information on sample preparation, we recommend the reviews published by: Mann (1956), Merritt (1973), van der Eijk et al., (1973), Lowental and Wyllie (1973), Campion (1975), Le Gallic (1977), Lally and Glover (1984), Mann et al. (1988),

Fettweis et al. (2003), Thomson (2003), Sibbens et al. (2003) and, especially, the excellent work of Sibbens and Atzitzoglou (2007).

Sample preparation for LSC can be seen in Chapter 7, Volume 1 of this book, gamma spectrometry in Chapter 4, Volume 1, alpha spectrometry in Chapter 5, Volume 1, internal gas counting in Unterweger (2007), and environmental radioactivity in Jerome et al. (2007) and Chapters 2 and 3 of Volume 2 of this book.

In this section, we only discuss quantitative methods of sample preparation. Qualitative methods, which are of particular interest in spectroscopy, are not considered here. The first thing to examine is the amount of radioactivity deposited in a sample either gravimetrically or volumetrically. We will focus mainly on how to carry out the solutions, the quantitative deposition of drops and the mass determination for obtaining a good sample preparation procedure.

B. Sample preparation for radionuclide metrology

1. Supports for extended samples

Methods to measure extended samples require that the sample holder be ultrathin. The support is usually a foil that lets radiation through. Preparation and use of foils can be made with different materials, such as polypyrrole polymer, polyaniline films, polyethylene dioxythiophene/polyvinyl chloride, polyvinyl chloride-polyvinyl acetate copolymer (VYNS). See the works of Miyahara et al. (1987), Dobilovri et al. (1988), Los Arcos et al. (1992), Was et al. (1993), Du et al. (1996), De Sanoit et al. (1998), Pate and Yaffe (1955), and Lowental and Smith (1964). VYNS is the most popular of all. To prepare the films, the polymer was dissolved in a solvent such as cyclohexane. VYNS concentration in the solution determines film thickness. It can vary from a few μg cm^{-2} to several hundred μg cm^{-2}. Film thickness is determined gravimetrically after depositing the film in a very thin "annuli" of aluminum or stainless steel and determining the area of its surface.

The film must be metallized so as not to disturb the electric field inside the counter. A thin layer of gold is evaporated on the film (Moura and Parker, 1975; Lowenthal and Smith, 1964). The thickness of the gold can also be determined by the difference in weight of the film before and after metallization. In addition to depositing the samples, the films are used to cover the radioactive sample and increase absorption in beta extrapolation methods. VYNS films have good resistance to acids and alkalis.

VYNS films with electrical conductors are best for covering the radioactive sample and thus vary the parameters N_c/N_γ required to establish the dependence of the efficiency of coincidence equation. This method of change N_c/N_γ is preferable to self-absorption methods, as it is simpler, produces consistent results and shows greater control in variation of efficiency. The entrapment of gas bubbles on the radioactive source must be prevented. This often occurs as a result of a heavy charge. To avoid this phenomenon, we lay the source of VYNS for a few minutes in an acetone vapor atmosphere. Trapped gases escape rapidly through the micropores and the films adhere well and tense when we remove the acetone atmosphere.

2. Dilutions in aqueous solutions

Very often, the activity of the radioactive solution is too high for direct measurement. In this case, a quantitative dilution is required to obtain an appropriate concentration for the radioactivity counter (van der Eijk and Vaninbroukx, 1972; Iroulart, 2006, 2007). When the dilution factor is around 1000 or higher, it is best to carry out a multistage dilution. For concentration factors below 1000, we can proceed to a one-step dilution. An important point is to keep the diluted sample stable; and this depends on the carrier concentration in the diluted sample. NCRP (1985) presents a list of chemical data for various radionuclides as well as recommendations for choosing the carrier concentration in the solution. It is advisable, as good practice prior to dilution, to prepare an outline of the steps to be taken.

The dilution is carried out in a rinsed glass that was previously rinsed with a nonradioactive solution containing the carrier, thus reducing the possible absorption of the radioactive sample on the vessel wall when the radioactive sample is incorporated into the container. The container is first weighed empty (w_1) and after adding the carrier solution, which will serve as a basis for the dilution, it is weighed again (w_2); the weight of liquid solvent is determined as the mass difference. The incorporation of radioactive solution is made using a pycnometer, which is prepared from a polyethylene pycnometer of about 5 mL. First, we prepare the output capillary of the pycnometer, heating the tip and stretching by rotating while pulling the tip with tweezers to form a capillary. Once prepared and cooled, the pycnometer is filled with the right amount of radioactive solution. The amount of incorporated radioactive solution in the bottle, in which the dilution will be performed, is measured by weighing the pycnometer before and after dispersing the radioactive solution. If the weight before dispersion of the radioactive solution is w_{pl} and after dispersion it is w_{p2}, the dilution factor is:

$$\text{Dilution factor} = \frac{w_{pl} - w_{p2}}{(w_{pl} - w_{p2}) + (w_2 - w_1)} \qquad (7.145)$$

We must ensure that there is a good homogenization of the solution before use. First, you have to seal the container and then mix the solution well by swirling.

3. Drops deposit in the sample holder

When we standardize a sample we obtain its activity, but in general what we want is to determine the activity of a radioactive solution, or determine the activity per unit of mass for the solution. Therefore, it is necessary to determine the mass or volume of the radioactive solution in the sample holder. The simplest solution is to deposit the solution using pipettes, but for small samples and good accuracy, the gravimetric method by a pycnometer is recommended.

The manipulation of the pycnometer must be carried out with tweezers to avoid electrostatic charging and heating.

4. Determination of mass

In metrological applications, mass must be known with less than 0.1% uncertainty. Regarding the issue of determining the mass, we recommend the excellent monograph by Davidson et al. (2004). As the average solution mass deposited on a sample is about 20 mg, this means that the balance should be accurate to a few micrograms. This requires taking a series of precautions for the environment and positioning of the balance. The balance must be in a room with temperature and humidity controls, avoiding direct sunlight and currents of air. It should also be placed on a vibration-free horizontal table. On the other hand, when using the pycnometric method, it must be handled with a pair of tweezers to prevent the deposit of moisture, fat from fingers and electric charges on the plastic of the pycnometer. A static charge eliminator is recommended.

With respect to the scales, they must meet three criteria: linearity, precision and accuracy. Linearity implies that there exists a linear relationship between the mass of the sample and the response of the scale. In the case of modern electronic scales, the deviation from linearity is about 10^{-7}. The precision of weighing depends on the repeatability of the instrument, or the ability to give the same result when a sample is measured repeatedly. Finally, the accuracy of the scale is linked to the ability to produce the same results as a standard. In this case, we must use a box of calibrated weights traceable to the BIPM, which should be tested frequently and at different ranges.

Commonly we use one of the following two methods: direct and indirect. In the direct method, zero is recorded (w_0) when the scale is empty or the scale is set to zero before weighing the sample. The mass of the sample is then $w = w_1 - w_0$. In this expression w_1 is the sample weight. In the substitution method, we chose weights from the box of calibrated weights to approximate the weight of the sample (w_1). The sum of all substitution weights determined by weighing in the balance (w_s) is compared with the sum of the masses of the certificate weights (w_c). The mass of the sample is $w = w_c + (w_1 - w_s)$.

In all weighing procedures, we must apply a correction for air thrust. Thrust is the force exerted on an object immersed in a fluid by the fluid displaced by the object. In our case, the fluid is air and force is equal to the weight of air displaced by the sample. The sample mass corrected for thrust is:

$$M_c = M_{\mathrm{nc}} \frac{d(d_{\mathrm{cal}} - d_{\mathrm{air}})}{d_{\mathrm{cal}}(d - d_{\mathrm{air}})} \tag{7.146}$$

where M_c is the sample mass corrected for thrust, M_{nc} is the mass of the sample without correcting for the thrust, d is the density of the sample, d_{cal} the density of calibrated weights and d_{air} the air density. All these quantities must be expressed in appropriate units; for example, if mass is expressed in grams (g), density is expressed in grams per cubic centimetre (g cm^{-3}). Air density depends on pressure, temperature and humidity. To determine air density, the International Committee of Weights and Measures (Commité International des Poids et Mesures) recommends the following equation (Davis, 1992):

$$d_{air} = 10^{-3} \times \left(\frac{0.348444 \times p + 0.020582 \times H - 0.00252 \times T \times H}{T + 273.16} \right) \tag{7.147}$$

where T is air temperature in degrees Celsius ($^{\mathrm{o}}$ C), H is relative humidity (%) and p is atmospheric pressure measured in mbar. At each weighing, the operator records the temperature and humidity of the air and the atmospheric pressure in the room containing the scales.

5. Methods for verifying and improving the quality of the source

In radionuclide metrology, the maximum precision achieved is limited more by the quality of the sample than detector performance. A solid radioactive sample of high-quality takes the form of a homogeneous and uniform thin layer of radioactive material. There are several methods to check this quality. First we can view the structure and irregularities of the source under a microscope. The distribution of radioactivity and its homogeneity can be visualized by autoradiography, using for example a photographic film (Nageldinger et al., 1998; De Senoit et al., 2004) as illustrated in Fig. 7.17. Another way to determine the quality of a source is to measure their self-absorption from the beta efficiency variation of the sample (De Sanoit et al., 2001) or from the parameters that define a spectral alpha peak (Denecke et al., 2000).

Sample uniformity and homogeneity can be improved by depositing a wetting and seeding agent in the support of the source, before depositing the radioactive material. It is advisable to use commercial detergents as wetting agents,

(2004), reprinted with permission of Elsevier Science.*

such as Tween 20, Catanac (Leprince and De Sanoit, 2002; Miguel et al., 1984) or tetra ethylene glycol (TEG). To produce small crystals we use a seeding agent such as colloidal silica (Ludox), microspheres (K-007) or ion exchange resins (Merritt et al., 1960; Lachance and Roy, 1972; Lowental and Wyllie, 1973; Chen et al., 1989; Du et al., 1986; Blanchis et al., 1990).

The quality of a sample is also given by the drop drying procedure. A common procedure is to dry outdoors without air flows. Another method is to use a laminar flow, both at room temperature or heating with an infrared lamp. Generally we must apply a dry atmosphere, although in some cases it is useful to use the freeze-drying technique (Hutchinson, 1965; De Sanoit et al., 2004). Finally, we have also used dry warm nitrogen jets (Denecke et al., 2000).

In the case of source preparation (De Sanoit et al., 2004), freeze-drying under vacuum consists of the dehydration of the radioactive drop by sublimation. The apparatus is composed of a 300 mm diameter stainless steel ice condenser chamber (ICC) with its associated cooling system and a vacuum pump (pump rate: 5.6 m^3/h) in order to speed up the drying process. The experimental layout is shown in Fig. 7.18.

In most cases, drying a liquid drop of a radioactive solution results in an agglomeration of crystals, the final size of which depends mainly on the time available for the crystals to grow. A usual practice was to dry the sources in a fume hood by air draft (Van der Eijk and Zehmer, 1977). The results were often unsatisfactory as large crystals were formed mainly at the boundary of the drop and at dust particle inclusions. In some cases the liquid withdrew to a much smaller area than the initial drop size, resulting in a very inhomogeneous distribution of the deposit. The uniformity of the deposit was improved by stirring the drop with a dry nitrogen jet. However, due to the long drying time of typically 10−20 minutes, crystals could still grow to large sizes. Employing a gas jet at an elevated temperature substantially accelerated the evaporation of the solvent. By using multiple gas jets and rotating the source at the same time, more turbulence was caused within the drop. This turbulence prevented the formation of a few large crystals at the three-phase boundary between the drop and the substrate. As a result of steady remixing, a large number of small crystals, uniformly distributed over the original drop size, were formed. Intense evaporation begins when temperature and gas flows are set high. In this phase, mainly water evaporates and only a film of the concentrated acid solution remains on the substrate. At this point, the heat input to the gas jets must be reduced to limit the temperature rise of the deposit and substrate and to reduce the buildup of material stresses in the deposit. These stresses may tear a thin foil substrate or reduce adherence between the deposit and the substrate.

The drying apparatus Figs. 7.19 and 7.20, consists of a turntable with variable speed, four gas jets with adjustable gas flow and temperature, a transparent bell jar and a vacuum pump. Gas jets at an elevated temperature impact directly onto the rotating liquid drop deposited on a substrate. Jet distances and positions are adjustable. A geared asynchronous motor using frequency control varies the rotation speed from 5 to 150 rpm. Placing the bell jar over the tabletop creates a closed and dust-free environment around the drop source. Pumping is needed to remove the water vapor from the closed container and enables control of pressure between 5 and 101.3 kPa, which also accelerates evaporation.

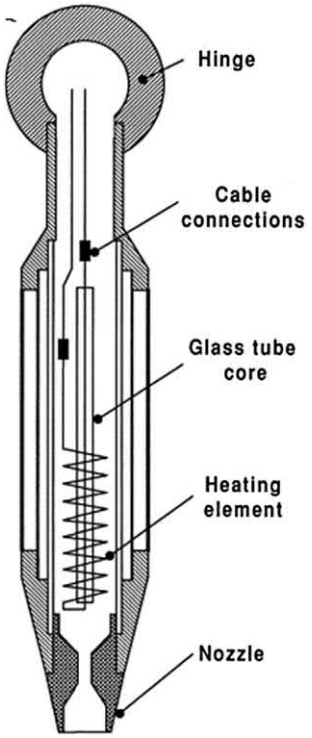

FIGURE 7.19 Construction of the hot gas jet. The heating element, a helix of resistive wire on a glass tube core, is centered inside the gas duct close to the outlet. Two thin-walled tubes thermally insulate the duct. A narrow nozzle forms the gas jet. *From Denecke et al. (2000), reprinted with permission of Elsevier Science.*

Agustín Grau Malonda

Agustín Grau Malonda holds a BSc degree from the Complutense University, Madrid 1962; Doctorate in Electronics from Toulouse University (France) 1965; PhD in Physics from the Complutense University, Madrid, 1981. He worked in the JEN (Atomic Energy Commission), Radiochemistry Section, 1965–71 and Radionuclide Metrology Section, 1972–84. Agustín Grau Malonda subsequently held numerous positions as Director of the Basic Research Department (CIEMAT) 1984–86; Director of the Department of Fusion and Particle Physics (CIEMAT) 1987–98; Director of the Institute for Energy Studies (CIEMAT) 1999–2003; Deputy Director of Strategic Projects (CIEMAT) 2004–08; Associate Professor of Physics, Madrid Polytechnic University, 1969–77; Professor of Nuclear Engineering, Madrid Polytechnic University, 1977–85. In addition, he was a member of the following working groups and committees: Consulting Committee for the Fusion Program (EU) 1996–2000, (Vice Chairman) 1991–2000; Joint European Torus (JET) Council, 1986–2000; JET Executive Committee, 1986–99; Fusion Technology Steering Committee (EU) 1986–90; Fusion Power Coordinating Committee (OECD) 1998–2002; L3 Committee (CERN) 1986–99; International Committee for Radionuclide Metrology (ICRM), 1975–2003 (Vice Chairman, 1998–99); EUROMET, 1990–99; EURATOM Scientific and Technical Committee, 1992–2003; Adviser Committee for the Central Bureau for Nuclear Measurements, JRC, Geel (Belgium) 1989–95. Awards: Department of Commerce, NBS, USA, Guest Worker Contributions, 1982, 1983; Men of the Year in Sciences, Cambio 16 Journal, 1991; and Encomienda de la Orden de Isabel la Católica, Spanish King, 2001.

Agustín Grau Carles

Agustín Grau Carles holds a PhD in Physical Sciences from the Complutense University of Madrid. During 1991–2000, he worked at the Center for Environmental and Technological Energy Research (CIEMAT), together with chemists, developing new spectrometric techniques for radioisotopes, based on liquid-scintillation counting. From 2002 to 2004, he

collaborated with biologists from the Center for Astrobiology (CAB) in the calibration of ultraviolet lamps for the irradiation of extremophile cultures. He was also involved, in collaboration with geologists, in the development of new meteorite authentication techniques from radioisotopes originated by cosmic radiation. Between 2004 and 2010, he worked at the Spanish National Research Council (CSIC) in his own Ramón y Cajal project to study the feasibility of a nanodosimeter based on scintillation gels. Currently he directs the BIC Academy (Goods of Cultural Interest), which teaches courses on the need for Science to understand art, as well as archaeological and paleontological goods.

I. Introduction

In the measurement process, the object to be observed is always affected by an undetermined interaction between the observer and the observed. As a result, the measured magnitudes are always reproduced with a certain inherent uncertainty caused by the instrument. This uncertainty in the measurements makes the use of error theory essential. When we measure radioactive substances, the situation becomes even more complicated, because the radioactivity decay is a random process. In radioactivity counting, two types of fluctuations are basically generated, one related to the activity of the sample, when the half-life of the radionuclide is short, and another caused by the random nature of radioactivity decay, which modifies the disintegration rates with time. Since the measurement of radioactivity involves values with different degrees of reliability and validity, the principles of counting statistics must be applied (Larson, 1969; Eadie et al., 1971).

In many types of measurement such as mass, volume, time, length, etc., the measured quantity has a given value and only the measurement conditions introduce statistical variations. The situation is different, however, in radioactivity measurements. The radioactive decay process follows Poison statistics, so a sample's activity value is not a specific value but a mean value that varies with time. If we measure the emission of a radioactive source, as shown on Table 8.1, repeated measures are not equal. But there is a clear condition: if the measuring equipment does not introduce a perturbation, the emission and measurement rates must follow the same statistical law, so their

mean and variance rates are equal from a statistical perspective.

Example 8.8 represents a detailed analysis of the set of measurements shown on Table 8.1. We see that they are not affected by the counter. Example 8.9, 8.10, and 8.11 present different cases in which counting rates are affected by the counter. Example 8.9 corresponds to the case where the counting rate is reduced by counter resolution time. It is also shown that corrections are required to correct the results of the measurements, as well as the tests to be applied. Example 8.10 shows the results of counting when counting differences are very close, smaller than expected. Example 8.11 presents the corrections to be applied to the measures of Example 8.10 to obtain results that follow the Poisson law. In all of these examples, the respective tests are applied to support the results.

II. Statistical distributions

In this section we shall study all basic characteristics of both the Poisson and the normal (or Gaussian) distributions, and their relation to radioactivity counting statistics. Although the Poisson distribution involves all processes of radioactivity decay, and therefore the detection of particles and radiation, the normal distribution is applied more often by far and is better known in the majority of cases. Since the application of the Poisson distribution to counting statistics may be tedious and time consuming, and considering that both distributions give identical results, when the total number of counts becomes large, our final objective will be the determination of some characteristic parameters, which will allow one to exchange the Poisson distribution by the normal one.

A. The Poisson distribution

The Poisson distribution describes a random process for which the occurrence probability of a certain event is constant and small. This distribution not only concerns radioactivity counting statistics (Helstrom, 1968) or nuclear decay, but it is also applied to evaluate, in a more or less approximate way, many other processes (Garwood, 1936; Grau Malonda, 1999). Some examples of daily life that verify Poisson statistics are, for example, the number of phone calls received at a phone switchboard several minutes before noon, the number of annual strikes in a factory, the number of misprints on a book page, the number of times a piece of a machine fails in a given period of time, and the number of fatal traffic accidents each week in a city. Przyborowski and Wilenski (1935) present an application of Poisson law and construct rules to minimize the chance of errors in tests and samples.

In radioactivity decay, four aspects are fulfilled: all radioactive nuclei have the same decay probability for a given time period, the decay process of one nucleus is not affected by the decay of other nuclei, the total number of nuclei and measurement time intervals are sufficiently large, and the nuclei half-life is long compared with the detection pulse. Therefore, the radioactivity decay is a random process, in which a discontinuous random variable is defined as the number of times a decay event takes place in a continuous period of time t. Additionally, the probability of one decay event occurring in a time increment Δt must be asymptotically proportional to Δt, independently of the time value in the interval Δt and all previous decay events. Under these conditions, the Poisson distribution takes the form:

$$P_x(t) = \frac{e^{-at}(at)^x}{x!},\ x = 0,\ 1,\ 2, \ldots \tag{8.1}$$

where $P_x(t)$ is the probability that a number of x decay processes take place in time t and a a constant to be determined. The expression (8.1) may be derived in three different ways: by approximation from the binomial distribution (Hoel, 1984), considering first principles (Evans, 1982), or basing all calculations on a Markov process (Feller, 1968; Rozanov, 1977).

Three important properties derived from Eq. (8.1) are the following:

$$\sum_{x=0}^{\infty} P_x = 1 \tag{8.2}$$

$$\sum_{x=0}^{\infty} xP_x = at \tag{8.3}$$

$$\sum_{x=0}^{\infty} (x - at)^2 P_x = at \tag{8.4}$$

The normalization condition (Eq. 8.2) states that the summation of all possible probabilities P_x of the Poisson distribution is one. The expression (8.3) defines the parameter a as the average value of the distribution divided by t, i.e., the number of decay processes per unit of time. The third expression (8.4) refers to the identity relation between the variance and the mean, when the Poisson

distribution is applied. The most important consequence derived from the three properties (Eqs. 8.2 to 8.4) is that the single parameter a enables one to determine the first and second order moments (i.e., $\sum_{x=0}^{\infty} xP_x$ and $\sum_{x=0}^{\infty} x^2P_x$) of the Poisson distribution. By defining the average number of decay processes in time t as the product $\mu = at$, the Poisson distribution can be expressed as

$$P_x = \frac{e^{-\mu}\mu^x}{x!} \tag{8.5}$$

The Poisson distribution is asymmetric, and its shape depends on the parameter μ, which is a real value greater than zero.

Example 8.1. The measurement of a radioactive sample of ^{238}U ($T_{1/2} = 4.47 \times 10^9$years) during 3 days gives a total number of counts 133,747. (a) Evaluate the average counting rate, and compute the probability of counting: (b) less than one count in 1 second, (c) exactly 1 count, (d) less than 3 counts, (e) a number of counts between 1 and 4, and (f) more than 3 counts.

Solution:

a. The average counting rate is: $\mu = \frac{133{,}747}{3\times24\times60\times60} = 0.516$ counts/s

b. The probability of **counting** less than one count is computed as follows:

$$P(X<1) = P_0 = e^{-0.516} = 0.597$$

c. The probability of **counting** exactly one count:

$$P(X=1) = \frac{\mu^1 e^{-\mu}}{1!} = 0.516 \times e^{-0.516} = 0.3$$

d. The probability of counting less than 3 counts is the addition of the probabilities of counting **none**, 1 and 2 counts

$$\begin{aligned} P(X<3) = \sum_{x=0}^{2} P_x &= P_0 + P_1 + P_2 \\ &= e^{-\mu} + \mu e^{-\mu} + \frac{\mu^2}{2}e^{-\mu} \\ &= e^{-\mu}\left(1 + 0.516 + \frac{0.516^2}{2}\right) = 0.984 \end{aligned}$$

e. The probability of counting a number of counts between 1 and 4 is the addition of the **probabilities** of counting exactly 2 and 3 counts

$$\begin{aligned} P(1<X<4) = P_2 + P_3 &= \frac{\mu^2 e^{-\mu}}{2!} + \frac{\mu^3 e^{-\mu}}{3!} \\ &= e^{-\mu}\left(\frac{\mu^2}{2!} + \frac{\mu^3}{3!}\right) \\ &= e^{-0.516}\left(\frac{0.516^2}{2} + \frac{0.516^3}{6}\right) = 0.093 \end{aligned}$$

f. The probability of counting **more** than 3 counts is

$$\begin{aligned} P(X>3) = \sum_{x=4}^{\infty} P_x &= 1 - \sum_{x=0}^{3} P_x \\ &= 1 - (P_0 + P_1 + P_2 + P_3) \\ &= 1 - e^{-\mu}\left(1 + \mu + \frac{\mu^2}{2!} + \frac{\mu^3}{3!}\right) \\ &= 1 - e^{-0.516}\left(1 + 0.056 + \frac{0.516^2}{2} + \frac{0.516^3}{6}\right) = 0.00196 \end{aligned}$$

It should be remarked that a linear combination of the two random variables X and Y, which both follow the Poisson distribution, gives a third random variable, which does not necessarily follow the Poisson distribution. For the following three random variables $V = aX$, $Z = X + Y$, and $W = X - Y$, only Z follows the Poisson distribution.

B. The Gaussian distribution

In general, it is assumed that the random variable X follows a normal distribution of mean μ and variance σ^2, when the probability density function of a set of measured values x yields the function

$$p(x) = \frac{1}{\sigma\sqrt{2\pi}}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \tag{8.6}$$

where $(-\infty < x < \infty)$, $(-\infty < \mu < \infty)$, and $(0 < \sigma^2 < \infty)$.

Frequently, in the course of a number of measurements, we are interested in evaluating the probability that a new measurement of the random variable X verifies a certain condition relative to the value x. This probability is

computed in terms of the accumulated distribution function, which is defined as follows:

$$P(X \leq x) = \frac{1}{\sigma\sqrt{2\pi}} \int_{-\infty}^{x} \exp\left[-\frac{(t-\mu)^2}{2\sigma^2} \right] dt \qquad (8.7)$$

Geometrically, the integral (8.7) is interpreted as the area under the curve between the limits of the interval $-\infty \leq X \leq x$. Since each pair of values (μ, σ^2) defines a different distribution, there is no simple way to tabulate the accumulated distribution function. This inconvenience is partially resolved by defining the normalized random variable Z

$$Z = \frac{X-\mu}{\sigma} \qquad (8.8)$$

for which the probability density and the accumulated distribution functions can be defined as follows:

$$p(z) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{z^2}{2} \right) \qquad (8.9)$$

$$P(Z \leq z) \equiv \Phi(z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{z} \exp\left(-\frac{t^2}{2} \right) dt \qquad (8.10)$$

Although the tabulated values of the accumulated distribution function (Eq. 8.10) are found in the majority of statistics manuals, the symmetric character of the distribution makes two different criteria of tabulation possible, which may cause confusion. For instance, Triola (2009) assumes the integration interval $0 \leq Z \leq z$, while Newbold (2009) and Abramowitz and Stegun (1972) consider $-\infty < Z \leq z$. These intervals are shown in Fig. 8.1. Since the normal distribution is normalized to one, both criteria of tabulation make the values simply differ in 0.5. Bevington (1969) defines the normalized random variable Z as the absolute value of the difference between the means $|X-\mu|$ divided by the standard deviation

$$Z = \frac{|X-\mu|}{\sigma}$$

The integration interval is $-\infty < Z < \infty$ and the values of $\Phi(Z)$ are two times the values for the interval $0 < Z < \infty$.

Example 8.2. By searching in Table 8.2, calculate the accumulated distribution function Φ for the following limits of the standard random variable Z: (A) $0 \leq Z \leq 1.75$, (B) $-1.75 \leq Z \leq 0$, (C) $Z \geq 1.85$, (D) $Z \leq 1.10$, and (E) $Z \leq -1.45$.

Solutions:

a. The second column in Table 8.2 shows the accumulated distribution function Φ for the values of z listed in the first column. The remaining columns, from third to eleventh, list the intermediate values of Φ when z is incremented in 0.01. Therefore, the sought value of $\Phi(1.75) = 0.4599$ is given in column seven.

b. Taking into account the symmetry of the curve with respect to the origin we have

$$\Phi(-1.75 \leq Z \leq 0) = \Phi(0 \leq Z \leq 1.75) = 0.4599$$

c. Since the total area under the curve is 1, we obtain

$$P(Z \geq 1.85) = 0.5 - P(0 \leq Z \leq 1.85) = 0.5 - 0.4678 = 0.0322$$

d. Since the area under the curve for the interval $-\infty < Z \leq 0$ is 0.5, we have

$$P(Z \leq 1.10) = 0.5 + P(0 \leq Z \leq 1.10) = 0.5 + 0.3643 = 0.8643$$

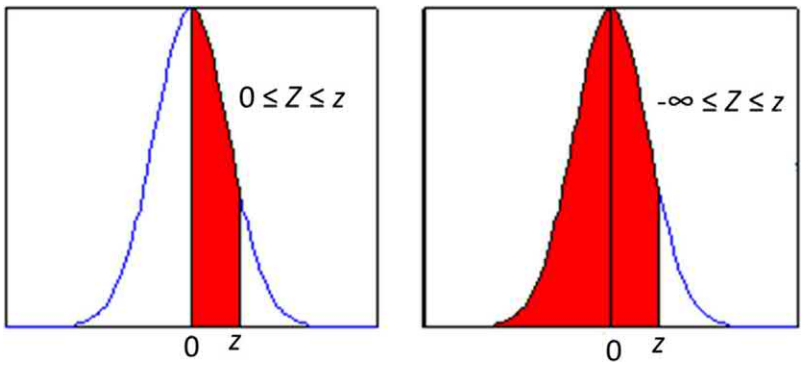

FIGURE 8.1 Integration intervals corresponding to two different criteria for tabulation.

e. By applying both the normalization and symmetry properties of the curve, we obtain

$$P(Z \leq -1.45) = 0.5 - P(-1.45 \leq Z \leq 0)$$
$$= 0.5 - P(0 \leq Z \leq 1.45) = 0.5 - 0.4265 = 0.0735$$

In practice, the random variable Z has no physical meaning. For this reason, the notation $N(\mu, \sigma^2)$ is adopted preferably in those statistical problems that apply the normal distribution. However, to perform calculations, the tabulated values of the standard normal distribution are still valid. The following examples make it clear how to manage Table 8.2, when the notation $N(\mu, \sigma^2)$ is adopted.

Example 8.3. Consider the random variable X that follows the normal distribution $N(16, 16)$. Compute the accumulated distribution probability $P(X \geq 17)$ from Table 8.2

Solution. The average and the standard deviation are $\mu = 16$ and $\sigma = 4$, respectively. The limits of the interval for the standard random variable Z are obtained from Eq. (8.8)

$$Z = \frac{X - \mu}{\sigma} = \frac{17 - 16}{4} = 0.25$$

Hence,

$$P(X \geq 17) = P(Z \geq 0.25) = 0.5 - P(0 \leq Z \leq 0.25)$$
$$= 0.5 - 0.0987 = 0.4013$$

Example 8.4. The normal distribution $N(20, 4)$ has the accumulated distribution probability 0.30 for $X \leq x_0$. Compute x_0.

Solution. Since $P(Z \leq z_0) = 0.30 < 0.5$, z_0 must be negative. By making use of Table 8.2, we find $z_0 = -0.84$. Now, from Eq. (8.8), $-0.84 = (x_0 - 20)/2$. Thus, $x_0 = 20 - 1.68 = 18.32$.

In contrast to the Poisson distribution, the linear combination of the two random variables X and Y, which are characterized by the normal distribution, generates a new random variable $W = aX + bY$, which always follows the normal distribution. This important property clearly indicates how advantageous the application of the normal

distribution compared to the Poisson distribution may be. For large average values of μ, the Poisson distribution is generally approximated to the normal distribution $N(\mu, \mu)$. In such a case, the accumulated distribution satisfies the equation

$$P(X \leq x) = e^{-\mu} \sum_{n=0}^{x} \frac{\mu^n}{n!} \approx \Phi\left(\frac{x + \frac{1}{2} - \mu}{\sqrt{\mu}}\right) \tag{8.11}$$

This approximation sets the standard deviation of the normal distribution equal to the standard deviation of the Poisson distribution, and yields results commonly denoted as $\mu \pm \sigma$, where $\sigma = \sqrt{\mu}$. Since the area under the curve for the interval $(\mu - \sigma,\ \mu + \sigma)$ is 68% of the total area, the probability that new measurements give results lying in the interval $(\mu - \sigma,\ \mu + \sigma)$ is 68%. Table 8.3 shows such a probability for different intervals.

III. Analysis of a sample of results

Both the Poisson and normal distributions are applied to analyze the results of experiments with a large number of observed events. In practice, however, that is not the case, and the observed events in an experiment are frequently limited in number. All statistical information of one experiment is contained in the population distribution (or limit distribution). When a radioactive sample is analyzed, the amount of accumulated results depends on the counting rate and the measuring time, but what about the true value? This section will try to answer this and other questions relative to the analysis of a statistical sample of results.

A. Best estimate of the true value

For a symmetric distribution, the best estimate of the true value is given by the center of symmetry of the distribution. This center of symmetry is by definition the single value that agrees with its symmetrical position in the distribution. Since the mean, median, and mode all represent the center of symmetry of the distribution, nothing can be concluded about which one is the best to describe the true value.

For an asymmetric distribution, the mean, median, and mode take on different values. Therefore, the best estimate of the true value may be selected among these three possibilities by considering the requirements of the problem. Certain special cases may lead one to choose the median or the mode as the best estimate, but the mean of the population distribution is the one preferred in the majority of situations.

Let us assume the average of a sample $\bar{x}$ as the best estimate of the true value for a sample of results $x_1, x_2, \ldots, x_n$ that follow an unknown distribution

$$\bar{x} = \frac{1}{n} \sum_{i=1}^{n} x_i \tag{8.12}$$

Obviously, when the total number of measurements $n \to \infty$, the sample of results conforms to the population distribution, and the true value X agrees with the mean value of the distribution μ. Eisenhart (1963) analyzes the concepts of true value and uncertainty in measurement instruments.

TABLE 8.3 Probability for different intervals.

Interval	Probability
$\mu \pm 0.67\sigma$	0.50
$\mu \pm \sigma$	0.68
$\mu \pm 1.64\sigma$	0.90
$\mu \pm 2\sigma$	0.95
$\mu \pm 3\sigma$	0.997

B. Best estimate of precision

The analysis of the results of an experiment makes it necessary to define the concept of uncertainty. The width of the distribution shows graphically the uncertainty in symmetrical distributions. The two simplest expressions that represent the uncertainty are the absolute mean deviation τ and the standard deviation σ

$$\tau = \int_{-\infty}^{\infty} |x - X| p(x) dx \tag{8.13}$$

$$\sigma^2 = \int_{-\infty}^{\infty} (x - X)^2 p(x) dx \tag{8.14}$$

where X is the true value of the distribution, commonly associated with the mean of the distribution.

To define the absolute average deviation, the absolute differences between x and the true value X are multiplied by the relative frequencies of x in the distribution, and integrated for all possible values of x. On the other hand, Eq. (8.14) squares the difference instead of taking the absolute value. In both cases, the result of integration is a positive number that becomes larger with the distribution width.

The difference between the terms error and uncertainty have been widely discussed in the literature (Burns et al., 1973; Campion et al., 1973; Rabinovich, 2005).

An easy description of error theory is given in Beers (1957). The term "error" is generally applied to describe the

difference between the measured and the true values, while the term "uncertainty" is related to the inaccuracy of the measurements, and is always accompanied with the corresponding confidence probability. The International Vocabulary (1993) defines uncertainty as "an interval having a stated level of confidence." We illustrate the difference between the two definitions with an example, such that the error can be 1%, whereas the uncertainty is ±1% with a level of confidence of 95% (observe how the error can be +1% or −1%, but never ±1%).

The simplest counting statistics is when we have only one counting result and we are interested in associating with it an uncertainty. This is possible because the radioactive emissions follow Poisson statistics and, if the measurement does not perturb the process, the standard deviation of the total counts is its square root.

When the counting statistics includes n measurements $x_1, x_2, \ldots, x_n$, the sample variance is given by the expression

$$s_n^2 = \frac{1}{n-1}\sum_{i=1}^{n}(x-\overline{x})^2 \tag{8.15}$$

which coincides with the variance (Eq. 8.14) for $n \to \infty$.

C. Error propagation

In radioactivity counting statistics, the Poisson distribution gives the uncertainty in the total number of counts. Other related quantities, e.g., counting rate or the number of counts without background are obtained by error propagation (Natrella, 2005; Nicholson, 1966).

Suppose the triple measurement of one radioactive sample gives the three independent results x, y, z for the total number of counts, then the respective standard deviations are $\sigma_x = \sqrt{x}$, $\sigma_y = \sqrt{y}$, $\sigma_z = \sqrt{z}$, and the standard deviation of a function of these three variables x, y, z, when these are independent, is given by

$$\sigma_u^2 = \left(\frac{\partial u}{\partial x}\right)^2\sigma_x^2 + \left(\frac{\partial u}{\partial y}\right)^2\sigma_y^2 + \left(\frac{\partial u}{\partial z}\right)^2\sigma_z^2 \tag{8.16}$$

On the other hand, when the three variables x, y, z are correlated, we have

$$\begin{aligned}\sigma_u^2 = {} & \left(\frac{\partial u}{\partial x}\right)^2\sigma_x^2 + \left(\frac{\partial u}{\partial y}\right)^2\sigma_y^2 + \left(\frac{\partial u}{\partial z}\right)^2\sigma_z^2 \\ & + 2\rho_{xy}\left(\frac{\partial u}{\partial x}\right)\left(\frac{\partial u}{\partial y}\right)\sigma_x\sigma_y + 2\rho_{yz}\left(\frac{\partial u}{\partial y}\right)\left(\frac{\partial u}{\partial z}\right)\sigma_y\sigma_z \\ & + 2\rho_{xz}\left(\frac{\partial u}{\partial x}\right)\left(\frac{\partial u}{\partial z}\right)\sigma_x\sigma_z\end{aligned} \tag{8.17}$$

where ρ_{xy}, ρ_{xz}, ρ_{yz}, are the correlation coefficients for the variables xy, xz, yz, respectively. These coefficients are defined by

$$\rho_{xy} = \frac{1}{(n-1)\sigma_x\sigma_y}\left(\sum_{i=1}^{n}x_iy_i - n\overline{XY}\right) \tag{8.18}$$

$$\rho_{xz} = \frac{1}{(n-1)\sigma_x\sigma_z}\left(\sum_{i=1}^{n}x_iz_i - n\overline{XZ}\right) \tag{8.19}$$

$$\rho_{yz} = \frac{1}{(n-1)\sigma_y\sigma_z}\left(\sum_{i=1}^{n}y_iz_i - n\overline{YZ}\right) \tag{8.20}$$

The corresponding correlation coefficient for two independent variables is $\rho = 0$, while for two completely correlated variables it is given by $\rho = \pm 1$. Table 8.4 shows several common functions and their respective partial derivatives. To compute the standard deviations for the counting parameters listed in column 1 of Table 8.5, the application of the error propagation equations in Table 8.4 is required.

Example 8.5. Two students are discussing how to apply the error propagation equations of Table 8.4 on function $u = 2x$ to obtain the standard deviation. Student A considers the standard deviation $\sigma_u = 2\sigma_x$ the best, while student B, after transforming the function into $u = x + x$, obtains the standard deviation $\sigma_u = \sqrt{2}\sigma_x$. Then a third student C joints the discussion arguing that the standard deviation is $\sigma_u = 2\sqrt{5}\sigma_x$ by transforming the function into $u = z - v$, where $z = 4x$ and $v = 2x$. Explain the discrepancies in the standard deviations obtained by the three students.

Solution. Only the standard deviation given by student A is correct. The assumption of student B is not valid, because the two terms into which the function u has been separated are correlated. Therefore, from Eq. (8.17) we have

$$\sigma_u^2 = \sigma_x^2 + \sigma_x^2 + 2\sigma_x\sigma_x = (\sigma_x + \sigma_x)^2 = 4\sigma_x^2$$

TABLE 8.4 Error propagation.

Equation	Standard deviation
$u = ax$	$\sigma_u = a\sigma_x$
$u = x \pm y$	$\sigma_u = \sqrt{\sigma_x^2 + \sigma_y^2}$
$u = a + bx + cy$	$\sigma_u = \sqrt{b^2\sigma_x^2 + c^2\sigma_y^2}$
$u = xy/z$	$(\sigma_u/u)^2 = (\sigma_x/x)^2 + (\sigma_y/y)^2 + (\sigma_z/z)^2$
$u = \log x$	$\sigma_u = \sigma_x/x$

TABLE 8.5 Application of uncertainty transmission errors to different counting results.

Result	Equation	Standard deviation
Counting rate	$b = C_B/t_B$	$\sigma(b) = \sigma(C_B)/t_B = \sqrt{C_B}/t_B$
Net gross counting	$C_S = C_{S+B} - C_B$	$\sigma(C_s) = \sqrt{\sigma^2(C_{S+B}) + \sigma^2(C_B)}$ $= \sqrt{C_{S+B} + C_B}$
Net counting rate	$c_S = C_{S+B}/t_{S+B} - C_B/t_B$	$\sigma(c_s) = \sqrt{\sigma^2(C_{S+B})/t_{S+B}^2 + \sigma^2(C_B)/t_B^2}$ $= \sqrt{C_{S+B}/t_{B+S}^2 + C_B/t_B^2}$
Channel ratio	$Q = N_A/N_B$	$(\sigma(Q)/Q)^2 = (\sigma(N_A)/N_A)^2 + (\sigma(N_B)/N_B)^2$ $= 1/N_A + 1/N_B$

so

$$\sigma_u = 2\sigma_x$$

in agreement with the result given by student A. The argument of student C is also devoid of the correlation concept. To be correct, the standard deviation should be expressed as

$$\sigma_u^2 = \sigma_z^2 + \sigma_v^2 - 2\sigma_z\sigma_v = 16\sigma_x^2 + 4\sigma_x^2 - 2 \times 4\sigma_x \times 2\sigma_x = (4\sigma_x - 2\sigma_x)^2 = 4\sigma_x^2$$

so

$$\sigma_u = 2\sigma_x$$

which also agrees with the result obtained by student A.

Error propagation is of great interest in planning experiments. Optimization of experiments allows one to reduce to a minimum the uncertainties of experimental results. A good example is the optimization in isotopic dilution as is shown by Angoso et al. (1973). Optimization of the figure of merit to obtain the best compromise between sample and background counts can be seen in the papers of Loevinger and Berman (1951), Thomas (1950), Jaffey (1960), Reynolds (1964), Donn and Wolke (1976), and Wyld (1970).

D. Accuracy of the mean value

In the previous sections, the mean value μ of a distribution of infinite events was taken as the best estimate of the true value X. In practice, however, the number of available measurements is finite, and frequently low. Since this number varies depending on the experiment, one question that immediately arises is: How can we approximate the mean value to the true value? In other words, how many measurements are necessary to obtain an accuracy better than a certain value?

The verification of one experiment by repeating the same sequence of measurements should provide similar average values X_n, and be in good agreement with the true value X, when the total number of measurements is large. The average value for a sequence of n independent measurements is given by

$$X_n = \frac{1}{n}(x_1 + x_2 + \ldots + x_n) \tag{8.21}$$

By applying the error propagation theory to Eq. (8.21), the following standard deviation of the mean is obtained

$$\sigma(X_n) = \left(\frac{\sigma^2(x_1)}{n^2} + \frac{\sigma^2(x_2)}{n^2} + \ldots + \frac{\sigma^2(x_n)}{n^2}\right)^{1/2} \tag{8.22}$$

Since x_1, x_2, …, x_n come from measuring the same quantity, we have

$$\sigma^2(x_1) = \sigma^2(x_2) = \ldots = \sigma^2(x_n) = \sigma^2(x) \tag{8.23}$$

thus

$$\sigma(X_n) = \frac{\sigma(x)}{\sqrt{n}} \tag{8.24}$$

By taking the average quadratic deviation Eq. (8.15) as the best estimate of the measurements, we obtain

$$S_n = \sigma(X_n) = \frac{\left(\sum_{i=1}^{n}(x_i - X)^2\right)^{1/2}}{\sqrt{n(n-1)}} = \frac{\sigma_n(x)}{\sqrt{n-1}} = \frac{s_n(x)}{\sqrt{n}} \tag{8.25}$$

which indicates the degree of accuracy of the mean value X_n. The standard deviation S_n in Eq. (8.25) is called the **standard error**, and gives the best estimate of the true value when written as

$$X = X_n \pm S_n \tag{8.26}$$

where S_n is a function of the total number of counts and measurements. The increment of the number of measurements makes the accuracy improve proportionally with the square root.

Frequently the best estimate of one experiment is computed from the mean values instead of directly from the measurements. Suppose X_n and Y_n are the corresponding mean values of two sets of n and m measurements, then the mean value of the new variable $z = x \pm y$ is $Z_{nm} = X_n \pm Y_m$, and its standard deviation is given by

$$\sigma(Z_{nm}) = \sqrt{\sigma^2(X_n) + \sigma^2(Y_m)} \tag{8.27}$$

so

$$S_{nm} = \sqrt{S_n^2 + S_m^2} = \sqrt{\frac{\sigma_n^2(x)}{n-1} + \frac{\sigma_m^2(x)}{m-1}} \tag{8.28}$$

E. Combination of measurements

We are by now quite familiar with the computation of the uncertainty of nonmeasured quantities from the uncertainty of directly measured quantities by error propagation. However, how can we combine results from experiments in which we have applied different methods?

Suppose that the successive measurements carried on one radioactive sample give $X_n \pm S_n$ by applying one procedure and $X_m \pm S_m$ by applying another. If both methods were of similar precision, a good estimate of the true value could be

$$X_{n,m} = \frac{X_n + X_m}{2} \tag{8.29}$$

In practice, however, one procedure may be more precise than the other, and the best estimate of the true value is given by the weighted mean

$$X_{n,m} = \alpha X_n + (1-\alpha)X_m \quad \text{where} \quad 0 \le \alpha \le 1 \tag{8.30}$$

The numerical value of the weight α is computed from S_n and S_m. By applying error propagation to Eq. (8.30) we obtain the equation

$$S_{n,m}^2 = \alpha^2 S_n^2 + (1-\alpha)^2 S_m^2 \tag{8.31}$$

The error function $S_{n,m}$ becomes minimum when the derivates vanish

$$\frac{dS_{n,m}^2}{d\alpha} = 2\alpha S_n^2 - 2(1-\alpha)S_m^2 = 0 \tag{8.32}$$

That is, when

$$\alpha = \frac{S_n^{-2}}{S_n^{-2} + S_m^{-2}} \quad \text{and} \quad 1-\alpha = \frac{S_m^{-2}}{S_n^{-2} + S_m^{-2}} \tag{8.33}$$

Hence, the best estimate of the true value will be given by

$$X_{n,m} = \frac{1}{S_n^{-2} + S_m^{-2}}\left(\frac{X_n}{S_n^2} + \frac{X_m}{S_m^2}\right) \tag{8.34}$$

and the standard deviation

$$S_{n,m}^2 = \frac{S_n^{-2} + S_m^{-2}}{\left(S_n^{-2} + S_m^{-2}\right)^2} = \frac{S_n^2 S_m^2}{S_n^2 + S_m^2} \tag{8.35}$$

so

$$S_{n,m}^{-2} = S_n^{-2} + S_m^{-2} \tag{8.36}$$

The subsequent generalization of Eqs. (8.34) and (8.36) to more than two procedures generates the following equations:

$$X_{n,m,p,\ldots} = \frac{1}{S_n^{-2} + S_m^{-2} + S_p^{-2} + \ldots}\left(\frac{X_n}{S_n^2} + \frac{X_m}{S_m^2} + \frac{X_p}{S_p^2} + \ldots\right) \tag{8.37}$$

and

$$S_{n,m,p,\ldots}^{-2} = S_n^{-2} + S_m^{-2} + S_p^{-2} + \ldots \tag{8.38}$$

Frequently, these equations are written applying the following notation:

$$X = \sum_{n=1}^{N} \frac{x_n}{S_n^2} \Big/ \sum_{n=1}^{N} \frac{1}{S_n^2} \tag{8.39}$$

$$S_{in}^2(X) = 1 \Big/ \sum_{n=1}^{N} \frac{1}{S_n^2} \tag{8.40}$$

where the subscript *in* denotes an inner type standard deviation. On the other hand, the subscript *out* is used for outer standard deviations that verify

$$S_{out}(X) = \left[\frac{\sum_{i=1}^{N} (x_i - X)^2 / S_i^2}{(N-1)\sum_{i=1}^{N} 1/S_i^2}\right]^{1/2} \tag{8.41}$$

Both types of standard deviation, S_{out} and S_{in}, are equal for samples taken from the same normal population. However, in many situations, the ratio S_{out}/S_{in} differs from unity, adopting the expression defined by Topping (1972):

$$Z = \frac{S_{out}}{S_{in}} = \left[\frac{\sum_{i=1}^{N} (x_i - X)^2 / \sigma_i^2}{N-1}\right]^{1/2} \tag{8.42}$$

The observed data can only be considered consistent when the value of Z does not differ significantly from unity.

TABLE 8.6 Energy and uncertainty of ^{60}Co gamma ray.

E_γ[keV]	Uncertainty
1332.483	0.046
1332.560	0.050
1332.540	0.040
1332.509	0.015
1332.508	0.015

In such a case, the best value for the error of the weighted average is given by the greatest of the two values S_{out} or S_{in}. On the other hand, when Z differs significantly from unity, the conclusion is that systematical errors are present in the measurements. This leads to weights that do not verify Eq. (8.33), and depend more on other conditions such as the right performance of the experiment.

Example 8.6. The measurement of the energy emitted by one of the gamma-ray transitions of ^{60}Co was carried out by five different methods. The resulting energies and their respective uncertainties are shown in Table 8.6. Find the mean value and the inner and outer standard deviations. Also compute the value of Z and analyze the consequences of its proximity to unity.

Solution. The computation of the weighted average gives

$$X = \frac{\sum_{n=1}^{5} x_n/S_n^2}{\sum_{n=1}^{5} 1/S_n^2} = \frac{1.3840098 \times 10^7}{1.0386478 \times 10^4} = 1332.511 \text{ keV}$$

For the inner and outer type standard deviations we have

$$S_{in} = \frac{1}{\sqrt{\sum_{n=1}^{5} 1/S_n^2}} = \frac{1}{\sqrt{1.0386478 \times 10^4}} = 0.0098$$

and

$$S_{out} = \left[\frac{\sum_{n=1}^{5} (x_n - X)^2/S_n^2}{(5-1)\sum_{n=1}^{5} 1/s_n^2}\right]^{1/2} = \left(\frac{1.914313}{4 \times 1.0386 \times 10^4}\right)^{1/2} = 0.0068$$

respectively.

For the value of Z we obtain

$$Z = \frac{\sigma_{out}}{\sigma_{in}} = \frac{0.0068}{0.0098} = 0.69$$

By applying the F-test in the way shown in Example 8.17, we conclude that we have no reasons to think of different standard deviations.

F. Interlaboratory comparisons

Interlaboratory comparisons have been a research subject in recent years (Chuvnovkina et al. (2008), Shirono et al. (2010), Pommé and Spanova (2008), Pommé and Keightley (2015), and Sahagia et al. (2016). The problem is that in most interlaboratory comparisons some results are very far from the mean of the result sets considering all the laboratories involved. This prevents us from using global uncertainty u_i as a measure of the uncertainty of the mean for the set of measures. On the other hand, it is not clear whether widely differing results can be admitted or rejected, and also the terminology used is very specific. For example, the resulting reference value evaluated from the data set (x_i, u_i) from N laboratories participating in the intercomparison is called the KCRV (Key Comparison Reference Value).

In this section we examine the following means: AM (Arithmetic Mean), WM (Weighted Mean), M-P mean (Mandel and Paule, 1971; Paule and Mandel, 1982; Mandel, 1991), PMM (Power-Moderate weighted Mean) (Pommé, 1912), as well as the associated uncertainties. Different models have been proposed for the evaluation of intercomparison data. In general, all the methods can be classified into two main groups:

- The first group consists of all methods for evaluating consistent data. These methods do not require any additional information other than the results of the measures and their uncertainties. The KCRV (Key Comparison Reference Value) is calculated by the weighted mean, and its uncertainty is relative to the mean.
- The second group includes methods for evaluating inconsistent data. All these methods are based on additional assumptions, the validity of which must be analyzed in each case.

In May 2013, the Consultative Committee for Ionizing Radiation, Section II, Measurement of Radionuclides, of the International Committee of Weights and Measurements (CIPM-CCRI (II)) decided to adopt the new concept of Power-Moderate weighted Mean (PMM) in the calculation of the KCRV, its typical uncertainty and degree of equivalence.

TABLE 8.7 Two sets of measured values.

Method	A						B	
Measured values	202.0	201.0	201.5	201.8	201.2	201.7	216.3	216.8
Coded values	2.0	1.0	1.5	1.8	1.2	1.7	16.3	16.8

To better understand the new PMM method, we will first consider the Paule and Mandel method, which we will call the PM method.

1. Philosophy of the Paule and Mandel method

In essence, the Paule and Mandel method attempts to introduce a series of effects linked to systematic uncertainties that have not been taken into account or have been lost in calculating the internal variance of the measures, as a random variance.

To clarify the above point, we will consider a simple example. Suppose we have two sets of measurements A and B of equal precision, but set A has more measurements than B (See Table 8.7). If we observe the average values obtained for each set of measures, we see that they are very different ($\overline{x}_A = 1.53$ and $\overline{x}_B = 16.55$). On the other hand, the typical deviations of the means are quite small ($s(\overline{x}_A) = 0.154$ and $s(\overline{x}_B) = 0.250$), while the discrepancies between the means are large. This is because the calculated variances only describe the internal variability of measures A or B and do not recognize the variability between the sets of measures to obtain "a between set component of variance" and include it in the overall variance of the measures set.

The use of "a between set component of variance" treats the collection of systematic errors of the various sets of measures as a source of random variability.

The systematic errors mentioned here are errors that remain after the measurement process. There is no possibility of attributing these systematic errors to any given set of measures. It is therefore reasonable to assume that all sets of measures are affected by these uncertainties and that the actual variance of each set of measures will be affected by a variance that will be added to the internal "within" variance. The real variance value is obtained by means of an iteration process.

2. Calculation of the variance of the between set

We know that the weight for $\overline{x}_i$ is $w_i = 1/\mathrm{Var}(\overline{x}_i)$ and the estimation of the weight is:

$$w_i = \left(\frac{s_{wi}^2}{n_i} + s_b^2\right)^{-1} \tag{8.43}$$

From the definition of w_i we get the relation:

$$w_i \mathrm{Var}(\overline{x}_i) = 1 \tag{8.44}$$

Or:

$$\mathrm{Var}(\sqrt{w_i}\overline{x}_i) = 1 \tag{8.45}$$

For a given set of weights w_i, the variance can be calculated by this formula:

$$s^2(w_i\overline{x}_i) = \frac{\sum_{i=1}^{m} w_i(\overline{x}_i - \widetilde{x})^2}{m-1} \tag{8.46}$$

Where m is the number of sets considered and $\widetilde{x}$ is given by

$$\widetilde{x} = \frac{\sum_{i=1}^{m} w_i\overline{x}_i}{\sum_{i=1}^{m} w_i} \tag{8.47}$$

we see that

$$\frac{\sum_{i=1}^{m} w_i(\overline{x}_i - \widetilde{x})^2}{m-1} = 1 \tag{8.48}$$

This equation supplies the means to calculate s_b^2. For this, we define the function

$$F\left(s_b^2\right) = \sum_{i=1}^{m} w_i(\overline{x}_i - \widetilde{x})^2 - (m-1) \tag{8.49}$$

We see that s_b^2 must have a value such that $F\left(s_b^2\right) = 0$. Following Paule and Mandel (1982), we will use $s_b^2 = v$ for ease of notation. We will start with an approximate value, v_0, and must find a value of dv such that $F(v_0 + dv) = 0$. Using a truncated Taylor series development, we obtain:

$$F(v_0 + dv) = f_0 + \left(\frac{\partial F}{\partial v}\right)_0 = 0 \tag{8.50}$$

Then

$$dv = \frac{F_0}{\left[\sum_{i=1}^{m} w_i^2(\overline{x}_i - \widetilde{x})^2\right]_0} \tag{8.51}$$

The new adjusted value for v is

$$\text{New } v_0 = \text{Old}v_0 + dv$$

This new value is introduced into Eqs. (8.43), (8.46), (8.47), and (8.49), and an iteration is applied until dv is close to zero. The following is a simplified numerical example to illustrate the procedure. (When the respective uncertainties are available as well as the data of the average values, it can be used as a criterion to optimize $\tilde{\chi}^2_{obs}$, which must be equal to one. This point will be expanded in our description of the PMM method.)

Example. 8.7. Consider the case of two sets of measures that we will call A and B, with different number of measurements each as shown in Table 8.7. Let us apply the theory described above to calculate the mean value and the most acceptable standard deviation. We will use the encoded values as they simplify the calculations (Paule and Mandel, 1982).

Solution. In the first iteration we will consider that $s_b^2 = v_0 = 100$.

The mean values of the measures of A and B are:

$$\bar{x}_A = \frac{\sum_{i=1}^{n_A} x_{iA}}{n_A} = \frac{9.20}{6} = 1.533$$

$$\bar{x}_B = \frac{\sum_{i=1}^{n_B} x_{iB}}{n_A} = \frac{32.90}{2} = 16.55$$

The corresponding variances are:

$$s^2(\bar{x}_A) = \frac{\sum_{i=1}^{n_A} (x_{iA} - \bar{x}_A)^2}{n_A(n_A - 1)} = \frac{0.7133}{5 \times 6} = 0.02378$$

$$s^2(\bar{x}_B) = \frac{\sum_{i=1}^{n_B} (x_{iB} - \bar{x}_B)^2}{n_B(n_B - 1)} = \frac{0.125}{1 \times 2} = 0.0635$$

The within set variances are:

$$s^2_{wA} = \frac{\sum_{i=1}^{n_A} (x_{iA} - \bar{x}_A)^2}{n_A - 1} = \frac{0.7133}{6 - 1} = 0.14266$$

$$s^2_{wB} = \frac{\sum_{i=1}^{n_A} (x_{iB} - \bar{x}_B)^2}{n_B - 1} = \frac{0.125}{1} = 0.125$$

Calculation of weights:

$$w_A = \frac{1}{\frac{s^2_{wA}}{n_A} + s_b^2} = \frac{1}{\frac{0.14266}{6} + 100} = 0.0099976$$

$$w_B = \frac{1}{\frac{s^2_{wB}}{n_B} + s_b^2} = \frac{1}{\frac{0.125}{2} + 100} = 0.0099938$$

The weighted average of the two values of m: A and B is

$$\tilde{x} = \frac{\sum_{i=1}^{m} w_i \bar{x}_i}{\sum_{i=1}^{m} w_i} = \frac{w_A \bar{x}_A + w_B \bar{x}_B}{w_A + w_B} = \frac{0.18072}{0.01999} = 9.040$$

and the calculation of F is

$$F(s_b^2) = \sum_{i=1}^{m} w_i (\bar{x} - \tilde{x})^2 - (m - 1)$$

$$= 0.0099976(1.533 - 9.040)^2 + 0.0099938(15.35 - 9.040)^2 - (2 - 1)$$

$$= 0.563415 - 0.563651 - 1 = 0.127066$$

The calculation of dv is

$$dv = \frac{F_0}{\left[\sum_{i=1}^{m} w_i^2 (\bar{x}_i - \tilde{x})^2\right]} = \frac{F_0}{w_A^2(\bar{x}_A - \tilde{x})^2 + w_B^2(\bar{x}_B - \tilde{x})^2}$$

$$= \frac{0.127066}{0.0001 \times 56.355 + 0.000099 \times 56.400}$$

$$= \frac{0.127066}{0.0056355 + 0.0056344} = \frac{0.127066}{0.0112699} = 11.2748$$

Now we perform the second iteration. We now have

$$v = v_0 + dv = 100 + 11.2748 = 111.2748$$

We calculate the weights again to give

$$w_A = \frac{1}{\frac{s^2_{wA}}{n_A} + s_b^2} = \frac{1}{\frac{0.14266}{6} + 111.2748} = 0.0089848$$

$$w_B = \frac{1}{\frac{s^2_{wB}}{n_B} + s_b^2} = \frac{1}{\frac{0.125}{2} + 111.2748} = 0.0089817$$

Calculation of $\tilde{x}$ yields

$$\tilde{x} = \frac{\sum_{i=1}^{m} w_i \bar{x}_i}{\sum_{i=1}^{m} w_i} = \frac{w_A \bar{x}_A + w_B \bar{x}_B}{w_A + w_B} = \frac{0.013774 + 0.148647}{0.0179657}$$

$$= 9.0402$$

The calculation of F_0 is the following:

$$F_0 = F\left(s_b^2\right) = \sum_{i=1}^{m} w_i(\overline{x} - \widetilde{x})^2 - (m-1)$$

$$= 0.0089844(1.533 - 9.0402) + 0.089817(16.55 - 9.0402) - 1$$

$$0.506343 + 0.506519 - 1 = 0.0129068$$

And the calculation of dv is

$$dv = \frac{F_0}{\left[\sum_{i=1}^{m} w_i^2(\overline{x}_i - \widetilde{x})^2\right]} = \frac{F_0}{w_A^2(\overline{x}_A - \widetilde{x})^2 + w_B^2(\overline{x}_B - \widetilde{x})^2}$$

$$= \frac{0.0129068}{0.000807 \times 56.35805 + 0.000807 \times 56.3971}$$

$$= \frac{0.129068}{0.0045481 + 0.0045512} = 1.4184$$

Now we execute the third iteration for which the calculations are the following:

$$v = v_0 + dv = 111.2748 + 1.4184 = 112.6932$$

$$w_A = \frac{1}{\frac{s_{wA}^2}{n_A} + s_b^2} = \frac{1}{\frac{0.14266}{6} + 112.6832} = 0.0088718$$

$$w_B = \frac{1}{\frac{s_{wB}^2}{n_B} + s_b^2} = \frac{1}{\frac{0.125}{2} + 112.6832} = 0.0088687$$

Calculation of $\widetilde{x}$:

$$\widetilde{x} = \frac{\sum_{i=1}^{m} w_i\overline{x}_i}{\sum_{i=1}^{m} w_i} = \frac{w_A\overline{x}_A + w_B\overline{x}_B}{w_A + w_B} = \frac{0.013774 + 0.148647}{0.0177405}$$

$$= 9.0402$$

Calculation of F_0:

$$F_0 = F\left(s_b^2\right) = \sum_{i=1}^{m} w_i(\overline{x} - \widetilde{x})^2 - (m-1)$$

$$= 0.0089848(1,533 - 9.0402)^2 + 0.0089817(16.55 - 9.0402)^2 - 1$$

$$0.506366 + 0.5065418 - 1 = 0.0129068$$

Calculation of dv:

$$dv = \frac{F_0}{\left[\sum_{i=1}^{m} w_i^2(\overline{x}_i - \widetilde{x})^2\right]} = \frac{F_0}{w_A^2(\overline{x}_A - \widetilde{x})^2 + w_B^2(\overline{x}_B - \widetilde{x})^2}$$

$$= \frac{0.129068}{0.0045481 + 0.0045512} = \frac{0.0129068}{0.0090993} = 1.141844$$

Performing the fourth iteration yields the following:

$$v = 111.3748 + 1.41844 = 112.69324$$

Calculation of weights

$$w_A = \frac{1}{\frac{s_{wA}^2}{n_A} + s_b^2} = \frac{1}{\frac{0.14266}{6} + 112.6932} = \frac{1}{112.7170}$$

$$= 0.0088718$$

$$w_B = \frac{1}{\frac{s_{wB}^2}{n_B} + s_b^2} = \frac{1}{\frac{0.125}{2} + 112.6932} = \frac{1}{112.7557}$$

$$= 0.0088687$$

Calculation of $\widetilde{x}$:

$$\widetilde{x} = \frac{\sum_{i=1}^{m} w_i\overline{x}_i}{\sum_{i=1}^{m} w_i} = \frac{w_A\overline{x}_A + w_B\overline{x}_B}{w_A + w_B} = \frac{0.0136005 + 0.146777}{0.0177405}$$

$$= \frac{0.1603775}{0.0177405} = 9.0402$$

Calculation of F_0:

$$F_0 = F\left(s_b^2\right) = \sum_{i=1}^{m} w_i(\overline{x} - \widetilde{x})^2 - (m-1)$$

$$= 0.0088718 \times 56.35805 + 0.0088687 \times 56.397096 - 1$$

$$= 0.499997 + 0.50017 - 1 = 0.00167$$

Calculation of dv:

$$dv = \frac{F_0}{\left[\sum_{i=1}^{m} w_i^2(\overline{x}_i - \widetilde{x})^2\right]} = \frac{F_0}{w_A^2(\overline{x}_A - \widetilde{x})^2 + w_B^2(\overline{x}_B - \widetilde{x})^2}$$

$$= \frac{0.00167}{0.000787 \times 56.35805 + 0.000787 \times 56.397096}$$

$$= \frac{0.00167}{0.0044354 + 0.0044385} = \frac{0.00167}{0.0088739} = 0.01882$$

Performing the fifth iteration yields the following:

$$v = 112.69324 + 0.01882 = 112.712$$

Calculation of weights:

$$w_A = \frac{1}{\frac{s_{wA}^2}{n_A} + s_b^2} = \frac{1}{\frac{0.14266}{6} + 112.712} = \frac{1}{112.7358}$$

$$= 0.0088703$$

$$w_B = \frac{1}{\frac{s_{wB}^2}{n_B} + s_b^2} = \frac{1}{\frac{0.125}{2} + 112.712} = \frac{1}{112.7745}$$
$$= 0.0088673$$

Calculation of $\widetilde{x}$:

$$\widetilde{x} = \frac{\sum_{i=1}^{m} w_i \overline{x}_i}{\sum_{i=1}^{m} w_i} = \frac{w_A \overline{x}_A + w_B \overline{x}_B}{w_A + w_B} = \frac{0.013598 + 0.1467538}{0.0177405}$$
$$= \frac{0.160352}{0.0177376} = 9.0402$$

Calculation of F_0:

$$F_0 = F\left(s_b^2\right) = \sum_{i=1}^{m} w_i (\overline{x} - \widetilde{x})^2 - (m-1)$$
$$= 0.0088703 \times 56.35805 + 0.0088673 \times 56.397096 - 1$$
$$= 0.4999128 + 0.500090 - 1 = 0.0000028$$

Calculation of dv:

$$dv = \frac{F_0}{\left[\sum_{i=1}^{m} w_i^2 (\overline{x}_i - \widetilde{x})^2\right]} = \frac{F_0}{w_A^2 (\overline{x}_A - \widetilde{x})^2 + w_B^2 (\overline{x}_B - \widetilde{x})^2}$$
$$= \frac{0.000028}{0.0000787 \times 56.35805 + 0.0000786 \times 56.397096}$$
$$= \frac{0.0000028}{0.0044354 + 0.0044328} = \frac{0.0000028}{0.0088682} = 0.000316$$

This is a value low enough to end the iterations here. Thus:

$\widetilde{x} = 9.0402$ and the true value is: $\widetilde{x} = 209.0402$

$$v = s_b^2 = 112.712$$

$$s^2(w_i \overline{x}_i) = \frac{w_A (\overline{x}_A - \widetilde{x})^2 + w_B (\overline{x}_B - \widetilde{x})^2}{m-1} = 1.0000028$$

$$\text{Standard error} = \frac{1}{\sqrt{w_A + w_B}}$$
$$= \frac{1}{\sqrt{0.0088703 + 0.0088673}} = 7.51$$

The result is found to be the following: 209.04 ± 7.51.

3. Power-Moderate mean

The arithmetic mean can be used when there are no discrepant results:

$$\overline{x} = \frac{1}{n} \sum_{i=1}^{n} x_i \tag{8.52}$$

and its uncertainty is

$$u(\overline{x}) = \frac{1}{n} \sqrt{\sum_{i=1}^{n} u_i^2} \tag{8.53}$$

Individual variances can be replaced by an estimate of variance of the sample

$$u(\overline{x}) = \frac{1}{n} \sqrt{n u^2} = \frac{u}{n} = \left[\sum_{i=1}^{n} \frac{(x_i - \overline{x})^2}{n(n-1)}\right]^{1/2} \tag{8.54}$$

As indicated by the PM method, the calculated uncertainty of the mean can be abnormally low, so the two uncertainties of the mean are compared and the largest uncertainty is chosen, that is:

$$u(\overline{x}) = \text{Max}\left[\frac{1}{n}\sqrt{\sum_{i=1}^{n} u_i^2}\,,\quad \sqrt{\sum_{i=1}^{n} \frac{(x_i - \overline{x})^2}{n(n-1)}}\ \right] \tag{8.55}$$

The weighted average is calculated using the formula:

$$\overline{x}_{\text{weig}} = \frac{\sum_{i=1}^{n} \frac{x_i}{u_i^2}}{\sum_{i=1}^{n} \frac{1}{u_i^2}} \tag{8.56}$$

And the uncertainty is:

$$u\left(\overline{x}_{\text{weig}}\right) = \frac{1}{\sqrt{\sum_{i=1}^{n} \frac{1}{u_i^2}}} \tag{8.57}$$

The weighted mean and its uncertainty are inadequate when applied to discrepant data with underestimated uncertainties. The discrepancy can be verified by applying the chi-square test.

$$\widetilde{\chi}_{\text{obs}}^2 = \frac{1}{n-1} \sum_{i=1}^{n} \frac{\left(x_i - \overline{x}_{\text{weig}}\right)^2}{u_i^2} \tag{8.58}$$

If we get values higher than one, we have a clear signal that the data are inconsistent.

TABLE 8.8 Radionuclide activity concentration of the sample reported by participants.

Laboratory	1	2	3	4	5	6
x_i	17.1	14.0	23.5	19.8	16.0	13.8
u_i	2.7	7.0	14.3	11.0	9.0	0.6
u_i^2	7.29	49.0	204.3	121	81	0.36

In this case, we can use the Paule−Mandel mean. In the exercise given above as an example of the application of the PM average, we only take values of the measures without their uncertainties. We will now consider that, in addition to the values of the measures, we have their associated uncertainties, in which case the chi-square that we apply will be:

$$\widetilde{\chi}^2_{\text{obs}} = \frac{1}{n-1}\sum_{i=1}^{n}\frac{\left(x_i - \overline{x}_{\text{weig}}\right)^2}{u_i^2 + s^2} \tag{8.59}$$

where s is what we previously called s_b, and it takes into account uncontrolled systematic uncertainties. The procedure of successive approximations is based on the criterion that the value of the chi-square must be equal to or less than one. As before, an initial value of s will be chosen and the weighted mean and its uncertainty will be calculated using the new formulas:

$$\overline{x}_{\text{weig}} = \frac{\sum_{i=1}^{n}\frac{x_i}{u_i^2} + s^2}{\sum_{i=1}^{n}\frac{1}{u_i^2} + s^2} \tag{8.60}$$

$$u\left(\overline{x}_{\text{weig}}\right) = \frac{1}{\sqrt{\sum_{i=1}^{n}\frac{1}{u_i^2} + s^2}} \tag{8.61}$$

The PM mean does not give good results when the uncertainties of the data are underestimated, which often occurs in practice. The PMM average moderates the effect of underestimation of uncertainties. For this, we calculate the magnitude S defined as:

$$S^2 = n \times \text{Max}\left[\frac{1}{\sum_{i=1}^{n}\frac{1}{u_i^2 + s^2}}, \frac{\sum_{i=1}^{n}\left(x_i - \overline{x}\right)^2}{n(n-1)}\right] \tag{8.62}$$

and it is applied to the calculation of the mean and the uncertainty, replacing the factor $1/\left(u_i^2 + s^2\right)$ by the term

$$\left[\left(\sqrt{u_i^2 + s^2}\right)^{\alpha} S^{2-\alpha}\right]$$

The value of α is linked to the number of data n by the equation:

$$\alpha = 2 - \frac{3}{n} \tag{8.63}$$

Example. 8.8. Calculation of the PMM average and its uncertainty. Consider the following Table 8.8 in which the results of 6 laboratories and their uncertainties are presented (Sahagia et al., 2016). The square uncertainty has been added for convenience of calculation.

We will calculate the different magnitudes involved in obtaining the PMM mean.

Solution. The arithmetic mean of the measures is:

$$\overline{x} = \frac{\sum_{i=1}^{n} x_i}{n} = \frac{103.3}{6} = 17.216$$

Median:

$$x_{\text{med}} = \frac{17.1 + 16}{2} = 16.6$$

Standard deviation of the arithmetic mean:

$$s = \sqrt{\frac{\sum_{i=1}^{n}\left(x_i - \overline{x}\right)^2}{n(n-1)}} = \sqrt{\frac{65.433}{6.5}} = \sqrt{2.1943} = 1.48$$

Weighted mean:

$$\overline{x}_{\text{weig}} = \frac{\sum_{i=1}^{n}\frac{x_i}{u_i^2}}{\sum_{i=1}^{n}\frac{1}{u_i^2}} = \frac{41.433}{2.961} = 14.0$$

Standard deviation of the weighted mean:

$$u\left(\overline{x}_{\text{weig}}\right) = \frac{1}{\sqrt{\sum_{i=1}^{n} 1/u^2}} = \frac{1}{\sqrt{2.961}} = \pm 0.58 \approx \pm 0.6$$

Reduced observed chi-squared value:

$$\chi^2 = \frac{1}{n-1}\sum_{i=1}^{n}\frac{\left(x_i - \overline{x}_{weig}\right)^2}{u_i^2} = \frac{2.1185}{5} = 0.4236 \approx 0.42$$

Paule–Mandel mean ($s = 0$):

$$\overline{x}_{P-M} = \frac{\sum_{i=1}^{n}\frac{x_i}{(u_i^2+s^2)}}{\sum_{i=1}^{n}\frac{1}{(u_i^2+s^2)}} = \frac{\sum_{i=1}^{n}\frac{x_i}{u_i^2}}{\sum\frac{1}{u_i^2}} = 14.0$$

Standard deviation of the Paule–Mandel mean ($s = 0$):

$$u(PM) = \frac{1}{\sqrt{\sum_{i=1}^{n}\frac{1}{u_i^2+s^2}}} = \frac{1}{\sqrt{\sum_{i=1}^{n}\frac{1}{u_i^2}}} = 0.6$$

S-value:

$$S = \sqrt{n \times \mathrm{Max}\left[u^2(\overline{x}), u^2(\overline{x}_{\mathrm{P-M}})\right]}$$
$$= \sqrt{6 \times \mathrm{Max}(1.40^2,\ 0.6^2} = 3.43$$

α-value:

$$\alpha = 2 - \frac{3}{n} = 2 - \frac{3}{6} = \frac{3}{2} = 1.5$$

4. Power-Moderated weighted Mean (PMM)

First we calculate $u(x_{\mathrm{PMM}})$

$$u(x_{\mathrm{PMM}}) = \frac{1}{\sqrt{\sum_{i=1}^{n}\left(u_i^2+s^2\right)^{-\alpha}S^{\alpha-2}}}$$

$$= \frac{1}{\sqrt{\sum_{i=1}^{n}\left(\sqrt{u_i^2}\right)^{-\alpha}S^{\alpha-2}}} = \frac{1}{\sqrt{\sum_{i=1}^{n}\left(\frac{1}{u^\alpha}\right)S^{\alpha-2}}}$$

$$= \frac{1}{\sqrt{2.76 \times \frac{1}{S^{2-\alpha}}}} = \frac{1}{\sqrt{2.76 \times \frac{1}{3.43^{0.5}}}}$$

$$= \frac{1}{\sqrt{1.49}} = 0.82$$

PMM mean:

$$\overline{x}_{\mathrm{PMM}} = u^2(\overline{x}_{\mathrm{PMM}})\sum_{i=1}^{n}\frac{x_i}{\sqrt{\left(u_i^2+s^2\right)^{\alpha}}S^{2-\alpha}}$$

$$= u^2(\overline{x}_{\mathrm{PMM}})\sum_{i=1}^{n}\frac{x_i}{\sqrt{\left(u_i^2\right)^{\alpha}}S^{2-\alpha}}$$

$$= u(\overline{x}_{\mathrm{PMM}})\sum_{i=1}^{n}\frac{x_i}{u_i^{\alpha}S^{2-\alpha}} = 0.82^2\sum_{i=1}^{n}\frac{x_i}{u_i^{\alpha}\times 3.43^{0.5}}$$

$$= \frac{0.672 \times 39.36}{1.852} = 14.3$$

The result: 14.3 ± 0.8.

Sahagia et al. (2016) repeat the previous calculation by removing the value 23.5 reported by Participant #3 of Table 8.8. In this case, the value obtained with the five remaining data is: 14.3 ± 1.1. This shows that this discordant data contributes little to the final result.

G. The statement of the results

The concept of uncertainty is commonly applied to evaluate the degree of feasibility in the results of one experiment. The uncertainty considers two limits to determine how the best estimate may deviate from the true value in terms of probability. The uncertainty of the results of a measurement is generally determined by several components, which may be grouped into two categories, according to the procedure used to determine the numerical values:

- Uncertainties evaluated following statistical procedures (Type A evaluation)
- Uncertainties evaluated by means of other procedures (Type B evaluation)

There is no correspondence between the classification of the uncertainty components in the two categories A and B, and the usual classification into random and systematic errors. A detailed discussion on systematic uncertainties is given by Eisenhart (1963). The nature of an uncertainty is conditioned by the use of the corresponding quantity or, more clearly, the way in which the quantity appears in the model describing the measuring process. When the corresponding quantity is used in different ways, the random component may be transformed into systematic or vice

versa. Therefore, the terms accidental and systematic uncertainties may be misleading when they are used in practice. An alternative nomenclature sometimes used is:

- "uncertainty component arising from a random effect"
- "uncertainty component arising from a systematic effect"

In these statements, the random effect generates a possible random error in the process of measurement, while a systematic effect may generate a possible systematic error. A clear description of the different uncertainties involved in sample standardization is presented in the paper of Zimmerman et al. (2001).

Each uncertainty component, which contributes to the resultant uncertainty of a measurement by means of an estimated standard deviation, is referred to as the **standard uncertainty** and denoted by u_i. The u_i value is the positive square root of the estimated variance u_i^2.

The uncertainty component of category A is represented by means of statistics: The estimated standard deviation s_i, which is equal to the positive value of the square root of the estimated variance s_i^2 and the number ν_i of the associated degrees of freedom. For this component the standard uncertainty is $u_i = s_i$. The computation of the uncertainty by means of the statistical analysis of an observed set is referred to as **Type A uncertainty** computation, which may be considered as an approximation to the corresponding standard deviation.

In a similar way, the **Type B uncertainty** component, denoted by u_j, may be considered as an approximation to the corresponding standard deviation. To understand the background of the statement of uncertainty, we refer to the paper of Müller (1979).

1. Type B calculation of typical uncertainty

As there are statistical methods available for the Type A calculation of typical uncertainty, Type B calculation of uncertainty is grounded on a scientific reasoning based on all the relevant information at our disposal. We will describe some, but by no means all, illustrative situations. In any case, the history of the primary measures of some fundamental magnitudes is very illustrative. In all cases, accidental errors were underestimated. For example, the value of the charge of the electron was 4.7700×10^{-10} esu in 1929; in 1955, it was 4.8025×10^{-10} esu; and in 1973, it was $4.803{,}242(14) \times 10^{-10}$ esu. It is clear that the first two measures had differences that were far superior than accepted uncertainties.

Let us outline some practical considerations. If, in determining the value of a quantity, we can estimate the lower a_- and upper a_+ limits, so that the likelihood that the true value lies between these limits is 100% or, in other words, when the model to be applied is a uniform rectangular likelihood distribution, the best estimate of the value of the magnitude is:

$$X = \frac{a_+ + a_-}{2} \tag{8.64}$$

and the typical uncertainty is:

$$u_j = \frac{1}{\sqrt{3}} \frac{a_+ - a_-}{2} \tag{8.65}$$

If instead of a uniform rectangular distribution we have a triangular distribution, then the mean value is given by (8.64) but the uncertainty is:

$$u_j = \frac{1}{\sqrt{6}} \frac{a_+ - a_-}{2} \tag{8.66}$$

When the magnitude considered can be modeled by a normal distribution, there are no finite limits containing 100% of the possible values. As $\pm 3\sigma$ contain 99.73% of the possible values, $\pm 3\sigma$ can be chosen as the limits. Then the mean value will be that obtained by formula (8.64), but the uncertainty will be calculated by the expression:

$$u_j = \frac{1}{3} \frac{a_+ - a_-}{2} \tag{8.67}$$

In other situations we can assume that the distribution is normal and estimate a lower limit a_-, and an upper limit a_+, so that the best estimate of the value of the magnitude is given by Eq. (8.64) and, in addition, there is a 50% likelihood that the value of the measured quantity is in the (a_-, a_+) range. In this case:

$$u_j \approx 1.48 \frac{a_+ - a_-}{2} \tag{8.68}$$

On the other hand, when the likelihood that the true value is within the limits a_- and a_+ is 67%, the uncertainty is obtained by the expression:

$$u_j \approx \frac{a_+ - a_-}{2} \tag{8.69}$$

Example 8.9. The width of a strip of paper can be measured with a graduated ruler by applying two different procedures:

1. Adjust the zero of the ruler at one end and read the width at the other. The value sought is between divisions 104 and 105 mm. Find the value of the width and its uncertainty by applying a Type B calculation.
2. The ruler is placed randomly on the width of the paper, the values at both ends are read and then subtracted. The results obtained are: 105, 104, 104, 105, 105, 105, 104, 105, 104, 105 mm. Find the width and its uncertainty by applying a Type A calculation.

Solution.

1. When the procedure is Type B:

$$a_+ = 105 \text{ mm} \quad \text{and} \quad a_- = 104 \text{ mm}$$

The mean value will be:

$$X = \frac{a_+ + a_-}{2} = \frac{209}{2} = 104.5 \text{ mm}$$

If we assume that the distribution is uniform and rectangular, the standard deviation is:

$$u = \frac{1}{\sqrt{3}} \frac{a_+ - a_-}{2} = \frac{1}{2\sqrt{3}} = 0.29 \text{ mm}$$

so that

$$X = 104.5 \pm 0.03 \text{ mm}.$$

2. When the calculation procedure is type A, the mean is:

$$X = \frac{\sum_{i=1}^{10} x_i}{n} = \frac{1046}{10} = 104.6 \text{ mm}$$

The standard deviation of the mean is:

$$u = \left[\frac{\sum_{i=1}^{10} (x_i - X)^2}{n(n-1)} \right]^{1/2} = \sqrt{\frac{2.4}{90}} = 0.16$$

So that:

$$X = 104.6 \pm 0.16 \text{ mm}$$

Example 8.10. In view of the result obtained by repeating the measurements, we could carry out 1000 measures and obtain very low uncertainty. Suppose that we measure (from the above example) the width of the tape 1000 times and the result is 105 mm, 564 times; and 104 mm, 436 times. Find the mean and standard deviation.

Solution. The mean value is:

$$X = \frac{\sum_{i=1}^{1000} x_i}{1000} = \frac{564 \times 105 + 436 \times 104}{1000} = 104.564$$

The standard deviation of the mean is:

$$u = \left[\frac{\sum_{i=1}^{1000} (x - X)^2}{n(n-1)} \right]^{1/2} = \sqrt{\frac{245.904}{999000}} = 0.016 \text{ mm}$$

It is concluded that with 1000 measures we are able to appreciate up to hundredths of a millimeter with a ruler divided into millimeters. If we increase the number of measures, we could reach a negligible uncertainty, which does not seem logical. The result obtained is so, because we have greatly simplified the problem. In addition to random uncertainties, there are other uncertainties linked to the instrument, measurement system, and environmental conditions. If we calibrate the ruler, we can observe that in 100 mm there is a discrepancy of 0.1 mm, so the associated type B uncertainty will be:

$$u = \frac{1}{\sqrt{3}} \frac{0.1}{2} = 0.028$$

The total uncertainty will be:

$$u = \sqrt{0.016^2 + 0.028^2} = 0.032$$

Although the random uncertainty was very small, we would always have the calibration, which is constant.

2. Combined standard uncertainty

The combined standard uncertainty, u_c, of a measurement is obtained from the individual standard uncertainties, obtained from Type A and B evaluations. The rules given in the error transmission section will be applied here.

The combined standard uncertainty is used in the determination of fundamental constants, in fundamental metrology research and in comparisons.

On the other hand, for commercial, industrial, or regulatory applications, the required uncertainties must define an interval with a high probability that the result falls within it. In this case, it is convenient to introduce the concept of **expanded uncertainty**, U, obtained from multiplying u_c by a **coverage factor**, k, so that $U = ku_c$. Generally, the value of the coverage factor k is chosen so that we select a confidence level associated with the interval defined by $U = ku_c$. Two often used coverage factors, when the quantity is described by a normal distribution, are $k = 2$ and $k = 3$, which define intervals of confidence of 95.5% and 99.7%, respectively. Evaluation of precision and accuracy in instrument calibration systems is given by Eisenhart (1968).

3. Rules for expressing results

In this section, we follow the NIST recommendations given by Taylor and Kuyatt (1994): this guide is consistent with the guidelines of the Guide to the Expression of Uncertainty in Measurement (GUM) (JCGM 100, 2008). The result of a measurement may be followed by the sign $\pm$ and the corresponding uncertainty. The U value and the k factor or the applied u_c must always be specified. A complete uncertainty description for activity concentration for three measurement systems: liquid scintillation, ionization chambers, and $4\pi\gamma$ spectrometers are presented in the work of Zimmerman et al., 2001. It is recommended that the following information be included.

A list of all the components of the standard uncertainty with the appropriate degrees of freedom and the resulting value u_c. The uncertainty components should be identified in agreement with the method used to estimate the numerical values: Type A or B. A detailed description of how each component of the standard uncertainty has been evaluated must be presented. When we take $k \neq 2$, a description of how k has been chosen should be given. As an example, we present three different forms of writing the energy and the associated uncertainty for the gamma-ray energy of ^{51}Cr:

1. $E = (320.08419 \pm 0.00042)$ keV. The number after - $\pm$ symbol is the numerical value of the expanded uncertainty $U = ku_c$, with $u_c = 0.00021$ keV, and a coverage factor $k = 2$. We assume that the estimated values of a sample follow a normal distribution with a standard deviation u_c. The unknown energy value is believed to be in the interval defined by U with a level of confidence of 95%.
2. $E = (320.08419 \pm 0.00052)$ keV. Where the number following the $\pm$ symbol is the numerical value of the expanded uncertainty, $U = ku_c$, and a coverage factor based into a t distribution for $\nu = 9$ degrees of freedom. U defines an interval containing the unknown energy value with a confidence level of 95%.
3. $E = 320.08419$ keV with a combined standard deviation $u_c = 0.00021$ keV. We assume that the possible estimated energy values are distributed following a normal distribution with a standard deviation u_c. The unknown energy value is in the interval $E \pm u_c$ with an approximated confidence level of 68%.

IV. Statistical inference

From a very general point of view, we can consider statistical inference as a form of decision based on probability. In a more limited sense, however, one can say that the statistical inference allows an estimation or prediction from the data. Statistical inference gives responses to three types of problems: First, it permits one to test if a statement about the value of a parameter is correct. Second, it allows one to calculate the value of a parameter. Finally, it allows one to see whether some relationship exists between two or more variables and in the affirmative case, to determine this relationship. In this section, we analyze the hypothesis testing and the estimation techniques.

A. Hypothesis testing

A statistical hypothesis is an assertion about the probability density function of a random variable. Thus, the assertion that a random variable possesses a Poisson distribution is an example of a statistical hypothesis. The statement that the mean of a normal distribution is 5 is also a statistical hypothesis.

A test of a statistical hypothesis is a procedure for deciding whether to accept or reject the hypothesis. Before carrying out the test, we define a hypothesis called a **null hypothesis,** denoted by H_0. A null hypothesis is a statement about a population parameter that is being tested by the use of sample results and a decision-making process. This hypothesis must be contrasted with another called the **alternative hypothesis,** denoted by H_1. An alternative hypothesis is a statement to be accepted, if the null hypothesis is rejected. The alternative hypothesis utilizes the same parameter as the null hypothesis, but gives motivation for the rest of the test procedure. This is the statement we want to accept. Both hypotheses define complementary regions. The **critical region** is the portion of a distribution that provides values for the sample results causing the rejection of H_0. In other words, the critical region is the acceptance region for the alternative hypothesis. The critical value is the value that determines the critical region. Once the null and the alternative hypotheses have been established, we proceed to carry out the experiment and obtain the statistical sample to quantify the statistics of the test. If this one belongs to the critical region, we reject the null hypothesis and accept the alternative.

The result of our decision implies the possibility to guess correctly or make a mistake. We do not know with certainty what the true result is. To understand the meaning of a hypothesis test and the decision table established before carrying out the experiment, we consider the particular case of a sample, which may be radioactive. Only after carrying out the measurement experiment, may the analyst decide if the sample is or is not radioactive. Two correct and two incorrect decisions can be taken as is shown in Table 8.9.

The interpretation of Table 8.9 is the following:

- If the null hypothesis is certain and it is accepted, the decision is correct.
- If the null hypothesis is certain and it is rejected, the decision is incorrect and the error made is Type I. Its probability is represented by α.

TABLE 8.9 Possible consequences of a final decision.

Decisions	Reality	
	H_0 true	H_1 true
Accept H_0	Correct decision	Type II error
Reject H_0	Type I error	Correct decision

- If the alternative hypothesis is certain and it is accepted, the decision is correct.
- If the alternative hypothesis is certain and it is rejected, the decision is incorrect and the error made is Type II. Its probability is represented by β.

Therefore:

$$\alpha = P(\text{Type I error}) = P(\text{reject } H_0 \text{ being certain}) = P(\text{accept } H_1 \text{ when } H_0 \text{ is certain})$$

$$\beta = P(\text{Type II error}) = P(\text{accept } H_0 \text{ being uncertain}) = P(\text{accept } H_0 \text{ when } H_1 \text{ is certain})$$

The power of the test is defined as $1 - \beta$, the probability of rejecting a false null hypothesis:

$$1 - \beta = P(\text{accept } H_1 \text{ when it is certain})$$

Example 8.11. To decide if a sample is radioactive, we accept the following null hypothesis: "H_0:$\mu_s = 0$ (the sample is not radioactive)". (A) What cases can be given? (B) Which is the Type of error? (C) Which is the Type II error? (D) Which error is more dangerous? (E) What do you prefer: α small and β large or α large and β small?

Solution.

a. The following cases can be given:
The activity of the sample is null and the analyst decides that it is not radioactive. The decision is correct.
The activity of the sample is null and the analyst decides that it is radioactive. The decision is incorrect and a Type I error is made.
The sample is radioactive and the analyst decides that the sample has radioactivity. The decision is correct.
The sample is radioactive and the analyst decides that the sample has no radioactivity. The decision is incorrect and a Type II error is made.

b. A Type I error is made when the analyst decides that the sample is radioactive and it is not radioactive.

c. A Type II error is made when the analyst decides that the sample is not radioactive and it is radioactive.

d. In this case, it is more serious to make a Type II error than a Type I error. A Type I error obliges one to take unnecessary precautions with the sample. On the other hand, a Type II error makes us consider the sample as nonradioactive when in fact it is radioactive. That produces a situation with radiation risk.

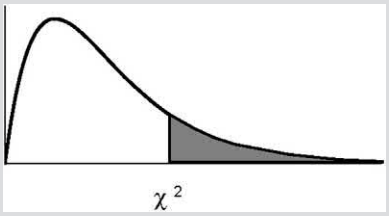
e. It is preferable to have α large and β small than the reverse.

It is not convenient to make α or β equal to zero. The most advisable is to choose a value for α equal to 0.01 or 0.05; when we examine a situation where H_0 is true, 1% or 5%, respectively, of the times we make incorrect decisions. The selected value for α will be determined by the severity of the circumstances of making an error. We have centered our attention on α, because the objective of hypotheses testing is to test the truth of the statement contained in H_0 and to make a decision related to the rejection of this hypothesis.

The value of α is equal to the area under the curve corresponding to the rejection region. It is usual to nominate α as the significant value or the size of the critical region. Therefore, the level of significance is the probability α of a Type I error. When we say that the results of a study are statistically significant, we indicate that a value α has been chosen and the hypothesis testing leads to the rejection of the null hypothesis.

When we give α, the area of the rejection region for the distribution is known. For one-tail tests the application of α is immediate. In two-tail tests we must take into account that $\alpha/2$ corresponds to each tail, so that the sum of the areas of the two regions is α. When one knows the area of a region of the normal or t distributions, the value of z or t is obtained directly from tables.

Up to here we have chosen a level of significance before solving the problem. This procedure allows one to obtain a decision in a clear and fast way, defining previously a value for α. Another strategy consists of using what is known as the P-value to express the level of significance achieved by the data. The P-value is defined as the probability of obtaining a statistical test more extreme than z^* if H_0 is true; in other words, the P-value $= P(z > |z^*|)$ where $|z^*|$ is the absolute value of z^*.



B. Confidence intervals

Interval estimators very probably contain the unknown population parameter. To formalize these statements, it is necessary to express them in terms of probability. Let us suppose that θ is the parameter to be estimated. Let us also suppose that we have extracted a random sample and from the sample information it is possible to find two random variables X_1 and X_2, such that $X_1 < X_2$. If these random variables have the property that $1 - \alpha$ is the probability that X_1 is smaller than θ and that X_2 is larger than θ, we can write

$$P(X_1 < \theta < X_2) = 1 - \alpha \tag{8.70}$$

where α is a number between 0 and 1. Then the interval X_1 and X_2 is an interval estimator of θ at $100(1-\alpha)\%$ of confidence. If we call x_1 and x_2 the realizations of both random variables, the interval x_1 and x_2 is the confidence interval at $100(1-\alpha)\%$ for θ. The quantity $1 - \alpha$ is the level of confidence for the interval. In other words, if we take random samples from the population a large number of times, the parameter θ will be contained in $100(1-\alpha)\%$ of the calculated intervals. Confidence intervals are written as $x_1 < \theta < x_2$.

TABLE 8.10 Chi-square (χ^2)distribution.

	α									
f	0.995	0.99	0.975	0.95	0.90	0.10	0.05	0.025	0.01	0.005

C. Statistical inference

1. Variance of a population

A problem that frequently appears in statistics is determining if the standard deviation of a sample corresponds to the standard deviation of a population. If we take random samples of size n from a normal distribution with variance σ^2, we know that the random variable χ^2 allows us to study σ or σ^2 from the probabilities of the curve χ^2.

In radioactivity measurements with pulse counters, it is assumed that a good counter does not perturb measurements and therefore the standard deviation of the total counting is equal to the standard deviation of radioactivity disintegration. To test the reliability of a counter, it is very useful to apply the χ^2 test. It allows one to check if a set of experimental data follows a preset statistical law. More details about the application of the χ^2-test in radioactivity measurements is given by Evans (1982). The χ^2 value is defined by the equation:

$$\chi^2 = \frac{\sum_{i=1}^{n} \left[(\text{observed value})_i - (\text{expected value})\right]^2}{\text{expected value}} \tag{8.71}$$

where n is the total number of independent classifications i in which the data have been grouped. The expected value is computed from Poisson frequency distribution and corresponds to the mean $\mu \approx \bar{x}$. The measured values x_i are the results of the counting; they should be at least 5. The previous expression is now

$$\chi^2 = \frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{\bar{x}} \tag{8.72}$$

We will compare $\sigma = \sqrt{\bar{x}}$ with $s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n-1}}$, where n is the number of measurements. The null hypothesis is:

$$H_0 : \ \sigma = \text{s} \tag{8.73}$$

and the alternative is:

$$H_1 : \sigma \neq \text{s} \tag{8.74}$$

From the alternative hypothesis we conclude that the test is bilateral. Therefore, we will reject the null hypothesis if we obtain (Table 8.10)

$$\chi^2 > \chi^2_{n-1,\alpha/2} \quad \text{or} \quad \chi^2 < \chi^2_{n-1,1-\alpha/2} \tag{8.75}$$

Example 8.12. A radioactive sample was measured with a Geiger counter 6 times. The duration of each measurement was 5 min. Check if the counter works well taking the measurements from Table 8.11.

TABLE 8.11 Counts of a radioactivity sample.

Measure	Counts	Δ	Δ^2
1	214	−10	100
2	222	−2	4
3	217	−7	49
4	210	−14	196
5	243	19	361
6	238	14	196

Solution. The average value of the number of counts accumulated in 5 minutes is:

$$\overline{x} = \frac{\sum_{i=1}^{6} x_i}{n} = \frac{1344}{6} = 224$$

The distribution standard deviation is:

$$\sigma = \sqrt{\overline{x}} = \sqrt{224} = 15.0$$

The observed standard deviation is:

$$s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \overline{x})^2}{n-1}} = \sqrt{\frac{906}{5}} = 13.5$$

The null hypothesis is:

$$H_0 : \sigma = s$$

The alternative hypothesis is:

$$H_1 : \sigma \neq s$$

The rejection region is obtained from Table 8.10 for $f = n-1 = 5$ and $\alpha = 0.05$. The critical values are $\chi^2_{5,0.025} = 12.83$ and $\chi^2_{5,0.975} = 0.831$. From the experimental data we have

$$\chi^2 = \frac{\sum_{i=1}^{n} (x_i - \overline{x})^2}{\overline{x}} = \frac{906}{224} = 4.04$$

The rejection region is $\chi^2 > 12.83$ and $\chi^2 < 0.831$. As χ^2 is outside the rejection region we do not reject the null hypothesis and we conclude that the counter works correctly. Other examples for the application of the χ^2-test to counters with anomalies are available from Grau Carles and Grau Malonda (2000).

Example 8.13. Ten measurements of 1-second duration were made with a counter with a resolution time of 250 μs. Analyze the results of the measures presented in Table 8.12.

Solution. The mean value is:

$$\overline{X} = \frac{\sum_{i=1}^{10} x_i}{10} = \frac{13278}{10} = 1327.8$$

The theoretical standard deviation is:

$$s_t = \sqrt{\overline{X}} = \sqrt{1327.8} = 36.4$$

The experimental standard deviation is:

$$s_{ex} = \sqrt{\frac{\sum_{i=1}^{10} (x_i - \overline{X})^2}{9}} = \sqrt{\frac{3376.3}{9}} = 19.4$$

It seems that the standard deviations are quite different. Apply the χ^2 test.

$$\chi^2_{ex} = \frac{\sum_{i=1}^{10} (x_i - \overline{X})^2}{\overline{X}} = \frac{3376.3}{1327.8} = 2.45$$

The values of $\chi^2_{9,0.025} = 19.02$ and $\chi^2_{9,0.975} = 2.70$ obtained from Table 8.10 enable us to determine that:

$$\chi^2_{ex} < \chi^2_{9,0.975}$$

Therefore, we reject the null hypothesis of equality of the standard deviations, and we can conclude that the experimental results do not follow Poisson's law. Considering that the counting rate is very high, some counts will have been lost due to the counter resolution time. The number of actual counts N_R, which the counter should have recorded had its resolution time been zero, can be calculated from counting rate N and resolution time τ by applying this expression:

$$N_R = \frac{N}{1 - N\tau} = \frac{N}{1 - (N \times 250 \times 10^{-6})}$$

Applying this formula to each of the measures in Table 8.12, we obtain Table 8.13 below:

The mean of the corrected count values listed in Table 8.13 is:

$$\overline{X} = \frac{\sum_{i=1}^{10} x_i}{10} = \frac{19877}{10} = 1987.7$$

The theoretical standard deviation is:

$$s_t = \sqrt{\overline{X}} = \sqrt{1987.7} = 44.6$$

TABLE 8.12 Ten measurements of 1-second duration.

Measure	Counts	Measure	Counts
1	1312	6	1337

TABLE 8.14 Measurements with a Geiger counter.

Measure	Counts	Measure	Counts
1	445	6	433
2	522	7	415
3	440	8	512
4	494	9	520
5	502	10	464

The experimental standard deviation is:

$$s_{ex} = \frac{1}{3}\sqrt{\sum_{i=1}^{10}\left(x_i - \overline{X}\right)^2} = \frac{1}{3}\sqrt{16921.04} = 43.4$$

Both standard deviations are quite close. We apply the χ^2 test to the experimental data:

$$\chi^2_{ex} = \frac{\sum_{i=1}^{10}\left(x_i - \overline{X}\right)^2}{\overline{X}} = \frac{16921.04}{1987.7} = 8.51$$

The values of $\chi^2_{9,0.025} = 19.023$ and $\chi^2_{9,0.975} = 2.700$, obtained from Table 8.10, enable us to write:

$$\chi^2_{ex} > \chi^2_{9,0.975} \text{ and } \chi^2_{ex} < \chi^2_{9,0.025}$$

and we conclude that the variances are equal and that the values of the corrected counts are correct.

Example 8.14. A radioactive sample has been measured with a Geiger counter, and the results obtained are shown in Table 8.14. Study the reliability of the results.

Solution. The mean value is:

$$\overline{X} = \frac{\sum_{i=1}^{10} x_i}{10} = \frac{4747}{10} = 474.7$$

The theoretical standard deviation is:

$$s_t = \sqrt{\overline{X}} = \sqrt{474.7} = 21.8$$

The experimental standard deviation is:

$$s_{ex} = \sqrt{\frac{\sum_{i=1}^{10}\left(x_i - \overline{X}\right)^2}{9}} = \sqrt{\frac{14301.98}{9}} = 39.9$$

The value of χ^2 is:

$$\chi^2_{ex} = \frac{\sum_{i=1}^{10}\left(x_i - \overline{X}\right)^2}{\overline{X}} = \frac{14301.98}{474.7} = 30.13$$

The critical value, obtained from Table 8.10, is $\chi^2_{9,0.025} = 19.023$, and as:

$$\chi^2_{ex} > \chi^2_{9,0.025}$$

TABLE 8.15 Nine measures of the total counts of a sample to study the reliability of the measures.

Measure	Counts	Measure	Counts
1	564	6	561
2	586	7	556
3	563	8	583
4	578	9	665
5	580		

we reject the null hypothesis that the standard deviations are equal. The counts do not follow Poisson's law. When the measures were studied, it was found that a good number of random parasitic pulses from the electric network arrived to the counter.

Example 8.15. We carried out 9 measures of 8 seconds duration and the counts obtained are listed in Table 8.15.

Study the reliability of the measures.

Solution. The mean value is:

$$\overline{X} = \frac{\sum_{i=1}^{9} x_i}{9} = \frac{5118}{9} = 568.67$$

The theoretical standard deviation is:

$$s_t = \sqrt{\overline{X}} = \sqrt{568.67} = 23.8$$

Both standard deviations are quite different. We apply the χ^2 test to the experimental data:

$$\chi^2_{ex} = \frac{\sum_{i=1}^{9}\left(x_i - \overline{X}\right)^2}{\overline{X}} = \frac{971.98}{568.67} = 1.71$$

The values of $\chi^2_{8,0.025} = 17.53$ and $\chi^2_{8,0.975} = 2.18$, obtained from Table 8.10, enable us to write:

$$\chi^2_{ex} > \chi^2_{8,0.975} \text{ and } \chi^2_{ex} < \chi^2_{9,0.025}$$

We reject the null hypothesis of equality of the typical deviations and we conclude that the variances are different. Studying the conditions of the measurement, it was observed that the counting device had a switch which allowed counting pulses from the electric network in one position or the counts detected by the detector in the other position. Due to a fault in the switch, the electric network cycles and the detected pulses were being measured at the same time. As the measurement time was 8 seconds, the number of pulses due to the network in each measurement was 400; therefore, this amount was subtracted from each of the measurements in Table 8.15 and we obtained the following Table 8.16:

The mean value is:

$$\overline{X} = \frac{\sum_{i=1}^{9} x_i}{9} = \frac{1536}{9} = 170.67$$

TABLE 8.16 Corrected counts of the nine measures listed in Table 8.15.

Measure	Counts	Measure	Counts
1	164	6	161
2	186	7	156
3	163	8	183
4	178	9	165
5	180		

The theoretical standard deviation is:

$$s_t = \sqrt{\overline{X}} = \sqrt{170.67} = 13.1$$

The experimental standard deviation is:

$$s_{ex} = \sqrt{\frac{\sum_{i=1}^{9}\left(x_i - \overline{X}\right)^2}{8}} = \sqrt{\frac{971.98}{8}} = 11.0$$

The value of χ^2_{ex} is:

$$\chi^2_{ex} = \frac{\sum_{i=1}^{9}\left(x_i - \overline{X}\right)^2}{\overline{X}} = \frac{971.98}{170.67} = 5.70$$

Both standard deviations are quite different. We apply the χ^2 test to the experimental data:

$$\chi^2_{ex} = \frac{\sum_{i=1}^{9}\left(x_i - \overline{X}\right)^2}{\overline{X}} = \frac{16921.04}{1987.7} = 8.51$$

The values $\chi^2_{8,0.025} = 17.535$ and $\chi^2_{8,0.975} = 2.180$ allow us to write:

$$\chi^2_{ex} > \chi^2_{8,0.975} \text{ and } \chi^2_{ex} < \chi^2_{9,0.025}$$

Thus, we accepted the null hypothesis that both standard deviations are equal. Therefore, the results of the measures are now acceptable from a statistical perspective.

2. Variance of two populations

Comparing variances requires the introduction of a new statistical test, the **F ratio**. Two population variances are compared by forming a ratio of their corresponding sample variance. The null hypothesis is $H_0 : \sigma_1^2 = \sigma_2^2$ and the statistical test is

$$F = \frac{s_1^2}{s_2^2} \tag{8.76}$$

The F-statistics is described by the F-distribution depending on the degrees of freedom. Now we have two samples and one degree of freedom for each sample: $f_1 = n_1 - 1$ is the degree of freedom for the numerator and $f_2 = n_2 - 1$ for the denominator. We write these as

$$f = (n_1 - 1,\ \ n_2 - 1) \tag{8.77}$$

Since s_1^2 and s_2^2 can never be negative, the F curves start at 0 and are skewed to the right as shown in Table 8.17. The total area under the curve is equal to 1.

The null hypothesis does not establish an order for σ_1^2 and σ_2^2. When we write $\sigma_1^2 = \sigma_2^2$, we could also write $\sigma_2^2 = \sigma_1^2$. It does not matter which sample variance goes in the numerator of F. When $H_0 : \sigma_1^2 = \sigma_2^2$ is true, under ideal circumstances, $F = s_1^2/s_2^2 = 1$. Thus, to carry out a hypothesis test we must see how far the computed values of F deviate from 1.

If we observe the sketch of Table 8.17, we can appreciate that this table gives critical values larger than 1 for the right-hand tail. This decision simplifies our work but it forces us to compromise such that the larger values of s must be in the numerator. If we accept this criterion, we can ignore the F values on the left-hand tail.

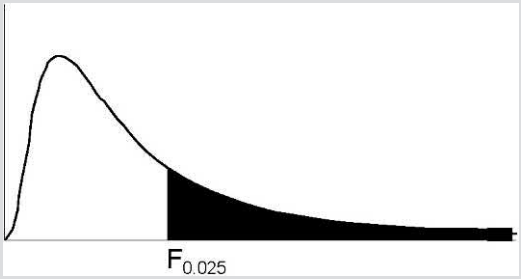
Let us examine in detail Table 8.17 corresponding to $\alpha = 0.025$. The rows of the table indicate the number of degrees of freedom of the denominator and the columns the number of degrees of freedom of the numerator. The critical value is in the intersection of the appropriate row and column. When the value of the degrees of freedom is not explicitly in the table the following approach must be followed: 1) choose the next degree of freedom, 2) if the degree of freedom in the table is halfway with that of the sample, the largest critical value will be taken.

Example 8.16. In example 8.6 the internal ($S_{in} = 0.0098$) and external ($S_{ex} = 0.0068$) uncertainties were obtained. Find if these uncertainties are different at the 95% level of confidence.

Solution. We assume that there is not any difference between the variances:

$$H_0 : S_{in}^2 = S_{ex}^2$$

The alternative hypothesis indicates that the variances are different



$$H_1 : S_{in}^2 \neq S_{ex}^2$$

This alternative hypothesis indicates the contrast is bilateral with $\alpha = 0.05$. The degrees of freedom are $f_{in} = f_{ex} = n - 1 = 4$. From Table 8.17 we obtain the critical value $F_{\alpha/2} = F_{0.025} = 9.60$. The rejection region is then $F_{0.025} > 9.60$. The computed value for $F^*_{0.025}$ is:

$$F^*_{0.025} = \frac{S_{in}^2}{S_{ex}^2} = \frac{0.0098^2}{0.0068^2} = 2.08$$

As the computed value is less than the critical one $\left(F^*_{0.025} < F_{0.025}\right)$, the null hypothesis cannot be rejected.

TABLE 8.17 F distribution.

	f. numerator								
f.deno.	1	2	3	4	5	6	7	8	9
1	647.79	799.50	864.16	899.58	921.85	937.11	948.22	956.66	963.28
2	38.51	39.00	39.17	39.25	39.30	39.33	39.36	39.37	39.39
3	17.44	16.04	15.44	15.10	14.89	14.74	14.62	14.54	14.47
4	12.22	10.65	9.98	9.60	9.36	9.20	9.07	8.98	8.90
5	10.00	8.43	7.76	7.39	7.15	6.98	6.85	6.76	6.68
6	8.81	7.26	6.60	6.23	5.99	5.82	5.70	5.60	5.52
7	8.07	6.54	5.89	5.52	5.29	5.12	4.99	4.90	4.82
8	7.57	6.06	5.42	5.05	4.82	4.65	4.53	4.43	4.36
9	7.21	5.71	5.08	4.72	4.48	4.32	4.20	4.10	4.03
10	6.94	5.46	4.83	4.47	4.24	4.07	3.95	3.85	3.78

Therefore, we conclude that there is no reason to think that S_{ex} and S_{in} are different.

V. Regression

The problems analyzed so far were characterized to have one or two independent random variables. In this section, we consider the case of two or more random variables related to each other. The form of the relationship may be highly varied and unknown, but, in many cases it is possible to guess, with good justification, a linear relationship. In other words, we consider two random variables X and Y, and we assume that the observations tend to be grouped in a straight line. In this case, we say that a linear relationship exists between the two random variables. Once a relationship has been established, we must obtain the function relating the random variables by means of a regression.

A. Linear regression

The degree of association between two random variables is obtained by applying the correlation between them. This correlation is symmetrical since it is indifferent to the correlation between X and Y or between Y and X. In this section we study the effect on the random variable Y when the random variable X takes a specific value. We limit our analysis to the simplest mathematical structure relating X and Y: the linear relationship. Variations of the problem of fitting a function to a set of data: curvilinear relationships, weighted least squares, nonlinear squares, etc., are analyzed by Draper and Smith (1998). Since we are working with random variables, over time for each value of X a distribution of Y values is obtained; therefore, we will use the concept of conditional distribution. An essential characteristic of this distribution is the mean or the expected value. We denote the expected value of the random variable Y with $E[Y|X = x]$, when the random variable X takes the specific value x. Our assumption of linearity implies that the conditional expected value has a linear dependence on x,

$$E[Y|X = x] = \alpha + \beta x \tag{8.78}$$

where α and β determine the correct line. The interpretation of each one of these constants is immediate. When $x = 0$ we have

$$E[Y|X = 0] = \alpha \tag{8.79}$$

where α is the expected value for the dependent variable Y when the independent variable X takes the value 0.

Let us suppose now that X is increased by 1 unit so that x becomes $x + 1$, then

$$E[Y|X = x+1] = \alpha + \beta\ (x+1) \tag{8.80}$$

and

$$\begin{aligned} E[Y|X = x+1] - E[Y|X = x] \\ = \alpha + \beta(x+1) - (\alpha + \beta x) = \beta \end{aligned} \tag{8.81}$$

Therefore, β, the slope of the line, is the expected increase in Y when X increases by unit.

In fact, the equations given previously are not verified exactly. Let us suppose that the independent variable takes the value x_i. If we represent by Y_i the corresponding value of the dependent random variable, the expected value is

$$E[Y_i|X = x_i] = \alpha + \beta\ x_i \tag{8.82}$$

But, in practice, the value of Y_i will deviate from the expected value. If the difference between the observed and the expected value is denoted by ε_i, we can write

$$\varepsilon_i = Y_i - E[Y_i|X = x_i] = Y_i - (\alpha + \beta\ x_i) \tag{8.83}$$

so that

$$Y_i = \alpha + \beta x_i + \varepsilon_i \tag{8.84}$$

where the random variable ε_i has a mean of 0. The last equation is known as the **population regression line** of data (x_i, Y_i).

We have just described the regression model illustrated in Fig. 8.2. For each possible value of the independent variable, the value of the dependent variable may be represented by means of a random variable whose mean is on the regression line. The regression line is drawn through the means of the distributions. For a value of x_i, the independent variable, the deviation of the dependent variable Y_i from the regression line is the error term ε_i.

The regression line is an interesting theoretical construction but, in practice, as we always work with samples of observations, we will never be able to obtain this one exactly. Instead of α and β we obtain their estimators: the number a and b The estimated line has as equation

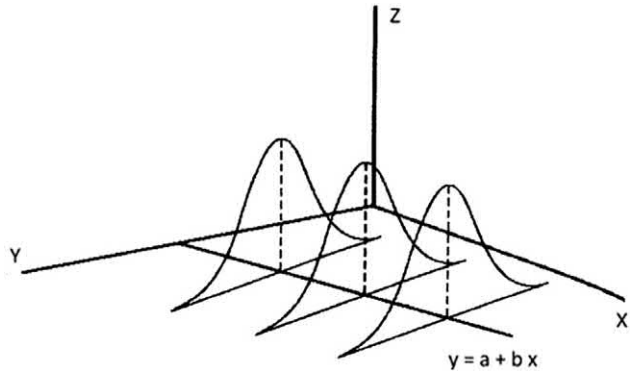


FIGURE 8.2 Probability density functions of the dependent variable for given values of x.

$$y = a + bx \tag{8.85}$$

Let us suppose that we have a sample of n pairs of observations (x_1, y_1), (x_2, y_2), …,(x_n, y_n). We are interested in obtaining the line that best fits to those data. We know that the value x_i produces the value y_i obtained from equation $a + bx_i$, but the exact value for the dependent variable is y_i. The difference between the two is

$$e_i = y_i - (a + bx_i) \tag{8.86}$$

The values of e_i may be positive or negative. If we want to give the same weight to the positive and negative values of the same quantity, a possibility is to work with the square of e_i. The sum of squared differences from the point to the line is

$$SQ = \sum_{i=1}^{n} e_i^2 = \sum_{i=1}^{n} (y_i - a - bx_i)^2 \tag{8.87}$$

The least squares method allows one to estimate the line of a population regression for which the sum of the squares is a minimum. The parameter b can be obtained from the equation

$$b = \frac{\sum_{i=1}^{n} x_i y_i - n\overline{xy}}{\sum_{i=1}^{n} x_i^2 - n\overline{x}^2} \tag{8.88}$$

and a with the equation

$$a = \overline{y} - b\overline{x} = \frac{\overline{y}\sum_{i=1}^{n} x_i^2 - \overline{x}\sum_{i=1}^{n} x_i y_i}{\sum_{i=1}^{n} x_i^2 - n\overline{x}^2} \tag{8.89}$$

where $\overline{x}$ and $\overline{y}$ are the respective means of the sample. The line

$$y = a + bx \tag{8.90}$$

is the **sample regression** line of Y on X.

The least squares method is a good procedure to estimate the regression line for the population. This procedure is the most appropriate when the regression line for the population

$$Y_i = \alpha + \beta\ x_i + \varepsilon_i \tag{8.91}$$

is required. This must fulfill the following conditions:

- Each value of x_i is a fixed number. That is equivalent to saying that the realization of a random variable X_i is independent of the error term ε_i.
- Errors are random variables with an expected value equal to zero:

$$E[\varepsilon_i] = 0\ \ (i = 1, 2, ..., n) \tag{8.92}$$

- All the random variables ε_i have the same variance σ_ε^2:

$$E\left[\varepsilon_i^2\right] = \sigma_\varepsilon^2 \quad (i = 1, 2, ..., n) \tag{8.93}$$

- The random variables ε_i are not correlated:

$$E[\varepsilon_i \varepsilon_j] = 0 \text{ for all } i \neq j \tag{8.94}$$

Bacon (1953) describes the least squares method of fitting a line for different conditions and analyzes the goodness of fitting results from different experiments.

1. Confidence intervals and hypothesis testing

We will analyze the problems of interval construction and the hypothesis testing for the regression parameters of a population. Suppose that the regression line is

$$Y_i = \alpha + \beta x_i + \varepsilon_i \tag{8.95}$$

and the conditions of the previous section are fulfilled. If σ_ε^2 is the common variance for the error terms ε_i, an unbiased estimator of σ_ε^2 is

$$s_e^2 = \frac{\sum_{i=1}^{n} e_i^2}{n-2} \tag{8.96}$$

where e_i are the residuals of the least squares. These residuals substitute the error terms ε_i, which are unknown. We divide by $n-2$, because we lose two degrees of freedom when estimating the parameters α and β.

If we designate with b the least squares estimate of the slope of the population regression line, the estimator of β is unbiased and the variance is

$$\sigma_b^2 = \frac{\sigma_\varepsilon^2}{\sum_{i=1}^{n} (x_i - \bar{x})^2} = \frac{\sigma_\varepsilon^2}{\sum_{i=1}^{n} x_i^2 - n\bar{x}^2} \tag{8.97}$$

An unbiased estimator of σ_b^2 is provided by

$$s_b^2 = \frac{s_\varepsilon^2}{\sum_{i=1}^{n} (x_i - \bar{x})^2} = \frac{s_e^2}{\sum_{i=1}^{n} x_i^2 - n\bar{x}^2} \tag{8.98}$$

In both cases, we assume that the conditions of the previous section are fulfilled.

Although the slope is the most interesting parameter, we give also the equation to compute the estimator of the variance of the ordinate on the origin. We substitute β, b and s_b^2 for α, a and s_a^2 to have

$$s_a^2 = s_e^2 \left(\frac{1}{n} + \frac{\bar{x}^2}{\sum_{i=1}^{n} x_i^2 - n\bar{x}^2} \right) \tag{8.99}$$

VI. Detection limits

Radioactivity measurements are characterized by a variable zero level due to background. This situation obliges one to work with detection and determination limits when the radioactivity of the source is very low.

In this section we analyze the problem of obtaining the detection limits for very low radioactivity measurements. A complete discussion of the detection limits, in a measurement process, requires the introduction of two specific levels: (i) a **decision limit** that allows one to deduce whether the result of the analysis indicates that the sample is or is not radioactive and (ii) a **detection limit** that indicates if an analytical process leads to a quantitative detection. The relationships between these limits and the equations to compute them are also given.

In a general way, two types of devices are considered: counters, characterized to accumulate the information in one channel; and spectrometers, where information is distributed in numerous channels. In the latter case, we distinguish between high-resolution detectors, such as Ge, and low-resolution detectors, such as NaI(Tl).

A. Critical levels

We will distinguish two fundamental problems in the measurement of very low radioactivity sources: i) given an observed net signal, S, to decide whether a real signal has been detected or, in other words, to decide whether the sample is indeed radioactive. ii) Is $\mu_S > 0$? This question can be addressed by the statistical theory of hypothesis testing, in which one first formulates a test hypothesis. In our case, the null hypothesis H_0 for μ_S is $\mu_S = 0$. This hypothesis and the alternative hypothesis H_1 $(\mu_S > 0)$ are mutually exclusive. Together they cover all possible values of μ_S. As a consequence of the intrinsic statistical variation in the counting rates, we can arrive at one of the following two types of judgment errors: i) The error of the first kind or Type I error states that true activity is greater than zero when, in fact, it is zero or ii) The error of the second kind or Type II error states that the true activity is zero when, in fact, it is greater than zero. The probability of making a Type I error is denoted by α and depends on the test procedure. The maximum value of α and the standard deviation of the net signal σ_0, when $\mu_S = 0$, allows one to establish the critical level L_C. An observed signal, S, must exceed L_C to yield the decision "detected". The probability distribution of possible outcomes, when the true net signal is zero, intersects L_C such that the factor $1 - \alpha$ corresponds to the correct decision "nondetected". Whereas the probability of making a Type II error, denoted by β, also depends on the size of the measured quantity, in the case of radioactive measurements it depends on the amount of radioactivity of the tested material. The most relevant papers

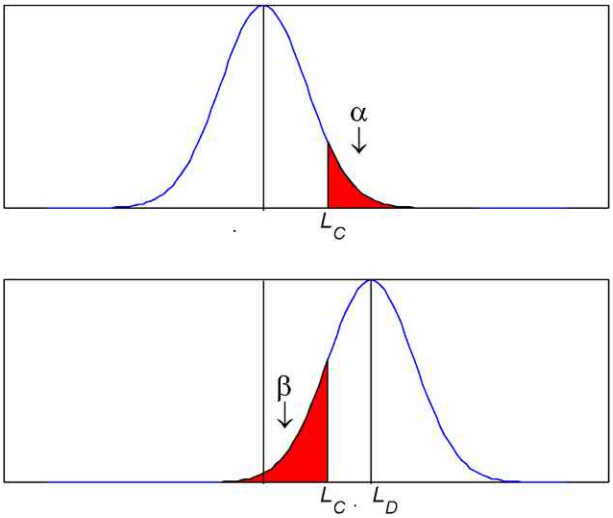

FIGURE 8.3 Type I and II errors.

about low-level detection limits are Altshuler and Pasternack (1963), Currie (1968), (1995), and Donn and Walke (1977).

When the critical level L_C has been established, an a priori detection limit L_D may be established by specifying L_C, the acceptable level β, for a Type II error and the standard deviation σ_D, characterizing the probability distribution of the net signal when its true value μ_S is equal to L_D. Fig. 8.3 shows the Type I and II error curves and the critical levels L_C and L_D. The mean μ_S may be between zero and L_D. When μ_S is between 0 and L_C, we agree that there is no radiation from the sample. When μ_S is between L_C and L_D, there may be radioactivity, but when $\mu_S = L_D$ the Type II error is minimum. Therefore, for $L_C < \mu_S < L_D$ although we can have detection, such detection cannot be considered reliable given that the Type II error is not a minimum.

The critical level L_C is given by

$$L_C = k_\alpha \sigma_0 \tag{8.100}$$

and the detection limit by

$$L_D = L_C + k_\beta \sigma_D \tag{8.101}$$

where $k_\alpha \equiv z_\alpha$ and $k_\beta \equiv z_\beta$ are the $k \equiv z$ scores of the standardized normal distribution corresponding to probability levels $1 - \alpha$ and $1 - \beta$, respectively.

When we analyze the pulses due to radioactivity emission, we can assume that the distributions of background and background + source follow the Poisson distribution. When the count number is sufficiently large, the distributions are approximately normal. Under such circumstances, the variance of the net counting is given by

$$\sigma^2 = \sigma_{S+B}^2 + \sigma_B^2 = \mu_S + \mu_B + \frac{\mu_B}{n} \tag{8.102}$$

where σ_B is obtained from n measurements without the source. Note than σ depends on the signal level.

If σ_0^2 is the variance when $\mu_S = 0$, and σ_D^2 is the variance for $\mu_S = L_D$, we have

$$L_C = k_\alpha \sigma_0 = k_\alpha \left(\mu_B + \sigma_0^2\right)^{1/2} \tag{8.103}$$

and

$$\sigma_D^2 = \sigma_{S+B}^2 + \sigma_B^2 = \mu_S + \mu_B + \sigma_0^2 = L_D + \sigma_0^2 \tag{8.104}$$

From Eq. (8.101) we get

$$L_D = L_C + k_\beta \left(L_D + \sigma_0^2\right)^{1/2} \tag{8.105}$$

Solving Eqs. (8.102) and (8.104) we obtain

$$L_D = L_C + \frac{k_\beta^2}{2}\left\{1 + \left[1 + \frac{4L_C}{k_\beta^2} + \frac{4L_C^2}{k_\alpha^2 k_\beta^2}\right]^{1/2}\right\} \tag{8.106}$$

The mean value and the standard deviation without the source allows one to compute L_C and L_D for selected values of α and β by means of Eqs. (8.102) and (8.105). If $k_\alpha = k_\beta = k$, we obtain a considerable simplification of Eq. (8.101), which is reduced to the form

$$L_D = k^2 + 2L_C \tag{8.107}$$

Example 8.17. Background and a source-plus-background are measured and the counting rates obtained are $C_B = 203$ counts/h and $C_{B+S} = 235$ counts/h. Previously, the background was measured for 200 h, accumulating a total of 40000 counts (counting rate $B = 200$ counts/h). Compute the values of L_C and L_D when $\alpha = 0.025$ and $\beta = 0.050$, in the following two cases: (a) when we know that the background does not change and we can use the value of B, and (b) when we cannot apply B, because the background changes.

Solution. The values $k_\alpha = 1.96$ when $\alpha = 0.025$ and $k_\beta = 1.645$ when $\beta = 0.050$ are obtained from Table 8.2 as follows: Given that $k_\alpha = z_{1-\alpha} = 0.975$, the value considered in Table 8.2 is 0.975−0.5 = 0.475. This value corresponds to row 1.9 and column 0.06, thus $k_\alpha = 1.96$. In the same way, $k_\beta = z_{1-\beta} = 0.95$ and the value to be carried to Table 8.2 is 0.95−0.5 = 0.45, this value is not included in the table; however, it is between 0.4495 and 0.4505, at row 1.6 and columns 0.04 and 0.05 (mean 0.045). Therefore, $k_\beta = 1.645$.

The background counting rate is $C_B = 203$ counts/h. As the expected background counting rate is $B = 200$ counts/h, it seems that the background has not changed. The net counting rate is

$$C_S = C_{B+S} - B = 235 - 200 = 35 \text{ counts/h}$$

and the critical counting rate is

$$L_C = k_\alpha\sqrt{\mu_B + \sigma_B^2} \approx k_\alpha\sqrt{B} = 1.96 \times \sqrt{200} = 27.7 \text{ counts/h}$$

Since 35 is greater than 27.7 our decision is that there is activity in the sample. The minimum significant measured counting rate is 27.7 counts/h.

The minimum detectable counting rate from Eq. (8.106) is

$$L_D = L_C + \frac{k_\beta^2}{2}\left\{1 + \left[1 + \frac{4L_C}{k_\beta^2} + \frac{4L_C^2}{k_\alpha^2 k_\beta^2}\right]^{1/2}\right\}$$

$$= 27.7 + \frac{1.645^2}{2}\left\{1 + \left[1 + \frac{4 \times 27.7}{1.645^2} + \frac{4 \times 27.7^2}{1.96^2 \times 1.645^2}\right]^{1/2}\right\}$$

$$= 52.5 \text{ counts/h}$$

and applying the approximate equation

$$L_D = (k_\alpha + k_\beta)\sqrt{B} = (1.96 + 1.645)\sqrt{200} = 51.0 \text{ counts/h}$$

When the background changes we cannot use the mean number B. The net counting rate is obtained applying the following expression

$$C_S = C_{S+B} - C_B = 235 - 203 = 32 \text{ counts/h}$$

and

$$L_C = k_\alpha\sqrt{\mu_B + \sigma_B^2} = k_\alpha\sqrt{\mu_B + \mu_B}.$$

$$= k_\alpha\sqrt{2\mu_B} \approx k_\alpha\sqrt{2C_B} = 1.96\sqrt{2 \times 203}$$

$$= 39.49 \text{ counts/h}.$$

Since the net counting rate is less than the critical net counting rate, our conclusion is that there is no significant radioactivity in the sample. The minimum detectable counting rate is

$$L_D = L_C + \frac{k_\beta^2}{2}\left\{1 + \left[1 + \frac{4L_C}{k_\beta^2} + \frac{4L_C^2}{k_\alpha^2 k_\beta^2}\right]^{1/2}\right\}$$

$$= 39.49 + \frac{1.645^2}{2}\left\{1 + \left[1 + \frac{4 \times 39.49}{1.645^2} + \frac{4 \times 39.49^2}{1.96^2 \times 1.645^2}\right]^{1/2}\right\}$$

$$= 75.6 \text{ counts/h}$$

and applying the approximate equation

$$L_D = (k_\alpha + k_\beta)\sqrt{2C_B} = (1.96 + 1.645)\sqrt{2 \times 203} = 72.6 \text{ counts/h}$$

B. Gamma Spectra

Ge detectors allow the experimental spectroscopists to obtain gamma- and X-ray spectra with high resolution compared with that obtained with NaI(Tl) detectors. This excellent resolution facilitates the qualitative and quantitative analysis of radionuclide mixtures for high and medium activities. However, for low-level samples the low efficiency and the similarity of the small peaks to the fluctuations of the background can make the discrimination between true and false peaks difficult.

Since NaI(Tl) detectors have a larger volume and lower resolution than Ge detectors, the detection of low activity peaks is different for each detector. Each one of the Ge peaks can be analyzed taking the two independent constituent parts: the peak and the Compton contribution. On the other hand, the NaI(Tl) peaks force us to consider the overlap contribution of the different spectral components in each of the peaks.

In this section, we analyze the determination and detection limits for Ge detectors. Based upon the acceptable risk of committing a Type I error, a minimum significant measured area for a peak is defined and for a Type II error, a minimum detectable true area is introduced. The study of complete response of the NaI(Tl) detector is carried out taking into account the contribution of the different spectral components.

1. High-resolution gamma spectra

In an experimental Ge gamma spectrum, the minimum detectable area of a peak is the minimum number of photopeak counts that make it detectable. The value of this minimum depends on the spectral background under the peak, but the background usually does not coincide with the detector background. The minimum is predetermined by the statistical risk of including an observed peak when it is not a real peak or concluding that a real peak is not present when it is really there.

The procedures to discern between real and false peaks are based on the assumption that real peaks show a Gaussian shape. This procedure gives good results when the peaks are sufficiently defined and the Gaussian hypothesis is valid; however, when the peaks are small, they can be taken as statistical fluctuations with Gaussian appearance. Therefore, a computational procedure dedicated to determining very small peaks must be able to detect false peaks.

There is a probability that a false peak is accepted as a true peak. This is called a Type I error. Based upon the acceptable risk of committing a Type I error, we define a **minimum significant measured area**. It is assumed that all the peaks in the spectrum whose measured areas are smaller than this limit are discarded and considered as false

peaks. This is the Type II error. Consequently, we can define a minimum detectable real peak area such that if the actual photopeak area is at least this large, the risks of committing Type I or Type II errors are less than some preselected values.

An application of this analysis consists of determining the minimum time required to be sure that the risk of making a Type I or II error does not exceed acceptable values. This allows one to predict the time required to assure the detection of small peaks.

a. False peaks distribution

Following Head (1972), to know the distribution of false peaks, it is necessary to carry out an experiment and have a peak identification computer program. In essence, the experiment consists of preparing "background" spectra with an average measure of 50 to 50,000 counts/channel. For the purpose of the experiment, the background in the energy range of 80−500 keV can be simulated by the Compton tails of the two ^{60}Co gamma lines, in order to determine false peaks. By means of another gamma source with peaks in the range given above we can produce the real peaks. ^{133}Ba can be used to generate real peaks. The objective is clear: The ^{60}Co Compton distribution produces the "background" and ^{133}Ba gives the true peaks for each background. For a certain background level and several resolution values (1.0, 1.5, 2.0, 2.5, and 3.0 channels, for a real resolution of 1.5 channels) we obtain the number of false and acceptable peaks. From the different analyzed backgrounds, we obtain the curves shown in Fig. 8.4, where the average area of the false peaks detected $\overline{A}$ and the widths $\sigma_{\overline{A}}$ of these areas as a function of the background B under the peak areas (due to the Compton tails of ^{60}Co gamma lines) are represented.

b. Minimum significant area

The probability of committing a Type I error or of concluding that a peak corresponds to a gamma ray, when in fact it is a false peak, depends upon the peak selection procedure and upon the level of the background under the peak. A minimum significant measured area A_I can be defined by the expression

$$\alpha = P\{\text{Measured area of a false peak} \geq A_I\} \tag{8.108}$$

A peak whose area is equal or larger than A_I is retained and all peaks whose area is less than A_I are rejected. If we do not have any additional information about the peak, the probability that it is false is α or in other words, the risk of accepting a false peak as true is α.

If we assume that the false peak area distribution is normal, the minimum significant area for committing a Type I error, for a given risk, is given by the equation

$$A_I = \overline{A} + z_\alpha \sigma_{\overline{A}} \tag{8.109}$$

where z_α is related to α by the equation

$$\alpha = \int_{z_\alpha}^{\infty} \frac{1}{\sqrt{2\pi}} \exp\left(u^2/2\right) \mathrm{d}u \tag{8.110}$$

$\overline{A}$ and $\sigma_{\overline{A}}$ may be obtained by interpolation in Fig. 8.4 for a given background B, the value of the minimum significant area $\overline{A}_I$, for a risk α, may be computed from Eq. (8.109).

c. Minimum detectable area

Assume that we have obtained A_T counts in the photopeak of a given gamma ray. When we compute the area by means of a fitting program, the fitted area A_F will seldom be equal to A_T. Due to statistical fluctuations, the measured area for a peak will usually be distributed about the real area $\left(\overline{A}_F = A_T\right)$ with a width σ_F. As we have seen in the last section, all peaks with mean areas lower than A_I will be discarded as not significant. A Type II error is committed when a real peak $A_T \geq A_I$, due to the spread in the fitted area, gives $A_F < A_I$ and consequently the peak is discarded.

The probability of committing a Type II error depends upon the value of A_I and the fitted area A_F. We define the minimum detectable area A_{II} as

$$\beta = P\{\text{Fitted area } A_F < A_I, \text{when the true area is } A_T = A_{II}\} \tag{8.111}$$

As the fitted area is normally distributed with variance σ_F^2 we have

$$A_{II} = A_I + k_\beta \sigma_F \tag{8.112}$$

where the relationship between β and k_β is the same as that between α and k_α. In this case, σ_F^2 is the variance of the fitted area distribution when $\overline{A}_F = A_T = A_{II}$.

We introduce a hypothesis that allows us to solve the problem with the data we have. We suppose that the variance of the fitted area distribution is similar to the variance of the false peak area distribution $\left(\sigma_F^2 \approx \sigma_{A_{II}}^2\right)$. As A_{II} is

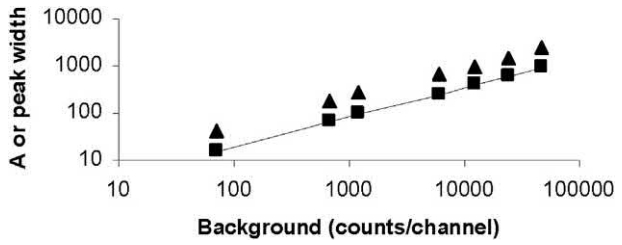

FIGURE 8.4 Average of the peak count area (triangles) and width of the peaks (squares) as a function of background. *From Head (1972); reprinted with permission of Elsevier Science.*

very close to A_I, we assume that $\sigma_F^2 \approx \sigma_{A_{II}}^2 \approx \sigma_{A_I}^2 \approx \sigma_{\overline{A}}^2$, consequently

$$A_{II} = A_I + k_\beta \sigma_{\overline{A}} \tag{8.113}$$

or

$$A_{II} = \overline{A} + (k_\alpha + k_\beta)\sigma_{\overline{A}} \tag{8.114}$$

$\overline{A}$ and $\sigma_{\overline{A}}$ may be obtained interpolating in Fig. 8.4.

Example 8.18. The background spectrum has $B = 10000$ counts/channel. Obtain the values of $\overline{A}$ and $\sigma_{\overline{A}}$. Compute A_I and A_{II} for $\alpha = 10\%$ and $\beta = 1\%$.

Solution. For a background $B = 10{,}000$ we obtain from Fig. 8.4

$$\overline{A} = 840 \text{ counts and } \sigma_{\overline{A}} = 320 \text{ counts}$$

The values of k_α and k_β, for $\alpha = 0.10$ and $\beta = 0.01$ are

$$k_\alpha = 1.28 \text{ and } k_\beta = 2.33$$

Therefore

$$A_I = \overline{A} + k_\alpha \sigma_{\overline{A}} = 840 + 1.28 \times 320 = 1250 \text{ counts}$$

and

$$A_{II} = \overline{A} + (k_\alpha + k_\beta)\sigma_{\overline{A}} = 840 + (1.28 + 2.33) \times 320 = 1995 \text{ counts}$$

The relationship between A_I, A_{II} and B is

$$A_{II} = K_{\alpha\beta} B^{0.619} \tag{8.115}$$

The exponent is obtained from the graphical representation of A_I and A_{II} as a function of B. The factor $K_{\alpha\beta}$ is a parameter independent of B containing all the information related to the Type I and II error risks that influence A_{II}. In fact, $K_{\alpha\beta}$ is a risk factor depending functionally on α, β and B. From Eqs. (8.114) and (8.115), we obtain

$$K_{\alpha\beta} = \frac{A_{II}}{B^{0.619}} = \frac{\overline{A} + (k_\alpha + k_\beta)\ \sigma_{\overline{A}}}{B^{0.619}} \tag{8.116}$$

It is observed that $K_{\alpha\beta}$ is symmetric in α and β.

d. Minimum counting time

We have just concluded that we may calculate a minimum area, A_{II}, so that a peak with this area cannot be false with a risk α and a real peak cannot be discarded as false with a risk β. It has been supposed that the background and the peak grow evenly during data accumulation by the spectrometer. In this situation we may compute the counting duration to assure that the peak is detectable with the risks α and β.

Let us suppose that a is the true counting rate for the peak, expressed in counts/h. If $t_{\alpha\beta}$ is the time required, in hours, assuming that the risks for the Type I and II errors do not exceed α and β, respectively, we can write

$$A_{II} = a t_{\alpha\beta} \tag{8.117}$$

$$B = b t_{\alpha\beta} \tag{8.118}$$

taking these expressions to Eq. (8.115) we have

$$a t_{\alpha\beta} = K_{\alpha\beta} (b t_{\alpha\beta})^{0.619} \tag{8.119}$$

the minimum counting time is given by

$$t_{\alpha\beta} = (K_{\alpha\beta}/a)^{2.62} b^{1.62} \tag{8.120}$$

Example 8.19. Table 8.18 shows the experimental values of B, $\overline{A}$ and $\sigma_{\overline{A}}$. Find the relationship between A_{II} and B when $\alpha = 0.10$ and $\beta = 0.01$ or 0.5. Show that $A_{II} = K_{\alpha\beta} B^c$ and compute $K_{\alpha\beta}$ and c. It is assumed that $K_{\alpha\beta}$ is a parameter independent of B.

Solution. Table 8.19 shows the values of A_{II} for different values of B.

Equation $A_{II} = K_{\alpha\beta} B^c$ may be fitted taking logarithms

$$\log A_{II} = \log K_{\alpha\beta} + c \log B$$

TABLE 8.18 Experimental values of B, $\overline{A}$ and $\sigma_{\overline{A}}$.

B	$\overline{A}$	$\sigma_{\overline{A}}$
100	50	18.8
500	135	50.9
1000	208	78.1
5000	563	211.6
10000	865	324.9
20000	1328	499.0
40000	2040	766.4

TABLE 8.19 Values of B and A_{II} for different α and β values.

$\alpha = 0.10$, $\beta = 0.01$		$\alpha = 0.10$, $\beta = 0.50$	
B	A_{II}	B	A_{II}
100	118	100	74
500	319	500	201
1000	490	1000	308
5000	1327	5000	834
10,000	2038	10,000	1281
20,000	3130	20,000	1967
40,000	4806	40,000	3021

This is a linear equation

$$y = a + cx$$

where

$$y = \log A_{II}$$

and

$$x = \log B$$

Applying least square fitting to the quantities of Table 8.19, when $\alpha = 0.10$, $\beta = 0.01$, we get $K_{\alpha\beta} = 6.81$ and $c = 0.619$, when $\alpha = 0.10$, $\beta = 0.50$, we get $K_{\alpha\beta} = 4.28$ and $c = 0.619$. As c takes the same values, we may compute $K_{\alpha\beta}$ applying the equation

$$K_{\alpha\beta} = \frac{\overline{A} + (k_\alpha + k_\beta)\sigma_{\overline{A}}}{B^{0.619}}$$

The values of B, $\overline{A}$ and $\sigma_{\overline{A}}$ may be values of Table 8.18 or interpolated logarithmically from Table 8.19; e.g., for $\alpha = 0.01$ and $\beta = 0.015$, when $B = 1000$, $\overline{A} = 208$ and $\sigma_{\overline{A}} = 78$, we have

$$K_{\alpha\beta} = \frac{208 + (2.33 + 1.96) \times 78}{1000^{0.619}} = 7.55$$

Example 8.20. Compute the values of $t_{\alpha\beta}$ when $\alpha = 0.01$, $\beta = 0.015$, the background counting rate is $b = 100$ counts/h and $a = 20$ counts/h.

Solution. From Eq. (8.120), taking into account that $K_{\alpha\beta} = 7.55$ from the last example we have

$$t_{\alpha\beta} = \left(\frac{7.55}{20}\right)^{2.62} 100^{1.62} = 135 \text{ h}$$

2. Low-resolution gamma spectra

NaI(Tl) detectors generate spectra with very poor resolution compared with the spectra obtained with Ge detectors. Consequently, the procedure described in the previous section is not generally applicable to low resolution spectra. Isolated peaks cannot be analyzed due to interference from other spectral components. In this section, we introduce a more general procedure based on considering the complete spectral response. This procedure introduces a larger complication in calculations, but it is inevitable when we have radionuclide mixtures and the spectrum of one of the radionuclides overlaps the other spectra and vice versa. In this situation, the background must be considered as an independent spectrum. A standard procedure for estimating the radionuclide concentration from gamma-ray spectrometer data is the method of weighted least squares fitting. In this case, it is assumed that the net spectrum of a radionuclide mixture is equivalent to some linear combination of the net characteristic spectra of the radionuclides existing in the sample. The concentration of these radionuclides is represented by the coefficients of the linear combination estimate. Consequently, the estimation of these coefficients is equivalent to the determination of their concentrations.

The solution of least squares is a function $\boldsymbol{\theta}' = (\theta_1, \theta_2, ..., \theta_m)$, which minimizes the sum of the squares of the count differences between observed and fitted channels. This sum of squares is denominated a residual variation.

We define the following n-dimensional vectors:

$\mathbf{x} = (x_1, x_2, \ldots, x_n)$ net counting rate corresponding to channels 1, 2, …, n.
$\mathbf{y} = (y_1, y_2, \ldots, y_n)$ gross counts (sample + background) in channels 1, 2, …, n.
$\mathbf{b} = (b_1, b_2, \ldots, b_n)$ background counts in channels 1, 2, …, n.

If t is the counting time of the sample and r the counting time of the background we may define the elements w_{jj} of the diagonal matrix $\mathbf{W}$ as

$$w_{jj} = \frac{y_j}{t^2} + \frac{b_j}{r^2} \tag{8.121}$$

The solution obtained by weighted least squares method is given by the estimator

$$\widehat{\boldsymbol{\theta}} = \left(\mathbf{A}\mathbf{W}^{-1}\mathbf{A}'\right)^{-1}\mathbf{A}\mathbf{W}^{-1}\mathbf{x} \tag{8.122}$$

where $\mathbf{A}$ is an $m \times n$ matrix called the calibration matrix. The dimension m corresponds to the number of calibration spectra and n to the number of channels of each spectrum.

The variance of the estimated concentration parameter for the ith radionuclide is the ith diagonal element of the matrix $\left(\mathbf{A}\mathbf{W}^{-1}\mathbf{A}'\right)^{-1}$. In order to test the goodness of fit we use the residual mean square statistic

$$s^2 = \frac{1}{n-m}\left(\mathbf{x} - \mathbf{A}'\widehat{\boldsymbol{\theta}}\right)'\mathbf{W}^{-1}\left(\mathbf{x} - \mathbf{A}'\widehat{\boldsymbol{\theta}}\right) \tag{8.123}$$

which is distributed as a chi-square random variable. A review of methods currently used to unfold particle spectra for measured pulse height distributions is presented by Matzke (2002).

a. Sample with a single radionuclide

To illustrate the procedure described in the previous section, we consider a simple case: the limit of detection determination when the sample has only one radionuclide and we use a two-channel counter. Eq. (8.122) becomes

$$\widehat{\theta}_1 = \left\{\frac{a_{11}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{12}^2}{y_2/t^2 + b_2/r^2}\right\}^{-1} \times \left\{\frac{a_{11}(y_1/t - b_1/r)}{y_1/t^2 + b_1/r^2} + \frac{a_{12}(y_2/t - b_2/r)}{y_2/t^2 + b_2/r^2}\right\} \tag{8.124}$$

the standard error is given by

$$S\left(\widehat{\theta}_1\right) = \left\{\frac{a_{11}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{12}^2}{y_2/t^2 + b_2/r^2}\right\}^{-1/2} \tag{8.125}$$

and the detection limit is given by

$$L_D = (k_\alpha + k_\beta)\left\{\frac{a_{11}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{12}^2}{y_2/t^2 + b_2/r^2}\right\}^{-1/2} \tag{8.126}$$

If the counter has only one channel, the estimate is

$$\widehat{\theta}_1 = \left\{\frac{a_{11}^2}{y_1/t^2 + b_1/r^2}\right\}^{-1} \times \left\{\frac{a_{11}(y_1/t - b_1/r)}{y_1/t^2 + b_1/r^2}\right\} = \frac{y_1/t - b_1/r}{a_{11}} \tag{8.127}$$

and

$$S\left(\widehat{\theta}_1\right) = \sqrt{\frac{y_1/t^2 + b_1/r^2}{a_{11}^2}} \tag{8.128}$$

The detection limit is

$$L_D = (k_\alpha + k_\beta)\sqrt{\frac{y_1/t^2 + b_1/r^2}{a_{11}^2}} \tag{8.129}$$

b. Sample with two radionuclides

Consider now a radioactive sample with two radionuclides and a counter with two channels. The standard error of the estimated concentrations for radionuclide 1 is $S\left(\widehat{\theta}_1\right)$ and $S\left(\widehat{\theta}_2\right)$ for the second radionuclide. It is straightforward to demonstrate the following equations

$$S\left(\widehat{\theta}_1\right) = \left\{\frac{1}{d}\left(\frac{a_{21}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{22}^2}{y_2/t^2 + b_2/r^2}\right)\right\}^{-1/2} \tag{8.130}$$

and

$$S\left(\widehat{\theta}_2\right) = \left\{\frac{1}{d}\left(\frac{a_{11}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{12}^2}{y_2/t^2 + b_2/r^2}\right)\right\}^{-1/2} \tag{8.131}$$

where d denotes the determinant of the matrix $\mathbf{AW^{-1}A'}$.

The individual estimate of concentrations is impossible when the shape of pulse distributions in both channels is similar. In this situation $d \to 0$.

The detection limit for radionuclide 1 is approximated by

$$L_D(1) = (k_\alpha + k_\beta)\left\{\frac{1}{d}\left(\frac{a_{21}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{22}^2}{y_2/t^2 + b_2/r^2}\right)\right\}^{-1/2} \tag{8.132}$$

and for radionuclide 2 by:

$$L_D(2) = (k_\alpha + k_\beta)\left\{\frac{1}{d}\left(\frac{a_{11}^2}{y_1/t^2 + b_1/r^2} + \frac{a_{12}^2}{y_2/t^2 + b_2/r^2}\right)\right\}^{-1/2} \tag{8.133}$$

c. Sample with several radionuclides

From the above discussion, it is evident that the standard error of the parameter to estimate the concentration of radionuclides depends on the following factors: counting time of the sample and background, relationship between the spectral shape included in the library and the concentration of the radionuclides present in the sample.

According to the description of Pasternack and Harley (1971), in the multi-radionuclide and multi-channel situation we may consider three different detection limits:

1. A radionuclide is assumed to be in the sample and the library contains only this radionuclide.
2. The sample contains only one radionuclide but the library contains this and other radionuclides.
3. The sample and the library each contain the same radionuclides.

The procedure to obtain the detection limits in case 1 is as follows: First we obtain the background spectrum of the system $\mathbf{b}' = (b_1, b_2, \ldots, b_n)$ and the spectrum for a mock sample $\mathbf{y}' = (y_1, y_2, \ldots, y_n)$. Generally we can use the background distribution $\mathbf{b}'$ in the place of $\mathbf{y}'$. Then we apply the least squares analysis and compute the standard error $S(\theta_1)$ from the square root of $\left(\mathbf{a}_1'\mathbf{W}^{-1}\mathbf{a}_1\right)^{-1}$, where $\mathbf{a_1} = (a_{11}, a_{12}, \ldots, a_n)$ denotes the radionuclide library spectrum. Thus

$$S\left(\widehat{\theta}_1\right) = \left\{\sum_{j=1}^{n} \frac{a_{1j}^2}{y_j/t^2 + b_j/r^2}\right\}^{-1/2} \tag{8.134}$$

and

$$L_D = (k_\alpha + k_\beta)\left\{\sum_{j=1}^{n} \frac{a_{1j}^2}{y_j/t^2 + b_j/r^2}\right\}^{-1/2} \tag{8.135}$$

When we take $\mathbf{b}'$ in place of $\mathbf{y}'$ ($t = r$) the detection limit is

$$L_D = (k_\alpha + k_\beta)\left\{\sum_{j=1}^{n}\frac{a_{1j}^2}{2b_j/r^2}\right\}^{-1/2} \tag{8.136}$$

For case 2, the procedure is the same, but the matrix **A** contains all the spectra of the library. For case 3, the procedure is again the same. It is recommended that the mock sample adequately simulates the sample absorption. When the library does not contain all the sample radionuclides, the estimate may be unacceptable. When the library contains more spectra than the sample, a reduction in precision is observed and the standard error increases; however, the estimates remain unbiased. Explicit mathematical expressions for the bias and the loss of precision when using inadequate calibration matrices are given by Pasternack and Liuzzi (1965).

VII. Metrology applications

A. Uncertainty budget

In all radionuclide standardization work, we must present a table that lists the various quantified uncertainties. We will take as an example the determination of the activity concentration of a ^{133}Ba solution (Simpson and van Wyngaardt, 2008). As was customary at the time, Table 8.20 shows only the different components of uncertainty and the uncertainty for each component. Table 8.20 is a technical table directed to experts. Along with many published uncertainty budgets, Table 8.20 does not fully comply with the guidelines of the GUM (see Section 7.1.4 of JCGM 100:2008), and would require an expert in the field using specialized knowledge to make an educated guess of the likely method of evaluation. In recent years, in the field of radionuclide metrology, a concerted effort is being made to include an explanation on how each uncertainty value was obtained in the uncertainty budget, similar to the remarks given in the following table. Here we asked Simpson and van Wyngaardt to provide us a table for nonexperts with more details. Table 8.21 describes the procedures for obtaining the different uncertainties as well as the type of uncertainty (A or B). We must mention that in the past 10 years, Dr. Simpson and the members of other laboratories have tried to include additional information in the uncertainty budget along the lines of Table 8.21.

B. Uncertainty calculation

Wang et al. (2001) obtained the activity concentration of a ^{125}I solution measuring 10 samples and applying the equation:

$$N_0 = T + \frac{N_\gamma N_{\alpha\beta}}{N_{\beta\gamma}(2N_{\alpha\alpha} + N_{\alpha\beta})}\left[N_\alpha + N_\beta - N_\gamma\left(\frac{N_{\alpha\beta}}{2N_{\beta\gamma}} + \frac{N_6}{N_{\beta\gamma}} - \frac{2N_{\alpha\alpha}}{N_{\alpha\beta}}\right]\right) \tag{8.137}$$

The values of different quantities are shown in Table 8.22. This table shows the activity of each of the samples (final column), the mean value of 10 samples and the relative standard deviation.

There are two procedures for calculating the uncertainty activity obtained with Eq. (8.137). The traditional option is to calculate the activity of each sample and then to obtain from them the standard deviation (Taylor, 1997). This is the

TABLE 8.20 Standard uncertainty budget for ^{133}Ba in percentage of the activity concentration.

Component	Relative standard uncertainty multiplied by a sensitivity factor (%)
Counting statistics	0.08
Weighing	0.035
Dead time	0.04
Coincidence resolving time	0.002
Satellite pulses (afterpulsing)	0.10
Counting time	0.001
Background	0.01
Adsorption	0.002
Half life	0.001
Extrapolation of efficiency curve	0.20
Combined uncertainty (in quadrature)	0.244

TABLE 8.21 Details of the ^{133}Ba standard uncertainty budget.

Component	Relative standard uncertainty multiplied by a sensitive factor (%)	Remarks	Evaluation Type (A or B)
Counting statistics	0.08	Statistical analysis of 5 extrapolation values (one value from each 5 counting sources)	A
Weighing	0.035	Mass ±0.01 mg, for source preparation using Mettler M3 balance. Mass ±1 mg, for dilution using Mettler B6 balance.	B
Dead time	0.04	Due to uncertainty in τ_D (typically ±0.05 μs for all the threshold settings.	B
Coincidence resolving time	0.002	Uncertainty in τ_R was typically ±0.001 μs.	B
Satellite pulses (afterpulsing)	0.10	$\theta \pm 1\sigma$ (reanalyzed data by increasing/decreasing the afterpulse correction values by their measured uncertainties for each threshold setting).	B
Counting time	0.001	Calibration of timer	B
Background	0.01	A combination of: Background square root statistics applied. Different background data sets interchanged.	A B
Absorption	0.002	Accounts for uncertainties in the final result due to residual ^{133}Baremaining after 5 rinsing in the ampoule received, as measured with a NaI (Tl) detector.	B
Half life	0.001	$t_{1/2} = 10.540 \pm 0.006$years	B
Extrapolation of efficiency curve	0.20	Alternative fits to data (activity conc. Range/$(2\sqrt{3})$, assuming the range to be uniformly distributed).	B
Combined uncertainty (in quadrature)	0.244	Quadratic sum of all uncertainty components (for k = 1).	

From Simpson and van Wyngaardt, 2011.

procedure followed by Wang et al., 2001. The results are shown in Table 8.22. The relative variance is

$$S = \sqrt{\frac{\sum_{i=1}^{10}\left(N_{0i} - \overline{N}_0\right)^2}{(10-1)}} = \sqrt{\frac{21.3}{9}} = 1.538$$

and

$$\frac{S}{\overline{N}_0} = \frac{1.538}{292.8} = 0.005$$

Another procedure, which we follow in this section, is known as uncertainty transmission. It consists of calculating the standard deviation and correlation of the different quantities in order to determine the uncertainty introduced by using a specific equation to calculate the activity of ^{125}I.

1. Uncertainty transmission in Eq. (8.137)

Consider uncertainty transmission for Eq. (8.137). Let

$$F_1 = \frac{N_\gamma N_{\alpha\beta}(N_\alpha + N_\beta)}{N_{\beta\gamma}(2N_{\alpha\alpha} + N_{\alpha\beta})}$$

$$F_2 = -\frac{N_\gamma^2 N_{\alpha\beta}}{N_{\beta\gamma}(2N_{\alpha\alpha} + N_{\alpha\beta})}$$

$$F_3 = \frac{N_{\alpha\beta}}{2N_{\beta\gamma}} + \frac{N_6}{N_{\beta\gamma}} - \frac{2N_{\alpha\alpha}}{N_{\alpha\beta}}$$

The expression to which we apply the uncertainty transmission is:

$$N_0 = T + F_1 + F_2F_3$$

TABLE 8.23 Partial derivatives of N_0 with respect to T, N_α, N_β and N_0.

$\frac{\partial N_0}{\partial T}$	$\frac{\partial N_0}{\partial N_\alpha} = \frac{\partial N_0}{\partial N_\beta}$	$\frac{\partial N_0}{\partial N_6}$
1	$\frac{N_\gamma N_{\alpha\beta}}{N_{\beta\gamma}(2N_{\alpha\alpha}+N_{\alpha\beta})}$	$-\frac{N_\gamma^2 N_{\alpha\beta}}{N_{\beta\gamma}^2(2N_{\alpha\alpha}+N_{\alpha\beta})}$

We deduce each of the partial derivatives relative to the various parameters. For convenience, we write the equations in tables. The left side of the equation is in the first row and the right side is in the second. We numerically calculate each of these partial derivatives (Tables 8.23–8.27).

2. Numerical calculation of uncertainty

The values to be applied to the equations are the mean values of different magnitudes. These mean values are shown in Table 8.28.

To calculate the numerical value of the partial derivatives, we first calculate some combinations of values that are repeated in the calculations (Table 8.29).

The calculated values of the partial derivatives are shown in Table 8.30.

If the quantities are correlated, correlation coefficients have to be calculated. Correlation coefficient is defined as:

$$\rho(x,y) = \frac{1}{(n-1)\sigma_x\sigma_y}\left(\sum_{i=1}^{n} x_i y_i - n\overline{xy}\right)$$

where $\overline{x}$ and $\overline{y}$ are the mean of the random variables X and Y, respectively. Table 8.31 shows the values of the correlation coefficients for different pairs of variables:

Variance and standard deviation equations ($\sigma_0 = \sigma_{N_0}$)

$$\sigma_0^2 = \left(\frac{\partial N_0}{\partial T}\right)^2\sigma_T^2 + \left(\frac{\partial N_0}{\partial N_{\alpha\beta}}\right)^2\sigma_{\alpha\beta}^2 + \left(\frac{\partial N_0}{\partial N_\gamma}\right)^2\sigma_\gamma^2 + \left(\frac{\partial N_0}{\partial N_\alpha}\right)^2\sigma_\alpha^2$$

TABLE 8.24 Partial derivative to calculate $\partial N_0/\partial N_{\alpha\beta}$, $\partial F_1/\partial N_{\alpha\beta}$, $\partial F_2/\partial N_{\alpha\beta}$, and $\partial F_3/\partial N_{\alpha\beta}$

$$+2\left(\frac{\partial N_0}{\partial N_\gamma}\right)\left(\frac{\partial N_0}{\partial N_6}\right)\rho(N_\gamma,N_6)\sigma_\gamma\sigma_6+2\left(\frac{\partial N_0}{\partial N_\gamma}\right)\times\left(\frac{\partial N_0}{\partial N_{\beta\gamma}}\right)\rho(N_\gamma,N_{\beta\gamma})\sigma_\gamma\sigma_{\beta\gamma}$$

$$+2\left(\frac{\partial N_0}{\partial N_{\alpha\alpha}}\right)\left(\frac{\partial N_0}{\partial N_{\alpha\beta}}\right)\rho(N_{\alpha\alpha},N_{\alpha\beta})\sigma_{\alpha\alpha}\sigma_{\alpha\beta}+2\left(\frac{\partial N_0}{\partial N_{\alpha\alpha}}\right)\times\left(\frac{\partial N_0}{\partial N_6}\right)\rho(N_{\alpha\alpha},N_6)\sigma_{\alpha\alpha}\sigma_6$$

$$+2\left(\frac{\partial N_0}{\partial N_{\alpha\alpha}}\right)\left(\frac{\partial N_0}{\partial N_{\beta\gamma}}\right)\rho(N_{\alpha\alpha},N_{\beta\gamma})\sigma_{\alpha\alpha}\sigma_{\beta\gamma}+2\left(\frac{\partial N_0}{\partial N_{\alpha\beta}}\right)\times\left(\frac{\partial N_0}{\partial N_6}\right)\rho(N_{\alpha\beta},N_6)\sigma_{\alpha\beta}\sigma_6$$

$$+2\left(\frac{\partial N_0}{\partial N_{\alpha\beta}}\right)\left(\frac{\partial N_0}{\partial N_{\beta\gamma}}\right)\rho(N_{\alpha\beta},N_{\beta\gamma})\sigma_\alpha\sigma_{\beta\gamma}+2\left(\frac{\partial N_0}{\partial N_6}\right)\times\left(\frac{\partial N_0}{\partial N_{\beta\gamma}}\right)\rho(N_6,N_{\beta\gamma})\sigma_6\sigma_{\beta\gamma}$$

The numerical value of the uncorrelated variance is:

$$\text{Var1} = 46.4319$$

and the variance of the correlation is:

$$\text{Var2} = -44.2895$$

Therefore, the variance of the activity is:

$$\sigma_0^2 \approx S_0 = \text{Var1} + \text{Var2} = 2.1424$$

and the standard deviation is:

$$S_0 = 1.4637$$

Corresponding to the relative standard deviation:

$$\frac{S_0}{N_0} = 0.00502 \approx 0.5\%$$

This value coincides with that obtained by the traditional method. The difference between the two procedures is that, in the first measurements are independent and therefore there is no correlation between them. However, they may or may not be correlated in the second procedure. In our example, the quantities are not independent, so correlations are required, complicating the calculation.

Whenever possible it is advisable to apply the first procedure, but there are situations where we need to apply the second. We emphasize that in uncertainty transmission the quantities are not always correlated. Therefore, we only apply correlations when the quantities involved are not independent.

Agustín Grau Malonda

Agustín Grau Malonda holds a BSc degree from the Complutense University, Madrid 1962; Doctorate in Electronics from Toulouse University (France) 1965; PhD in Physics from the Complutense University, Madrid, 1981. He worked in the JEN (Atomic Energy Commission), Radiochemistry Section, 1965–71, and Radionuclide Metrology Section, 1972–84. Agustín Grau Malonda subsequently held numerous positions as Director of the Basic Research Department (CIEMAT) 1984–86; Director of the Department of Fusion and Particle Physics (CIEMAT) 1987–1998; Director of the Institute for Energy Studies (CIEMAT) 1999–2003; Deputy Director of Strategic Projects (CIEMAT) 2004–2008; Associate Professor of Physics, Madrid Polytechnic University, 1969–77; and Professor of Nuclear Engineering, Madrid Polytechnic University, 1977–85. In addition, he was a member of the following working groups and committees: Consulting Committee for the Fusion Program (EU) 1996–2000, (Vice Chairman) 1991–2000; Joint European Torus (JET) Council, 1986–2000; JET Executive Committee, 1986–99; Fusion Technology Steering Committee (EU) 1986–1990; Fusion Power Coordinating Committee (OECD) 1998–2002; L3 Committee (CERN) 1986–1999; International Committee for Radionuclide Metrology (ICRM), 1975–2003 (Vice Chairman, 1998–1999); EUROMET, 1990–1999; EURATOM Scientific and Technical Committee, 1992–2003; and Adviser Committee for the Central Bureau for Nuclear Measurements, JRC, Geel (Belgium) 1989–1995. Awards: Department of Commerce, NBS, USA, Guest Worker Contributions, 1982, 1983; Men of the Year in Sciences, Cambio 16 Journal, 1991; and Encomienda de la Orden de Isabel la Católica, King of Spain, 2001.

Agustín Grau Carles

Agustín Grau Carles holds a PhD in Physical Sciences from the Complutense University of Madrid. During 1991 to 2000, he worked at the Center for Environmental and Technological Energy Research (CIEMAT), together with chemists, developing new spectrometric techniques for radioisotopes, based on liquid-scintillation counting. From 2002 to 2004, he collaborated with biologists from the Center for Astrobiology (CAB) in the calibration of ultraviolet lamps for the irradiation of extremophile cultures. He was also involved, in collaboration with geologists, in the development of new meteorite authentication techniques from radioisotopes originated by cosmic radiation. Between 2004 and 2010, he worked at the Spanish National Research Council (CSIC) in his own Ramón y Cajal project to study the feasibility of a nanodosimeter based on scintillation gels. Currently he directs the BIC Academy (Goods of Cultural Interest), which teaches courses on the need for Science to understand art, as well as archaeological and paleontological goods.

I. Introduction

Radionuclide imaging is the production of an image revealing the distribution of radionuclides in biological specimens or in matter. Among the various radionuclide imaging techniques commonly available, only beta imaging is able to give high spatial resolution. As beta particles cannot cross animal bodies or thick layers, these radiotracers can only be visualized in thin sections of tissues or thin layers.

Autoradiography was the initial technique for beta imaging. Beta-emitting radionuclides present in thin slices of labeled materials or biological tissues were revealed using film or liquid emulsions placed in contact with the samples. Autoradiography was originally conducted with radionuclides decaying by beta emissions. Not only are these beta emitters able to emerge out of materials, but they can also efficiently ionize emulsions. They first produce a latent image followed by a visible image after chemical development of the emulsion. This process was named conventional autoradiography.

As the sensitivity of this technique was low, further developments were introduced including an intensification process, such a fluorography, to amplify the results. The various methods proposed shortened film exposure times. However, these techniques had limited success, as the gain in rapidity was affected by a loss in resolution.

In the 1990s, a new concept of autoradiography based on phosphor screen imaging emerged to replace the emulsion detection. The principle of phosphor screen imaging was also based on the storage of a latent image, obtainable after a tenfold shorter contact time than the emulsion method.

More recently, new physics detectors capable of directly counting the radioactivity of the sample and providing real-time images were introduced. All of these methods will be described in detail in the following chapters.

II. Autoradiography principles

A. History

Autoradiography was discovered at the beginning of last century when Henri Becquerel observed that a "mysterious" radiation coming from uranium impressed photographic plates (Becquerel, 1896). Not long after Becquerel's discovery of radioactivity, Vilard (1900a, 1900b) at the École Normale Supérieure, Paris, used autoradiography to demonstrate his discovery of gamma radiation. With autography, Villard demonstrated the existence of a radiation that would not deviate (bend) in a magnetic field. This radiation was later given the name of gamma radiation by Rutherford (1903). For a detailed description of these early works by Becquerel and Villard among other discoveries by pioneers through the 20thcentury, see historical accounts (L'Annunziata, 2007, 2016).

The word "autoradiography" comes from the fact that the sample is not placed between the source of radiation and the detector as in radiography but contains within itself the source of radiations. The radiation from within the sample interacts with the photographic emulsion in contact with it, thus providing an image of the distribution of the radioactivity in the sample.

Autoradiography has been widely used in various fields of biology science, essentially from the 1950s. Thanks to this technique, histologists discovered the unsuspected mobility of various molecules and cells. It allowed cell biologists to monitor the kinetics of DNA synthesis in the cell cycle (Howard and Pelc, 1951). It revealed to the biochemists the mechanism of uptake of steroid hormones in the nucleus of their target cells (Bogoroch and Edelman, 1970), demonstrating the direct action of these hormones on the genetic machinery. Autoradiographic visualization of protein flow along the axon allowed the neurologists to discover several neuronal pathways (Leblond, 1976). A great number of other examples could be cited showing the impact of autoradiography as a research tool in the biological sciences.

Over the years, autoradiography has become a set of techniques where radioactive tracers within a sample are imaged in close contact with a detection media. The initial medium was based on photographic emulsion, either coated on a film or directly coated on the sample. According to the media and the uses, it was divided into macro-autoradiography, which includes whole-body autoradiography (WBA) and microautoradiography (MARG), which entailed the use of the optical or electron microscope.

WBA was developed by Ullberg (1954), who made first sections of the entire body of mice using a large microtome in a walk-in freezer. Later, sections of even larger animals were prepared in a large microtome held inside a chest freezer. Leica Microsystems, Inc. (Nussloch, Germany) began to manufacture these large cryomicrotomes, which are still available today.

Quantification of autoradiographs was the next challenge, but the methods developed for film between 1974 and 1987 were of limited success, because of the inherent nonlinearity of the film. Nevertheless, during this time, Schweitzer et al. (1987) developed an image calibration method using ^{14}C-spiked blood standards with concentrations bracketing the sensitivity of phosphor plates. This method is still used by many investigators today. In the same time, Luckey (US Patent No. 3 859 527, 1975) made a fundamental breakthrough for WBA by developing and patenting phosphor-imaging technology later named autoradioluminography, which provided digitized images, providing a powerful image analysis with direct determination of quantitative tissue concentrations over four to five orders of magnitude. Thus, quantitative whole-body autoradiography (QWBA) began to be widely used and was validated and published later (Coulson and Carr, 2000). A

few years before, in 1994, a group of autoradiographers in the pharmaceutical industry founded the Society for Whole-Body Autoradiography whose mission was to promote the use of QWBA to replace the use of traditional dissection and liquid scintillation counting (LSC).

In addition to autoradiography and autoradioluminography, direct nuclear imaging technologies have been developed, some based on gaseous chambers (Jeavons, 1978) and others based on scintillators (Laniece, 1994). These technologies, still on the market, will be described later on in this chapter.

In light of the limitations of QWBA, which reveals the concentration of radioactivity without providing the actual molecular identity of the radioactive compound, a few investigators developed a method combining the results of WBA with the identification of radioisotope-labeled entities extracted on the same sample. This new approach of ex vivo molecular imaging was initiated (Rohner et al., 2005; Kathib-Shahidi, 2006).

B. General features

Autoradiography is mainly applied to studies on the physiology of living systems where the radioactive tracer is related to a drug effect or to a specific biologic process that can be localized and measured. To provide meaningful interpretations, the following concepts must be kept in mind:

1. The autoradiography image represents only the localization of the radionuclide in the sample. The chemical or molecular structure within which the radionuclide tracer resides remains unknown. There is no guaranty that the original chemical form of the tracer is maintained.
2. Caution must be taken during sample preparation to prevent the diffusion of nonbound radionuclide prior to obtaining the autoradiograph.
3. Blank autoradiography controls are required to establish the background and to ensure that no artifact occurs during the autoradiography process.

1. Isotopes used

Classically, soft-beta-emitting radionuclides are candidates for autoradiography. These include isotopes of the atoms most encountered in biological tissues, such as hydrogen, carbon, sulfur, and phosphorus.

All beta tracers exhibit a continuous spectrum, between zero and a maximum energy, characteristic of the isotopes. The mean energy is roughly the third of the maximum energy. The principle beta isotopes used in autoradiography are as follows:

- ^{3}H (tritium) can be used to label proteins, nucleic acids, and many other molecules and probes. It is often involved in binding techniques to test the affinity of a radioligand for its receptor.
- ^{14}C is used to replace nonradioactive carbon to trace chemical and biochemical reactions involving pharmacological substances.
- ^{35}S is used to label proteins, nucleic acids, and amino acids containing a thiol group such as cysteine and nucleotides. This is done by substitution of an oxygen by a sulfur in a phosphate group, which is often involved in gene expression studies by in situ hybridization.
- ^{45}Ca is used for the labeling of calcified tissues and the measurement of calcification process and rates in metabolism studies.
- ^{33}P is used for the labeling of nucleotides and ^{32}P for the labeling of nucleic acids and phosphor proteins used as tools in molecular biology.

The aforementioned radionuclides emit pure β^- ionizing particles whereby there is no interference or concern for gamma or X-rays with the detector. Energy deposition of β^- particles in matter is high enough to provide good detection efficiency and resolution. Nevertheless, as we will explain later, the lower the β energy, the better the spatial resolution. This is due to the shorter path or range of the low-energy particle in the medium. Hence, ^{3}H gives the highest resolution and could therefore arguably be considered the most interesting isotope, whereas ^{32}P would be the worst according to this criterion when high-resolution imaging is a concern.

Note that high-resolution imaging can be done with any kind of charged particles, which includes also alpha emitters and also all nuclear medicine isotopes. Actually, the gamma emission of nuclear medicine isotopes is always in competition with another mechanism, namely, internal conversion. In this mechanism, the nuclear decay energy is not released by gamma ray emission, but it is transferred to an atomic electron, whose energy is the energy of the gamma minus the atomic electron binding energy. For example, 15% of ^{99m}Tc disintegrations are followed by the emission of an electron, the energy of which is 110 keV (140 keV minus 30 keV of binding energy).

The radionuclide ^{125}I used in nuclear medicine decays preferentially with the emission of low-energy X and γ rays. It is often used in autoradiography for physiological applications. Radioisotopes commonly used in conventional autoradiography are listed in Table 9.1.

2. Physical principles of beta interaction and applicability in high-resolution radionuclide imaging (autoradiography)

The purpose of this section is to give some guidelines on how to estimate the resolution and level of signal, knowing

TABLE 9.1 Radioisotopes used in conventional autoradiography with most common labeling technique and biological applications.

Isotope (rays)	Half-life $T_{½}$	E_{max} for β^- or discrete energies	Labeling technique	Biological applications
^{3}H (β^-)	12 years	18 keV	**Isotopic exchange**	Binding
^{14}C (β^-)	5730 years	156 keV	**Synthesis**[a]	Pharmacology
^{32}P (β^-)	14.3 days	1710 keV	**Synthesis**[a]	Molecular biology
^{33}P (β^-)	25.4 days	249 keV	**Synthesis**[a]	Molecular biology
^{35}S (β^-)	87 days	168 keV	**Synthesis**[a]	In situ hybridization
^{45}Ca (β^-)	163 days	257 keV	**Incorporation**	Metabolism
^{125}I (γ,X, e)	60 days	(γ: 35.6 keV, e: 3.7 and 26.3 keV)	**Incorporation by electrophilic substitution**	Physiological applications

[a]*When used in organic form, direct synthesis of the organic compounds is made.*

the isotopes and sample thickness. Included also are some recommendations on how to calculate the amount of measurable beta particles versus the thickness of the sample.

a. Transport of beta particles in matter

As most of the imaging techniques in biology, quantification in autoradiography is somewhat similar to what a physicist may consider as an ill-posed problem. What autoradiography users actually want to know is the distribution of a radiotracer in a thin but volumetric sample. Unfortunately, as illustrated in Fig. 9.1, with a given simple configuration, the total amount of radioactivity emitted in the sample thickness is not in a one-to-one relation with the radioactivity measured at the surface. The deeper the radiotracers are located within the sample, the lower the radioactivity measured at the surface.

To overcome this fundamental problem, the detection system should be able to measure both the angle of emission and the energy of the beta particles emerging from the surface. None of the systems available on the market, in the past and probably in the future, are capable of such a performance, even though it is not necessarily insuperable. Hence, the quality of autoradiographic data is related to the basic assumption that the radioactive distribution along the thickness axis can be considered as constant. To fulfill this requirement, the sample must be sufficiently thin. We will see further on in this chapter how to verify this condition.

Boltzmann transport equation. The fundamental physics problem involved in autoradiography is the transport of beta particles, and more generally, the transport of electrons in matter. To get some prediction, one has to find formulas to answer, at least approximately the following question: Given a volumetric activity in a sample, what emerging activity can be expected out of the sample?

As many problems in physics, the equation driving the behavior of electrons can be found with reasonable endeavor. In this case, it is the so-called Boltzmann transport equation, which can be used also for neutron or gamma photon transport in matters. An overview of this type of equation can be found in Zheng-Ming and Brahme (1992).

This equation expresses the conservation of charge and energy in each volume element of the matter in which the electrons travel. Unfortunately, this equation is highly nonlinear and can be solved only in very simple cases (homogeneous medium, constant cross sections, stationary distribution of energy) from which autoradiography is excluded. As often in physics, we are confronted with an equation of a "nice formal beauty" but of very poor use. Of course, this equation can be solved numerically, considering the media as water-like

Bethe equation and the range of beta particles. To get a more pragmatic approach, it is instrumental to take an interest in another concept, the stopping power of the medium. By definition, the stopping power is the amount of energy lost by an electron per unit distance. The most famous formula, which describes the stopping power, is the Bethe formula (Bethe and Ashkin, 1953):

$$\frac{dE}{dx} = -\frac{4\pi}{m_e c^2}\cdot\frac{nz^2}{\beta^2}\left(\frac{e^2}{4\pi\varepsilon_0}\right)^2\left[\left(\frac{2m_e c^2\beta^2}{I\left(1-\beta^2\right)}-\beta^2\right)\right] \quad (9.1)$$

where $\beta = v/c$, v is the velocity of the particle, E is the particle energy, x is the distance traveled by the particle, c is the speed of light, z is the particle charge (in elementary charge units), e is the charge of the electron, m_e is the electron rest mass, n is the electron density of the target (mean atomic number), I is the mean excitation potential of the target, and ε_0 is the vacuum permittivity.

This formula leads to the concept of range of an electron, which represents the total distance covered by an electron before being stopped. This property can be calculated (at least numerically) using the following integration, and the Bethe formula:

$$R(E) = \int_0^E \frac{dE}{(dE/dx)} \tag{9.2}$$

Eq. (9.2) provides useful information in the case of autoradiography. Given the high-end energy of beta particles, the corresponding range yields the thickness of the sample over which no electrons can reach the surface and therefore cannot be detected. Tables of electron range are widely available (Pages and Bertel, 1972), including the online NIST Electron Stopping Power and Range (ESTAR) data (https://physics.nist.gov/PhysRefData/Star/Text/method.html).

However, the range is always a "pessimistic" parameter because it expresses the total length of the trajectory of the particles. However, electrons or beta particles undergo frequent scattering inside matter, and their trajectories are closer to a random walk rather than a straight line. One usually prefers to use another quantity, the projected range, written R_p, which is the mean distance between the emission point of an electron in a medium and its stopping point. It gives the depth over which no beta particles can surface out of the sample. Unfortunately, this quantity is out of reach of any calculation and must be estimated by Monte Carlo simulations or with empirical formulas. One of these formulas according to Sauli (1977) is:

$$R_p = 0.71E^{1.72} \tag{9.3}$$

where Rp is expressed in mg/cm^2, and Rp must be divided by the density of the medium (around unity for biological tissues). Actually, it is an experimental fact that the ability of electrons to go through a medium is mainly dependent on the energy and on the density of the medium. The other physical parameters (atomic weight, atomic number) have much less impact. This is mainly due to the small size or mass of electrons. Thus, any collision with any atom (even the lighter atoms) randomizes the direction of the electron, and the main factor (at a given energy), which determines the length of the path of travel of the electron, is the number of collisions, itself dependent mainly on the density of the medium.

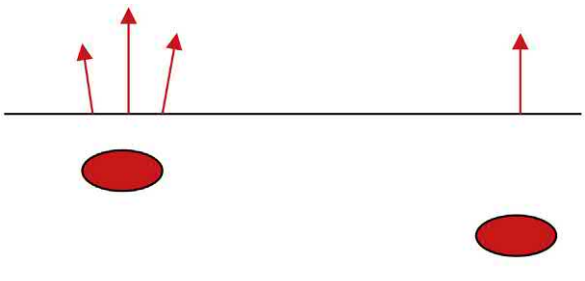

FIGURE 9.1 Brief description of the flawed correspondence between emission at the surface of the sample and actual distribution of the radioactivity. Two identical sources give different results depending on the depth of their location.

Monte Carlo simulations. As an alternate to the former equations, which also need computers to be solved, one can directly use Monte Carlo programs to simulate the behavior of electrons one-by-one. Today, this approach is the most widely used with programs such as Geant 4 (www.geant4.org/geant4), which includes all the necessary cross sections. Nevertheless, it must be kept in mind that Monte Carlo simulations are hugely computer-time-consuming, especially if small confidence intervals are needed. Simulating the behavior of electrons to get a good approximation for their probability of emerging out of the sample requires several millions of trajectories, which can take days of computing. Furthermore, Monte Carlo methods always conceal a bit of the physics involved (i.e., the computer is the physicist) and must therefore be used by persons with a high level of expertise.

Empirical formulas. In the early days of atomic physics, when computers did not exist or at least were not commonly used, physicist would derive empirical formulas to predict the probability for electrons to go through a certain amount of matter. One of the most used formulas for monochromatic electrons (^{125}I, ^{99}Tc in autoradiography) required the knowledge of the range $R(E)$ for the initial energy (Coquerel, 1996):

$$P(E,x) = e^A \cdot e^{\frac{-A}{1-\frac{x}{R(E)}}} \left(1 - \frac{x}{R(E)}\right)^B \tag{9.4}$$

where $P(E, x)$ is the probability for the electrons emitted at a depth x to go through the sample. The formula is slightly sensitive to the parameter B, which can be chosen to be equal to one. The practical range is then roughly two- or threefold lower than the total path. For a biological sample, A can be chosen equal to 3, and one can see that for a sample with a thickness of one quarter of the range, only 50% of the electrons go through the sample. Actually, in the case of autoradiography, as the emission is isotropic, this value must be divided by 2. With such a formula, it is possible to correlate the number of beta particles emitted by the sample with the number of radioactive atoms per unit volume or per gram (considering the concentration of radioactivity as constant throughout the thickness of the sample):

$$N = \frac{1}{2}\left(N_0 \cdot \int_0^{E_M} \left(I(E) \cdot \int_0^X P(E,x)dx\right) dE\right) \tag{9.5}$$

where N is the number of electrons surfacing out of the sample, N_0 is the number of disintegrations, $I(E)$ is the beta spectrum, E_M is the end-point energy of the beta spectrum, and X is the sample thickness. Another experimental rule may be the most appropriate for our purpose, which has been established in the 1950s when physicists tried to characterize beta particles, namely, the attenuation of a beta particle source can be approximated with good accuracy by an exponential attenuation law, such as the one used to describe X-ray attenuation (Evans, 1955):

$$N = N_0 e^{-\mu x} \tag{9.6}$$

This result is an accidental consequence of the shape of the beta energy spectrum and of the variation of electron absorption versus energy. Eq. (9.6) can actually be understood if the shape of the beta energy spectrum remains nearly constant throughout the media and if the angular distribution of beta emitters in the media is randomized from the first layers. One can then define an attenuation coefficient for beta particles versus energy, and an empirical formula for this is:

$$\mu = \rho \cdot \frac{17}{E^{1.14}} \tag{9.7}$$

where ρ is the sample density, E is the maximum energy of the beta particles (in MeV), and μ is given in cm^{-1}. As customary, in biology, the density will be considered as close to unity. With this attenuation coefficient, one can calculate a mean free path for absorption ($1/\mu$). For tritium, ^{14}C, and ^{32}P, we arrive at, respectively, 6 μm, 70 μm, and 1 mm. Eq. (9.7) clearly overestimates the value for tritium (the actual value is of the order of 1 μm), whereas it is relatively correct for ^{14}C and ^{32}P. Eventually, we can use Eq. (9.7) to calculate the emerging activity versus the activity per unit mass for a given sample thickness (integration of the former formula over the thickness), assuming the sample is water-like.

b. Quantification and calibration

There are two types of detection systems, which are the following:

- Energy storage systems (film, phosphor screen)
- Particle counting systems (gaseous detectors)

The first type measures the amount of energy emitted by the sample (a beta particle will contribute to the signal in proportion to its energy), whereas the second type measures the number of particles emitted by the sample. For quantification purposes, for any type of system, a relation between dpm/g and surfacic activity must be established, using a well-known sample (standard). This is the calibration phase.

Quantification for low-energy isotopes (< 30 keV). Low-energy isotopes, such as tritium, have a convenient property in that the range of the beta particles are so small that in most cases the activity emerging out of the sample is not dependent on the sample thickness. In fact, only the two first microns of the sample are really contributing to the signal. This means that the calibration procedure (giving the relation between dpm/g and surfacic activity) can be done with any kind of standard, and if sensitivity stays constant, only once in the lifetime. Of course, sensitivity is never constant during the lifetime of a system, and calibration must be done periodically. However, this recalibration is easy to perform because no specific requirement on the thickness of the sample is required.

Quantification for medium-energy isotopes (> 30 keV, < 300 keV). The situation is more complex for medium-energy isotopes such as ^{14}C, ^{35}S, and ^{33}P. The practical range is of several dozens of microns, which is the typical sample thickness. A large dependency of emerging activity on the thickness of the sample is then expected, and this dependency is everything but linear.

In absolute terms, calibration for these medium-energy isotopes should be done with a standard made of the same "matter" and of the same thickness as the samples measured. For energy storage systems, the dependency of the measurement is lower than for particle counting systems. This is due to the fact that beta particles originating from the deep layers of the sample are more attenuated and their contribution to the signal is much smaller than beta particles originating from the first sample layers. However, for reliable quantification, the thickness of the standard should always be comparable to the thickness of the sample.

Quantification for high-energy isotopes (> 300 keV). For high-energy isotopes such as ^{32}P, ^{89}Y, and ^{90}Sr, the situation is indeed simpler than for medium-energy isotopes. The practical range is always larger than the thickness of the sample (e.g., in the case of ^{32}P, the practical range is 2.5 mm). Furthermore, the probability for a beta particle to escape the sample, on the detector side, is close to 50%, except for very thick samples. Finally, the relation between the surfacic activity and dpm/g is proportional to the thickness of the sample. Therefore, using a standard of known thickness will simplify quantification, as the data can be multiplied by the ratio between the thickness of the sample and the thickness of the standard.

c. Spatial resolution limitation

Generally, spatial resolution is imposed by the capabilities of the detection (imaging) system. Nevertheless, if we consider the case of film as an example, the resolution can be better than 10 μm. In this case, the resolution can be determined also by the sample itself as well as the isotopes

used. The calculation of the point spread function of an isotope, knowing the thickness of the sample, is much more complex than establishing the number of particles emitted by the sample. This may be done with Monte Carlo simulation or solved numerically with the Boltzmann equation. But, as discussed previously, these are complex methods. Nonetheless, with some basic arguments, one can give recommendations on how to determine the sample thickness or the choice of isotope.

Low-energy isotope Resolution. For low-energy isotopes, and especially for tritium, the thickness of the sample is not a limitation for resolution. One micron is enough to absorb more than 50% of the tritium disintegrations. Therefore, most of what can be detected originates from the first micron of the sample. The intrinsic resolution of the method can then be estimated between one and two microns. The resolution can be better for emulsion, which is directly in contact with the labeled site.

Medium-energy isotopes. For the quantification of medium-energy isotopes (e.g., ^{14}C, ^{35}S, ^{33}P), the situation of resolution is much less clear. The practical range is between 40 and 100 μm, and the beta particles coming from the first microns of the sample are of course emerging closer to the disintegration point. Nevertheless, among the beta particles emitted in the opposite direction of the detector, a certain number are backscattered by the sample itself or by the support of the sample, if the latter is thinner than the practical range. For a theoretical "infinitively thin" sample, this backscattered fraction is about one-third of the total signal, and it is spread over a distance at least as large as the practical range. This means that the spatial resolution is somehow limited, and if a very sharp resolution of intracellular structures is required, medium-energy isotopes are not really recommended, whatever the thickness of the sample.

High-energy isotopes. For high-energy isotopes (e.g., ^{32}P), the situation in terms of resolution achievable is even worse because scattering of the beta particle prevails and because the loss of energy is much lower at the start of the beta particle path of travel than at the end, i.e., when the beta particle is far from its point of emission from the sample. The resolution with high-energy isotopes is never really better than 100 μm in the best of cases. This type of isotope is more applicable to gels and thin-layer chromatography (TLC), than to in situ analysis on slides.

3. Sample preparation

For every experiment, optimal conditions for imaging can be considered before preparing the samples. This can be made regarding the energy of the beta rays of the isotope used and the amount of radioactivity fixed in the tissues, taking into account the precision required for the best quality of image recorded.

Basically, the samples are whole sections of small animal bodies obtained by means of slicing the initially frozen body whether it has been embedded or not in a cryopolymerizable resin or in a substance used for maintaining the physical integrity of the tissues. The sections can be made by using a slicing cryostat. Some cryostats are dedicated to whole animal sections and others to organs or small pieces of tissue. The sections can be recovered on adhesive tape for autoradiography or on films or glass histology slides, for liquid emulsion techniques. The thickness of the sections is typically 10−30 microns for macroautoradiography and 5−20 microns for microautoradiography (Ulberg, 1977). The sections are dehydrated in a frozen atmosphere and taken in dry conditions. In the case of microautoradiography, the sections are stained after development of the emulsion and before observation with a microscope. Sample preparation has to preserve the radioactivity bound in the tissues.

III. Energy-storage latent imaging

In this section, we will focus on imaging devices for which images are the consequence of energy storage. This means mainly all the imaging techniques related to photographic emulsions and techniques related to phosphor screens (autoradioluminography).

A. Photographic emulsions

1. Macroautoradiography with film

In macroautoradiography, the distribution of a radionuclide tracer is obtained over a relatively large area such as a thin-layer chromatogram or an animal whole-body section. The dried and flat sample is placed in contact with the emulsion side of the film in the dark room. After a given period of exposure, the film is developed and fixed. The localization of the radionuclide distribution in the sample is first determined visually.

The detection of the radiations, electrons or beta particles, is based on the conversion of silver ions to metallic silver (observed as black grains) within a photographic emulsion (a suspension of silver bromide crystals in gelatin). The photographic mechanism behind this technique has been explained by different authors (Gurney and Mott, 1938) and refined by Rogers (1979), according to whom, the process of ionization, produced by radiations in the emulsion, allows excited electrons to travel from one ion to another until they are trapped at specific sites, which are in fact structural defects in the crystal, whereby a silver ion can absorb a passing electron to become reduced to a silver atom. The crystals sensitized in this way produce a latent image, which can only be visible after application of a chemical developer to reduce all the silver ions of the

affected crystals. The crystals with no reduced silver are then dissolved out of the emulsion using a chemical fixer, leaving only a black image representing the traces left by the radiations in the emulsion in proportion to the amount of radioactivity passing through the emulsion (see Fig. 9.2, inspired by http://www.cheresources.com/content/articles/other-topics/chemistry-of-photography).

Digitizing equipment like CCD cameras or light and laser densitometers have been used to convert the blackening of the emulsion to a digital image based on optical density analysis of the initial image (Orr, 1993). Such a principle is valuable for emulsions layered on film used in macroautoradiography methods and for liquid emulsion embedded sections of tissue, as is the case for microautoradiography techniques (Arimatsu, 1982).

For further details regarding history, chemistry, and physics of film autoradiography, see Rogers (1969), Gahan (1972), L'Annunziata (1987, 2007, 2016).

a. Performance

Sensitivity. For film as well as for any energy storage devices, it is more convenient to consider sensitivity in terms of disintegrations per mm^2 (several hundred for film, several tens for a phosphor screen), which is a measure of the minimum deposited energy that can be detected for a given isotope. It is possible to reach such levels of sensitivity for weak signals at the cost of very long exposure times. It has been reported that film can detect activities as low as 0.02 dpm/mm^2, but the exposure time, to achieve this minimum level, can take months and it depends on the isotope. Of particular concern is the poor detection efficiency of film emulsions for low-energy beta particles ($E_{max} < 30$ keV), such as the beta emissions of ^{3}H ($E_{max} = 18$ keV) for which special films without an anti-scratch layer applied to the surface have been developed, thus enhancing the sensitivity by limiting the absorption of the radiations in any protective surface layer of the emulsion.

For practical purposes, in the course of this chapter, sensitivities will be discussed in terms of exposure times at which comparable levels of activity can be detected with respect to radionuclide imaging. Film autoradiography is best suited, in terms of sensitivity for the detection of isotopes such as ^{14}C and ^{35}S, which emit beta particles of $E_{max} = 156$ and 167 keV, respectively. The sensitivity of film is also limited for higher-energy beta particles, such as ^{32}P, and for X-rays, such as those of ^{125}I, because the high-energy beta particles or X-ray photons pass right through the film without any significant effect, whereas only a small proportion is detected by the film.

Spatial resolution. In photography, resolution is defined in terms of the minimal distance that must separate two objects before they can be distinguished as separate. In film autoradiography, the factors that can affect the

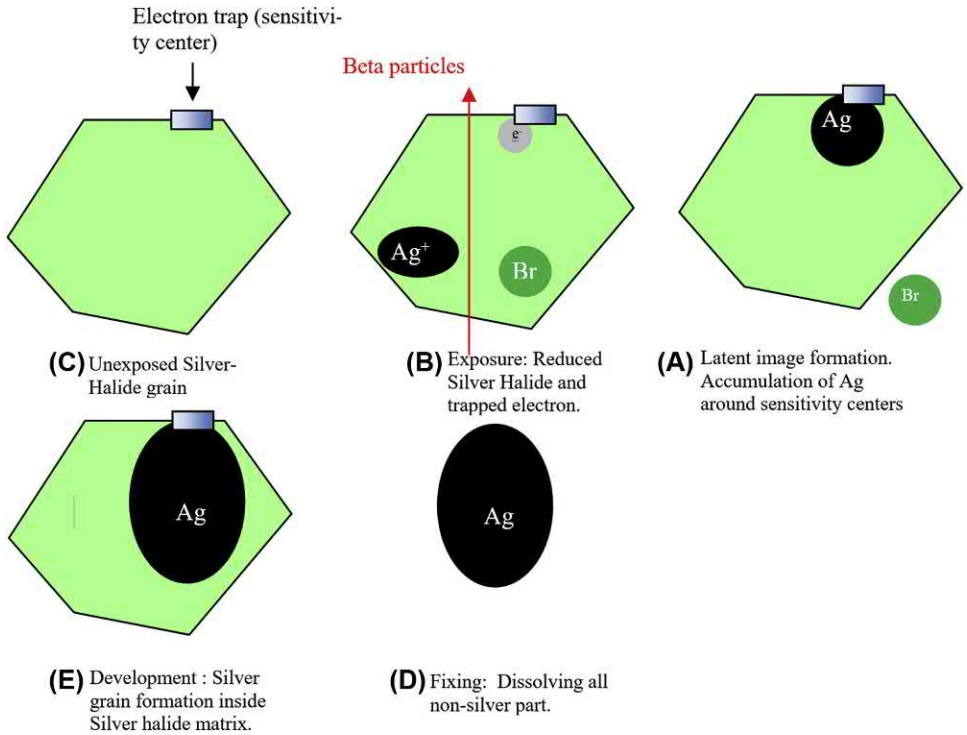

FIGURE 9.2 Schematic view of the different steps involved in the formation of an image on film. For the color version of the figure, the reader is referred to the online version of the book.

resolution to be achieved in radionuclide analysis are associated with the source of activity and with the composition of the film itself. With regard to factors linked to the source of activity, the first one is the choice of isotope. Lower-energy isotopes having shorter path lengths of travel in matter provide better resolution than higher-energy isotopes, which travel further into the emulsion. The distance between source and emulsion as well as sample thickness, are also determining factors, as resolution is inversely proportional to both distance between sample and emulsion and sample thickness.

With regard to film quality, two main factors will affect resolution:

1. the thickness of the emulsion (i.e., thicker emulsions enhance sensitivity but diminish resolution)
2. the size of the silver crystals (i.e., smaller grains give more precise localization)

The length of the exposure is sometimes considered as a factor improving the resolution, but it is not totally correct. Actually, the only contribution of exposure time to resolution is related to statistics. A minimum number of beta particles are required for a reliable measurement, but in any case, the exposure time will affect the width of the distribution of energy. For film, the mathematical tool used to characterize the resolution is the contrast transfer function (CTF). It gives the contrast on the image, versus the frequency, when the radioactive source is made of a periodic line pattern. For example, a CTF of 33% at two line pairs per mm means that the contrast on the image is 33% when the lines are half a millimeter spaced. One usually considers that the resolution limit is given by the frequency for which the CTF is under 10%. Another definition, based on the point spread function (response of the film to a point source), is the resolution, which is the distance to the point source at which the grain density falls to one-half of the maximum (Rogers, 1969). As resolution can vary significantly from one experiment to another, the best resolutions that one could expect based on isotope and emulsions plus light microscopy compared with film are listed in Table 9.2.

TABLE 9.2 Resolution of films and emulsions. The potential resolution of film and that of emulsion autoradiography methods are compared.

Isotope	Emulsions (μm)	Films (μm)
$^{3}H/^{125}I$	0.5–1.0	2.8–5.7
$^{35}S/^{14}C$	2–5	11–28
^{32}P	5–10	28–56

Values are based on 0.1 μm distance of sample to emulsion, 3 μm distance of sample to film and thinnest possible emulsions.
Rogers (1969); reprinted with permission from Elsevier © 1969.

Linear dynamic range. The darkening of film is not a linear function of the energy stored or of the exposure time. There is a threshold for the ionization process under which no darkening of the emulsion occurs. On the other hand, there is a saturation value over which no more darkening is possible (over exposure). Between these two thresholds, the darkening is in a linear relation with activity on a range between 1.5 and 3 logs. This signifies that film autoradiography requires more precaution for the quantification of radioactivity than the techniques we describe further on in this chapter, and a set of standards is always needed to get reliable measurements. Fluorography has also been used to improve sensitivity and the linear dynamic range of film autoradiography (Laskey and Mills, 1975).

b. Quantification

Many commercial systems (light densitometers, scanners, video and CCD camera systems) are available for the quantification of optical density of film involving the transmission of white light through it, light capture, and digitization of data to form a quantitative digital image for software analysis. For an absolute quantification of radionuclide activity from the autoradiogram, standards must be exposed simultaneously on the film as well as the samples. In fact, the optical density of the film is a function of not only the activity of the sample but also the conditions of exposure, the type of film, and the development procedure. So, a calibration of each system is necessary by using standards of known activity, allowing the quantification of the activity per mm^2 for the image of standards and translation of these data to the sample areas of interest.

Additionally, various techniques for the optimization of the quantitative analysis of radionuclide activity were developed. Intensifying screens that are thin sheets of inorganic material placed behind the films emit multiple photons of light when hit by the radioactivity passing through the film, improving the efficiency of detection and enhancing the linear dynamic range of the film.

Similarly, with fluorography, the detection of lower-energy isotopes, such as ^{3}H and ^{14}C, may be enhanced by the use of an organic scintillator (e.g., PPO, 2-5-diphenyloxazole), which converts the energy of a beta particle to visible light (L'Annunziata, 1987), increasing the sensitivity by a factor of 10–100 for ^{3}H and 5–10 for ^{14}C. In addition, an inflated resolution appears by suppression of background with respect to the enhanced signal.

Despite advantages, these techniques introduced errors during the quantification process. Thus, methods for the correction of these errors were introduced by Laskey and Mills (1977) with a "preflashing" of film and exposure at −70°C for fluorography and by Fujita (1982) with "corrections by a graphical method" for the case of intensifying screens.

c. Applications

A typical example of results obtained by pioneers in autoradiography on film can be seen in Fig. 9.3.

2. Microautoradiography with emulsions

If the visualization of radionuclide locations is required at the cellular or subcellular levels within cells or tissue sections placed on microscope slides, a "microautoradiography" is needed since the use of film is limited by the lack of proximity of the silver emulsion to the radionuclide of the sample. Two methods can be used for microautoradiography. The most common method involves the dipping of slides that carry the histological sections into a liquid emulsion. This method requires the fixation of the sample prior to coating with an emulsion and development of the coated sample such that the silver grains are in direct contact with the radioisotope-labeled sites. This technique is employed with light microscopy for the observation of the silver grains. The method is not fully appropriate in the case of diffusible substances. For example, the aforementioned method is good if the ligands are covalently or irreversibly bound to the receptors. There is another alternative method, named the "coverslip technique" in which emulsion-coated coverslips are tightly apposed to sections. This method is ideal for ligands not covalently or irreversibly bound such that they could lose their ligand-receptor integrity by the dipping method. After exposure, coverslips are detached, developed, and examined microscopically to count silver grains depicting the position of the radiolabeled receptors.

Despite the fact that great interest in this second technique has been demonstrated, it is definitely disused, as the product is no longer manufactured today. Detailed protocols for the analysis and quantifications of radionuclides by microautoradiography can be found in Sharif and Eglen (1993).

Ultrastructural autoradiography is also a powerful technique used in conjunction with high-resolution electron microscopy to characterize silver grain distribution inside very small structures or cellular organelles. Two techniques were developed: (1) a "dry" technique, which preserves all the diffusible substances, and (2) a "wet" method for large molecules, fixable lipids, and tightly bound small molecules (Stumpf and Sar, 1975; Williams, 1981).

The most popular nuclide used for microautoradiography is ^{3}H because of the short range of its low-energy beta particles providing the best resolutions as required in these techniques. ^{125}I also provides high-resolution microautoradiographs thanks to its internal conversion electrons emitted with low energy so having a short range as well.

a. Performance

Sensitivity. As the sample requires a thin layer of emulsion in the context of microautoradiography, the efficiency of detection of the ionizing radiations is lower than that of film. Where an exposition time lasts several weeks for a film, the same activity exposed to a liquid emulsion can take months before being revealed. Depending on the isotope, the sensitivity is about 5−10 times weaker than in macroautoradiography.

Resolution. The reachable resolution with liquid emulsions and the light microscope is limited by the optical resolution of the microscope and the minimum observable grain size. However, with the electron microscope, resolutions ranging from 0.1 to 0.2 μm have been reported and considered as the limits of resolution with currently available emulsions and developers.

b. Quantification

In the case of light or electron microscopic autoradiography, the quantification can be obtained by counting the grains, which is referred to "quantitative microscopy autoradiography." The individual silver grains in the emulsion, above a particular microscopic zone of interest, may be counted in the microscope field and correlated with grain counts obtained above other locations of the sample section as well as the background. Counts can be averaged from several thin sections, and the standard deviation can be calculated. Background counts, obtained from developed emulsions not exposed to radioactive sections, must be subtracted from microscopic autoradiographs.

In most recent applications, digitized images recorded by a computer linked to the video camera of the microscope can be analyzed and correlated directly to the real radioactivity in Bq/g after comparison with standards.

c. Applications

The following are some typical images obtained in microautoradiography. The first is an example of microautoradiography of cells visualized by light microscopy illustrated in Fig. 9.4.

An example of ultrastructural autoradiography visualized by electron microscopy is provided in Fig. 9.5.

Receptor studies are also a common application for microautoradiography. Receptor microscopic autoradiography for cell and tissue localization of drugs is reviewed by Stumpf (2012), including its development history, multiple testing, extensive applications, and significant discoveries along time, the radiolabeled compounds used

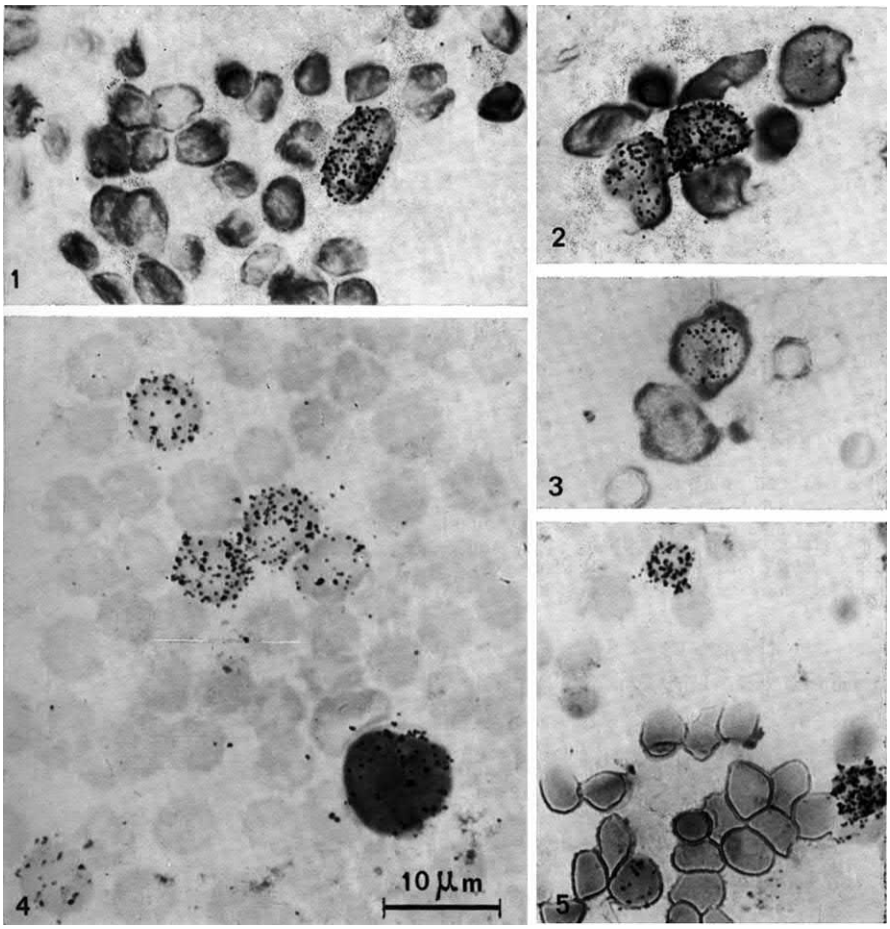

FIGURE 9.4 Microautoradiographs 1, 2, and 3: Bone marrow cells taken from a rat injected with ^{3}H-thymidine. The radioactive cells are those in S phase during the incubation and which have thus incorporated the precursor into their DNA (magnification 1,900X). Microautoradiographs 4 and 5: Blood cells of rat exposed to ^{3}H-leucine during 30 min. The radioactive cells are reticulocytes, which synthesized protein during the incubation. A white blood cell can be seen, which is slightly radioactive (magnification 1900×). *From Simmonnet et al. (1976). Figure reproduced with permission, from Simmonnet et al. being essentially tagged with ^{3}H or ^{125}I for a guaranty of high-resolution imaging.

B. Phosphor screen technology (autoradioluminography)

1. History

In the early 1980s, two companies (Fuji and Kodak) intended to suppress the use of radiographic film in medical imaging, first because silver salts were not reusable, excessive price, and the creation of pollutants. Moreover, the need of providing digital radiographic data was in the air, as the use of computers was becoming part of the daily routine. The acquisition of digital data with film was an indirect process, involving high-resolution scanners in the second phase after revelation. Also, film had demonstrated to be of limited sensitivity to radiation and exhibited a poor dynamic range. Research was then oriented toward both improvement of the dynamic range and sensitivity, and the direct generation of digital images. In the framework of the research, photostimulable screens or phosphor screen technology was developed, and the first commercialized instrument was provided by Fuji Film in 1983. It was initially presented as a method providing long linear dynamic range images for medical X-ray imaging (Sonoda et al., 1983). Later, storage phosphor screen technology was adopted as the method of choice for imaging radionuclides and began to replace film for a great number of applications in molecular biology, pharmacology, and receptor autoradiography (Hamaoka, 1990). Today, phosphor screens are still available on the market with three main manufacturers: General Electric (Typhoon FLA 7000 and Typhoon FLA 9500), Bio-Rad (PharosFX), and PerkinElmer (Cyclone). The screen technology is comparable for General Electric and PerkinElmer, both inheriting from the former Fuji technology, whereas the Bio-Rad range of products is related to the former Kodak technology.

2. General principles

a. Image formation

It must be kept in mind that phosphor screen technology has a strong analogy with film autoradiography (contrary to electronic autoradiography systems). Both are energy storage devices for which the sensitive area is first exposed to the sample by close contact. This is the **exposition** step whereby the energy deposited by the beta electrons (or any kind of ionizing radiation) onto the sensitive area is stored in lattice defects of the material (silver bromide for film, bromofluoride of barium for phosphor screens). This first step is followed by a **revelation** step during which the image is spawned, in a chemical way for film or in an optical way for phosphor screen. This separation of exposition and revelation procedures can be considered as a significant drawback because there is no possibility of checking a current level of exposition "on the fly" (for film as well as for phosphor screens, the revelation process clears the stored energy and the exposition must be repeated, if the exposure is inadequate). This frequently leads to under- or overexposition, especially in new studies where the level of activity is unknown. From an operational point of view, it can actually be considered as an advantage (compared with electronic autoradiography) because the revelation step is much shorter than the exposition step (several hundred times faster in autoradiography), up to several hundreds of samples can be exposed in parallel and revealed one-by-one later on.

Let us return to the specific case of phosphor screen technology. Phosphor screens are usually made of grains of barium fluorobromide (mean size 5 μm), containing traces of divalent europium (Eu^{2+}). Europium atoms are not directly involved in the energy storage phenomenon but are essential for the revelation. The defects of the lattice are usually bromine vacancies that behave as electron traps. When a beta particle enters the sensitive layer, it ionizes atoms of europium (which become Eu^{3+}) along its path, and the electrons produced in this way are trapped in the bromine vacancies. These traps are metastable states that can last up to several weeks (even months), which allows very long exposition times. There is a limitation in increasing exposition time, for ultraweak activity samples, when the mean time between ionizations is of the order of

the lifetime of the metastable state. The screen then tends to lose as many charges as created, and the signal is no more linear, neither in terms of activity nor exposition time (Amemiya, 1995).

The phosphor screen quality is directly related to the density of bromine vacancies and to the density of europium atoms. For example, for an excessively high density of vacancies, the lifetime of electron traps tends to shorten and, following former remarks, the sensitivity decreases due to the higher rate of recombination of electrons with ions.

b. Phosphor screen revelation and quality

As mentioned previously, europium ions are essential for the revelation of the phosphor screen image. This revelation is no longer chemical but optic. When the phosphor screen is exposed to light (more often a He—Ne laser light, discussed further on), the energy of photons is transferred to the trapped electrons, which are released in the conduction band until they meet an ionized europium (Eu^{3+}). Then, a recombination between the electron and the europium takes place and europium returns to its ground state, emitting a UV-blue photon, the mean energy of which is 390 nm. The schematic of whole physical steps involved in the image formation is given in Fig. 9.6.

This mechanism, sometimes named upconversion, is noticeable because the screen reemits more energy than it absorbs (a red laser is used and a blue light is emitted). Of course, this can be simply explained if we consider that the missing energy arises from the part of the energy of the initial beta particle spent to store electrons in the vacancies. As we will discuss later, the spatial performance of such a technology depends not only on the scanning system but also on the intrinsic characteristics of the screen such as the size of the grains in phosphor screen (usually 5 μm) and the total thickness of the sensitive layer. An excellent overview of the physics involved in phosphor screens is available in Rowlands (2002).

c. Scanning mechanism and light collection optics

To preserve the localization, the revelation process is done point by point by scanning the phosphor screen with a laser

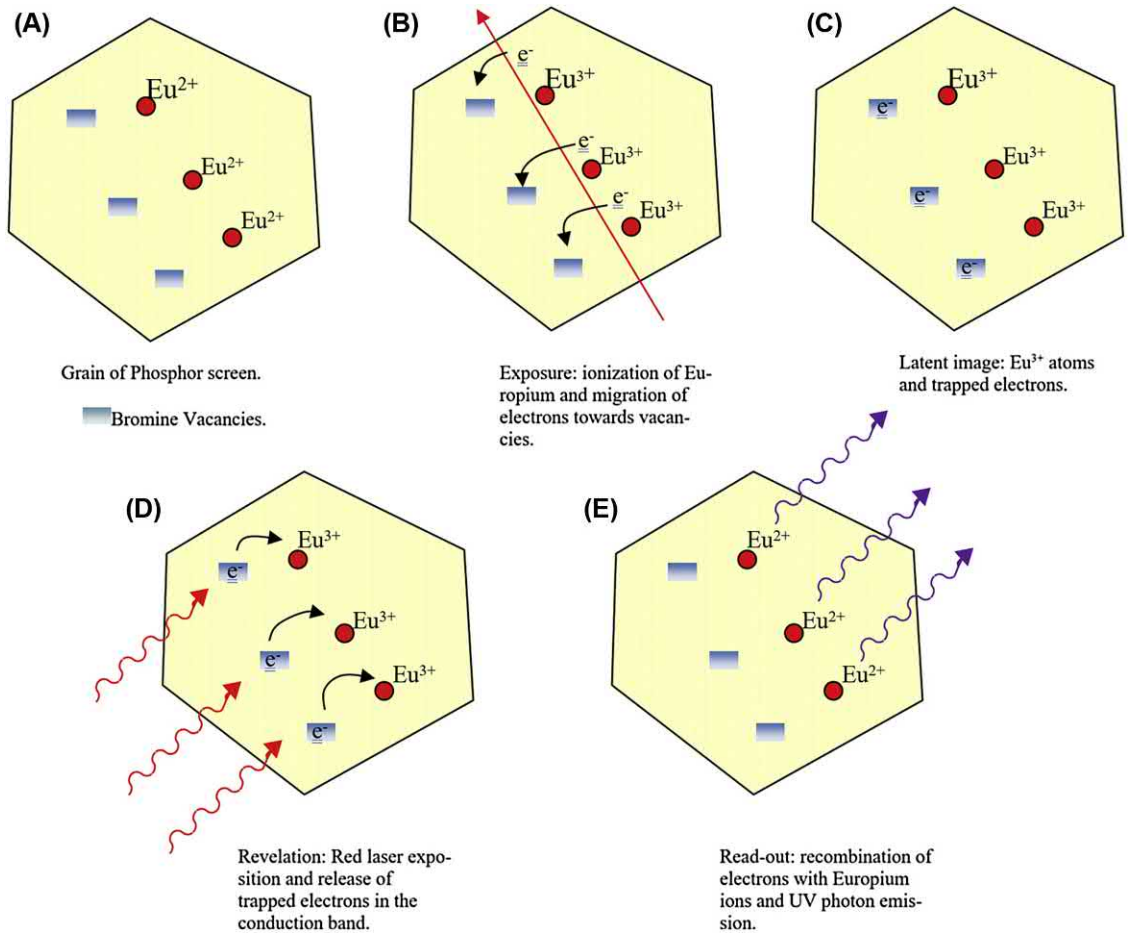

FIGURE 9.6 The five steps involved in the formation of an image in a phosphor screen. For the color version of the figure, the reader is referred to the online version of the book.

spot. There are mainly two ways of implementation of the scanning mechanism for the revelation phase: (1) the phosphor screen is kept in a flat plane while the laser (He–Ne) sweeps across the screen as it is reflected by a galvanometric mirror, and (2) for flexible phosphor screen, the screen is loaded on a cylinder that spins at 360 revolutions per minute, whereas the laser follows a translation movement, parallel to the axis of the cylinder.

In both cases, the measurement is done by collecting the UV light on a photomultiplier with optic fibers or a lens placed in close proximity of the laser dot, followed by digitalization of the signal (Coquerel, 1996) (Fig. 9.7).

3. Various phosphor screens

The screens are mainly derived from two technologies; the Fuji and the Kodak ones. Hence, there are two main chemical forms. Each type of screen comes in different models, putting the emphasis either on resolution, on sensitivity, on medium/high-energy, or on low-energy isotopes. The optimization for resolution is mainly a matter of thickness, whereas the optimization for sensitivity is related to a slight change in the chemical form (more Europium ions, for example).

Even though these modifications are visible to the user, they do not dramatically change the performance of one type of screen or another. Most screens are unable to detect low-energy isotopes because they are covered by a protective layer too thick to let the tritium (for example) beta particles reach the sensitive layer. To make phosphor screens compatible with low-energy isotopes, Fuji commercialized a special type of screen without a protective layer for this special purpose. Nevertheless, this screen cannot be cleaned and is very sensitive to contamination, hence of very little reusability.

4. Performance

a. Spatial resolution

Spatial resolution is often expressed in terms of CTF (contrast transfer function), which gives the contrast versus the frequency in terms of line pairs per millimeter. One can also have a more intuitive idea with the resolving power, which can be defined as the minimum distance for which two radioactive sources can be resolved. Table 9.3 provides resolution data for different screens of the Cyclone system and for a frequency of 2.5 lp/mm (400 μm).

In terms of resolving power, the SR and TR screens give roughly a resolving power for ^{14}C between 150 and 200 μm, whereas the TR screen for ^{3}H gives a resolving power of 70–90 μm. These numbers are far from what could be

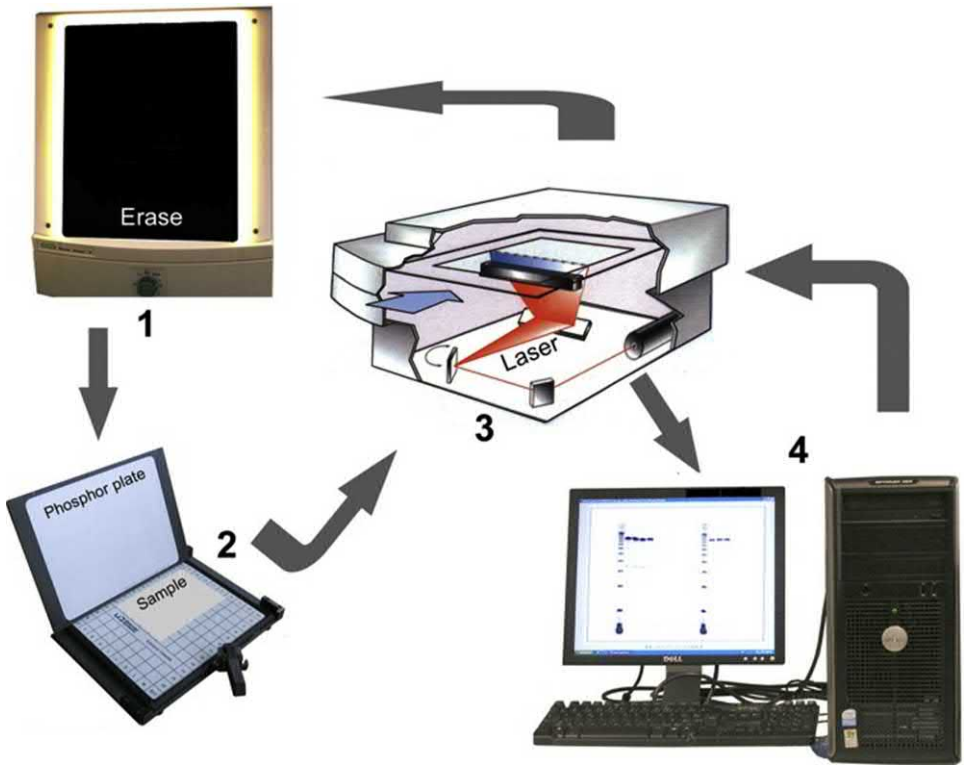

FIGURE 9.7 Schematic of the principle of operation of a phosphor screen. 1: residual signal erasing by exposing the screen to intense light, 2: exposition by contact to the screen into a cassette, 3: readout of the screen by scanning it with a laser beam; light is captured by a light collection guide and measured by a photomultiplier tube (not shown here), 4: image analysis with dedicated software for image processing and quantification by a computer. For the color version of the figure, the reader is referred to the online version of the book.

TABLE 9.3 Spatial resolution of various phosphor screens.

Screen	ST (high sensitivity)	MP (multipurpose)	SR (high resolution)	TR (tritium, uncoated)
^{14}C	17%	25%	33%	38%
^{3}H	N/A	N/A	N/A	69%

expected knowing the range of beta particles in the material (1 μm for ^{3}H, 10–20 μm for ^{14}C). This signifies that the restriction factors for resolution come mostly from the screen laser scanning readout and especially from light scattering inside the medium. Under a certain value of the laser spot (around 50 μm), there is no real improvement in the resolution. The light scatters inside the material, and the local measurement is spoiled by the untrapping of electrons in the vicinity of the current point. This is confirmed by the different values of resolution measured for different screens. The ST screen is the most sensitive. It is also the screen for which the sensitive layer is the thickest, whereas for SR and TR screens, the sensitive layers are thinner. Nonetheless, light scattering is higher in ST screens due to their thickness.

b. Dynamic range and sensitivity

The sensitivity of the phosphor screen is known to be much better than film, especially for medium-energy radionuclides (^{14}C, ^{35}S). The unit used to determine the sensitivity is dpm/mm^2/h, i.e., the minimal detectable activity for a 1-h exposition. One dpm/mm^2/h corresponds to 60 disintegrations per mm^2. The usual ultimate sensitivity for phosphor screens depends on the isotope: the higher the energy, the better the sensitivity. Typical data are 0.5 dpm/mm^2/h (30 disintegrations per mm^2) for ^{35}S and 0.1 dpm/mm^2/h (6 disintegration per mm^2) for ^{32}P. To calculate the sensitivity versus exposure time, a first approximation is to divide the previous number by the exposure time (in hours). For 10 h of acquisitions, the detection limit is then supposed to be 0.05 and 0.01 dpm/mm^2 for ^{35}S and ^{32}P, respectively. Of course, this rule of thumb is not entirely correct because background noise tends to increase with exposure time due to cosmic ray interactions.

The linear dynamic range, which can be defined as the range of activity over which the signal measured from the phosphor screen is linear (measurements stay proportional to the activity), is a fundamental parameter, as it represents the screen's ability to record very low and very high activities on the same image. The linear dynamic range of phosphor screens is typically between 10^4 and 10^5 (Johnston and Pickett, 1990). This is a major advantage compared with film, which exhibits a poor linear range of 10^2, although the total range of detection in film (including the nonlinear part for low and high activities) can exceed 10^3 with film.

5. Quantification methods

Phosphor screens are intrinsically powerful tools for quantification in autoradiography, but some precautions must be taken. First and foremost, as standard screens are highly reusable, any previously accumulated charge must be erased from the screen before a new exposure. The laser readout process actually records only a part of the signal, and if no erasing procedure is carried out to clear the screen, a ghost image will spoil the next acquisition. Common clearing procedures involve exposure of the screen to fluorescent light for 3–5 min (Reicherts, 1992). Note that for most systems, a fluorescent light is also included in the laser scanning apparatus to perform the deletion. As light, and specially fluorescent light, is used to erase the screens, a classic recommendation when handling the screen before the laser readout phase is to minimize accidental exposure to light bulbs, which create a risk of spoiling the acquisition.

A slow deletion of the signal also occurs over time. Thus, it is also recommended that the readout be performed within a reasonable time frame after exposure. Signal fading of up to 50% with 2 months postexposure has been reported (Amemiya, 1995).

Cleaning of the screen is also advised to remove any contaminating material. As samples are pressed against the screen, it is not unusual for traces of radioactivity to remain on the cover of the screen. Residual salts, or dyes from stained samples, can also linger on the screen and disturb ulterior measurements. Manufacturers usually sell screen cleaning solutions for such a purpose.

Phosphor screen technology is less sensitive to sample thickness than particle counting systems because the devices are only energy sensitive and because beta particles coming from deeper layers of the sample are less energetic. This property is an asset but the conversion between optical units and dpm/mm^2 requires knowledge of the isotopes present in the samples. This means that multiple labeling experiments with several isotopes on the same sample cannot really be quantitative with energy storage techniques such as phosphor screens.

As discussed previously, quantification in autoradiography implies a fundamental connection between the measurements obtained with the imaging technique (in optical units or in dpm/mm^2) and the real data of interest, i.e., the mass activity (dpm/g). There is no magic formula giving mass

activity versus measurements (even in dpm/mm^2). The exposure of a sample of known mass activity is always more rigorous. Phosphor screens have a very wide linear dynamic range. Therefore, only one calibration standard should be required, preferably with an activity chosen in the upper part of the dynamic range. It is necessary to compensate for sample thickness artifacts produced by medium-energy isotopes (^{14}C, ^{35}S), which can create a mismatch in the proportionality between mass activity and dpm/mm^2. Therefore, it is always recommended that one choose a standard of similar thickness as the sample.

6. Advantages and drawbacks

Compared with film autoradiography, the advantages of phosphor screen technology are numerous:

- Reusability (limited for TR screen).
- No chemistry involved.
- No dark room required, i.e., each step of the analysis can be carried out under normal lighting conditions and at room temperature.

The only drawback of phosphor screens compared with film is actually their resolution (over 70 μm), which is far from what a film can provide, although sufficient for most applications. Compared with electronic autoradiography, the main advantage is the possibility of parallelization of exposure (with several screens), which leads to a much higher throughput, except for low-energy isotopes.

7. Applications

The range of applications for which researchers use storage phosphor screens technology in the field of biological science is wide, including whole-body autoradiography (Mori and Hamaoka, 1994), receptor autoradiography (Lidow, 1997) (Lidow, 1997), high-resolution gel analysis, DNA sequencing, Western blotting, TLC plates, and DNA microarray (Jiao and Zho, 2002; Hodges and Smoller, 2002). Some of these applications require both high spatial resolution and reliable quantification within a large range of radioactivity concentrations located in the samples, as well as much shorter exposure times than with photographic emulsion (days compared with week).

- **Whole-body autoradiography:** For pharmacology and toxicology studies, the fate of a potential therapeutic agent is often determined by studying the distribution of radiolabeled compounds in test animals. After the administration of a labeled substance, the time course of absorption, distribution, metabolism, and elimination (ADME) functions are followed by autoradiography of organ sections (Li et al., 2008). Many examples can be found in the literature. An article by Solon and Kraus (2002) gives a remarkable review on QWBA and displays some examples taken from studies on drug discovery or drug development.
- **Receptor autoradiography:** Checking the affinity of a compound for a specific receptor is often processed via a radioligand binding and quantitative autoradiography using a phosphor plate system. A basic procedure involves incubating slide-mounted tissue sections with radioligands, washing and drying of the sections with specifically bound ligands under conditions that preserve ligand binding, and visualizing and quantifying the binding sites in the tissues. A large number of examples can be exhibited. Three of them are mentioned here, which illustrate recent advances in therapy research:
  - The first is related to the mechanism of action of an immunomodulatory drug in autoimmune affections in the central nervous system (CNS) using QWBA and autoradioluminography (Foster and Billich, 2007) (Fig. 9.8),
  - The second concerns molecular cancer therapy research in which the authors are investigating antitumor efficacy, tolerability, pharmacokinetic properties as well as toxicology profiles using autoradioluminography (Massey, 2010) (Fig. 9.9).
  - The third is chosen in the field of neuropsychopharmacology where the researchers explore a regulation mechanism of dopamine D1-like receptors under the action of a pharmacologic substance, by means of a tritiated ligand and the use of a phosphor plate (Kobayashi and Haneda, 2012).

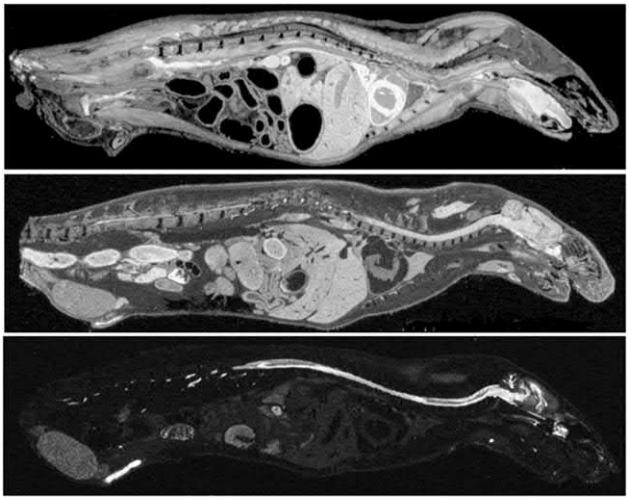

FIGURE 9.8 Whole-body autoradiogram of a median sagittal section of a male Han WIST rat at 72 h after dosing of the ^{14}C-labeled oral immunomodulatory drug FTY720 showing high concentrations in the CNS white matter (Foster and Billich, 2007). *Printed with permission copyright © 1998–2010. JPET Online by American Society for Pharmacology and Experimental Therapeutics.*

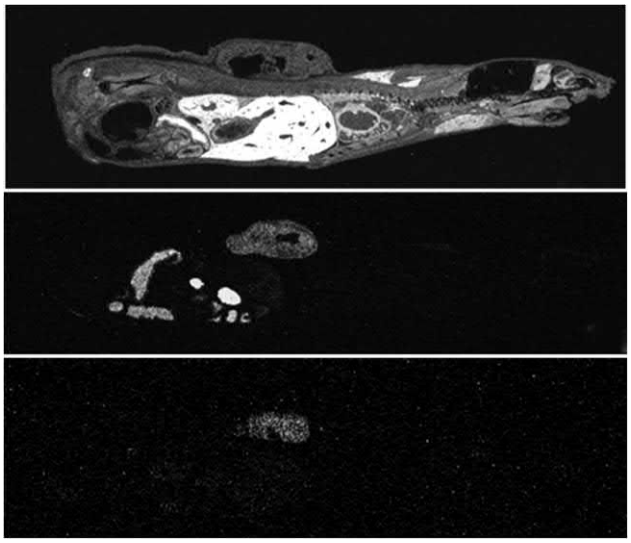

FIGURE 9.9 Whole-body autoradiograms of median sagittal sections of tumor bearing female HsdNpa mice at 5 min and 24 h after IV dosing of a ^{14}C-labeled synthetic Hsp90 ATPase inhibitor foreseen for the treatment of solid tumors and hematological malignancies: top image shows that radiolabeled compounds were taken up into the viable tumor at 5 min postdose; bottom image shows no radioactivity detected in any tissue except viable tumor and GIT content at 24 h postdose. *Data courtesy of Alain Schweitzer.*

For these applications in drug development and therapeutics, readers can also review two synthesis papers (D'argy & Sundwall, 2000; Solon and Schweitzer, 2010).

Other examples will be shown in the next section of this chapter, in comparison with real-time imagers, in the field of molecular biology (e.g., TLC and blots).

IV. Particle counting imaging systems

Particle counting systems, also referred to as electronic autoradiography systems, are an alternate principle of imaging based on the detection and localization of beta particles (more generally of any kind of energetic charged particles), one-by-one. These systems are purely electronic, with no intermediate storage step before revelation, and the image appears during the experience. Particle counting systems are all based on a physical amplification phenomenon (e.g., amplification of charge in a gas or amplification of light in a photomultiplier), which yields a pulse magnitude large enough to spawn an electronic signal for each beta particle. This electronic signal is then processed, and the localization data are stored in a file.

Electronic autoradiography systems were first commercialized during the 1980s, with systems such as the Ambis, the DAR (Berthold), and the Instant Imager (Packard Instruments now PerkinElmer, Inc.). All three were based on the use of an MWPC (multiwire proportional chamber), developed in the late-1960s by Georges Charpak, Nobel Laureate for Physics 1992 (Charpak and Bouclier, 1968).

Particle counting imaging systems are classified as real-time imaging systems because the image is displayed on-the-flight as beta disintegrations occur. One of the greatest advantages of this property is that there is no under- or overexposure for this type of technology: the acquisition is monitored by the number of counted disintegrations. For high-activity samples, the acquisition is stopped after a very short time, whereas for low-activity samples, the systems can monitor their own acquisition time, waiting for a minimum amount of disintegrations. This property makes these systems particularly useful in an early stage of studies when the biologist does not have even a rough idea of the activity of the samples.

On the other hand, particle counting imaging systems are "one acquisition at once" systems. This means that, contrary to phosphor screens or film, there is no "parallelization" of the analysis, which can be a drawback for large studies requiring the "simultaneous" analysis of tens of samples. Nevertheless, for low-energy isotopes, such as tritium, the time saving is so important that particle counting systems are always considered as the better alternative, whatever the number of samples.

Today, some researchers continue to use autoradiography; however, as the autoradiography market has slowed down, the former systems (Ambis, DAR, and InstantImager) are being discontinued. Today, particle counting systems are still present on the market through products manufactured by companies such as Biospace Lab or Ai4R. In the framework of this book, we have decided to focus on what is in the forefront of research in the biosciences today, i.e., the BetaIMAGER TRacer, the BetaIMAGER DFine, and the BeaQuant systems.

A. Gaseous detector

1. History: from MWPC to PPAC (BetaIMAGER TRacer) and to micropattern gas detectors (BeaQuant^{TM})

Gaseous detectors were initially single channel detection systems with no real capabilities of localization. They were used predominantly as Geiger counters for the quantitation of radioactivity levels (Fig. 9.10).

A first improvement was made with the proportional counter, which was also a single channel detection system, but whose main property was to deliver a signal proportional to the quantity of charge initially created by the incident particles. This proportional relation between signal and initial charge was made possible by the choice of gas,

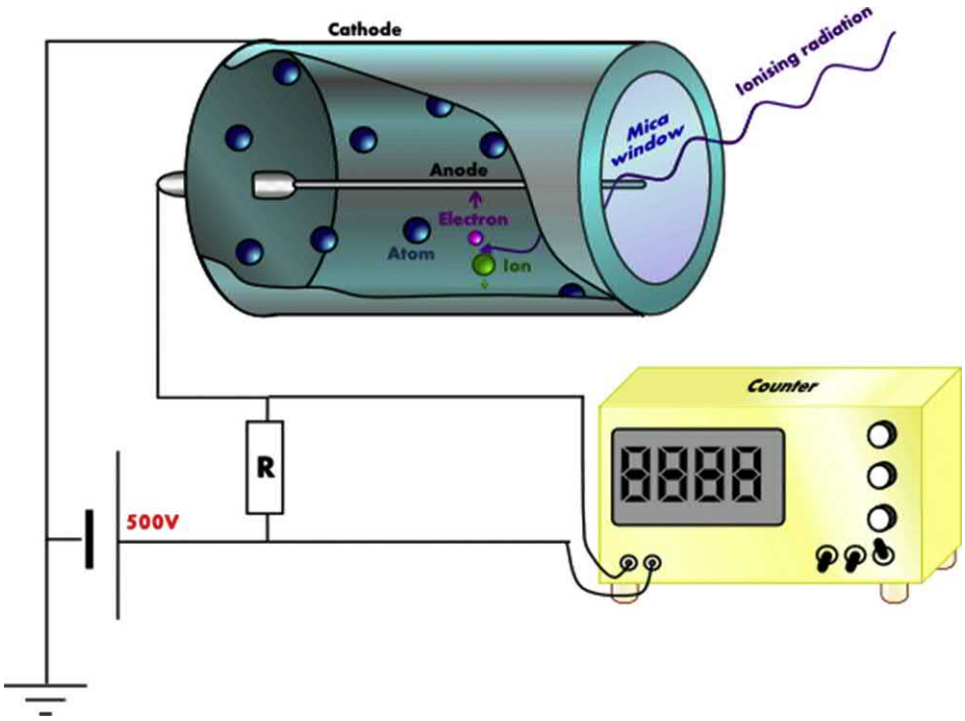

FIGURE 9.10 Schematic diagram of the first gaseous detector, the Geiger counter. A cylindrical vessel fitted with a small wire in its central axis and filled with air. A high voltage is set between the wall of the cylinder and central anode wire. When an ionizing radiation enters the wall, the electron created by the ionization is accelerated and spawns a limited spark, which is detected by the electronic sensor. For the color version of the figure, the reader is referred to the online version of the book.

i.e., noble gases with a small amount of hydrocarbon. Noble gases are fundamental in gaseous detectors because they are more easily ionized, thus facilitating the avalanche process. Small amounts of hydrocarbon (ethane, methane, etc.) play the role of quencher of the avalanche process. Without hydrocarbon, the gas amplification process is unstable, and sparks occur frequently.

In 1968, Georges Charpak (Charpak and Bouclier, 1968) made a determining step by conceiving a system made of a set of parallel wires in the middle of two flat electrodes, which he named multiwire proportional chamber (MWPC). The wires are set at a high positive voltage, whereas the two flat electrodes are grounded. Fig. 9.11 illustrates the principle of operation of the MWPC. The first ionization charge resulting from the initial particles (the beta particle, for example) drifts toward the closest wires. The gas amplification process takes place in the vicinity of the wire where the electric field is much higher than in the rest of the chamber. This fast moving charge cloud induces a fast electric signal on every electrode. Localization is achieved in one direction by identifying the wire close to which the amplification took place. In the orthogonal direction, the flat electrodes are made of an electric strip, and localization is achieved using the electric signal induced on the strips.

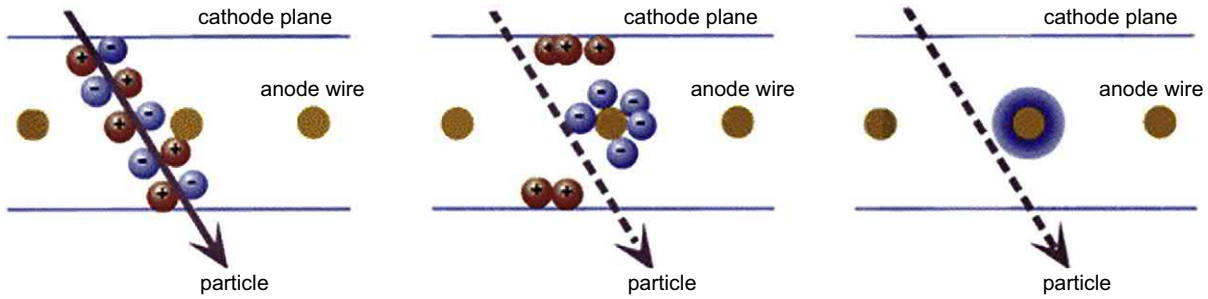

FIGURE 9.11 Principle of operation of the multiwire proportional chamber. Electrons created by the incident ionizing particles are accelerated near the wires. This creates a charge cloud proportional to the initial number of electrons. Localization is achieved by measuring the direct and induced electric signals on the wires. For the color version of the figure, the reader is referred to the online version of the book.

MWPCs are very sensitive, and each beta particle entering the gas chamber is usually detected. The main drawback of this technique, when applied to autoradiography, is the spatial resolution because the space between two wires cannot be smaller than 1 mm. Under 1 mm, the MWPC loses its properties of charge amplification in the close proximity of the wires and begins to be unstable. To overcome this lack in resolution, another gaseous detector geometry has been proposed, namely, the parallel plate avalanche chamber (PPAC). The PPAC is the simplest possible gas detector, since it is made of only two flat electrodes between which a high electric field is applied (Charpak and Dominik, 1989). The following mechanism of amplification is very simple: under a high electric field, first ionization electrons are accelerated until they reach the energy at which they can themselves ionize the atoms of a noble gas. The new electrons created during this secondary process are then accelerated until they can ionize themselves, and so on. The process is characterized by the distance covered between two ionizations and can be described accurately by an exponential of the distance between the location of the initial charge and the anode (Fig. 9.12).

This exponential proportionality between gain and position of initial charge during the avalanche process is the reason for the good spatial resolution of this instrumental design. Even though the thickness of the detector is large (3−6 mm), only the first ionization electrons created by the beta particles in the first layer noticeably contribute to the size of the avalanche and consequently to the total electrical signal (or optical signal in the case of the BetaIMAGER TRacer). As a matter of fact, the PPAC behaves like a very thin detector (50−100 μm), thinner than the sensitive layer of a phosphor screen (Fig. 9.13), and hence, its spatial properties.

2. Description of BetaIMAGER TRacer

a. Principles

The BetaIMAGER TRacer was derived from experiments conducted by Georges Charpak at the CERN laboratory in Geneva. It is a gaseous detector with a parallel plate proportional avalanche chamber with the exception that the readout device (the part of the system that calculates the position of the particles) is very different from its predecessors (Ambis, Instant Imager, etc.). The difference is the following: instead of using a complex electronic system, a vapor of triethyl amine (TEA) is added to the gas mixture (Peskov and Charpak, 1989) as illustrated in Fig. 9.14. This vapor has the convenient property of being electroluminescent in the UV spectrum (260−300 nm), which makes the avalanche scintillate during its development. Therefore, each beta particle creates a small UV light spot, which can be visualized by an intensified CCD camera at a typical frame rate of 50 frames/s.

The video signal is then digitalized, and the center of gravity (COG) of each spot is calculated by the computer. This COG is the best approximation of the emitting point. The principle behind the COG calculations is illustrated in Fig. 9.15:

COG calculations allow for a very high resolution using medium-size CCDs. In fact, the estimation of the center of the spot is much more precise than the pixel size, so that it is possible to localize the particle with three- to fourfold

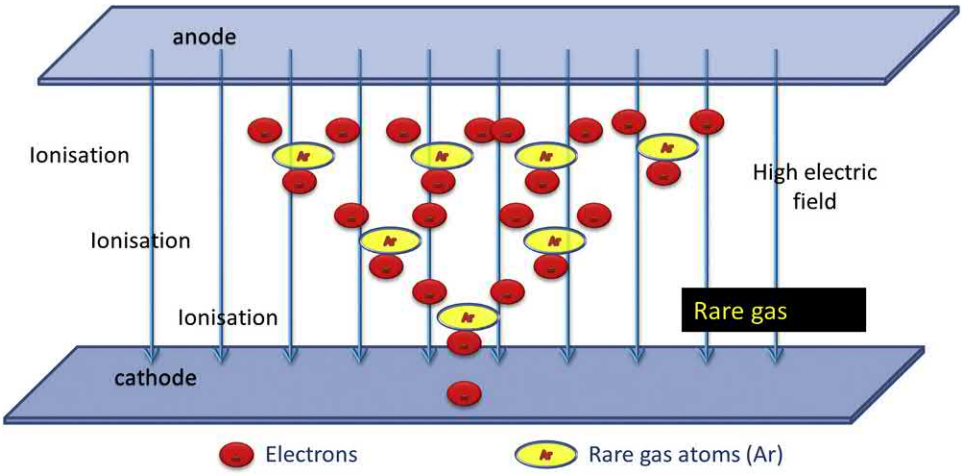

FIGURE 9.12 View of the exponential amplification process in a parallel plate avalanche chamber. The gain is exponentially proportional to the distance between the position of the initial charge and the anode. For the color version of the figure, the reader is referred to the online version of the book.

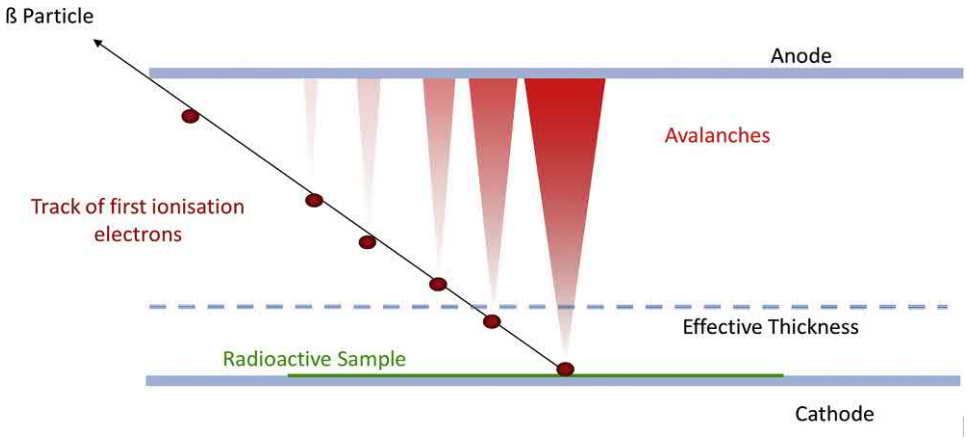

FIGURE 9.13 Skin effect in a parallel plate avalanche chamber. As the distance to the anode is longer for electrons created in close proximity of the cathode, the corresponding avalanche is much larger, due to the exponential behavior. Hence, only a thin layer close to the cathode is really contributing to the signal. For the color version of the figure, the reader is referred to the online version of the book.

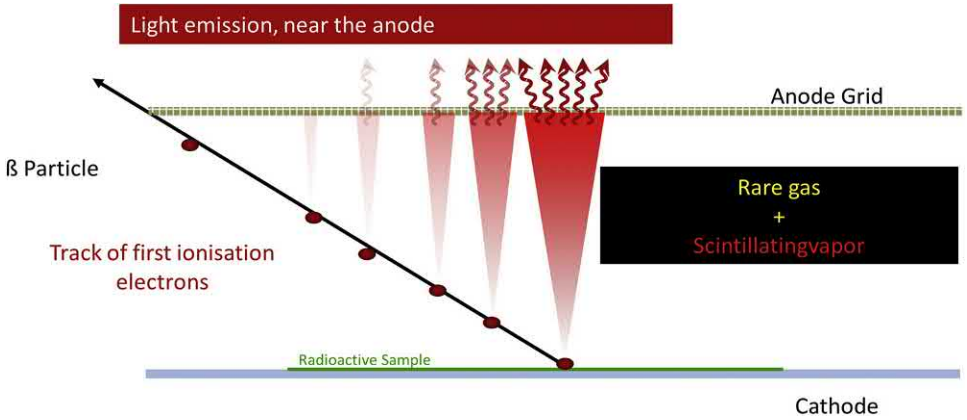

FIGURE 9.14 Light readout of avalanches in a parallel plate avalanche chamber. Triethyl amine (TEA) vapor is added to the gas. This vapor emits UV light in a proportional manner to the number of collisions between electrons and TEA molecules. Most of the emitted light is produced in close proximity of the anode. For the color version of the figure, the reader is referred to the online version of the book.

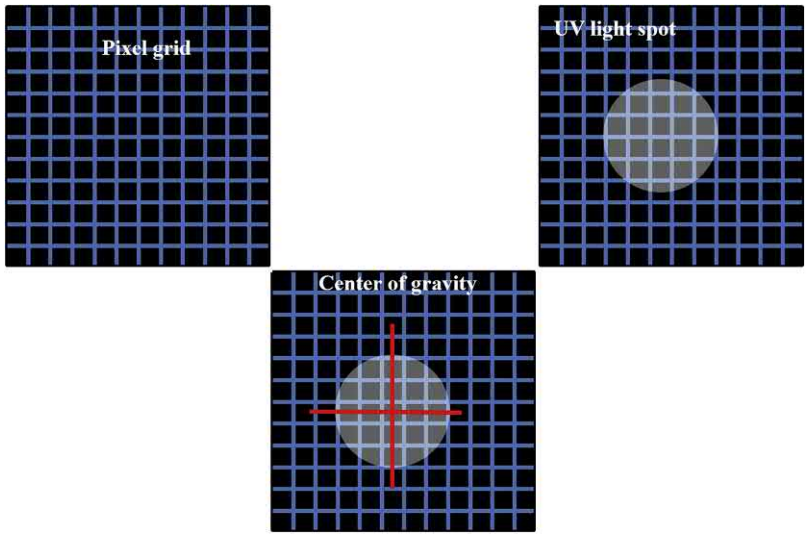

FIGURE 9.15 Principle of localization of the beta particles. The image recorded by the camera is digitalized, and for each light spot, the computer calculates the center using a simple center of gravity formula for which the weighting coefficients are the gray levels. For the color version of the figure, the reader is referred to the electronic version of the book.

better accuracy than the pixel size. A schematic representation of the BetaIMAGER TRacer is shown in Fig. 9.16.

b. Sample management

Sample management with the BetaIMAGER TRacer is a little more complex than with phosphor screens. To get the best results, in terms of resolution and sensitivity, the sample must be placed directly in the gaseous chamber so that the avalanche process can begin as close to the sample as possible. As the electric field is applied directly to the sample, the latter must be fully dried and as clean as possible (no dust). Different cassettes are proposed depending on the shape of the sample (slides, whole-body sample, TLC plates, blot analysis gel samples) as illustrated in Fig. 9.17.

For specific samples that do not fit the aforementioned dryness and cleanliness requirements (whole body, TLC, gels, etc.), it is possible to use other cassettes with either a conductive grid or a conductive Mylar membrane to isolate the sample from the gas chamber. One can notice a little loss of resolution and sensitivity with these types of sample holders compared with the standard slide cassettes.

c. Shape of the light spots

An interesting property of gaseous detectors is their ability to discriminate among different isotopes by analysis of the energy deposited in the gas by the beta particles. In the case of the BetaIMAGER TRacer, the difference between beta-particle emission from radionuclides with different beta-energy maxima (E_{max}) can be directly observed with the camera by simply looking at the intensity and the shape of the light spots, as described in Fig. 9.18.

For low-energy isotopes, such as tritium or ^{125}I, the light spots appear round and bright, whereas for higher-energy isotopes, the light spot appears elliptic in shape and is of lower brightness. It is therefore possible to segregate different isotopes by recording the characteristics of the light spots for each event. This property opens the door to dual-isotope labeling possibilities that traditional storage techniques cannot provide. Another prerequirement for dual-label experiments is the property of particle counting systems to take into account all beta disintegrations in the same way, whatever their energy.

3. Description of the BeaQuant system

a. Principles

Recent advances in gaseous detectors based on the use of micromeshes have made possible thinner structures than MWPC or PPAC, with typical distances of a few tenths of millimeters between the electrodes instead of few millimeters. These geometries (Derré et al., 2000), namely MPGD (micropattern gas detector), are now widely used in high-energy particle experiments, and they also present real potentials for beta-particle imaging. The reason is due to the higher electric field that can be applied between two

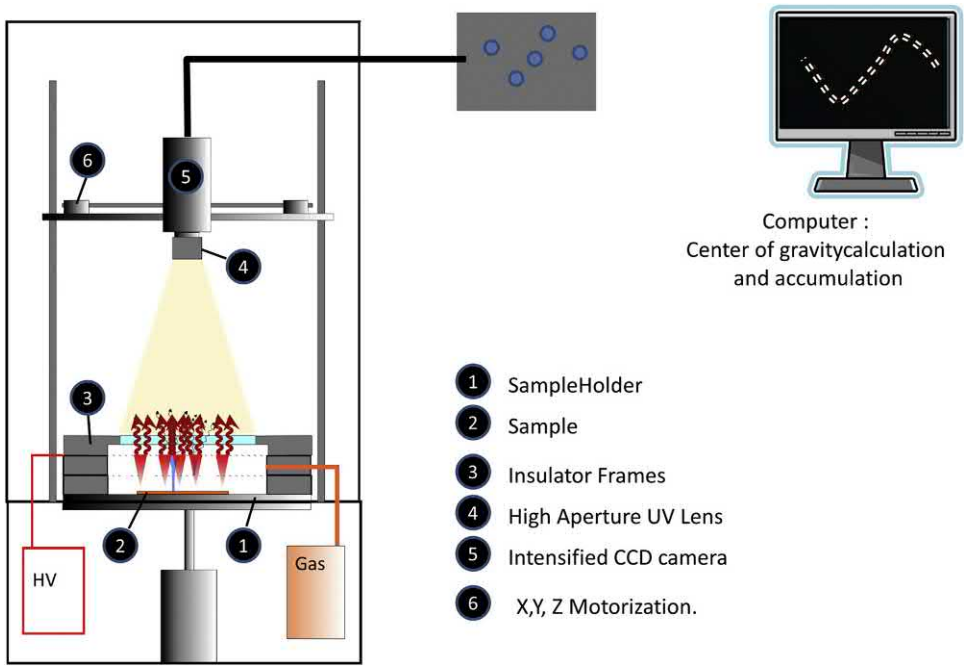

FIGURE 9.16 Schematic representation of the different parts of the BetaIMAGER TRacer. 1, 2, and 3 are integral parts of the gaseous chamber (the sample also acts as an electrode). 4 and 5 are parts of the optical block used to record the emitted light spots. The optical block is motorized to enhance the resolution by moving closer to the sample. For the color version of the figure, the reader is referred to the online version of the book.

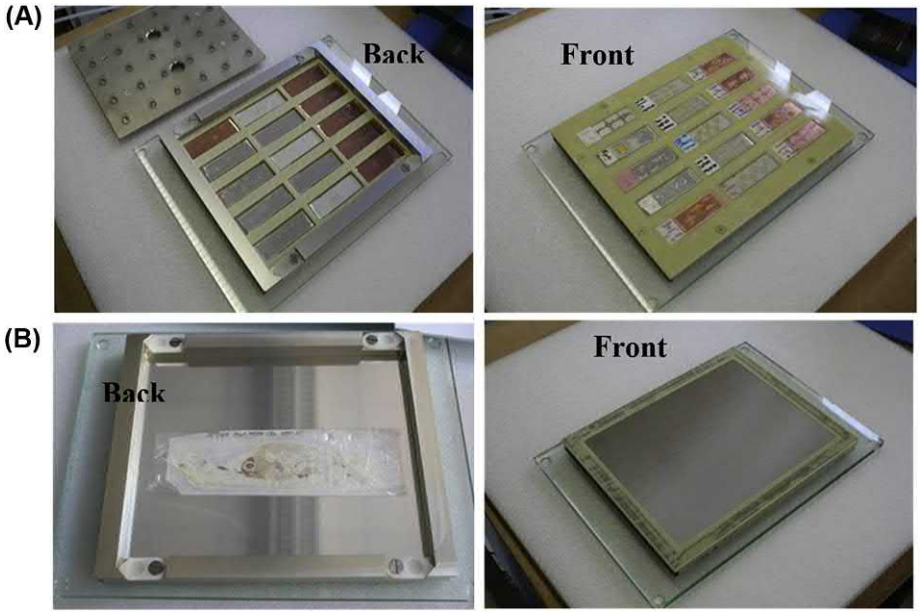

FIGURE 9.17 Two types of BetaIMAGER TRacer sample cassettes. A: Cassette for tissue sections laid on standard glass slides. B: Cassette with a Mylar membrane for whole-body autoradiography, gels, and thin-layer chromatography. For the color version of the figure, the reader is referred to the online version of the book.

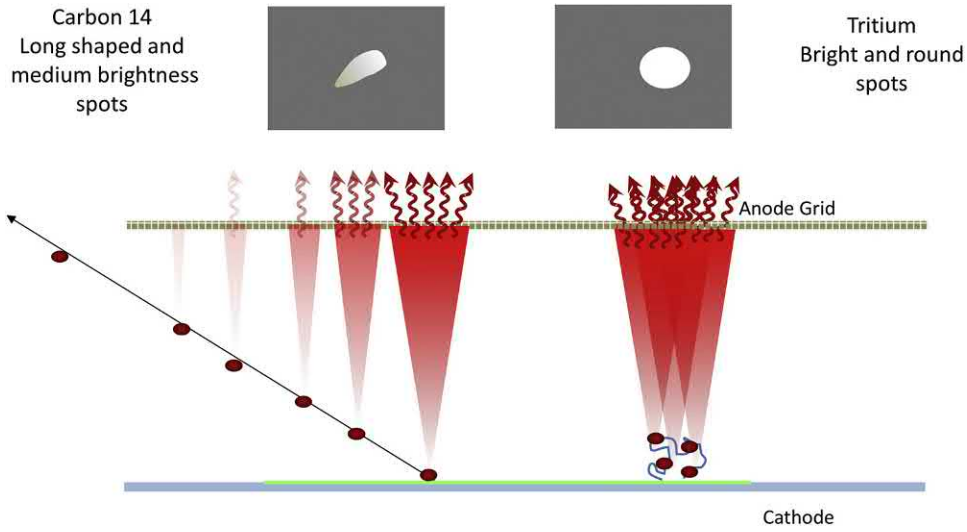

FIGURE 9.18 Typical light spot shapes depending on the isotope. For low-energy isotopes, the initial cluster of charge is compact and close to the cathode. The avalanches overlap, and the resulting shape appears round. For higher-energy isotopes, the initial charge cluster is spread over the whole chamber along an oblique line, resulting in a spot with an elongated, roughly elliptic shape. For the color version of the figure, the reader is referred to the online version of the book.

electrodes distant from a few tenths of millimeters and filled with conventional rare gas-quencher mixture. Typical electric fields for PPAC are usually between 5 and 8 kV/cm, whereas MPGD electric fields can reach up to 30 kV/cm. With such electric fields, the exponential amplification already mentioned for the PPAC exhibits a much higher gain per unit distance, thus allowing equivalent amplification factors to thicker geometries. Furthermore, this higher gain-per-distance unit makes the structure behave as an ultrathin detector with effective thickness lower than 50 μm (Samarati et al., 2004).

MGPD-based detectors dedicated to alpha- and beta-particle imaging have been commercialized since 2013 under the trade name BeaQuant (formerly BeaverTM) by the company AI4R, France. The structure of the detector is named PIM, which stands for parallel ionization multiplier.

It presents some similarities with PPAC structures, but as mentioned before, the main difference is found in the distance between the electrodes, which is roughly one order of magnitude lower. Fig. 9.19 depicts the standard geometry of a PIM detector, as implemented in the BeaQuant system:

The structure of the PIM detector can be split into three different functional parts (Donnard et al., 2009):

1. A first amplification gap of 200 μm, the cathode of which is actually the sample to be analyzed (a 75 × 25 mm standard glass histology slide, for example). The electric field in this amplification gap is around 30 kV/cm only, allowing the very first primary electrons to be amplified noticeably. The anode of this gap is made of a nickel micromesh with a pitch of around 40 μm.
2. A drift space of 1 cm in which the electric field is moderate (1 kV/cm), between the first and a second identical micromesh. Electrons generated in the first amplification gap are partially transmitted to this drift gap to a second amplification gap of 50 μm, between the second micromesh and a grounded segmented electrode, which is used to collect the charge and hence calculate the COG of the electron cloud. The purpose of this second amplification gap is to reach a total gain of several hundreds of thousandfold required by the electronics.
3. A second amplification gap of 50 μm, between the second micromesh and a grounded segmented electrode, is used to collect the charge and hence calculate the COG of the electron cloud. The purpose of this second amplification gap is to reach a total gain of several hundreds of thousandfold required by the electronics.

The gas mixture of the PIM detector is different from PPACs or MWPCs. It is also mainly constituted of rare gas, but neon is used instead of argon. The quencher is also different, as carbon dioxide is used instead of methane or ethane (or triethylamine in the case of the BetaIMAGER TRacer).

b. Electronics and localization of beta particles

The localization of the centroid of the electron cloud is not done using optical means, but by electronics. The central component for doing this calculation is the segmented electrode of the second amplification gap, a picture of which is shown in Fig. 9.20.

The segmented electrode is made of elementary pixels of 170 × 170 μm separated by 30 μm, thus providing a pitch of 200 μm. These elementary pixels are connected to two underlying boards of strips thanks to microholes machined by laser etching. Each underlaying strip is placed diagonally to reduce the capacitance between 2 strips. One pixel out of two is connected to the same strip by a geometrical multiplexing, thus reducing the total number of readout channels to 256. One of the underlaying boards is dedicated to the X-coordinate, whereas the other is dedicated to the Y-coordinate.

The electronic readout is performed with the Gassiplex chip (Santiard et al., 1994). This chip is composed of a charge-sensitive amplifier, a pulse-shape amplifier, and an

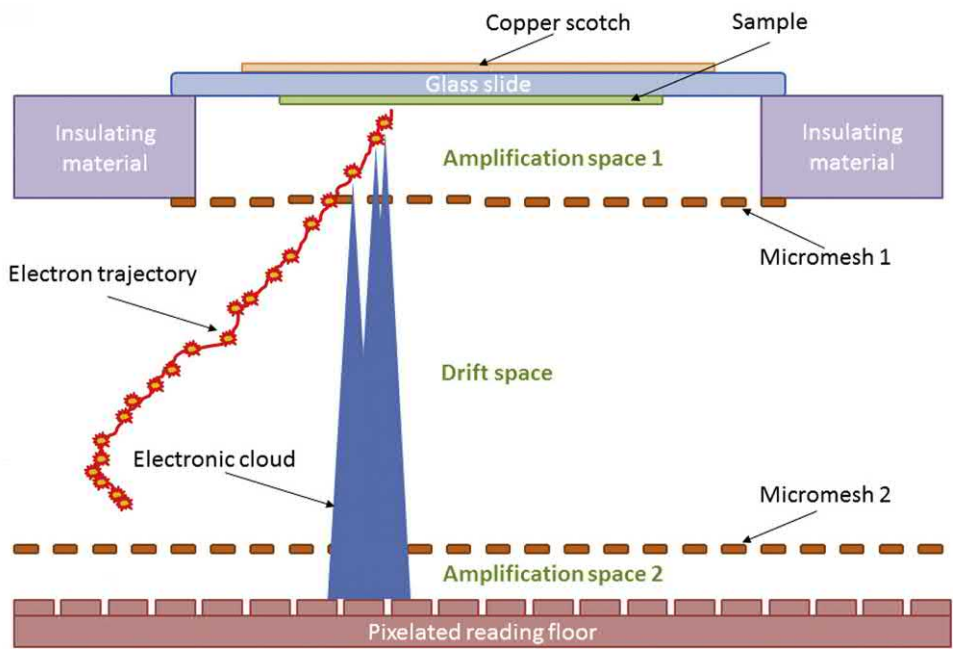

FIGURE 9.19 Sketch of the parallel ionization multiplier detector (courtesy of AI4R). For the color version of the figure, the reader is referred to the online version of the book.

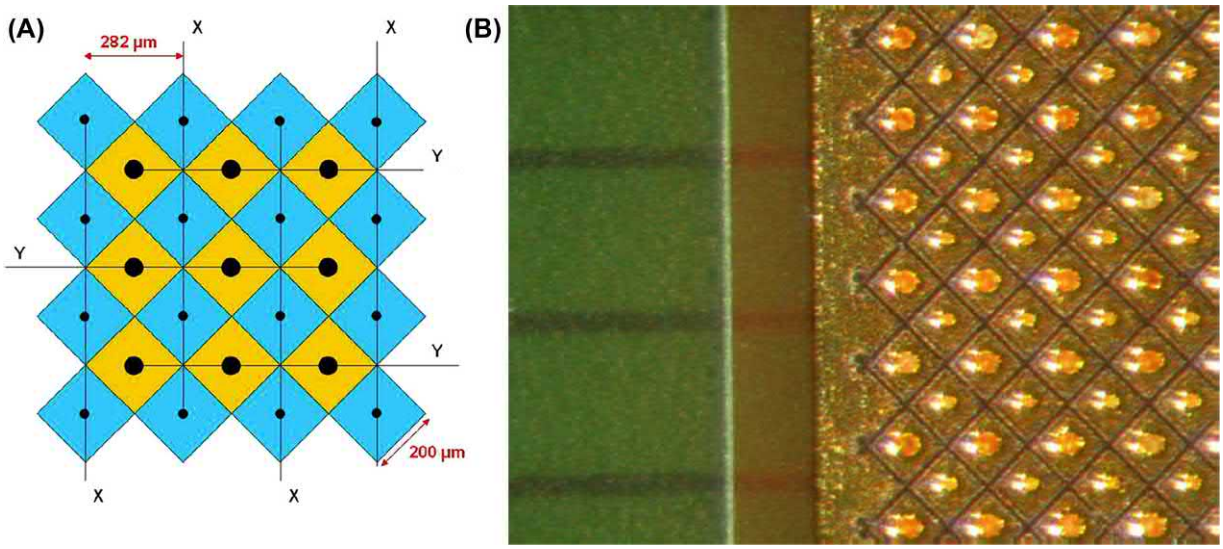

FIGURE 9.20 (A) Multiplexing between strips and pixels. (B) Left border of the segmented anode. Pixels of 170 × 170 µm can be observed together with an underlying strip of the X-plane readout placed diagonally (Courtesy of AI4R). For the color version of the figure, the reader is referred to the online version of the book.

internal analogical memory. An external analog-to-digital converter (ADC) is used to convert the multiplexed analogical output of the chip. Calculation of the position is done by a weighted sum of the converted charge.

The formation of the image is done by real-time accumulation of the detected particles, as it is done in any other particle counting device. It has then the same important property of limiting the risk of over- or underexposition. Nevertheless, for very high-activity samples, as for any particle counting system, a phenomenon of saturated counting occurs, which degrades the quantification.

c. Performance

The PIM structure has the capacity of rather high resolution thanks to the high electric fields. For tritium, resolutions of 20−30 µm have been reported, whereas for higher-energy isotopes such as ^{14}C, documented resolutions are around 50 µm. With regard to fields of view (FOV), the BeaQuant system has a sensitive area of 23 × 23 cm^2.

Sensitivity values of 0.0005 cpm/mm^2 are given by the manufacturer, which is in the same range as other particle counting systems. Another feature, in common with other particle counting systems, is its isotope separation capabilities (e.g., for samples labeled with several radioisotopes). The principle of separation is here based on the total charge collected by the segmented electrode, which depends on the number of primary electrons amplified and therefore on the mean energy of the radioisotope. Fig. 9.21 depicts the collected charge difference between ^{3}H and ^{14}C.

The difference of 30% and the weak overlap between the two distributions (shown in Fig. 9.21) allow for an efficient separation between the two isotopes.

d. Sample management

In addition to the differences in gaseous structure, another difference of the BeaQuant system compared with the BetaIMAGER TRacer is in the way samples are loaded. In the BeaQuant, samples are loaded from the top, and the system does not comprise a drawer. Instead, a sample holder is simply placed on the top of the system and locked in place with a light proof lid. The geometry of the sample holders depends on the type of samples.

The BeaQuant system is capable of imaging both small tissue sections directly laid on standard glass histology slides and large sections placed on tape (e.g., for QWBA). For standard glass slides, the samples are prepared by adding conductive tape on the opposite side of the slide to establish electrical conduction between the sample and the top electrode of the system. Connection is achieved thanks to a set of springs evenly repartitioned on the alveolar surface of the sample holder (one spring per alveolus per sample). For large sections laid on tape, the sample holder is actually a large glass plate equipped with handle, the backside of which is covered with a copper layer and is therefore conductive. Tissue sections are transferred to the glass plate using a transfer tape, as depicted in Fig. 9.22.

Once the acquisition is carried out, sections can be removed from the glass plate, hence making it reusable. This type of sample holder exists in two sizes: 10 × 10 cm and 20 × 20 cm.

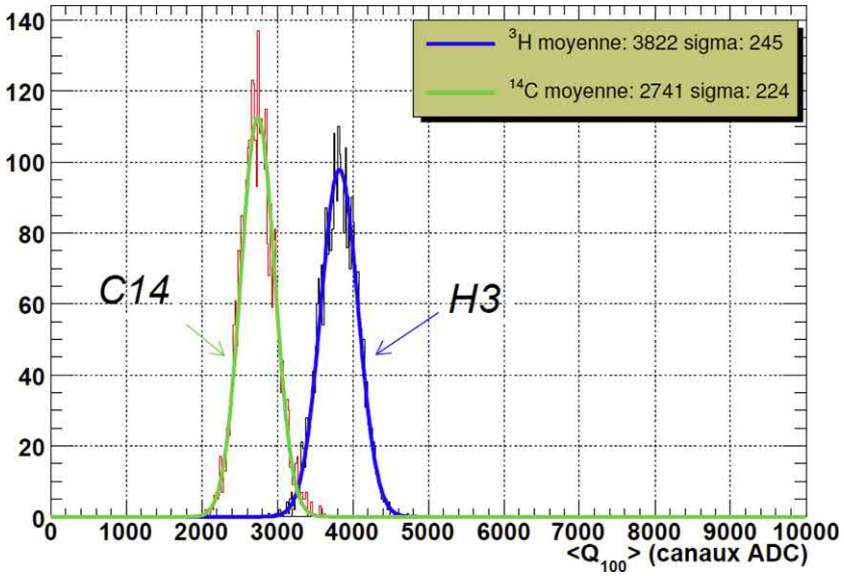

FIGURE 9.21 Distribution of charges in a parallel ionization multiplier imager for ^{3}H and ^{14}C in arbitrary units. The mean collected charge for ^{14}C is about 70% of the one collected for tritium. X and Y axes are, respectively, the electric charge in arbitrary units and the number of counts (Courtesy of AI4R). For the color version of the figure, the reader is referred to the online version of the book.

B. Solid membrane detector (digital microautoradiography)

1. History (BetaIMAGER DFine, formerly MicroImager)

The BetaIMAGER DFine (formerly MicroImager) was developed initially at the Institute of Nuclear Physics IN2P3—CNRS—ORSAY France (Laniece, 1994). The purpose of this development was to conceive an electronic autoradiography system, the spatial resolution of which would be as close as possible to film and emulsion, whereas its sensitivity would be comparable with or better than other electronic systems, such as the DAR, Ambis, and instant imager (especially for applications with tritium). At the beginning of the 1990s, the best electronic autoradiography systems could only demonstrate millimetric resolution, thus restricting their application to molecular biology and electrophoresis experiments and to neurological studies on slice in the case of in situ hybridization (ISH). There was therefore no real alternative to film or emulsion.

The initial specifications of the BetaIMAGER DFine were a spatial resolution at the cellular level and a dramatic improvement in sensitivity compared with film and emulsion (especially for tritium that is widely used for ligand studies).

2. Description of the BetaIMAGER DFine

a. Principles

The technological choice was based on contact imaging with a scintillating membrane. This membrane is made of a 10-μm foil of Mylar on which a monolayer of scintillating powder (Y_2SO_4 or ZnS) is sputtered (Fig. 9.23).

The medium grain size of the scintillating powder is 3 μm. The sample is pressed on the scintillating face. By hitting the closest grain of scintillating powder, the beta particle creates a small burst of light of tens of photons for tritium and around 50−100 photons for higher-energy isotopes such as ^{14}C. This burst of light is far too weak to be recorded and processed directly. A light intensifier with two MCP channels and a light gain of 10^6 is therefore used to amplify the burst. A conventional digital CCD is fastened to the light amplifier and delivers a light spot for

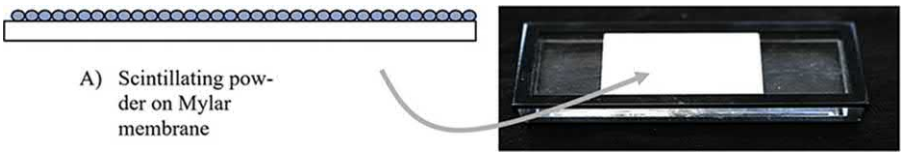

FIGURE 9.23 Left: Schematic diagram of a scintillating membrane. Its total thickness (Mylar + powder) is approximately 15 μm. Right: The scintillating membrane placed on the slide on a holding tray.

each beta particle, in a similar manner as the BetaIMAGER TRacer (Fig. 9.24).

b. Sample management

Fig. 9.25 is a schematic representation of the BetaIMAGER DFine.

The system has three functional parts:

- **The carousel** makes a 90 degrees rotation before lifting another sample into position. The sample platform can contain up to four samples.
- **The sample holder** receives the sample holding the slide and maintains the scintillating membrane against the sample.
- **The intensified camera** is fitted with an intensifier tube with a 40 mm diameter. The FOV is therefore 24 × 32 mm (half a standard glass slide).

The sample platform is both a carrousel and an elevator that lifts and presses the sample against the intensifier windows. The sample is lifted back down at the end of the acquisition. One additional feature of BetaIMAGER DFine is the optical block, which is fitted with LED lights. Its function is to illuminate the sample to acquire an optical image, which is then used for registration purposes. This feature is useful with samples for which the autoradiography image is too complex to decipher.

c. Shape of the light spots

As any other electronic autoradiography system, the BetaIMAGER DFine can record data (e.g., time of occurrence, etc.) in list mode files. The BetaIMAGER DFine can also segregate isotopes, according to the shape of the light spots. Fig. 9.26 illustrates how the BetaIMAGER DFine discriminates between isotopes.

C. Characteristics and performances of particle-counting imagers

1. Isotopes used

All of the beta emitters involved in conventional autoradiography are detected by the two radioimagers previously described, namely, the BetaIMAGER TRacer and BetaIMAGER DFine: ^{3}H (E_{max} = 18 keV), ^{14}C (E_{max} = 156 keV), ^{35}S (E_{max} = 167 keV), ^{33}P (E_{max} = 250 keV), ^{45}Ca (E_{max} = 257 keV), ^{32}P (E_{max} = 1710 keV), ^{90}Sr (E_{max} = 546 keV), and ^{90}Y (E_{max} = 2280 keV).

As mentioned previously, gamma emitters also emit internal conversion and Auger electrons and can be detected such as ^{125}I, which emits 35.6 keV gamma-ray photons + conversion electrons <4 keV). Likewise, other radioisotopes, such as ^{99m}Tc (a major marker of radiopharmaceuticals used in nuclear medicine), can be detected,

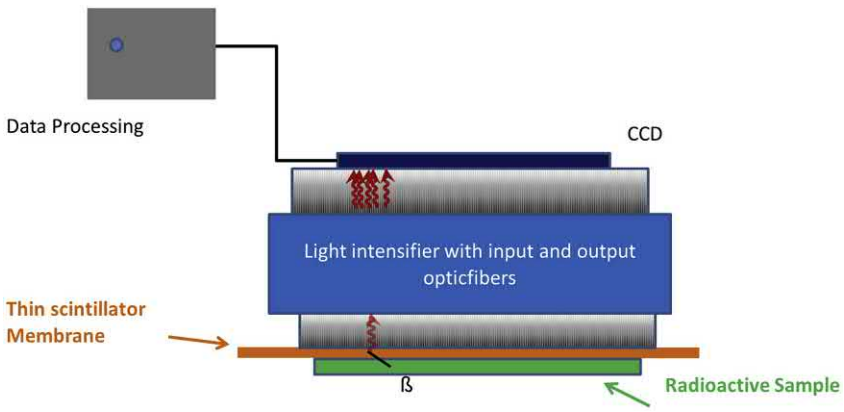

FIGURE 9.24 Operating principle of the BetaIMAGER DFine. The scintillator foil and intensifier tube are pressed against the sample. A small burst of light is created when a beta particle hits the scintillator. This burst is amplified by a factor of 10^6 by the intensifier and is then recorded by the CCD. For the color version of the figure, the reader is referred to the online version of the book.

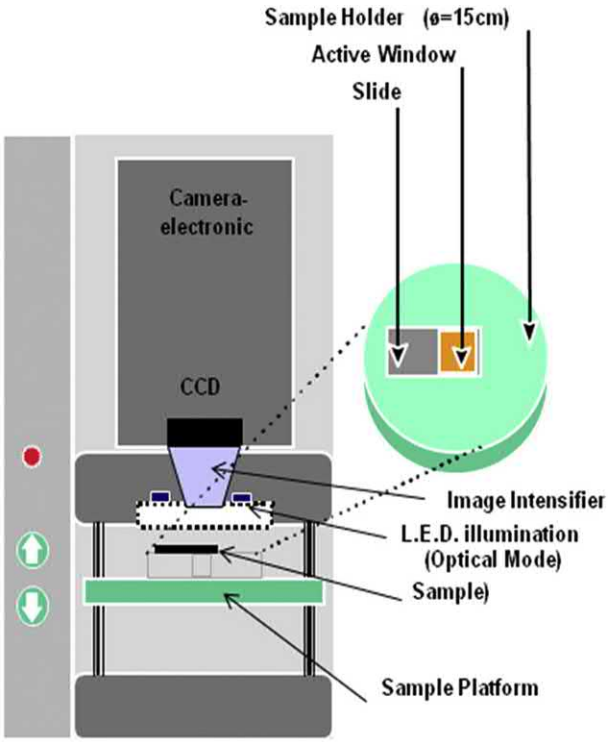

FIGURE 9.25 Schematic view of the BetaIMAGER DFine. For the color version of the figure, the reader is referred to the online version of the book.

as they emit many low-energy electrons. The main advantage of these imagers in the detection of radionuclides used in nuclear medicine, compared with film or phosphor screens, is their insensitivity to γ rays, which preserve resolution. Common gamma emitters used in nuclear medicine are ^{99m}Tc (γ: 140 and 2 keV + electrons 2, 15 and 120 keV), ^{111}In (γ: 171 and 245 keV + electrons 1, 4−9 and 18−27 keV), ^{123}I (γ: 159 keV + electrons 3, 23 and 127 keV) ^{131}I(γ: 365 keV + β^- (E_{max} = 247 keV) + electrons 45 keV), and ^{201}Tl (γ: 135 and 167 keV + electrons 1, 4, 8−5, 15.7−19.9 and 52.2−84.3 keV). β^+ emitting isotopes are ^{11}C (γ: 511 keV + β^+ E_{max} = 961 keV), ^{13}N (γ: 511 keV + β^+ E_{max} = 1.19 MeV), ^{15}O (γ: 511 keV + β^+ E_{max} = 1.72 MeV), and ^{18}F (γ: 511 keV + β^+ E_{max} = 650 keV). The above positron emitters as well as other positron emitters commonly used for PET (positron emission tomography) imaging can also be efficiently imaged with these systems without any parasitic image coming from the annihilation γ rays. Alpha emitters can also be detected because of the higher energy deposition by alpha particles; however, they require a specific adjustment of the gaseous gain with the BetaIMAGER TRacer.

2. Performance

The performance of these two systems with regard to sensitivity, linearity, and spatial resolution attributes to these instruments' excellent characteristics as state-of-the-art real-time fast imaging devices. Furthermore, background noise is low. These systems have typical detection thresholds of 0.007 cpm/mm^2 for ^{3}H and 0.01 cpm/mm^2 for ^{14}C with the BetaIMAGER Tracer and 0.4 cpm/mm^2 for ^{3}H and 0.004 cpm/mm^2 for ^{14}C with the BetaIMAGER DFine.

When checked with calibrated standards or short half-life sources, the linearity of these devices was superior to 10^4, a large dynamic range compared with 10^2 with film.

The spatial resolution, determined by measuring the full width at half maximum (FWHM) of radionuclide-labeled lines on engraved microscope slides according to Rogers (1969), was evaluated for the two systems. For the BetaIMAGER TRacer, the spatial resolution depends on the energy of the particles emitted by the radiolabeled lines. The best achieved performances are 50 μm for ^{3}H or ^{99m}Tc and 150 μm for ^{32}P or ^{18}F.

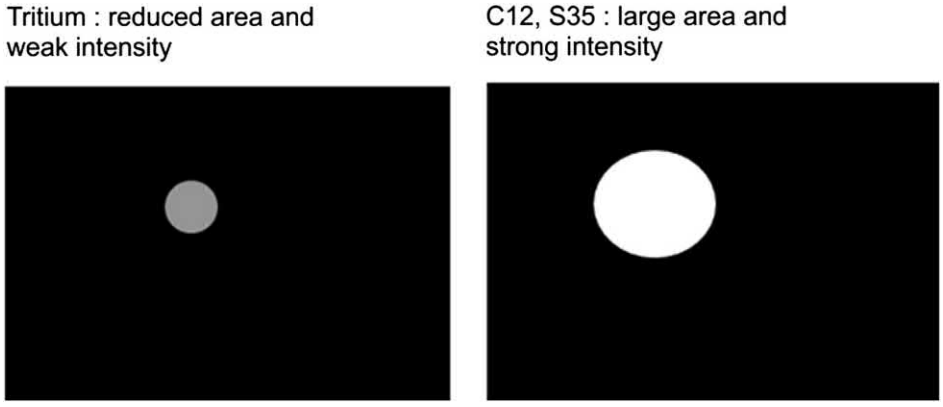

FIGURE 9.26 In the BetaIMAGER DFine, the shape of the light spot is proportional to the energy deposited in the scintillator. Hence, the brighter spots correspond to medium-energy isotopes.

In the case of the BetaIMAGER DFine, the typical spatial resolution is 10 μm for ^{3}H and of 20 μm for ^{14}C or ^{35}S, which is of the order of the dimensions of biologic cells. Spatial resolution is closer to 20 μm for higher-energy radionuclides because of backscattered electrons from the sample slide.

3. Quantification

Quantification is much easier and more precise with these imaging detectors than with classical autoradiography because the detectors are based on the direct measurement of the radioactivity. In particular, particle counting techniques give results from the first detected beta particles and do not have a pedestal in the lower part of their sensitivity curve. This extreme sensitivity can even appear as a drawback because images coming from particle counting systems look noisy compared with film or phosphor screens. In fact, one should keep in mind that with particle counting techniques, it is possible to quantify an image even with a very limited number of detected particles. For example, if the number of counts in a region of interest (an organ) is 100, the standard error will only be 10% (Poisson noise), which is an arguably reasonable accuracy in biology. Hence, the data are reliable even though the result may be visually noisy. The reason why phosphor screens or film images always look statistically better is that their detection threshold does not make images possible for very low levels of radioactivity. For instance, considering a detection limit of 30 disintegrations per mm^2 for ^{14}C, a phosphor screen requires 3000 disintegrations over a region of interest of 1 cm^2 (heart of rat for example) to provide a result. This is why particle-counting techniques are always much faster than energy storage devices. Manufacturers of particle-counting imaging devices often include, in their analysis software, image processing filters that can smooth the noise, thus allowing a better rendering of the image while preserving quantification.

As previously mentioned, in the case of phosphor screens, mass activity (in Bq/g) is often the real data of interest. This imposes the preparation of a reference standard of known radioactivity. Standards really must be made of the same material and preferably with the same thickness as the measured samples because particle-counting techniques are slightly more sensitive to sample thickness than energy storage techniques. The standards must be read together with the samples for each acquisition to allow accurate sample quantification by means of proportionality.

D. Data analysis for particle-counting imaging systems

1. List mode files

One of the main assets of particle-counting systems is the particular way in which they store imaging data. Instead of recording images as tables of numbers (each number corresponds to the intensity of the radioactivity measured for one pixel), data are recorded as a sequence of variables (coordinates, time, etc.) for each disintegration. This type of data is called a list mode file. Fig. 9.27 illustrates the organization of a list mode file.

As discussed previously, each beta particle will be counted as 1, whatever the isotope. Certain list mode file-based detectors can also record the particle's energy, but, contrary to energy storage devices, this information will not have any weight in the final image. The image can subsequently be produced by choosing a display resolution and scanning the various coordinates stored in the file. The value of a given pixel will be incremented each time a particle's coordinate corresponds to that pixel. The coordinates (*i.e.*, COG) can be calculated with a resolution of 5−10 μm, whereas the resolution of the final image can be chosen subsequently according to the size of the area of interest. Time information is another key feature of list mode files, as it allows the extraction of partial acquisitions. This can be useful when developing experimental conditions; for instance, it is possible to extrapolate the minimum acquisition time required for optimal measurements from partial acquisitions extracted from one initial long acquisition. Time information is also important in experiences involving short-lived isotopes, such as the ones used in nuclear medicine, as these isotopes can be segregated according to their half-life.

Similarly, supplementary information related to the morphology of the light spots, including the number of pixels (area of the spot), total intensity (luminosity, proportional to the energy deposited), and ellipticity, can be stored in list mode

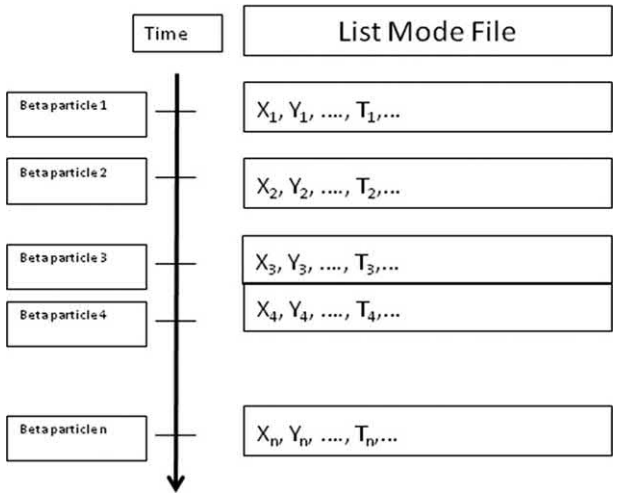

FIGURE 9.27 Principle of list mode file recording. For each event (light spot resulting from one disintegration), a set of data is recorded, including position (*X*, *Y*), time of disintegration (*T*), and other parameters related to the isotope (luminosity, etc.).

files. All these additional criteria can be used to discriminate between isotopes according to their energy.

Even though this type of data can be considered as memory consuming, one should keep in mind that the amount of data is proportional to the number of recorded beta particles; and most of the time, the list data files are actually more compact than conventional raw images files, particularly for low-activity samples.

2. Multiisotope separation according to energy

As previously described, the morphological criteria of the light spots recorded by the CCD camera (area, light intensity, ellipticity, perimeter, etc.) give information on the energy of the detected particles, therefore permitting the separation of two isotopes of different energy. According to their energy characteristics, good candidate radionuclide pairs for a separation are $^{3}H + {}^{14}C$, $^{3}H + {}^{35}S$, $^{3}H + {}^{33}P$, $^{3}H + {}^{45}Ca$, etc. Separate standards of each radionuclide of the dual-radionuclide pair are needed to establish the statistical distribution of the instrumental criteria used for radionuclide discrimination. The need for standards is mostly due to the effect of sample thickness on energy distribution. The radionuclide discrimination is then processed by means of proprietary algorithms developed by BioSpace Lab. Given two isotopes A and B, and using the former criteria, the software will first calculate the probability of a disintegration to originate from isotope A and from isotope B. For each disintegration, the two probabilities are recorded in two new list files, which are then used to establish one image for each isotope after discrimination. Fig. 9.28 shows a schematic representation of the process.

Fig. 9.29 shows an example of the separation of ^{35}S and ^{3}H separation in a CNS study using the BetaIMAGER DFine. The difference in labeling between right and left hippocampus in this rat brain section is clearly visible. The lack of tritium in the right hippocampus is proportional to the lack in oligonucleotide probe. The difference in gene expression after an electric stimulus can therefore be quantified.

As the energy deposited by the beta particles can be dramatically altered by the sample itself, this technique cannot segregate more than two isotopes at once. Furthermore, some isotope pairs cannot be separated because their respective beta particle energy maxima (E_{max}) are too close to each other (e.g., $^{14}C-{}^{35}S$, $^{14}C-{}^{33}P$, etc.).

3. Multiple isotope separation according to decay

Autoradiography can also be used as a control for PET or single photon emission computed tomography (SPECT) experiments in preclinical nuclear medicine studies. Most isotopes used in nuclear medicine have very short half-lives (as compared with tritium and ^{14}C). This characteristic can be used in particle-counting imaging systems for multiradioisotope labeling. The time information recorded in list mode files is used in a similar manner as energy discrimination. In this case, it is the time information that will be used as the key criterion for radioisotope discrimination. For every event (or particle) location registered in the list mode file, the software will compare the signal recorded over time to a prediction of the exponential decay expected for pure isotopes. Thus, a set of list files, each corresponding to the probability for one isotope, will be created.

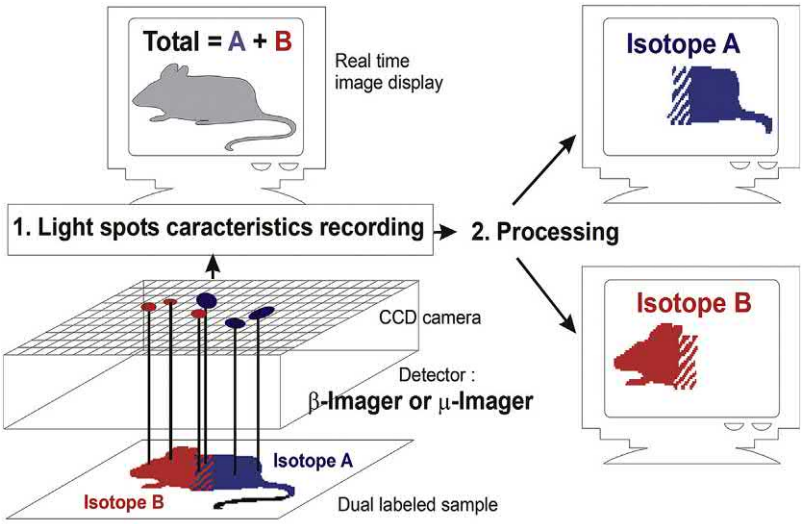

FIGURE 9.28 Principle of energy-based isotope discrimination. Using the knowledge of the statistical distribution of the different criteria for each isotope, the software calculates the probability for each disintegration to originate from isotope A and from isotope B. For the color version of the figure, the reader is referred to the online version of the book.

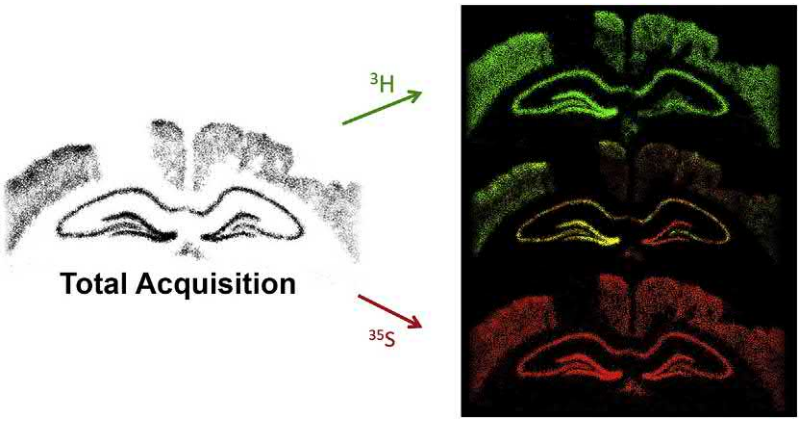

FIGURE 9.29 Example of energy-based dual-isotope labeling. Two oligonucleotide probes (the first labeled with ^{35}S, the second with ^{3}H) were hybridized on the section of a rat brain. An asymmetric neural stimulation was carried out on the left part of the brain prior to sacrifice. An asymmetric distribution in gene expression is clearly visible in the right hippocampus (Salin, 2000). For the color version of the figure, the reader is referred to the online version of the book. *Reprinted with permission from SAGE open.*

This method is less restrictive, with regard to the number of isotopes that can be separated compared with energy-based separation. Three isotopes can commonly be isolated, but more should also be possible, as long as the following requirements are filled:

- The ratio between two consecutive half-lives (from the shorter to the longer) must be larger than 2.
- The total duration of the acquisition must be longer than the half-life of the latter isotope of the radioisotope combination (always from the shortest to the longest half-life). Examples are provided below.
- If one of these requirements is not met, the quality of the separation will be drastically reduced, potentially making it unusable, especially in the case of low-activity samples.
- Examples of radioisotope combinations and respective optimum acquisition times for their adequate separation are listed below:
  - ^{18}F ($t_{½} = 108$ min), ^{99m}Tc ($t_{½} = 6$ h), ^{123}I ($t_{½} = 13$ h). Acquisition time > **6 h (^{99m}Tc)**
  - ^{18}F ($t_{½} = 108$ min), ^{123}I ($t_{½} = 13$ h), ^{111}In ($t_{½} = 68$ h). Acquisition Time > **13 h (^{123}I)**

The last isotope of the list may even be a long-lived isotope (such as tritium or ^{14}C).

Fig. 9.30 illustrates an example of multiisotope labeling experiment for which histologic sections were obtained from rat heart tissues 1 month after coronary occlusion. The animals were fed glucose and received intravenous injections of ^{18}F-fluorodeoxyglucose (FDG), ^{99m}Tc-sestamibi, and ^{111}In-diethylenetriamine pentaacetic acid (DTPA) prior to imaging. ^{111}In-DTPA is an extracellular tracer and exhibits retention in the extracellular fluid of necrotic tissue. ^{18}F-FDG is a tracer for glycolitic metabolism, while the myocardial distribution of the tracer ^{99m}Tc-sestamibi is proportional to blood flow.

The three images clearly show a predominant blue ^{111}In signal in the necrotic area at the extreme left of the heart section, while the ^{18}F signal (in red) is excluded from necrotic tissue but increased in the surrounding area, compared with the rest of the myocardium.

Hence, in this multiradioisotope labeling experiment, the levels of both necrosis, expressed as the ratio between ^{111}In signal and ^{99m}Tc signal in the necrotic area, and ischemia-related metabolic enhancement (^{18}F-FDG/^{99m}Tc) in the border zone, can be determined in parallel.

V. Comparative use of the different techniques

A. Applications in biochemical analysis

Except for the BetaIMAGER DFine, all other radioisotope-imaging systems can be used for the detection of samples with large surface areas traditionally revealed on film, including Western blot membranes and electrophoresis agarose gels used for DNA and RNA analysis. The two main advantages of imaging systems are acquisition speed (10−50 times faster than film) and sensitivity. They also have a higher dynamic range typically around four to five orders of magnitude, and therefore, they provide quantitative reliability. Also, their spatial resolution is sufficient for biochemical analyses, such as the separation of proteins or DNA/RNA molecules according to their size or isoelectric properties.

However, whereas the BetaIMAGER TRacer or the BeaQuant system can only accept a limited number of samples at any given time, phosphor plate radioisotope imagers can be equipped with multiple storage tanks allowing the processing of several plates in parallel and therefore simultaneous analysis of large sample numbers, a prerequirement in high-throughput screening, for example.

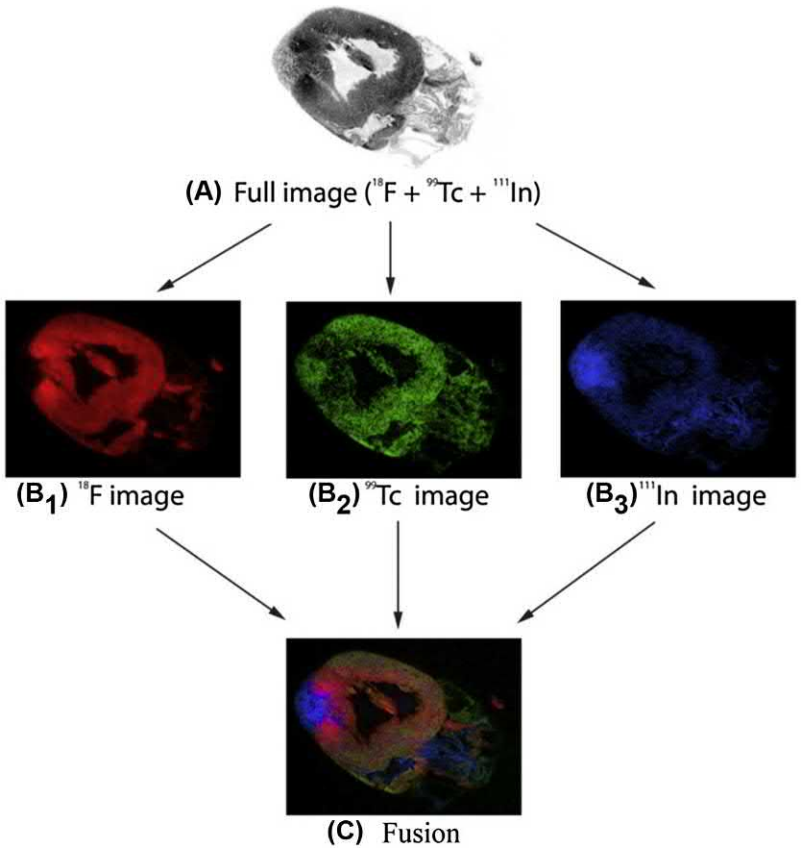

FIGURE 9.30 Time-based isotope separation. Image of an infarcted heart of a rat labeled with the three radioisotope markers: ^{18}F-FDG, ^{99m}Tc-Sestamibi, and ^{111}In-DTPA. For the color version of the figure, the reader is referred to the online version of the book. *Courtesy of Sylvain Poussier, Department of Nuclear Medecine, CHU-Nancy-France.*

In the early 2000s, high interest had been devoted to the BetaIMAGER DFine for DNA microarrays used in the biosciences to measure the expression levels of large numbers of genes simultaneously or to genotype multiple regions of a genome. With ^{33}P-radiolabeled probes, a spatial resolution of 15 μm could be obtained with a BetaIMAGER DFine, whereas it is limited to 150 μm with a phosphor plate. Nevertheless, these analyses are today "old-fashioned," even though their sensitivity remains incomparable.

B. Advantages and limitations of radioimagers in histological studies

Older electronic radioimagers of the MWPC generation typically had insufficient spatial resolution (300−700 μm) resulting in a loss in contrast (by a volume effect) for images of histological sections. They were used nonetheless because of their high sensitivity (reduced latency of images) and their performances in quantification (high dynamic range or linearity capabilities), thus allowing the rapid validation of experimental conditions and/or tracer labeling process.

Among other high-resolution radio imagers that can be used to quantify radioisotope-labeled substances in tissue sections, the BetaIMAGER TRacer has a spatial resolution of 100−150 μm and is therefore a good alternative to phosphor plate radio imagers, especially when the radioactive signal is weak, as in binding or ISH experiments, for example, and especially when the radionuclide of choice is tritium because of the great efficiency of this detector to detect low-energy beta emissions. As the sample is placed directly inside the gas chamber, interaction of low-energy particles with the detection medium is optimal. Phosphor screens cannot offer equivalent efficiency except when the protective antiscratch layer has been removed, thus exposing the screen to potential damage and preventing it from reuse. If the most efficient radio imager (i.e., BetaIMAGER DFine) has a resolution similar to film, it is generally recognized that histological analysis is more precise on film, which is still nowadays used as a complement to the data obtained with the phosphor screen or a particle-counting system.

In pharmacological experiments, such as radiolabeled ligand displacement studies, spatial resolution is less important than response linearity for dose-effect quantifications. Such pharmacological studies actually often imply the use of frozen tissue sectioned with a cryostat. Tissue damages can occur during this process due to dilacerations caused by the formation and subsequent evaporation of ice after the spreading of the section. This often creates

inhomogeneities of more than 100 μm in the tissue surface, thus making the BetaIMAGER's spatial resolution of 50−100 μm adequate for the precise analysis of radioactive ligands in histological samples.

With respect to tissue quantification of radioligand distribution in binding studies, comparative studies with ^{125}I have shown that results were comparable with those achieved with film and that quantifications in the highest radioactive regions were more reliable with the radio imagers. Similarly, in RNA expression studies, ISH with radioisotope-labeled oligonucleotide probes generally requires an image resolution at the cellular scale. The BetaIMAGER DFine is the most suited system for this type of imaging. For other applications, including less classical tracers, such as gamma- or beta−gamma-emitting radionuclides, which have short half-lives, only the most sensitive imaging systems such as the BetaIMAGER Tracer, BeaQuant, and BetaIMAGER DFine will be able to acquire images prior to their total disappearance.

C. Potentialities for multiradionuclide labeling

The great advantage of the direct-counting, real-time imagers over other systems is their versatility in multidetection modes thanks to their specific detection processes allowing the discrimination among a range of radionuclide tracers. Multiple radionuclide tracers may be detected simultaneously by taking advantage of the differences in their beta-particle emission energies or decay characteristics.

D. Autoradiography associated with mass spectroscopy

Although QWBA is so far the most used imaging technique for localization and quantification of radioactive compounds in biological tissues or on thin specimens, this technique can only detect and quantify radioactivity. It cannot provide information on the nature of the analyte detected. Hence, the measured radioactivity may result from a mixture of the parent molecule and its metabolites and/or degradation products. Consequently other methods were developed to identify the precise nature of the radioactive compounds (Solon et al., 2010; Murray et al., 2016).

Initially, liquid chromatography mass spectrometry analysis on tissue extracts was carried out to identify and quantify compounds and their metabolites on the basis of exact mass measurements (Covey et al., 1986) or, more often, by profiling fragment ion spectra by characteristic of each molecule by MS/MS (Rohner et al., 2005; McDonnell and Heeren, 2007).

Historically, in the 1960s and 1970s emerged a new technology named mass spectrometry imaging (MSI). It was based on various ionization processes applied on the surface of tissue samples combined with mass spectrometry analysis of the produced ions. This opened a field of new developments in molecule identification with high levels of spatial resolution, sensitivity, and mass resolution. MSI is currently applied as a complement to QWBA in the field of pharmaceutical discovery and development where analytical laboratories must provide information on the ADME, of candidate ligands together with pharmacokinetic compound assessments prior to clinical trial clearance by regulatory bodies (Rohner et al., 2005; Stoeckli et al., 2007; Khatib-Shahidi et al., 2006).

A mass spectrometry image is an array of mass spectra obtained sequentially at regular spatial intervals, after bombardment, of a sample, under vacuum, by an energetic beam of ions or by pulsed laser irradiation. Atoms are ejected from the sample surface as charged particles and are guided by an electrostatic field toward a mass spectrometer. For any mass/charge (m/z) value in a mass spectrum, a quantitative image that represents the distribution of amounts of a particular ion can be calculated as illustrated in Fig. 9.31 (Solon et al., 2010).

A comprehensive review on MSI techniques was recently published elsewhere (Murray et al., 2016). This review describes the initial approach to MSI by secondary ion mass spectrometry (SIMS) first reported by Castaing and Slodzian in 1962. Furthermore, the sensitivity and the mass range of SIMS have been extended with time-of-flight (TOF) mass analyzers (Benninghoven, 1994) and cluster ion sources (Winograd, 2005; Bich et al., 2014). SIMS is adapted to the characterization of atoms or small molecules up to 1500 Da with a spatial resolution of a few hundred nanometers. The use of lasers for desorption/ionization in MSI appeared in the 1970s (Hillenkamp and Karas, 2000), performing in a mass range similar to TOF-SIMS, up to 1000 Da with a lateral resolution of about 1 μm. The matrix-assisted laser desorption/ionization (MALDI) was later developed around the late 1990s (Caprioli et al., 1997) extending the working mass range up to 30 kDa with a lateral resolution approaching 10 μm. MALDI uses the addition of a matrix applied on the sample to desorb and ionize the analytes from the surface upon impacts of laser pulses. For example, among many other matrices and matrix application protocols available, a manual application of α-cyano-4-hydroxycinnamic acid solution, using a conventional thin-layer chromatography sprayer to coat the sample, is well suited for simultaneous imaging of a compound and its metabolites in tissue sections. The same samples used for QWBA can also be used for analysis by MALDI-MSI. The sections are mounted on tape and immediately lyophilized for QWBA, whereas they are first frozen and then lyophilized before coating with a matrix in MALDI-MSI analysis. The sections are then rastered over with a laser in the mass spectrometer to acquire the

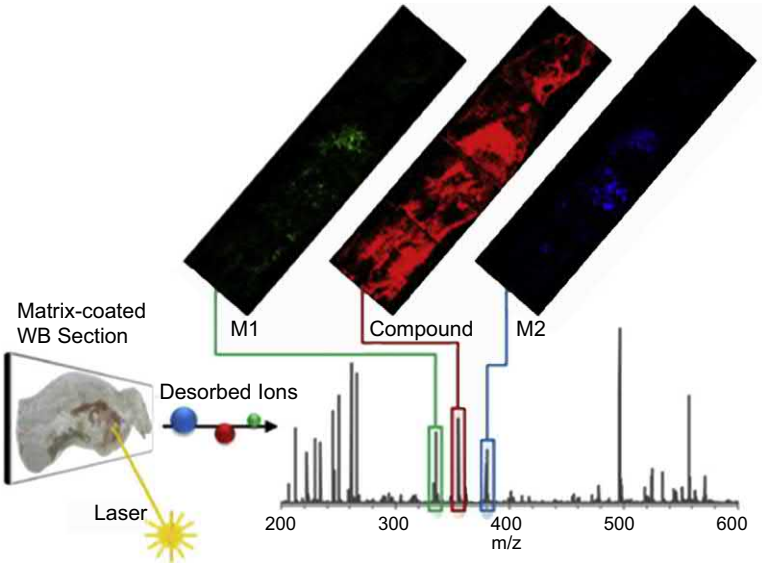

FIGURE 9.31 Matrix-assisted laser desorption/ionization mass spectrometric imaging process. Analytes are simultaneously desorbed from the animal section in a defined raster. Out of the acquired spectra, specific molecular images are calculated. For the color version of the figure, the reader is referred to the online version of the book. *Reproduced with permission from Solon et al. (2010).*

different spectra. An example of such an experiment is shown in Fig. 9.32.

Carried out on rat sections, this type of experiment can take around 1 hour for a laser raster of 0.5 mm. The spatial resolution depends on the diameter of the laser beam, which is typically around 100−20 μm and is limited by the matrix deposition method during which a delocalization of the analytes frequently happens (Rohner et al., 2005; Stoeckli et al., 2007). Higher-resolution images may be achieved by depositing other special matrices or by using recent SIMS methodology directly on biological tissue. Following the development of a variety of new MSI methods (oversampling, beam focus in reflection geometry and transmission geometry, high numerical aperture lens), MALDI is now capable to image tissue sections of 5 μm thickness or mammalian cell cultures. Moreover, progress in ionization methods, such as ambient and atmospheric pressure ionization or near-field laser ablation, allowed the detection of small features down to 0.6 μm resolution on polymer samples and to resolve cocaine biodistribution in mouse brain tissue at a lateral resolution of 15 μm (Murray et al., 2016).

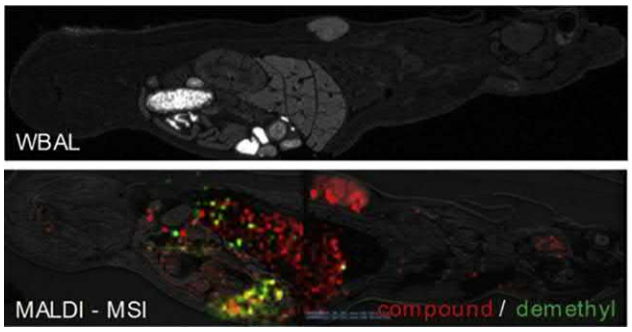

FIGURE 9.32 Comparison of mass spectrometry imaging (MSI), whole-body autoradiography (WBA), and matrix-assisted laser desorption/ionization mass spectrometric imaging (MALDI-MSI) results obtained from the same compound-dosed animal. MALDI-MSI allows the simultaneous discrimination between the labeled compound (red) and its metabolites (green, colocalized with label-free compound (yellow). For the color version of the figure, the reader is referred to the online version of the book. *Reproduced with permission from Solon et al. (2010).*

Alternatively, SIMS was successfully applied to the analysis of many biological tissues with an improvement in spatial resolution and an increase in the mass molecular weights being studied. Starting with the detection of radioactive or stable atoms (Galle, 1982), SIMS-MSI evolved toward the identification of large molecules or even cells, such as bacteria and cell cultures, allowing the acquisition of images of submicrometric spatial resolution for radioactive isotopes (Hindié et al., 1992) or for label-free molecules (Chandra et al., 2000).

In the SIMS ionization process, a beam of ions is projected on the tissue surface directly, resulting in a desorption of ionized atoms. The sample is gradually sputtered, starting with the most superficial layers of atoms, which are ejected from the sample surface as charged particles and are guided by an electrostatic field, resulting in a secondary ion beam. The latter is directed toward a mass spectrometer tuned to detect a given ion species, yielding an image that reflects the distribution of the selected emitter. As the mode of operation is by analysis of the material removed by sputtering, it is a locally destructive technique. This drawback, conjugated with limitations in mass ranges that can be successfully ionized, explains its limited use in biomedical research until the last decade. But, as a complement to MALDI, SIMS imaging has real potential for

the analysis of low-molecular-weight compounds at high spatial resolution for biomedical research purposes.

VI. Other applications

In biomedical research, applications to quantitative autoradiography and beta imaging are extremely broad, and these methodologies are very relevant because of the targeting properties of the labeled compounds and of the potential of the technique to locate and quantify them in the resulting image.

A good overview of the general applicability of these techniques is demonstrated in many publications covering all the domains in medical science. A few examples will be presented here with illustrations. These examples are not restricted to one specific method of detection (energy storage or direct counting), and both techniques are represented here.

A. Biochemistry of development studies

In biochemistry of development studies where physiological mechanisms are investigated in rodents, research has demonstrated the link between circulating peptides and their function in the animal body thanks to various autoradiographic approaches, including film whole-body autoradiography, sensitive emulsion for microautoradiography, and QWBA by digital beta imaging, providing a representative mapping of target organs as illustrated in Fig. 9.33 and finally a detailed organ-specific autoradiography by the BetaIMAGER TRacer (Rougeot et al., 1997).

A vast number of publications in this field were made with the general goal of identifying specific molecular interactions: for instance, plasma membrane proteins and lipids in binding experiments to evaluate membrane function and regulation (Bjorkholm et al., 2014) or information transduction across the membrane (Chiricozzi et al., 2015). Digital autoradiography of Western blotting PVDF membranes and eventual mass spectrometric analysis are among the methods used to identify compounds and processes involved in molecular interactions. In recent years, the development of translational medicine enhanced collaborations between various medical disciplines. New methods in molecular imaging, such as PET, together with the development of novel radiolabels, opened the way for innovative clinical and therapeutic applications. A typical example is detailed in a recent paper (Pant et al., 2015) where autoradiography and PET imaging were combined to investigate in vivo and ex vivo pharmacokinetics and biodistribution of a bioactive polymer known to exhibit anti-inflammatory activity in small animals. In the concluding section, the authors discussed potential nanomedical applications.

B. Bacteriology

In bacteriologic applications, a microautoradiography method is best utilized to localize the agent generally incorporated into the bacteria cells. Histological imaging of radioisotope-labeled agents is required, as illustrated in Fig. 9.34, for an immunological study concerned with protection against bacterial infection in mice (Phalipon et al., 2002). A similar imaging technique has been used for the study of the context of pathogenicity of *Helicobacter pylori* (Viala, 2004).

Today, MSI techniques are frequently combined with ISH and nanoscale secondary ion mass spectrometry (nanoSIMS) imaging in bacterial research. It has been demonstrated that SIMS-ISH does not alter the apparent isotopic composition of bacterial cells (Chapleur et al., 2013), thus providing means to detect phylogenetic identity and measure carbon isotopic composition at the single cell level.

In addition, multilabeling combined with stable-isotope probing offers the possibility of deciphering networks of biogeochemical processes catalyzed by uncultured microorganisms within complex environments (Lechene et al., 2006).

C. Physiology and gene expression

In the field of physiology and gene expression, an example is illustrated in Fig. 9.35 where interleukin signaling pathways in cognitive function were studied by using ^{35}S-labeled probes and the ISH analysis with a BetaIMAGER DFine (Carrié, 1999). Other similar studies, conducted in the same period, show very relevant results with high-resolution beta imaging (Zemni, 2000; Al Halabiah, 2005; Blanchet, 2005).

Besides conventional autoradiography, which is traditionally used to study the localization of neuroreceptors thanks to ^{3}H-labeled peptides as well as for binding assays and receptor occupancy assays, functional autoradiography uses ^{35}S-GTPgammaS, a nonhydrolyzable analog of guanosine triphosphate (GTP), to provide information on the extent of ligand−receptor interactions and downstream signaling (Sovago et al., 2001; Manuel et al., 2015). Functional autoradiography is based on the increase in G protein guanine nucleotide exchange upon agonist stimulation. Activation of G protein−coupled receptors can be visualized thanks to a local increase in ^{35}S-GTPgammaS radioactivity at the site of G protein activation. Localization of activated receptors can therefore be determined, but the level of receptor activation can also be quantified: the half maximal effective concentration (EC_{50}) can be calculated together with the efficacy equivalent to the maximal effect. Functional autoradiography on brain tissue sections has been widely applied in neuroscience since 1995, but it

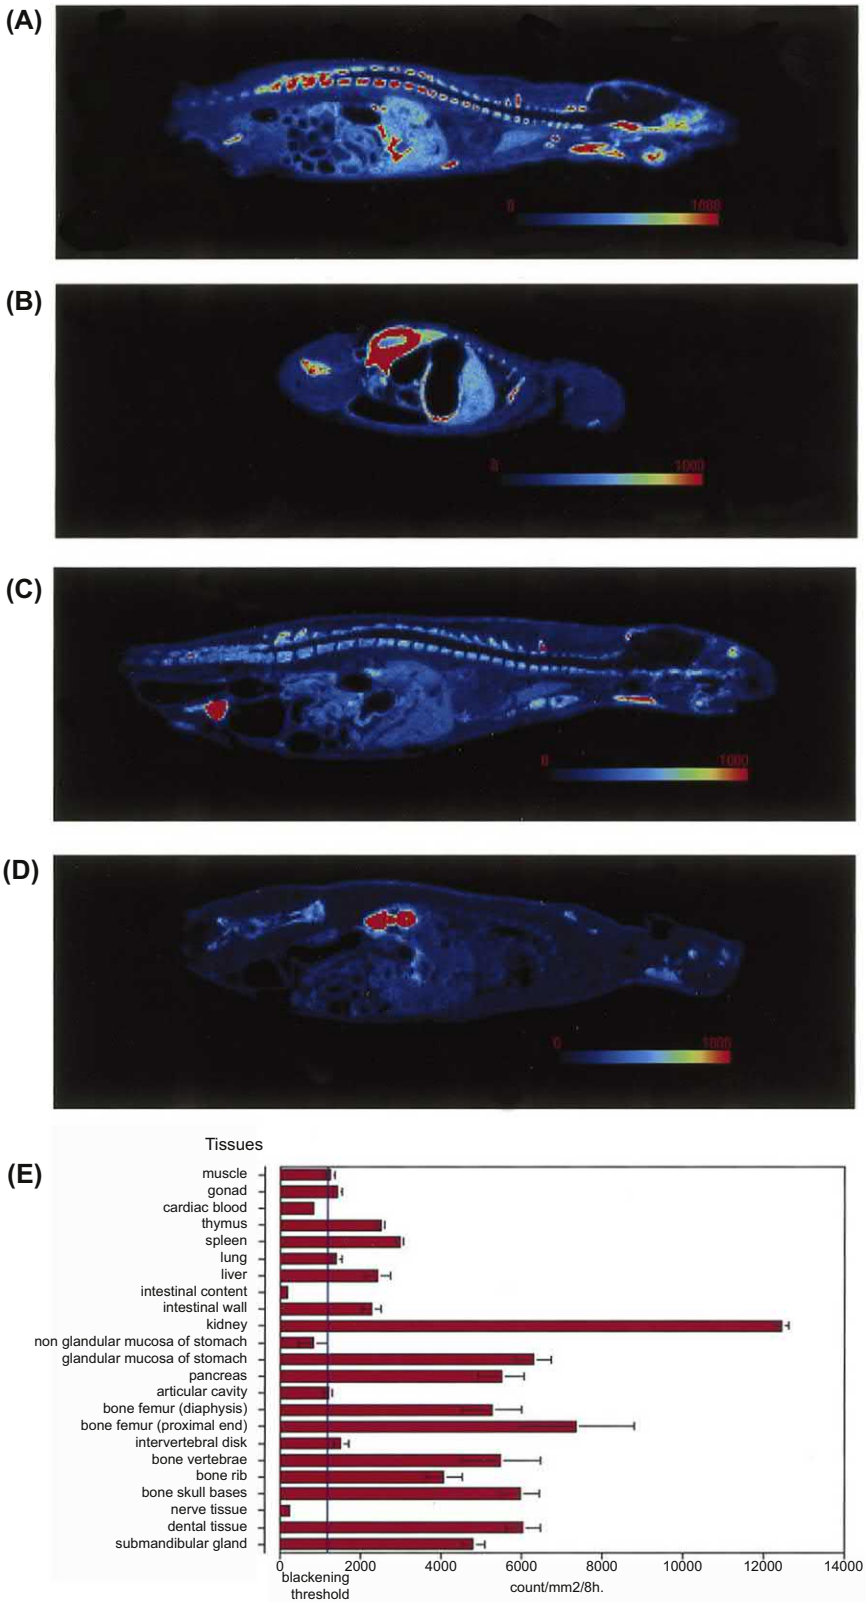

FIGURE 9.33 Representative mapping of target organs for SMR1-derived ^{3}H-pentapeptide using the high-resolution beta-radioimager (now BetaIMAGER TRacer, Biospacelab, France). (A) & (C) Midsagittal and (B) & (D) Lateral sagittal whole body sections of male (A & B) or female (B & C) rats, 60 min post injection of 3 nmol (6.7 MBq) tritiated peptide. Exposition Approx. 10 h. Red areas correspond to high uptake of radioactivity. can also be used to analyze membrane microarrays made from collections of membrane homogenates isolated from diverse tissues, organs, or even transgenic cells overexpressing specific proteins. Hence, the use of functional autoradiography for high-throughput screening of candidate compounds and drug discovery was suggested (Manuel et al., 2015). In this context, the technique could also be combined to mass spectrometry imaging, should a change in molecular structure of the native ligand be suspected.

Histological applications are often analyzed with a BetaIMAGER DFine system or with a radiosensitive emulsion, which reveals the true location of the labeled agent in the tissue or into the cell (Rigothier, 2002).

D. Molecular biology

Even though nonradioisotope techniques (fluorescence, chemiluminescence) are prominent in the field of molecular biology, radioisotope-based TLC, Western and Northern blots, or gels are used widely, mainly because of their quantification properties. Let us take a brief overview of these different techniques through some examples and images.

- **TLC plates** are used to identify molecules in a mixture. The separation is done by migration in a stationary solid phase (silica gel or alumina) or in a mobile liquid phase (solvent or mixture of solvents). It is frequently used for radiolabeled nucleotides, and the quantification can be easily done with a phosphor plate as in the following example, displayed in Fig. 9.36 (Jendresen et al., 2011):
- **High-resolution protein gels**: For molecular biology experiments, a sharp separation of biomolecules is often needed, which requires the use of agarose gel or polyacrylamide gel electrophoresis. The electrophoresis can separate DNA fragments, which differ in length by only a single base pair. Phosphor screen technology is then widely used for this high-resolution DNA sequencing such as in the following example (Fig. 9.37) (Sharma et al., 2010):
- **Northern, southern, and Western blots**: Northern blots start with extraction of total RNA from a homogenized tissue sample or from cells. RNA samples are then separated by gel electrophoresis. Since the gels are fragile and no probe is able to enter the matrix, the RNA samples, now separated by size, are transferred to a nylon membrane through a capillary or vacuum blotting system. In a second phase, they are hybridized with a probe to analyze their abundance in the tissues and quantify gene expression. Quantification can be made by autoradioluminography or with digital autoradiography systems (Belair et al., 2011). Southern blots are a similar transfer technique on a nitrocellulose membrane to detect DNA fragments after hybridization

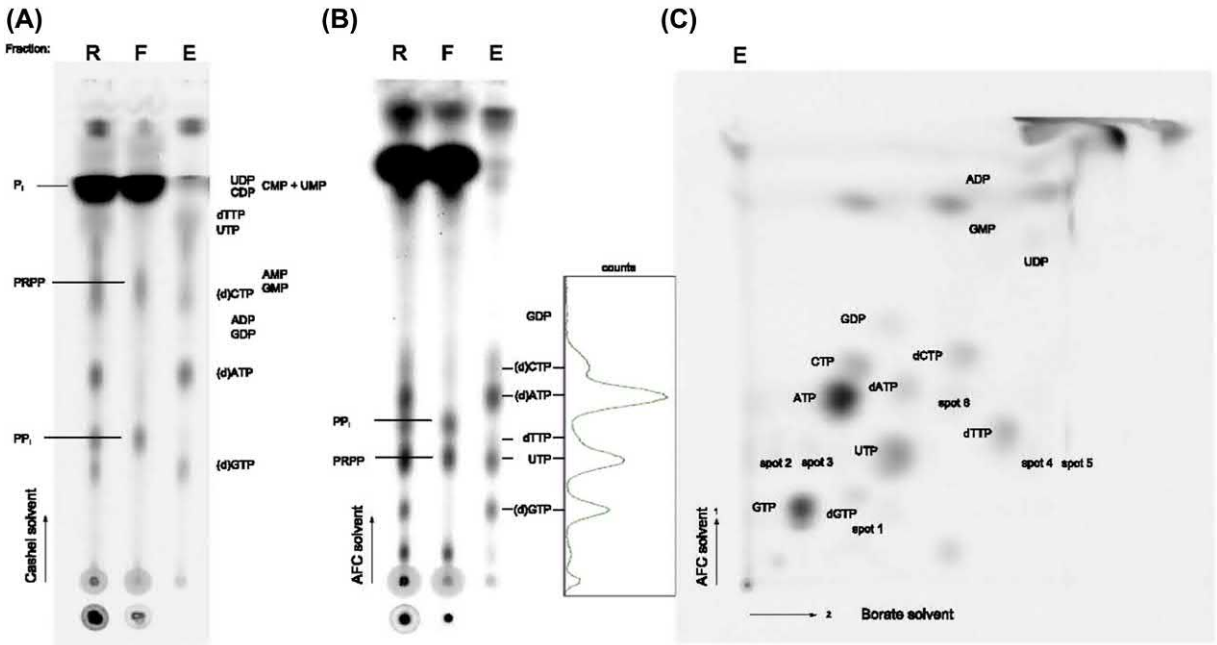

FIGURE 9.36 Thin-layer chromatography (TLC) of cell extracts: separation of nucleotides from a radiolabeled culture. An acid extract of *Lactococcus lactis* (raw (R) sample) was separated into a filtrate (F) and an eluate (E). Then an aliquot of the samples was separated by TLC either in one type of solvent (A) or in other type of solvent (B). Aliquots of diluted samples of the radioactive culture were spotted below the application points for measurement of total radioactivity. The radioactivity profile of the E lane is shown as well as a two-dimensional separation of an aliquot of the E sample (C). Quantitative determination of the nucleosides is made by autoradioluminography. See details in the text (Jendresen et al., 2011). *Printed with permission from Elsevier © 2011.*

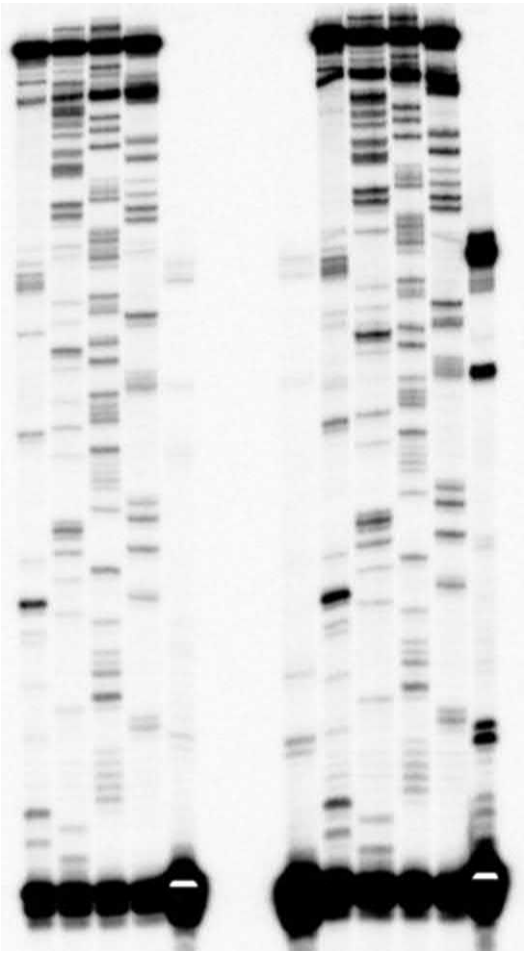

FIGURE 9.37 Example of a sequencing reaction resolved on a denaturing 5% polyacrylamide gel. Each lane G, A, T, and C contain the reaction for each dideoxynucleotide (Sanger sequencing method). In this experiment, the primer is 5′-end labeled with ^{32}P. *From Sharma et al. (2010). Reprinted with permission from Macmillan Publishers Ltd ©2010.*

with a complement probe. Western blots are an equivalent technique for proteins. In the following example (Fig. 9.38) of a Northern blot, microRNAs, posttranscriptional regulators of eukaryotic gene expression, are implicated in host defense against pathogens (*H. pylori*). The probe is labeled with ^{32}P, and the quantitative detection is by autoradioluminography.

E. Molecular imaging

As all imaging devices used for autoradiography are also sensitive tools for detecting radiopharmaceuticals used in nuclear medicine, various experiments with radionuclides of short half-life are possible with very high-spatial precision, as illustrated in Fig. 9.39. In this example, images exhibit a clear analogy between electronic autoradiography and film autoradiography of sections of a rabbit's kidney

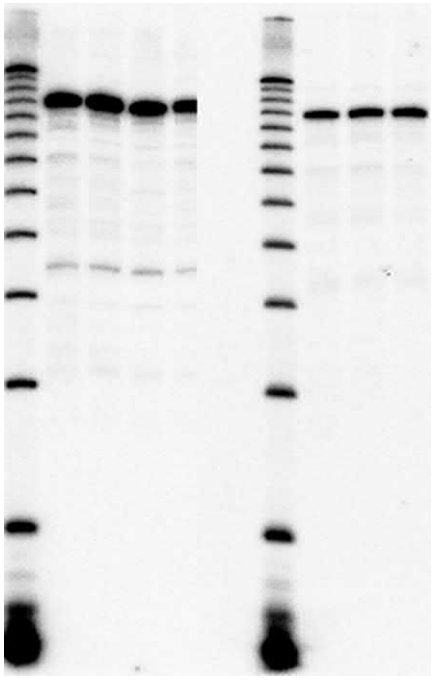

FIGURE 9.38 Example of a Northern blot analysis. A membrane is hybridized with a ^{32}P-radiolabeled oligonucleotide. The quantification is done by autoradioluminography with a PharosFX system (Belair et al., 2011). *Courtesy of Fabien Darfeuille.*

labeled with a ^{99m}Tc-radiopharmaceutical (Barthe et al., 2004).

In many experiments conducted in nuclear medicine early preclinical research, molecular imaging is used to visualize cellular function and to follow up a molecular process in living organisms without disrupting it. When nuclear medicine markers are used, a number of studies are performed both ex vivo by autoradiography of organ sections and in vivo by other radionuclide imaging modalities (e.g., SPECT, PET and, more recently, optical imaging). While in vivo imaging techniques are most important for such studies, ex vivo imaging is often required to validate in vivo results, as autoradiography can provide both high resolution and sensitivity. Autoradiography, combined with traditional molecular imaging methods, has therefore great potentials in many fields of translational research, including cancer, neurosciences, and cardiology (Temma et al., 2010; Dedeurwaerdere and Langlois, 2011; Ueda et al., 2011; Poisnel et al., 2012)

With recent developments in PET, SPECT, and multimodal imaging, investigations on molecular targets and their involvement in biological processes have considerably evolved in the past 20 years. Radiolabeled probes and contrast agents have been developed to investigate the molecular mechanisms of diseases and to assess therapeutic candidates in animal models using both in vivo and ex vivo methods.

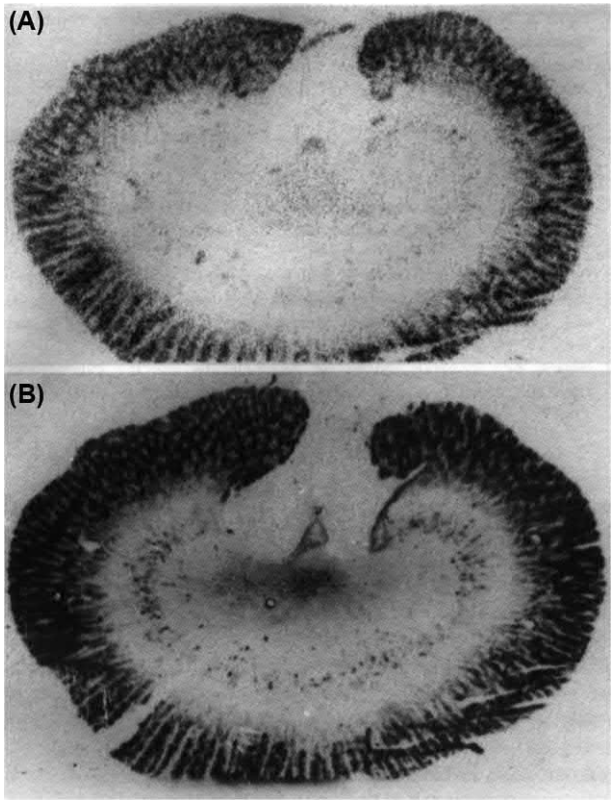

FIGURE 9.39 Beta imaging of the kidney of a rabbit injected with ^{99m}Tc-DMSA (section of 20 μm thickness) showing the renal distribution of the tracer after a 6-h acquisition with the BetaIMAGER TRacer (image A) and after a 24-h exposition on film (image B). The spatial resolution is similar in the two documents (Barthe et al., 2004). *Reprinted with permission from Elsevier © 2004.*

Beta imaging applications in the field of molecular imaging including both pre-clinical and clinical studies as well probe development will be considered later on in this chapter.

F. Nuclear waste decommissioning projects (analysis of potential radioactive contamination)

As nuclear power stations continue to age, the development of robust methods of characterization for their dismantlement, decommissioning, and remediation becomes of increasing importance. Characterization of nuclear waste is essential to optimize safety and efficiency in decommissioning and obtain representative calculations, in situ measurements, and samples/analyses providing an understanding of the radiological conditions that will be encountered during decommissioning.

Traditional methods for characterization involve a wide range of nondestructive and destructive techniques, which will vary depending on various factors such as the nature and intensity of the radioactivity, the physical and geometrical conditions, or the accuracy required for the result. Basic measurements of radiation fields with gas-filled detectors (ionization chambers, proportional, and Geiger–Müller counters) are well established. Nonetheless, while they may give rapid information on radiation levels for primary safety measures, they are not quantitative due to variations in distance between detector and monitored area. More accurate quantitation methods are therefore required to improve the geometric mapping and sampling process of contaminated areas. For instance, there is real need for innovative methods allowing precise measurements of low-energy, alpha and beta isotopes, which are more difficult to detect than gamma emitters (OECD and NEA, 2014). Current analytical methods are based on either topical smear samples or powder samples prepared by pulverization or pyrolysis followed by gamma ray spectrometry or LSC (Wang et al., 2007). More recently, the use of solid-state detectors has been described for precise and quantitative topographical measurements (Leskinen et al., 2013) and in situ quantitation (Haudebourg and Fichet, 2016).

Whereas excellent reviews on methods of characterization for decommissioning of nuclear installations are given elsewhere (IAEA, 1998; Laraia, 2012, Rehak, 2013), the focus of this chapter will be on digital autoradiography techniques. Digital autoradiography is particularly adapted to low- and medium-energy alpha and beta emitters (e.g., ^{3}H, ^{14}C, ^{36}Cl, ^{90}Sr). It allows sensitive measurements with a high dynamic range for quantitative purposes. Furthermore, digital autoradiography with direct photon-counting systems or multiple screen approaches allows the identification of isotope species according to their energy or decay, thus permitting discrimination of multiple emitters in composite samples (Haudebourg and Fichet, 2016).

Specialist laboratories such as the LASE laboratory, CEA, analytical support to facilities, France, or the National Nuclear Laboratory, Warrington, UK, have developed and proof-tested experimental protocols dedicated to the measurement of alpha and beta radiation for decommissioning facilities using various techniques, including digital autoradiography.

Current methods of digital autoradiography measurements for deactivation and decommissioning purposes are often adaptations of techniques from biological research and focus on mapping buildings under a dismantling process and sampling for predestructive analysis. Early work describing the use of digital autoradiography peculiarly originated from the building industry to study concrete cracking in delayed ettringite formation (DEF). Livingston et al. (2003) proposed to exploit the natural radioactivity of potassium (about 0.012% of all potassium is made of ^{40}K, roughly 89% of which decays by beta emission and 11% by electron capture with gamma ray emission) to monitor potassium levels in precast concrete bridge beams. Using

photostimulable storage phosphor plates, they produced digital autoradiography images of ^{40}K distribution in concrete cores with counting times of 24 h. Quantification of the radioactive signal confirmed increased potassium content in beams showing significant cracking from DEF-associated expansion compared with control beams.

More recently, Fichet et al. (2012) and Leskinen et al. (2013) demonstrated the applicability of the same reusable storage phosphor screen technology to measure ^{3}H and ^{14}C traces on concrete floor laboratories under dismantling process (Fig. 9.40). Floor areas of up to 285 m^2 were mapped with as little as 20 recycled standard size phosphor storage screens (12.5 × 25.2 cm, PerkinElmer). Digital autoradiography measurements could be compared with standard wipe test liquid scintillation, and although phosphor screens suffered from low limits of detection, they represented a cost-efficient and nondestructive approach with good quantitative results combined with precise information on space distribution of the remaining radioactive contamination. Other drawbacks to this method were the long exposure times required for detection of ^{3}H and ^{14}C. In addition, separate detection of ^{3}H and ^{14}C was not possible and had to be evaluated by wipe test for sampling and LSC for measurement.

To address this particular point, the same team developed two novel approaches to nondestructive identification of contaminating nuclides by phosphor screen stacking and differential phosphor screen analysis (Haudebourg and Fichet, 2016). They could profile 15 individual isotope species by plotting the ratio of measured signal between the layers (Screen n+1/Screen n) of a stack of up to 10 phosphor storage screens simultaneously exposed to the isotopes (Fig. 9.41). The technique was successfully applied to the identification of isotopes from steel blocks and drilled concrete cores.

For low-energy isotopes with nonpenetrating radiation (e.g., $^{3}H/^{233}U$), they exploited the availability of two types of phosphor storage screens, namely, TR (tritium) and MS (multisensitive) types from PerkinElmer. TR screens differ from MS screens by the absence of a thin protective overcoat layer that would block the nonpenetrative low-energy beta emission of ^{3}H. Isotope identification with the so-called "MS/TR" method simply consisted in calculating the ratio between signals measured with the MS type and TR type screens for the same sample, in identical exposure conditions, as shown in Table 9.4.

Although the two methods showed great potentials in characterizing individual isotopes, profiling of multielement mixtures and influence of matrix effects on emerging energy spectrum and transmission behavior remained to be addressed to fully validate these two approaches.

Novel methods of characterization may arise from both the biomedical and geological fields, which would allow rapid scanning times, high-resolution imaging, quantitative

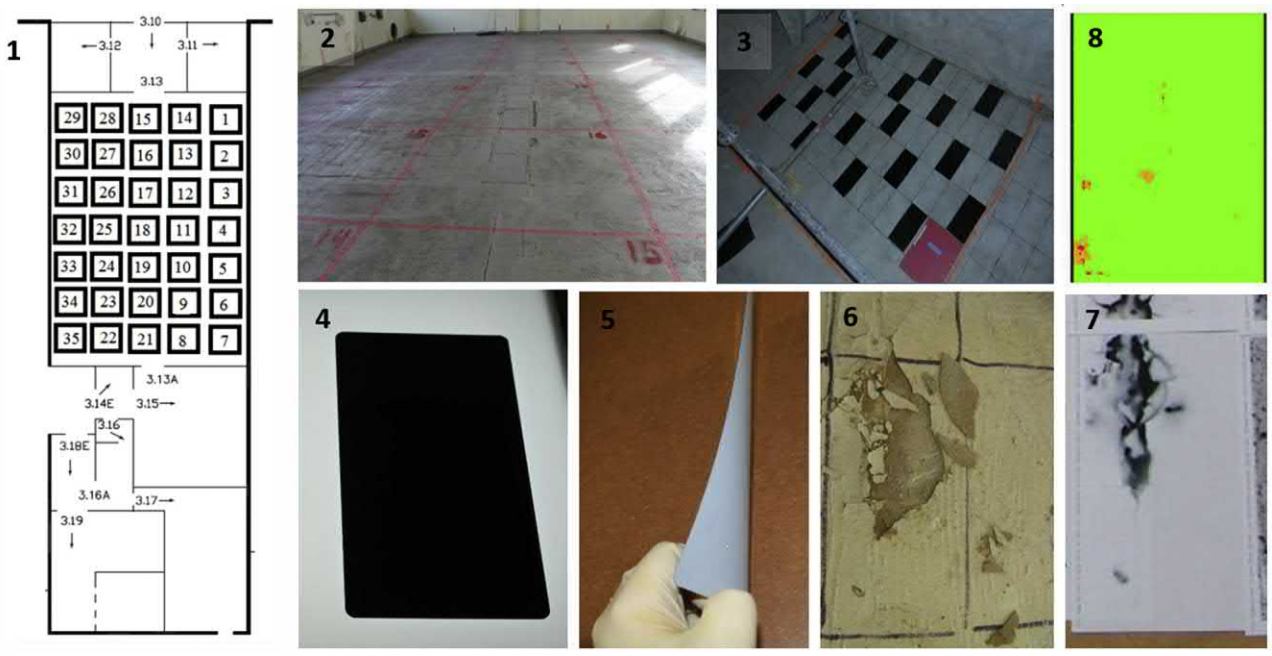

FIGURE 9.40 Geostatistical mapping of radioactive contamination in a contaminated laboratory using phosphor storage screen digital autoradiography. 1: Mapping of the area to be analyzed. 2: On-site delimitation of the monitored grid. 3: Homogeneous repartition of 20 phosphor storage screens over one area of the grid. 4: Storage phosphor screen. 5: Application of the phosphor screen on the flooring. 6: Typical contaminated area. 7. measurement, and isotope identification altogether. Digital autoradiography systems based on gaseous detectors, such as the BetaIMAGE TRacer (Biospace Lab, France) and BeaQuant (Ai4R, France) systems or solid scintillation–coupled photomultipliers (BetaIMAGER DFine, Biospace Lab), combine all the abovementioned capabilities. Their technology and applications in the biomedical field have been described in earlier chapters, and their potentials in the geological field emerged through various old and recent studies (Hellmuth et al., 1999; Ludwig et al., 2005; Sardini et al., 2016). Ludwig et al. (2005) used the BetaIMAGER DFine system to monitor the effect of light on $^{45}Ca^{2+}$ incorporation and spatial distribution in photic microbial mat calcic formations. Hellmuth et al. (1999) studied marble porosity by analysis of ^{14}C-polymethylmethacrylate impregnation patterns acquired with both BetaIMAGER TRacer and DFine systems. More recently, Sardini et al. (2016) demonstrated how specific tuning of the BeaQuant systems allowed the specific measurement of alpha emission from natural ^{238}U and ^{232}Th disintegrations in geological rock sections. Uranium radiation can also be measured with the BetaIMAGER systems, as shown in Fig. 9.42. As discussed in earlier chapters, both BetaIMAGER DFine and TRacer systems have proprietary algorithms exploiting the decay properties of short-lived isotopes and energy properties of long-lived isotopes for the specific identification of the radioactive signal associated with individual emitters in samples composed of isotope mixtures (Barthe et al., 2004; 2007; Maskali et al., 2005).

In conclusion, various digital autoradiography systems emerging from the biomedical field combine several advantages, including high sensitivity, high spatial resolution, fast sample analyzing speed, and isotope identification

TABLE 9.4 Ratios of signal measured with a multisensitive (MS)-type phosphor screen over signal measured with a tritium (TR-type screen in identical exposure conditions.

Radionuclide	Emission	Mean energy (keV)	MS/TR
^{3}H	Beta	6	
^{233}U	Alpha	4817	0.39
^{239}Pu	Alpha	5148	0.46
^{241}Am	Alpha	5542	0.49
^{244}Cm	Alpha	5795	0.55
^{14}C	Beta	49	1–1.6
^{55}Fe	X-ray	6	2
^{60}Co	Beta	96 + gamma 1253	3
^{137}Cs	Beta	188 + gamma 662	4.7
^{204}Tl	Beta	244	5
^{36}Cl	Beta	316	6.1
^{90}Sr/^{90}Y	Beta	562	6.5
^{40}K (concrete)	Beta	510 + gamma 1460	7.4

capabilities, which are necessary for the characterization of low-energy beta and alpha isotope contamination. Present and future developments of analytical methods exploiting these systems offer great potentials in the field of dismantlement and decommissioning.

VII. Perspectives and future developments

A. Autoradiography to validate in vivo imaging information

1. Preclinical applications. Development and validation of new molecular imaging probes

With advances in instrumentation and the introduction of novel targeted probes, molecular imaging has taken a major place in translational research. However, traditional in vivo techniques such as PET and SPECT present great constraints with regard to spatial resolution. To address this, multimodal imaging approaches, combining high-resolution anatomical information to high-sensitivity radiolabel imaging (PET-CT, SPECT-CT, PET-MRI), have been developed and are now commercially available for both preclinical and clinical applications. In addition, in vivo 3D tomographic information from optical genetic reporters (e.g., luciferase, iRFP) or functional fluorescent probes (e.g., MPPSense750, PerkinElmer or IRDye 680RD BoneTag, LI-COR Biosciences) can be aligned to anatomical information from μ-CT or preclinical MRI systems thanks to standardized digital imaging platforms such as DICOM (Digital Imaging and Communications in Medicine). In the near future, the synergy of multiple modalities should provide tools for better detection and quantification of optical and molecular targets. For instance, precise 3D anatomical information on organ localization, acquired by CT or MRI, may be used to correct optical and molecular quantifications by implementation of various physical parameters (e.g., scatter, absorption, refraction) inherent to individual tissue in the tomography algorithms (Young Chun, 2016). Meanwhile, ex vivo autoradiographic imaging remains the alternative of choice for high-sensitivity, high-resolution quantitation and localization of molecular markers in animal tissue. Examples of autoradiography applications to the validation of preclinical models of disease and the development of therapeutic strategies can be found for various biomedical specialties that are discussed in the following sections.

a. Oncology

In oncology, the biodistribution and specificity of new probes and drugs must be assessed and validated by PET imaging among other various imaging modalities, including autoradiography and histochemistry. Examples of such studies are given below (Alberini et al., 2015; Al-Ejeh, 2014; Wilson et al., 2014; Bailly et al., 2017).

Alberini et al. (2015) adopted a multimodal in vivo imaging strategy to monitor tumorigenesis and response to chemotherapy in a transgenic mouse model of mammary cancer. PET with 2-deoxy-2-^{18}F-fluoro-D-glucose (^{18}F-FDG)

and 3′-deoxy-3′-^{18}F-fluorothymidine (^{18}F-FLT) was applied, in conjunction with SPECT with ^{99m}Tc-TcO_4 (^{99m}Tc-TEC), X-ray computed tomography, fluorescent confocal endomicroscopy, and ex vivo autoradiography, to characterize tumor progression in female transgenic PyMT mice. Surprisingly, ex vivo autoradiography of lung tumor cryosections after ^{99m}Tc-TEC injection revealed uptake of ^{99m}Tc-TEC in only some of the metastases, suggesting reduced expression of the sodium-iodide symporter (NIS).

Wilson et al. (2014) used ^{18}F-NaF, a standard PET imaging probe for bone imaging to detect hydroxyapatite calcium deposits present in breast tumors by PET imaging. Biodistribution of ^{18}F-NaF was validated with high-resolution autoradiography combined with von Kossa histochemical staining. Bailly et al. (2017) evaluated novel molecular imaging probes, namely, ^{64}Cu-TE2A-9E7.4 (a ^{64}Cu-labeled anti-CD138 murine antibody) in a preclinical syngeneic model of multiple myeloma. Superior tumor uptake of ^{64}Cu-TE2A-9E7.4, compared with metabolic tracer $^{64}CuCl_2$, was quantified by digital autoradiography.

Al-Ejeh et al. (2014) characterized a murine monoclonal antibody DAB4 specifically targeted to apoptotic tumor cells. High-resolution autoradiography of excised PC-3 tumors showed binding of ^{177}Lu-DOTA-DAB4 within specific necrotic regions of the tumor as defined by histochemical hematoxylin and eosin staining.

Another excellent example was recently described (Kryza et al., 2016) where a group of chemists, geneticists, histopathologists, radiopharmacists, and nuclear physicists collaborated to prepare aptamers as new tumoral markers against a metalloproteinase involved in melanoma metastasis. Aptamers are three-dimensional oligonucleotides that can bind to a wide range of targets with high affinity and be chemically modified to act as specific tumor markers. Their tumor targeting efficiency was evaluated ex vivo by high-resolution beta imaging of tumor sections taken from mice bearing human myeloma implants and incubated with ^{111}In-DOTA-F3B aptamers, as illustrated in Fig. 9.43. Immunohistological analysis and fluorescence optical imaging confirmed the results.

b. Neuropharmacology

In neuropharmacology, quantitative assessment of the binding efficiency and selectivity of target peptides for specific neuroreceptors is carried out by digital autoradiography. Autoradiographic binding assays and receptor occupancy assays are indeed essential tools to determine fundamental pharmacological parameters, such as the dissociation constant (Kd), inhibitory constant (Ki), half maximal inhibitory concentration (IC50), and receptor occupancy (Bmax) from drug response curves.

An example of basic protocols to achieve quantitative film autoradiography to visualize serotonin (5-hydroxytryptamine, 5-HT) receptor subtypes in sections of frozen brain tissue was described by Cortes et al. (2016) (Fig. 9.44).

Other pharmaceutical applications may involve precise analysis of neuroreceptor biodistribution upon onset of neurological dysfunctions in dedicated animal models. Again, the high resolution achieved by autoradiography, combined with the fact that radiolabeling does not affect the organic chemistry of neuropeptide probes, thus ensuring optimal specificity for neuroreceptor binding, means that autoradiography is an essential tool for such studies. Representative examples include a study by Hu et al. (2017) looking at cannabinoid neuroreceptor biodistribution and one by Reid et al. (2016) investigating neuronal hypometabolism in HIV-1-associated cognitive disorder.

A novel approach of interest is described in Aitken et al. (2016) where quantitative autoradiography was applied to assess M1 muscarinic ACh receptor density in the hippocampus of rats following bilateral vestibular lesions. In this study, specific binding of ^{3}H-pirenzepine to rat brain cryosections was quantified by subtraction of the nonspecific binding signal measured in adjacent sections by coincubation of ^{3}H-pirenzepine with saturating amounts of cold pirenzepine. In addition, M1 receptor density in the specific hippocampus and striatum regions could be assessed by an overlay of the autoradiographic image acquired with the BetaIMAGER TRacer system to brain atlas information using the M3Vision analysis software (Fig. 9.45).

c. Psychopharmacology

Other applications are in the field of **psychopharmacology,** for example, receptor occupancy profiles of several NMDA (*N*-methyl-D-aspartate) receptor antagonists, which are of therapeutic interest for the treatment of mood disorders, participating in synaptic transmission and triggering synaptic plasticity, in comparison with the actions of ketamine, an analgesic agent studied for its antidepressant effect in individuals (Lord et al., 2013).

Similarly, studies with potential clinical impact use both ex vivo autoradiography and beta microprobes in vivo to examine the subcellular distribution of 5-HT1A receptors in dendrites from nucleus raphe dorsalis (autoreceptors) and hippocampus (heteroreceptors) after antidepressant treatment (Riad et al., 2004).

As another example, a recent study on cerebral metabolic depression following traumatic brain injury (TBI) validated glucoCEST-weighted imaging by chemical exchange saturation transfer (CEST) MRI with 2-deoxy-D-[^{14}C]-glucose (2DG) autoradiography in a closed-head model of diffuse TBI in rats (Tu et al., 2018).

As a last example, Sahlholm et al. (2017) examined whether genetic deletion of beta-arrestin2 prolonged or otherwise modified D2R-dependent responses, using

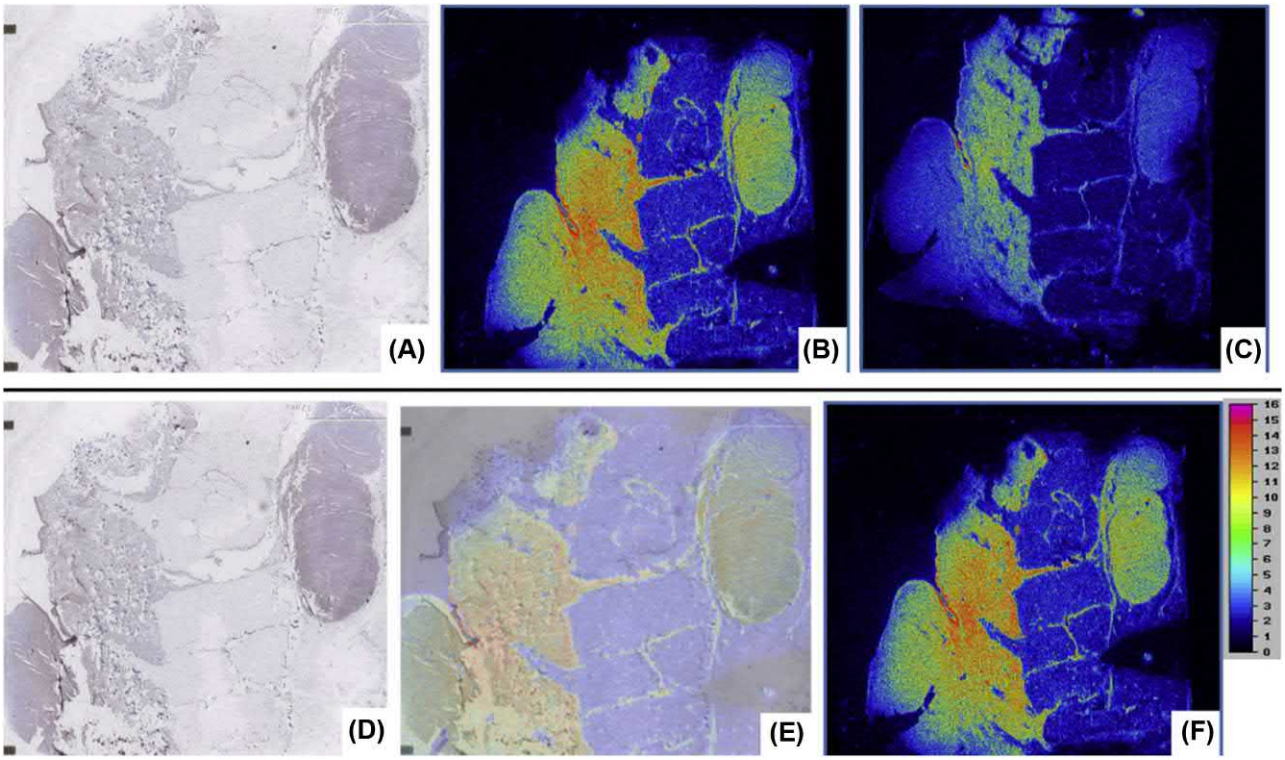

FIGURE 9.43 (A) Immunostaining of nodular melanoma using anti-hMMP-9 murine monoclonal antibody ab58803. Radiolabeling of adjacent tissue sections of nodular melanoma with ^{111}In-F3B-DOTA aptamers (B), and ^{111}In-DOTA-control sequence (C). (D) Immunostaining of nodular melanoma with the murine monoclonal antihuman MMP-9 antibody, ab58803. (F) Radiolabeling with ^{111}In-DOTA-F3B. (E) Merged immunostaining (D) and autoradiographic (F) images. Identifications of the primitive nodular melanoma and intrahypodermic nodes were possible with both techniques. Dark areas observed by immunohistochemistry correspond to regions of high radioactivity. For the color version of the figure, the reader is referred to the online version of the book. *Reproduced with permission from Kryza et al. (2016).*

functional magnetic resonance imaging (fMRI) to monitor blood-oxygenation-level-dependent signal changes induced with a dopamine agonist in wild-type and beta-arrestin2 knockout mice. Quantification was carried out by digital beta imaging with a BetaIMAGER TRacer system.

In the context of translational research, ex vivo beta imaging is also greatly involved in neuroinflammation studies in conjunction with in vivo multimodal imaging. Typical examples in Alzheimer's disease (AD), which is characterized by an accumulation and deposition of β-amyloid peptides and activation and exacerbation of inflammatory processes, are given below.

Current studies aim to develop or exploit specific radiolabeled biomarkers of amyloid plaque formation (Maeda et al., 2007; Yousefi et al., 2011; Manook et al., 2012; Marutle et al., 2013).

Maeda et al. (2007) first demonstrated how PET imaging could be used to monitor amyloid neuroinflammation with N-^{11}C-methyl-2-(4-methylaminophenyl)-6-hydroxybenzothiazol, ^{11}C-PIB ("Pittsburgh Compound-B") and ^{18}F-fluoroethyl-DAA1106, a radiotracer for activated glia. Ex vivo autoradiographic analysis was also applied to observe and quantify longitudinal amyloidosis-associated accumulation of ^{11}C-PIB in APP transgenic mouse brains.

Yousefi et al. (2011) evaluated the suitability of ^{18}F-labeled imidazo[2,1-b]benzothiazole (^{18}F-8) as a PET tracer for cerebral β-amyloid deposits in a transgenic mouse model of AD. Regional brain biodistribution and specific binding of ^{18}F-8 to Aβ was validated by autoradiography correlated to immunohistochemistry.

Marutle et al. (2013) applied an in vitro autoradiography imaging multitracer concept to investigate the relationship between regional neuroinflammatory processes, fibrillar Aβ deposition, and disturbances in cholinergic neurotransmission in AD brain using multiple binding studies with radioligands ^{3}H-L-deprenyl (activated astrocytes), ^{3}H-PIB (fibrillar Aβ), ^{3}H-PK11195 (microglia) as well as ^{125}I-α-bungaro-toxin (α7 nicotinic receptors, nAChRs) and ^{3}H-nicotine (α4β2 nAChRs) in postmortem brains from AD and nondemented patients. Using this multitracer imaging concept, they also characterized and compared the laminar distribution of activated astrocytes, fibrillar Aβ, as well as α7 and α4β2 nAChRs in hemisphere brain sections of an AD patient.

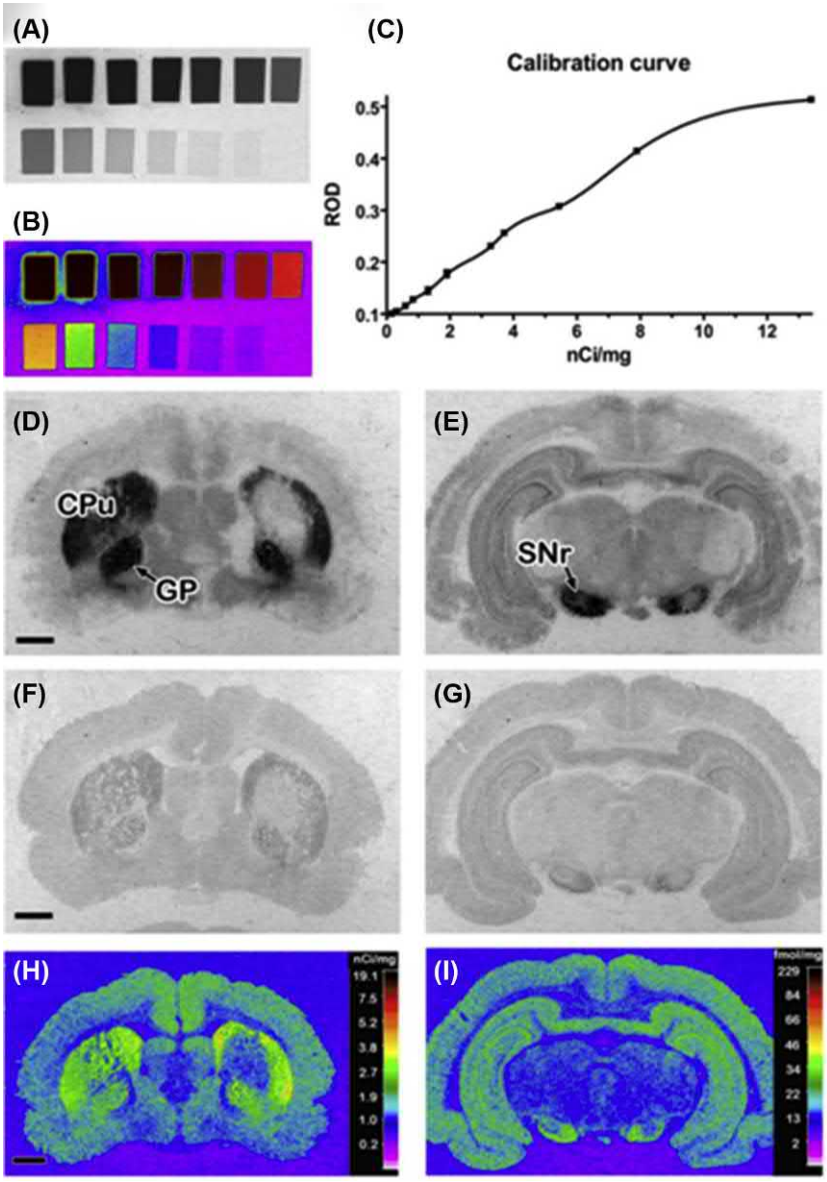

FIGURE 9.44 Quantitative autoradiography and brain lesion studies. Film exposure of radioactive standard scales together with incubated tissue sections allow for the quantification of the autoradiograms by microdensitometry. (A, B) Autoradiographic image of ^{3}H standards (American Radiolabeled Chemicals) exposed for 2 months and processed with an MCID image analyzer. (A) Gray levels or (B) RGB color-coded lookup table (LUT) rendering of the data. (C) Calibration curve produced from quantification of the ^{3}H standards from panels A and B. X-axis: Known standard radioactivity (nCi/mg). Y-axis: Recorded optical density (ROD). Smoothed spline is best fit curve. (D–I) Digital autoradiograms of 5-HT4 receptors in guinea pig brain. (D–G) Gray level representations (H, I). Color-coded representation of F and G. Sections in D and E were incubated with ^{125}I-SB 207710 prior to film exposure for 8 days. Consecutive sections (F and G) were incubated with ^{3}H-GR113808 and exposed for 2 months. Note that the ^{125}I-ligand provides stronger autoradiographic signal in much shorter exposure time than the ^{3}H ligand. The calibration of the MCID system with ^{3}H standards allows an overall estimation of receptor densities in different units, i.e., nCi/mg (H) or fmol/mg (I). Images taken from an animal that had received unilateral injections of quinolinic acid in the right striatum (CPu). The lesion resulted in the destruction of striatal neurons and a complete loss of local 5-HT4 receptors. Furthermore, a decrease in 5-HT4 binding sites also occurred in the ipsilateral substantia nigra pars reticulata (SNr), suggesting that these receptors might be localized on axon terminals of striatonigral projections. No major changes in binding to 5-HT4 receptors were observed in the globus pallidus (GP). Bar: 200 μm. For the color version of the figure, the reader is referred to the online version of the book. *Reproduced with permission from Cortès et al. (2016).*

Other studies in neurosciences may exploit multimodal molecular imaging tools to characterize pathology, course of disease, and treatment response. For instance, Buck et al. (2012) used MRI and PET/CT to image multiple sclerosis lesions in an animal model of autoimmune encephalomyelitis. Various PET tracers, namely ^{18}F-FDG, ^{18}F-FLT, and O-(2-^{18}F-fluoro-ethyl)-L-tyrosine (^{18}F-FET), were tested in comparison with MRI and autoradiography to select a suitable marker for in vivo detection of multiple sclerosis inflammatory lesions in patients.

A beautiful example of multimodal cross-validation for PET results with ex vivo and in vitro methodologies taken from Manook et al. (2012) is shown in Fig. 9.46.

d. Cardiovascular research

In cardiovascular research, functional information from molecular imaging studies is validated ex vivo with high-resolution quantitative beta imaging.

Good examples in the field of coronary artery disease where inflammatory cellular apoptosis processes are involved in atherosclerotic plaque rupture in rabbit aortas were described by Hyafil et al. (2015). They used PET imaging to monitor accumulation of ^{18}F-ML-10 (2-(5-fluoro-pentyl)-2-methylmalonic acid in apoptotic cells present in specific membrane. A strong correlation between the number of apoptotic cells on histological sections and the accumulation of the radiotracer by autoradiography was

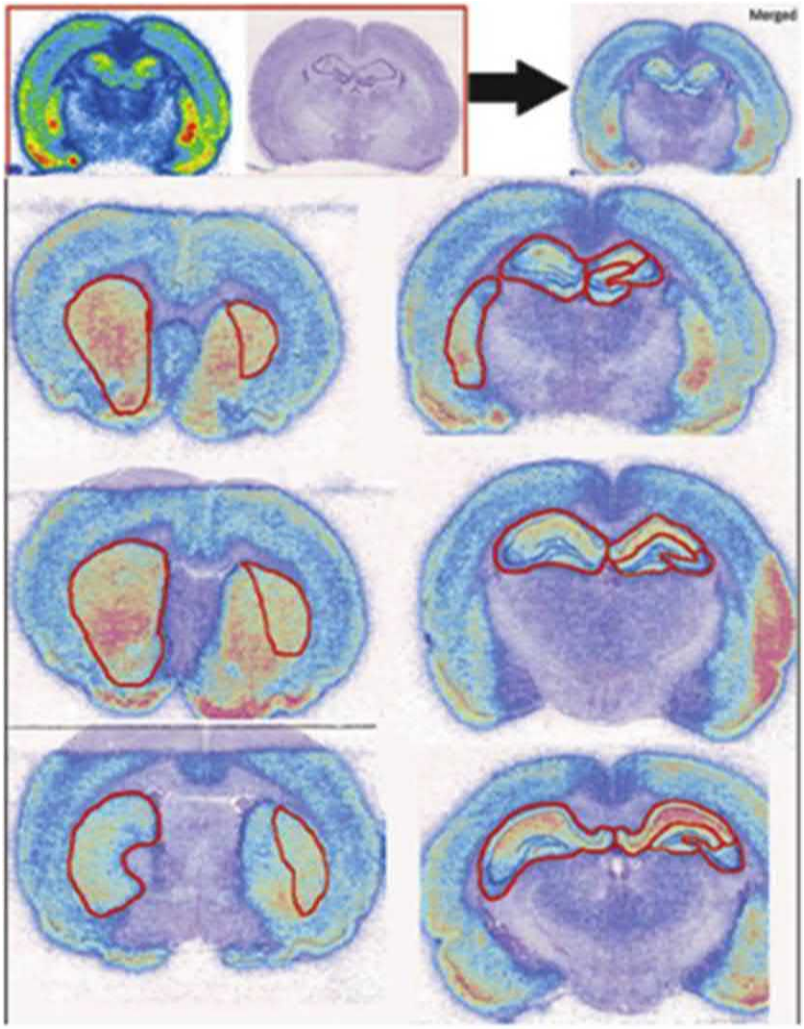

FIGURE 9.45 M1 ACh receptor expression following bilateral vestibular lesions using beta imaging autoradiography. The hippocampus (total, CA1, CA2/3, and DG) and caudate putamen (total, dorsal parafascicular inputs) were manually delineated using merged autoradiographic and histological images. For the color version of the figure, the reader is referred to the online version of the book. *Reproduced with permission from Aitken et al. (2016).*

also demonstrated. In a similar study, Tarkin et al. (2017) developed a novel cell−specific PET tracer (^{68}Ga-DOTATATE) targeted to somatostatin receptor subtype-2 and assessed its efficacy for imaging atherosclerotic inflammation. Moreover, they transposed the methodology to clinical studies where they could evaluate the risk of plaque rupture in ischemic stroke patients by PET imaging.

At the cardiac level, many studies focus on the metabolic mechanisms involved in infarction and consider angiogenesis as part of the repair process after ischemic injury. ^{18}F-labeled glycosylated $\alpha_v\beta_3$ integrin antagonist (^{18}F-galacto-RGD) is a recently introduced PET tracer that was shown to target specifically $\alpha_v\beta_3$ integrin expression. Higuchi et al. (2008) used ^{18}F-galacto-RGD PET imaging to study serial changes in myocardial uptake after ischemic intervention. Results were validated by autoradiography with a phosphor imager. Dual tracer autoradiography with ^{18}F-galacto-RGD and the myocardial imaging agent ^{201}Tl was also carried out in a rat heart to delineate risk areas during coronary occlusion with the BetaIMAGER DFine. In an earlier study, Maskali et al. (2005) managed to produce a wonderful triple-isotope autoradiographic image showing the metabolic processes of glycolysis (^{18}F-FDG), perfusion (^{99m}Tc-Sestamibi), and fibrosis (^{111}In-DTPA) involved in myocardial infarction using the BetaIMAGER DFine. This study is more thoroughly described earlier in Section IV-D.3 (Fig. 9.30).

e. Pneumology

In pneumology, there is a need for a whole-body imaging techniques that can detect pathogens at the early phase of infection and provide information on bacterial burden in response to targeted delivery of a powerful treatment.

Li et al. (2018) studied the efficiency of 2-^{18}F-fluorodeoxysorbitol (^{18}F-FDS) as an alternative to ^{18}F-FDG, which cannot distinguish infections from other

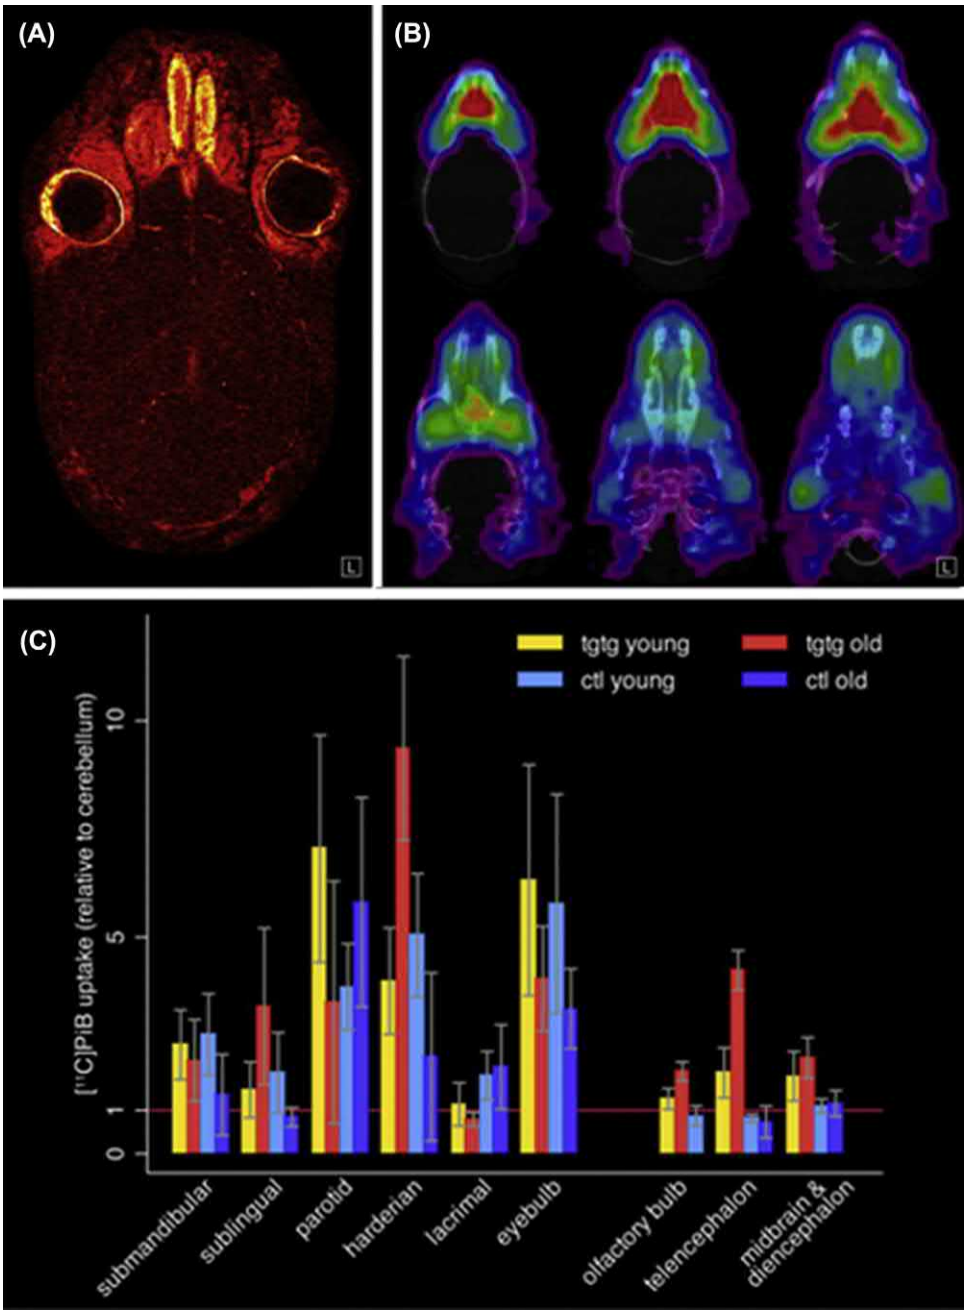

FIGURE 9.46 Extracerebral tracer retention. High ^{11}C-PiB uptake in regions frontal to the brain was accurately validated to be extracerebral. (A) Cranial ^{3}H-PiB ex vivo autoradiography. 15-μm-thick section of a complete mouse head showing exact anatomical locations of unspecific tracer retention. (B) CNS removal during $^{[11}$C-PiB PET. 9-month-old male homozygous APP/PS1 mouse was scanned in vivo for 30 min before the complete brain was extracted and scanned for further 30 min together with the skull. The skull of the ex vivo ^{11}C-PiB PET scan is coregistered to a cranial CT for better orientation and shown on six horizontal slices, which are 1 mm apart (top left horizontal level at about 21.9 mm Bregma in correspondence to all other figures). Both parotid glands can be seen on the bottom section. (C) Ex vivo biodistribution of ^{11}C-PiB relative to cerebellar uptake in glandular tissues and eye bulbs in both homozygous and control study groups. For the color version of the figure, the reader is referred to the online version of the book. *Reproduced with permission from Manook et al. (2012).*

afflictions such as cancer or inflammation, as its uptake remains nonspecific for bacterial imaging. ^{18}F-FDS is a derivative of the metabolic substrate for Enterobacteriaceae, Sorbitol. Uptake of ^{18}F-FDS and ^{18}F-FDG in mice inoculated intratracheally with either live or dead *Klebsiella pneumoniae* to induce either lung infection or lung inflammation, were compared by PET/CT during disease progression. The authors demonstrated the superior efficiency of

^{18}F-FDS in differentiating *K. pneumoniae* lung infection from lung inflammation compared with ^{18}F-FDG. Dual-label quantitative autoradiography imaging could have been used as a validating modality in this context.

f. Nephrology

In nephrology, the early detection and treatment of allograft rejection are crucial to limit the inflammatory process and preserve organ function after transplant. Reuter et al. (2010) proposed ^{18}F-FDG PET as a method to monitor acute rejection in an allogeneic-rat renal transplant (aTX) model. The rats were treated with cyclosporine A (CSA) to induce immunosuppression, and their response to treatment was compared with those of rats undergoing renal failure and an untreated control group. PET results were confirmed by histologic, functional parameters and autoradiographic analysis.

In another study, Gulaldi et al. (2013) investigated the applicability of a kinetic model based on three compartments (one blood and two tissue compartments connected in parallel) for the quantitative analysis of the renal kinetics of ^{11}C-KR31173, a PET radiotracer for the angiotensin II subtype 1 receptor (AT1R). Validation of the model was carried out by PET imaging in domestic pigs subjected to acute arterial occlusion followed by reperfusion to induce renal ischemia. The input function required for compartmental and for noncompartmental (deconvolution) analyses was obtained from metabolite-corrected arterial plasma samples. Differential binding of ^{11}C-KR31173 in renal cortex and medulla together with AT1R specific binding of ^{125}I-[Sar^{1}Ile^{8}]Ang II after AT2R antagonist PD-123,319 was quantified by digital autoradiography.

g. Biomaterial applications

In biomaterial applications, the development of biocompatible and bioactive biomaterials requires the study of their biodistribution and pharmacokinetic properties to better understand their metabolic fate. This implies radiolabeling to follow their localization and interactions with living tissue. In an experiment from Pant et al. (2015), a bioactive nanoscale water-soluble polymer, namely, dendritic polyglycerol sulfate (dPGS), was synthesized and radiolabeled with ^{3}H and ^{64}Cu to investigate its behavior in healthy mice and rats and determine its biodistribution both in vivo by PET imaging (^{64}Cu) and ex vivo by quantitative autoradiography (^{3}H). dPGS and its derivatives are known to exhibit antiinflammatory properties. The authors were therefore hoping to demonstrate its suitability for therapeutic and diagnostic applications. However, their results revealed a substantial organ accumulation of dPGS and its biometabolites, even after 3 weeks, setting doubts on the applicability of dPGS as a therapeutic agent. However, the neutral polymer dPG, which has inert properties, showed much improved renal clearance, suggesting that dPG might be a more suitable approach to a therapeutic candidate.

2. Clinical applications

The examples of autoradiography applications presented up to this point in this chapter were mostly linked to fundamental research or preclinical research. However, beta autoradiography imaging may also be applied in the clinical field to refine the characterization of established clinical radiotracers or validate their application for purposes other than their original use. Moreover, novel direct applications of autoradiography in the clinical theater are currently emerging where high-sensitivity and high-resolution data on radiotracer localization is to be rapidly collected and used as an input for surgical procedures. Examples of autoradiography applications in a clinical context are given below.

A set of clinical studies exploited a novel, last generation, high-affinity translocator protein (TSPO) radioligand, ^{18}FGE-180, for clinical PET imaging of patients to monitor inflammation. Unterrainer et al. (2018) examined the suitability of ^{18}FGE-180 as a clinical PET imaging radiotracer for patients with relapsing–remitting multiple sclerosis (RRMS) by comparing its ability to detect active inflammatory lesions with gold standard, contrast-enhanced MRI. TSPO PET with ^{18}F-GE-180 showed excellent performance for both visual and quantitative detection of focal microglia/macrophage activation in patients with RRMS. ^{18}F-GE-180 signal intensity corresponded to binding levels predicted from the patients' TSPO genotypes, which were classified as high-, medium-, or low-affinity binders (HAB/MAB/LAB). Lesions with only moderate or low inflammatory activity could be depicted. Moreover, high focal uptake was observed, not only in patients with HAB and MAB status but also in patients with LAB status. The results were in accordance with an earlier study from Fan et al. (2016) looking at the kinetic properties of ^{18}F-GE-180 in healthy patients. More recently, Narayan et al. (2018) evaluated cellular TSPO expression in knee synovium by PET imaging of second generation radioligand ^{11}C-PBR28 in both healthy volunteers and patients suffering from rheumatoid arthritis (RA). Cellular expression of TSPO in synovial tissue cryosections prepared from ultrasound-guided biopsies was evaluated through ^{3}H-PBR28 autoradiography. The results confirmed significantly higher ^{3}H-PBR28 binding in RA synovial tissue compared with healthy tissue and significantly correlated with TSPO immunohistochemical data.

Other studies describe direct autoradiography measurements on patient biopsies. Reubi et al. (1990) quantified the levels of somatostatin receptors in small needle tumor biopsies taken from liver metastases using two iodinated somatostatin analogues, namely [Leu8, Dtrp22, Tyr25]somatostatin-28 and octapeptide (Tyr3-octreotide). More recently, Fanchon et al. (2015, 2017) described a real-time ^{18}F-FDG PET/CT-guided biopsy procedure to reduce tumor registration errors during surgery. PET/CT scans acquired before and after needle insertion were registered using a deformable image registration algorithm for

evaluation and correction of the error in needle placement during biopsy.

In a follow-up paper, Kirov and Fanchon (2018) examined the suitability of this approach to produce adequate specimens for genomic analysis using digital autoradiography to quantify their metabolic activity. Quantitative particle-counting digital autoradiography of biopsy specimens acquired under ^{18}F-FDG PET/CT guidance produced signals with sufficient signal-to-noise ratio for samples with average activities of 3−9 kBq/mL, thus corresponding to the number of cells required for genomic analysis. Acquisitions could be carried out in less than 10 min, allowing enough time for procedure guidance. Moreover, autoradiography of the biopsies using either phosphor storage screens or the BetaIMAGER DFine system (Biospace Lab, France) showed sufficient resolution to quantify distribution of the activity along the specimens and define benign versus malignant sections as confirmed by histological analysis (Fig. 9.47).

Therefore, the combined approach of PET-guided biopsy and autoradiography analysis of biopsy specimens has great potential, not only for genomic profiling of tumors but also for other applications such as tumor boundary measurements, and could significantly increase the efficiency of biopsy procedures for cancer diagnosis as well as providing important input during surgery.

3. Bremsstrahlung radiation imaging

Bremsstrahlung is a very well-known physical phenomenon, used, for example, in any type of radiology equipment.

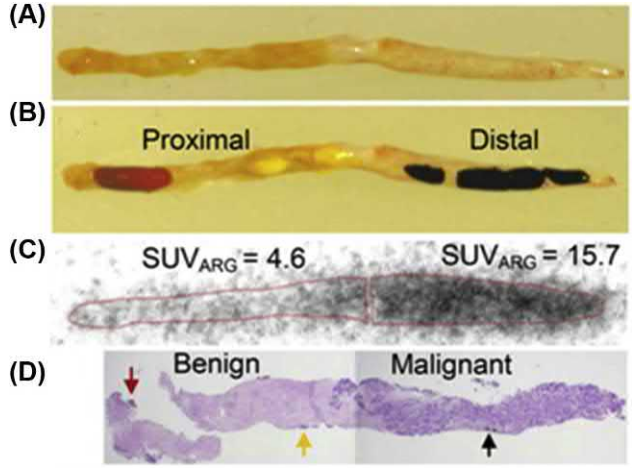

FIGURE 9.47 (A and B) Photographs of biopsy specimen from a patient with before (A) and after (B) marking with red, yellow, and black ink. (C and D) Corresponding autoradiograph (C) and histopathology slide (D). Colored arrows point to areas on micrograph where the ink marks are visible. For the color version of the figure, the reader is referred to the online version of the book. *Image reproduced with permission from Fanchon et al. (2015).*

When an electron or a beta particle passes through matter, it slows down, and a fraction of its energy is directly converted into X-rays. The spectrum of X-ray emission is continuous, and its maximum energy is the initial energy of the electron. For example, a beta emitter such as ^{14}C can emit X-rays of up to 156 keV in any given sample. The same phenomenon is used to produce X-rays in most X-ray sources. The Bremsstrahlung yield is actually proportional to the atomic number of the media and "roughly" proportional to the square of the energy (Evans, 1955). In the case of a biological tissue, the atomic number is low (between 7 and 8), and the yield stays very low. For ^{90}Y ($E_{max} = 2.2$ MeV), only 1% of the energy is converted into X-rays, i.e., 20 keV per beta particle, spread over a spectrum, the maximum energy of which is 2.2 MeV. In terms of probability, less than 20% of beta particles give an X-ray that can contribute to form an image. As usual collimators used for scintigraphy have an efficiency of 100 cps/MBq, even for high-energy beta-emitting isotopes, the total efficiency of Bremsstrahlung imaging is never more than 20 cps/MBq. For a lower-energy tracer, such as ^{14}C, the yield is at least 100-fold weaker and therefore not suitable. Bremsstrahlung radiation imaging is therefore mainly used in clinical imaging, where it is combined with high-energy tracers requiring visualization that could not be seen otherwise. A good example is ^{90}Y, a tracer widely used for radiotherapy. Bremsstrahlung scintigraphy allows imaging of the specific localization of the tracer to target tumor sites (Kim, 2011).

4. Cerenkov luminescence imaging

Bremsstrahlung yield combined with the poor efficiency of gamma collimators makes bremsstrahlung imaging more suitable for higher-energy beta isotopes, such as ^{32}P and ^{90}Y. For such isotopes, and in preclinical imaging, another alternative is to utilize the Cerenkov effect. The Cerenkov effect occurs when an electron travels faster than the speed of light in a medium. (The threshold energy for the Cerenkov effect with beta particles is 300 keV in biological tissue.) Along its path, the electron polarizes the medium that emits light when relaxing. This phenomenon will be familiar to some as the blue light seen on pictures of nuclear reactors. Theoretical analysis of the phenomenon and formulas to express the photon yield can be found in several references (Mead, 1958; Landau et al., 1960; L'Annunziata, 2007, 2016) and in Chapter 6, Volume 2 of this book. The Cerenkov light emits predominantly in the UV blue part of the visible spectrum, but a nonnegligible fraction also is emitted in the red part of the spectrum. Red photons can penetrate more than 1 cm deep across biological tissues (although they become strongly diffused) and can be detected outside the animal with a sensitive camera. To be more precise, the yield of Cerenkov visible

light is in the range of 350 ph/s/Bq (depending on the energy of the isotope), which leads to a typical brightness emitted by the surface of the animal in the range 10^4–10^5 ph/s/cm^2/sr for 15 MBq injected. Sensitive cameras capable of detecting these photons are used typically for bioluminescence imaging. Of course, due to the strong absorption and diffusion of light in tissues, this measurement is neither spatially accurate (3 mm) nor really quantitative. But the compactness and the wider availability of optical imagers compared with dedicated animal SPECT systems make Cerenkov a strong alternative to Bremsstrahlung radiation imaging. It is also a complementary technique to PET imaging for fast screening because the acquisition time is shorter than that for PET images.

Although this new technique does not allow high resolution, bimodal analysis is possible with a first series of optical in vivo measurements for screening and subsequent semiquantitative analysis, followed with a series of ex vivo autoradiography for precise quantification and localization. Finally, the sensitivity of certain bioluminescence optical imagers equipped with either EMCCD or iCCD cameras, such as the PhotonIMAGER (Biospace Lab, France) or the IVIS Kinetics systems (PerkinElmer, USA), permits the monitoring of radiotracer biodistribution in real time, as shown in Fig. 9.48.

In this example, the acquisition was made with an optical imager (PhotonIMAGER RT, Biospace Lab), which can work in photon counting mode (with list mode file data) for low light level. The three images are superimpositions of the Cerenkov list mode file with a photographic image, acquired shortly afterward with the same apparatus.

As mentioned earlier, the minimum energy required for an electron to produce Cerenkov light in a biological tissue is around 300 keV, but the yield becomes compatible with optical imaging only over 500–600 keV for beta tracers (or internal conversion electrons). Among these, one can include all PET tracers (^{18}F, ^{11}C, ^{13}N, ^{15}O), high-energy autoradiography isotopes (^{89}Sr, ^{32}P), and radiotherapy tracers (^{90}Y, ^{131}I). The list of isotopes potentially suitable for Cerenkov imaging is extensive and open to a wide range of applications, including some alpha tracers used for radiotherapy, which exhibit also a high-energy beta emission (alpha particles only produce Cerenkov light in the range of GeV, which is much higher than the energy of alphas emitted by nuclei). Illustrated Figs.9.49–9.51 are typical Cerenkov images using ^{32}P and ^{18}F-FDG as tracers.

In Fig. 9.49, 15 MBq of $Na_2H(^{32}P)O_4$ was injected 4 hours prior to imaging. Following the administration of the radionuclide tracer, the probe found that the radiotracer concentrated in rapidly proliferating tissues with high phosphorus content, such as bone marrow, lymph nodes, liver, and spleen. The distribution is also enriched in tumors, uptake being much higher in neoplastic tissues (Kautz, 1956). The two tumors are clearly visible by Cerenkov imaging (acquisition time: 5 min).

An interesting comparison on the same animal between a^{18}F-FDG PET image obtained with a small animal PET scanner and a Cerenkov image acquired with a cooled CCD camera is shown in Fig. 9.50. Even though the Cerenkov data are only semiquantitative, due to light absorption, a clear correlation between the two images can be established. For a more detailed description of imaging applications with the Cerenkov Effect, see works by Roberstson (2011), Ruggiero (2010), and Boschi et al. (2011).

In a review on Cerenkov imaging, Thorek et al. (2012) emphasized that Cerenkov luminescence imaging (CLI) was still an "emerging hybrid modality that utilizes the light emission from many commonly used medical isotopes and is of considerable interest as it enables the use of widespread luminescence imaging equipment to visualize clinical diagnostic (all PET radioisotopes) and many therapeutic radionuclides." The use of CLI to achieve imaging in preclinical models was also described. Other clinical applications of CLI, such as intraoperative

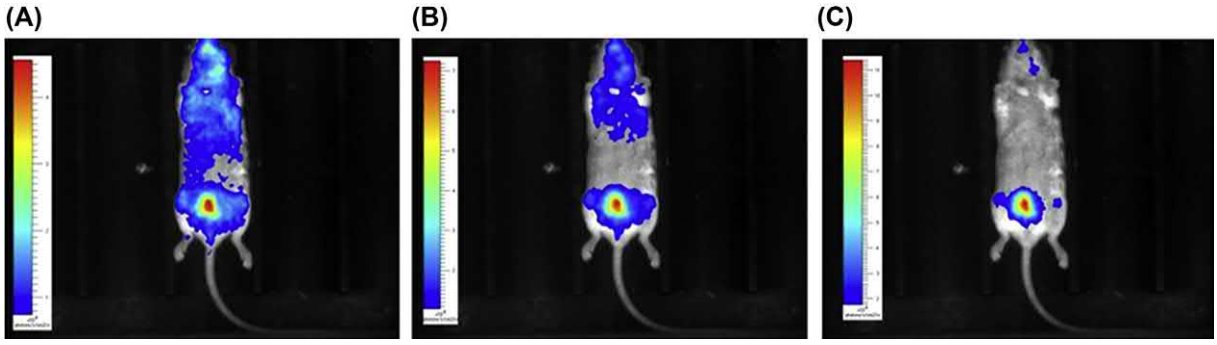

FIGURE 9.48 Example of biodistribution visualized by Cerenkov imaging following intraocular injection of 1.5 MBq ^{90}Y. Biodistribution of the radiolabel signal was followed in real time using the PhotonIMAGER RT system. Representative images are extracted from the temporal sequence. Signal integration at (A) 0–500 s, (B) 1000–1500 s, and (C) 2000–2500 s postinjection. Progressive accumulation in the kidney and clearance in the bladder can clearly be seen (Nicole Barthe, unpublished work). radionuclide-guided surgery, therapeutic efficiency monitoring, and tomographic optical imaging, have been evoked elsewhere (Spinelli et al., 2010). Moreover, the ability to perform multiplexed imaging using fluorophores excited by Cerenkov radiation is also emerging (Jain et al., 2015; Roussakis et al., 2015). Hence, Cerenkov imaging has great potentials to join the battery of traditional in vivo optical imaging tools (including fluorescence and bioluminescence, Optoacoustics, and Raman spectroscopy) for routine biomedical studies, perhaps in conjunction with other molecular imaging modalities, as shown in Fig. 9.51.

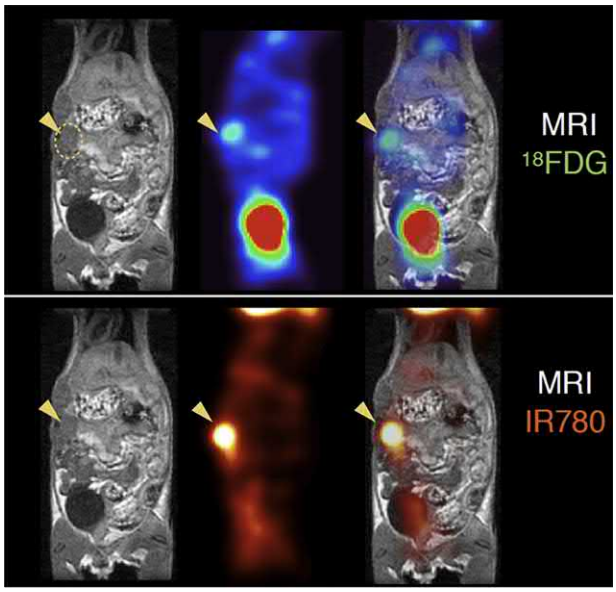

FIGURE 9.51 Multimodal tumor imaging of an orthotopic cecal tumor (2×10^6 cells) visualized by Cerenkov imaging with ^{18}F-FDG (500Ci/mouse injection i.v.). Fluorescence imaging with IR780 (0.2 mg/kg, injection i.v.) and MRI. Optical tomographic information (Cerenkov and FLI) was aligned to MRI data via DICOM. Arrows show positioning of the cecal tumor. Strong clearance of ^{18}F-FDG in the kidney can also be observed (top panel). Right panel, MRI. Central panel, Cerenkov (top) and FLI (bottom). Right panel, MRI/optical overlay. B. Autoradiography and alpha-particle imaging

Alpha particles are highly ionizing particles and can be of course imaged in the same way as beta particles are. Therefore, autoradiography is occasionally carried out with alpha-labeled samples. Nevertheless, their very short range and their large stopping power come with the following restrictions:

- Alpha particles must be imaged using detectors without a protecting layer.
- Alpha samples must be preferentially in contact or embedded in the imager.
- Imaging parameters must be adjusted due to a higher energy deposit.

The conundrum of the very short alpha-particle range can be solved by the use of TR screen when the chosen imaging technology is phosphor storage screens. The exposure time must be determined carefully because the energy deposition is, most of the time, much higher (several MeV per alpha particles, in comparison with the mean energy of tritium or ^{14}C, respectively, of 5.7 and 49 KeV). An example of

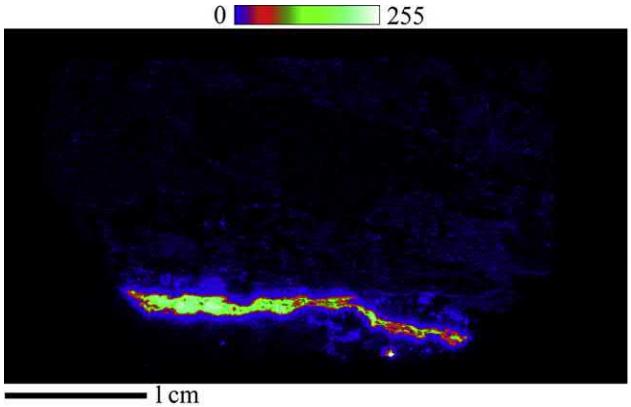

FIGURE 9.52 Autoradiography of an uraninite vein with the BeaQuant system. Exposure time is 40 h. For the color version of the figure, the reader is referred to the online version of the book. *Image printed with permission from Sardini et al. (2016).*

autoradiography measurements with a sample emitting alpha particles using a phosphor screen is shown in Fig. 9.41.

Particles counting detectors, especially gaseous detectors, are also convenient for autoradiography of alpha particles with a restriction regarding the applied voltage, which needs to be reduced in comparison with voltage applied for beta particles. This voltage reduction is important to limit the risk of discharge, which increases when the primary ionization is very large, as in the case of alpha particles. Therefore, the gaseous detector–based systems, such as the BetaIMAGER TRacer or BeaQuant, include a dedicated mode for alpha particles in their software. An example of alpha emission measurements from natural ^{238}U and ^{232}Th disintegration in geological rock sections (Sardini et al., 2016) is shown in Fig. 9.52.

VIII. Conclusions

Autoradiography was the first molecular imaging technique used for the localization of radiolabeled compounds in biological specimens. During the past 50 years, its importance has been essential, and it is still used due to its unequaled spatial precision, especially at a subcellular level. In parallel, over the years, technology has widely improved the acquisition time and quantification with phosphor plate technology. More recently, a new generation of real-time counting imagers allows researchers to optimize the exposition time. Their very low background and consequently very high sensitivity allow the detection of radionuclides of short half-life with the capacity of preserving reliable relationships between counts and radioactive concentrations over a large dynamic range. Moreover, their specific detection process allows the discrimination of several radionuclides in the same experiment.

All of these techniques are involved in new developments in association with other technological processes, such as laser desorption/ion mass spectrometry, providing subtle solutions to an old and difficult problem, namely, the separation between parent drugs and their metabolites. Finally, taking advantage of the detection of concomitant emissions (e.g., Bremsstrahlung or Cerenkov radiation) opens up new horizons in the field of bimodal imagery for ex vivo and in vivo parallel experiments of great interest in many molecular imaging applications.

Nicole Barthe

Dr. Nicole Barthe is a graduate of Nuclear Physics at the Faculty of Sciences of Bordeaux in 1975 and holding a Diploma of Study and Research in Human Biology (DERBH) in 1982 and Pharmacist in 2004. She held teaching and research positions at the joint laboratory Biophysics-INSERM Unit 1026 (Tissue Bioengineering: BioTis) at the University of Bordeaux and a position of Hospital Practitioner in Nuclear Medicine (Radiopharmacy) and Radiology (Bone Densitometry) until September 2017. Since the 1990s, Nicole Barthe worked in a scientific collaboration with the research teams of Nobel Laureate Prof. Georges Charpak (Biospace Measures, then Biospace lab). She has considerable experience in the imagery of radioactivity that she practices at the BioTis Laboratory and in the field of nuclear medicine over a period of many years. She is specialized in preclinical research using radioactive tracers, in particular, including the use of autoradiographic methods and high-resolution imaging of beta emitters.

Serge Maîtrejean

Serge Maîtrejean holds a PhD in Nuclear Physics from the University Paris VII (Diderot). He spent his first 10 professional years as Research Engineer and Project Manager working for Homeland Security on Cargo X-ray Inspection Systems and Explosive Detection Systems in luggage. Then, in 1996, he changed to the field of biomedical imaging, being Chief Scientist Officer and later Chief Operational Officer of Biospace Lab. During these years, he has developed numerous innovations as low-dose X-ray scanner for orthopedic diagnosis (EOS), systems for real-time autoradiography, preclinical gamma camera, and bioluminescence/fluorescence/Cerenkov imager. His extended expertise in imaging covers as well physics, mechanics, electronics as algorithmic, reconstruction, and software. He is currently consultant for companies working in the biomedical domain as well for companies working on security.

Nicolas Carvou

Nicolas Carvou holds a PhD and a BSc (hons) in Applied Biology from Nottingham Trent University, as well as French and European Technology Diplomas in Biomedical Sciences from the University Paris XII. Nicolas was awarded second place at the UK Universities Biotechnology in business competition (1995–96) and worked for several biotech companies, including the European Collection of Animal Cell Cultures (ECACC) and Molecular Light Technology Ltd, UK (now part of Gen-Probe, USA). Following a postdoctoral position at the Dana Farber Cancer Institute, Harvard Medical School (2001–2002), a research assistantship and associateship in the Department of Physiology, University College London, Nicolas joined the Biospace Lab in 2011 and was rapidly promoted to Scientific Applications Manager in 2012 and Applications Support Director in 2013. He is a specialist in digital autoradiography, in vivo optical and fluorescence microscopy imaging with several international scientific publications on intracellular trafficking.

Ana Cardona, *in Memoriam.*
(7/01/1957–23/08/2012)

Plate-forme d'imagerie dynamique, Institut Pasteur, 25 Rue du Dr Roux, 75724, Paris, France

She was a French-Uruguayan research engineer at the Pasteur Institute in Paris, who actively participated in the creation of the Pasteur Institute in Montevideo and contributed to numerous cooperation projects between France and Uruguay through the AFUDEST (Franco Uruguayan Association for Scientific and Technological Development).

She obtained a doctorate in veterinary medicine from the Veterinary Faculty of Montevideo in 1985. After a 2-year internship at the Pasteur Institute in the Hybridolab laboratory directed by Jean Claude Mazié, she obtained her PhD from Paris VII University at the Necker Hospital under the direction of Prof. Jean François Bach in 1994.

She returned to the PI in 1995 where she was recruited in the Laboratory of Cellular Technology, headed by Mrs. Lena Edelman, as a research engineer. Her work focussed on medical imaging techniques and more specifically on the applications of β-imager for the early detection of micro-metastases and this in the context of a collaboration with the team of Georges Charpak.

In 2001, she joined the Histopathology research and expertise unit headed by Michel Huerre until 2010, when she joined the dynamic imaging platform headed by Spencer Shorte and continued her projects on the applications of β-imager to quantitative imaging in the small animal.

I. Introduction

Flow-cell detectors are designed specifically for the measurement of radionuclide activity in a flowing system. The technology is applied most commonly in the biological sciences to the measurement of the activities of radioisotope-labeled organic compounds in high-performance liquid chromatography (HPLC) effluent streams, which is referred to at times as radio-HPLC. Numerous research papers in the past decade report the utilization of flow-cell radiation detectors in conjunction with HPLC in biochemistry, molecular biology, medical

Handbook of Radioactivity Analysis: Volume 2. https://doi.org/10.1016/B978-0-12-814395-7.00010-6
Copyright © 2020 Elsevier Inc. All rights reserved.

and drug research, agricultural chemistry, and related fields. These reports number in the several hundreds. The bio- and medical sciences often require the use of radio-HPLC to separate organic compounds labeled with radioisotopes, such as ^{3}H, ^{14}C, ^{33}P, ^{32}P, ^{35}S, and radiopharmaceuticals labeled with radionuclides, such as ^{90}Y, ^{99m}Tc, ^{18}F, and ^{11}C, among others. When radio-HPLC is used to study the metabolic fates or purity of these compounds, a flow-cell detector is often the instrument of choice to quantify the activity levels of the radionuclide label in the chromatogram-separated compounds. Also, in smaller numbers but of equal importance, there are research papers, which describe the use of flow-cell detectors in conjunction with liquid chromatography (e.g., ion chromatography), in the analysis of radionuclides in the fields of environmental and radioactive-waste monitoring.

The alternative to flow-cell radioactivity analysis is the collection of the HPLC effluent in fractions, which is a technique known as fraction collection, followed by the analysis of each fraction for radionuclide activity. The measurement of radionuclide activity in HPLC fractions is possible by collection of the fractions in separate plastic scintillation microplate wells followed by microplate scintillation counting (see also Chapters 6 and 9, Volume 1). Effluent fractions can number in the hundreds for a given HPLC run. Thus, fraction collecting is more tedious and time-consuming and expensive in terms of laboratory staff time. The analysis of fractions by microplate scintillation counting does not require fluor cocktail; however, drying of the sample wells prior to radioactivity analysis is required, and some sample loss through drying is possible. Also, the analysis of fractions cannot provide an online real-time radionuclide activity measurement of the HPLC effluent. Only flow-cell radioactivity detectors can provide real-time analysis during the HPLC run. A thorough study made by Rapkin (1993) compared the sensitivity and accuracy of low-level analysis (e.g., lower limits of detection of 20.8 CPM under conditions of 10 CPM background) for continuous flow scintillation analysis (FSA) and liquid scintillation analysis (LSA) of fractions. Flow scintillation analysis is the application of scintillation detection methods to the analysis of radioactivity in a flowing system. Statistical considerations suggested that fraction collection followed by LSA offered the possibility of greater sensitivity and accuracy of radioactivity measurements in HPLC eluates, although with considerable inconvenience. However, Rapkin (1993) demonstrated that, even for low-activity analysis, when the randomness of fraction collection is accounted for, the assumed advantages of fraction collection disappear and the trend to replace fraction collection with the continuous real-time radioactivity measurement of HPLC eluates is justified.

The first liquid radiochromatography flow cells were developed following the observation of Steinberg (1958, 1960) that the fluorescence of solid anthracene crystals was useful for the detection of the beta radiations of ^{3}H and ^{14}C when suspended in aqueous solutions containing these radionuclides. Simultaneous independent studies by Rapkin and Packard (1960) and Schram and Lombaert (1960, 1961) demonstrated the feasibility of counting ^{3}H and ^{14}C in flowing aqueous streams when these streams were passed over anthracene crystals within a cell placed between two photomultiplier detectors. Anthracene is no longer used as a scintillator for radioactivity measurements in flowing systems, as many developments have occurred in this field since these pioneering works were reported. For early reviews on the development of flow-cell radioactivity analysis, see previous works by L'Annunziata (1979, 1987) and Parvez et al. (1988).

This chapter will focus mainly on the state-of-the-art and current techniques in the application of flow-cell detectors for the online measurement of radioactivity in chromatography effluents. This includes (1) the measurement of radioisotope labels on organic compounds by FSA used often in conjunction with organic mass spectrometry (MS) and nuclear magnetic resonance (NMR) organic structural spectroscopy for the combined radioactivity analysis and organic structural analysis of separated molecular components in effluents of HPLC, which is popular in the biological sciences; and (2) the measurement of radionuclides separated by ion chromatography (IC), which is a vital technique utilized in the chemical sciences for the analysis of radionuclide sources and in the monitoring of the environment. In addition, reference will be made to the use of flow-cell detectors in the measurement of radioactivity in nonchromatography effluent streams.

II. High-performance liquid chromatography flow-cell analyzers

There are various flow-cell detector types applied to liquid chromatography. These will differ in design and type of detector depending on the radionuclides to be analyzed and the chromatographic separation method that is utilized (e.g., HPLC of organic compounds or IC of radionuclides). In applications utilizing HPLC for the chromatographic separation and analysis of organic compounds, the following types of flow cells are common: (1) the liquid scintillator (homogeneous) flow cell, (2) the solid scintillator (heterogeneous) flow cell, (3) the gamma cell, (4) the positron emission tomography (PET) cell, and (5) the luminescence flow cell. The gamma cell is manufactured according to three detector types to improve detection efficiencies for high-energy, low-energy, and annihilation-gamma radiation in HPLC effluents. The latter is also referred to as a PET cell, as it is designed to detect positron emitters in radiopharmaceutical compounds commonly used in PET. The various scintillation flow cells currently used to analyze the effluent streams in HPLC are listed in Table 10.1 together with their characteristics,

TABLE 10.1 Types of flow-cell detectors used for the measurement of radioactivity in high-performance liquid chromatography.[a]

I. Liquid scintillator (homogeneous) cell
- **A.** Characteristics
  - Coiled Teflon tubing, 35–5000 μL volume
- **B.** Radionuclides analyzed and %*E* (in parenthesis)
  - All β emitters, e.g., ^{3}H (20%–60%),^{14}C (70%–95%),^{35}S and ^{33}P (70%–95%),^{32}P (85%–95%)
  - Low-energy γ emitters, e.g.,^{125}I (60%–90%)
  - All α emitters (>95%)[b]
- **C.** Advantages
  1. High %*E*
  2. No adsorption of radionuclide on Teflon tube walls
- **D.** Disadvantages
  1. HPLC effluent is mixed with cocktail fluor and, an effluent stream splitter is required if separated compounds are to be analyzed online by MS or NMR spectroscopy
  2. An electronic stream splitter is required to obtain part of the effluent to enable other chemical and biological studies on separated compounds

II. Solid scintillator (heterogeneous) cell
- **A.** Characteristics

  Fine solid scintillator particles packed within coiled tubing, 150–600 μL volume, among which are:
  - **1.** Yttrium glass (YG) scintillator (e.g., YG-150, YG 40-x6M, YG 50-S5P)[f]
  - **2.** Monocrystalline SolarScint[c]
  - **3.** Polycrystalline cerium-activated yttrium silicate [YSi(Ce)]
  - **4.** High-pressure (high flow rate) cells containing one of the following scintillators:
    - **a.** Europium-activated calcium fluoride [CaF_2(Eu)]
    - **b.** Cerium-activated lithium glass [lithium glass(Ce)]
    - **c.** Cerium-activated yttrium silicate [YSi(Ce)]
    - **d.** Scintillating plastic beads (plastic scintillator)
- **B.** Radionuclides analyzed (cell detector types and %*E* in brackets)

  All β emitters

  ^{3}H [SolarScint[c], 3.0%; YG, 1.5%; YSi(Ce), 2.8%]

  ^{14}C [SolarScint[c], 70%; YG, 63%–86%; YSi(Ce), 68%]

  High-pressure, high-rate cells:

  ^{3}H [CaF_2(Eu), >5%; lithium glass(Ce), >1%; YSi(Ce), >2%; plastic, > 2.5%]

  ^{14}C [CaF_2(Eu), >85%; lithium glass(Ce), >45%; YSi(Ce), >65%; plastic, > 15%]

  All α emitters (50%–60%*E*)
- **C.** Advantages
  - **1.** Good %*E* except for ^{3}H
  - **2.** Sample in effluent is not destroyed (no cocktail fluor is used)
  - **3.** No chemical quench effects associated with fluor cocktail occur
  - **4.** Costs associated with the use and disposal of fluor cocktail are avoided
  - **5.** High salt, buffer, or pH gradients do not effect %*E*
  - **6.** High-pressure cells permit up to 3000 psi cell pressure and high flow rates
- **D.** Disadvantages
  - **1.** Sample may bind reversibly or irreversibly onto scintillator yielding peak broadening and high backgrounds
  - **2.** Low %*E* for ^{3}H

III. High-energy gamma cell
- **A.** Characteristics

  Coiled Teflon tubing with 6-mm-thick BGO windows; 35–550 μL volume (e.g., Gamma-B[c] flow cell) See Fig. 10.5. The BGO–X[f] flow cell (Berthold Technologies) is equipped with a 40-mm BGO crystal.
- **B.** Radionuclides analyzed and %*E* (in parenthesis)[d]

  High-energy γ emitters (>70 keV), e.g., ^{67}Ga (44%), ^{131}I (58%), ^{111}In (25%), ^{99m}Tc (63%), ^{201}Tl (35%), ^{54}Mn (19%), ^{60}Co (20%), ^{133}Ba (28%), ^{85}Sr (19%), ^{51}Cr (3%).
- **C.** Advantages
  - **1.** No liquid scintillation fluor cocktail required
  - **2.** No solid scintillator required in cell tubing
  - **3.** High signal-to-noise ratio
  - **4.** Good spectral resolutions for high-energy gamma (>300 keV)

Continued

TABLE 10.1 Types of flow-cell detectors used for the measurement of radioactivity in high-performance liquid chromatography.[a]—cont'd

- **D.** Disadvantages
  - **1.** Used exclusively for high-energy γ emitters or high-energy β emitters (e.g., ^{32}P,^{90}Y)

IV. Low-energy gamma cell

- **A.** Characteristics
  - Coiled Teflon tubing with 4-mm-thick CaF_2(Eu) windows; 10—650 μL volume (e.g., Gamma-C[c] flow cell or the Iodine cell, I 100—1000[f])
- **B.** Radionuclides analyzed and %*E* (in parenthesis)[d]
  - Low-energy γ emitters (<70 keV), e.g., ^{55}Fe (14%), ^{125}I (90%), ^{109}Cd (34%),^{201}Tl (28%), ^{99m}Tc (14%), ^{67}Ga (15%)
  - High-energy β emitters, e.g., ^{32}P (~60%*E*)[d], ^{90}Y (60%*E*)
- **C.** Advantages
  - **1.** No liquid scintillation fluor cocktail required
  - **2.** No solid scintillator required in cell tubing
  - **3.** High counting efficiencies (%*E*) for low-energy γ emitters (<70 keV)
- **D.** Disadvantages
  - **1.** Used exclusively for low-energy γ emitters or high-energy β emitters (e.g., ^{32}P (~ 60%*E*), ^{90}Y (60%E)

V. Cherenkov cell

- **A.** Characteristics
  - Coiled Teflon tubing sandwiched between solid scintillator windows. The flow cells are called "Cherenkov cells" because they are used to measure the activities of high-energy beta-emitting radionuclides by the Cherenkov effect (see Chapter 6, Volume 2). Cherenkov photons are produced in the narrow aqueous phase and wall of the Teflon tubing of the cell; however, most of the photons detected by the photomultipliers are produced in the solid scintillator on either side of the coiled Teflon tubing. Some typical Cherenkov cells are the following types:
  - Gamma-C[c] flow cell: coiled Teflon tubing sandwiched between CaF_2(Eu)
  - Cerenkov cell[e]: coiled Teflon tubing sandwiched between plastic scintillator; Cerenkov-Cell Z-200[f]
- **B.** Radionuclides analyzed and %*E* (in parenthesis)
  - High-energy beta emitters with a beta particle energy maximum much higher than the threshold energy for the production of Cherenkov photons in water; i.e., the E_{max} of the beta emissions should be >> 263 keV. Examples are ^{32}P (~60%*E*) and ^{90}Y (60%E).
- **C.** Advantages
  - **1.** No liquid scintillation fluor cocktail required
  - **2.** No solid scintillator required in cell tubing

VI. PET cell

- **A.** Characteristics
  - Coiled Teflon tubing with 6-mm-thick BGO windows opaque on one side; see Fig. 10.8 or the positron emission tomography (PET) cell MX-100[f]
- **B.** Radionuclides analyzed and %*E* (in parenthesis)
  - Positron (β^+) emitters such as those used in PET, e.g., ^{18}F (25%), ^{11}C (43%), ^{13}N, and ^{68}Ga
- **C.** Advantages
  - **1.** Low backgrounds approximately 1/10 of backgrounds from Gamma-B[c] flow cell with only 1/3 drop in %*E*
  - **2.** No liquid scintillation fluor cocktail required
  - **3.** No solid scintillator required in cell tubing
- **D.** Disadvantages
  - **1.** Used exclusively for positron β^+ emitters

VII. High-sensitivity PET cell[g]

- **A.** Characteristics
  - Coiled tubing (0.76 mm inner diameter) with 3-cm-thick BGO detectors on opposite sides and coincidence background reduction (see Fig. 10.11)
- **B.** Radionuclides analyzed
  - Positron (β^+) emitters such as those used in PET, e.g., ^{18}F, ^{11}C, and ^{13}N
- **C.** Advantages
  - An improved signal-to-noise ratio of 28:1 for the high-sensitivity PET cell compared with 5:1 for the conventional PET cell[g]

VIII. Narrow-bore cell

- **A.** Characteristics
  - **1.** Designed for applications using 2 mm ID narrow-bore HPLC columns
  - **2.** Cell sizes range from 15 to 250 μL
  - **3.** Effluent (sample) flow rates range from 133 μL/min to 1 mL/min
  - **4.** For homogeneous cells, liquid scintillation cocktail flow rates (3:1 cocktail:sample ratio) range from 400 μL to 3 mL/min
  - **5.** Heterogeneous cells use yttrium silicate, lithium glass, calcium fluoride, plastic scintillator, and SolarScint[c] formats

Continued

B. Radionuclides analyzed and %*E* (in parenthesis)
1. All radionuclides emitting radiations that produce significant scintillation with fluor cocktail in homogeneous cells or scintillation in solid scintillator heterogeneous cells, including α-, β^--, β^+-, X-rays, weak γ-rays, and Auger electrons, etc.
2. ^{3}H (35%–42%),^{14}C (80%–90%) in homogeneous cells
C. Advantages
1. Improved peak resolutions without peak tailing
2. Applied to simultaneous HPLC/FSA/mass spectrometry structure analysis
3. Reduced cocktail consumption and waste disposal costs compared with conventional FSA cells

IX. Microbore cell
A. Characteristics
1. Designed for applications using 1 mm ID narrow-bore HPLC columns
2. Cell sizes range from 3 to 100 μL
3. Effluent (sample) flow rates range from 25 to 150 μL/min
4. For homogeneous cells, liquid scintillation cocktail flow rates (3:1 cocktail:sample ratio) range from 75 to 450 μL/min
5. Heterogeneous cells use yttrium silicate, lithium glass, calcium fluoride, plastic scintillator, and SolarScint[c] formats
B. Radionuclides analyzed and %*E* (in parenthesis)
1. All radionuclides emitting radiations that produce significant scintillation with fluor cocktail in homogeneous cells or scintillation in solid scintillator heterogeneous cells, including α-, β^--, β^+-, X-rays, weak-γ-rays, and Auger electrons, etc.
2. ^{3}H (25%–35%),^{14}C (75%–80%) in homogeneous cells
C. Advantages
1. Up to 10-fold improved peak resolutions without peak tailing compared with conventional FSA cells
2. Applied to simultaneous HPLC/FSA/mass spectrometry structure analysis
3. Reduced cocktail consumption and waste disposal costs compared with conventional FSA cells

X. Very-high-pressure liquid chromatography (VHPLC) cell[h]
A. Characteristics
A homogeneous flow cell of 200 μL volume with 0.25 mm inner diameter designed for the separation and analysis of ^{3}H- and ^{14}C-metabolites in VHPLC effluents
B. Advantages
1. Improved separation of radioisotope-labeled metabolites by VHPLC with sensitivity comparable with that of conventional HPLC and radiation detection with the use of variable scintillation flow
2. Online mass spectrometric analysis is possible with effluent stream splitting as in conventional HPLC

XI. Luminescence flow cell for positron emitters (fLumo)[f]
A. Characteristics
An unshielded luminescence flow-through radio-HPLC detector sensitive to positrons (fLumo detector) and insensitive to gamma rays for applications in the analysis of PET radiopharmaceuticals
B. Advantages
1. No radiation shielding required. Thus, the detector can be used in a production "hot cell" to detect PET radiopharmaceuticals during a semipreparative HPLC purification
2. Exhibits excellent low limits of detection, linearity with activity and reproducibility (Thonon et al., 2013)
3. The low backgrounds achieved circumvent expensive coincidence counting with dual PMTs or other costly electronic background resuction methods
4. Various fLumo PET flow cells can be interchanged to accommodate HPLC effluent volumes of 10, 50, or 100 μL
5. The fLumo PET flow cells can be interchanged with fLumo gamma measuring flow cells (BGO-X) of 5, 30, and 150 uL cell volumes or other gamma measuring flow cells or 100–1000 μL
6. The fLumo detector for the measurement of positron emitting radionuclides in HPLC effluents can be interchanged with a NaI detector for the measurement of gamma photon–emitting radionuclides

XII. Hybrid silicon pixel detector (Medipix2)[i]
A. Characteristics
A 65k single-photon counting pixel array with a square pixel size of 55 μm on a 14 × 14 mm^2 detection area. The detector can act as a real-time counter and camera for positrons emitted from a flow-based system such as the effluent of an HPLC in a microfluidic setup. The detector counts positrons directly from positron-emitting radionuclides rather than the detection of annihilation gamma photons. Its small size limits the detector to microfluidic platforms.

Continued

TABLE 10.1 Types of flow-cell detectors used for the measurement of radioactivity in high-performance liquid chromatography.[a]—cont'd

B. Advantages
1. Much improved detection efficiency of positrons compared with NaI(Tl) scintillation detector of annihilation gamma photons for positron-emitting radionuclides
2. Much higher signal-to-noise (S/N) ratio compared with a NaI(Tl) detector
3. May be applied to the measurement of short-lived radionuclides used for PET particularly immediately after radionuclide production and purification on a silica-based monolithic column in a microfluidic platform

applications, and advantages and disadvantages. Scintillation flow cells may be interchangeable within a given flow scintillation analyzer (FSA) designed specifically for this purpose. The proper selection of the cell will provide the optimum detection efficiencies with lowest background as well as meet the needs of any particular flow cell analysis. A description of the flow cells will be provided in this section together with an account of their advantages and disadvantages.

HPLC flow-cell radioactivity detectors are available commercially from numerous commercial manufacturers and suppliers. In some instances, specific manufacturers may be mentioned throughout this chapter. These should not be taken as endorsements, as similar ones may be available from other manufacturers or suppliers. To assist the reader in exploring various suppliers of flow scintillation detectors for their radio-HPLC requirements, several suppliers are listed in alphabetical order in Table 10.2; however, the reader should not consider this list to be comprehensive. Other suppliers and even new suppliers may exist.

A. High-performance liquid chromatography flow cell analyzers

The principal components of a typical flow scintillation analyzer (FSA) linked to an HPLC system is illustrated as a block diagram in Fig. 10.1. The connection of the effluent stream from an HPLC system is illustrated at the upper left-hand corner of the figure. The scintillation flow cell is placed between the two photomultiplier tubes (PMTs), and it is interchangeable as several types are available. The scintillation flow cells differ according to the modes of radiation detection, efficiency for radiation types and radiation energy, and particular experimental requirements, including narrow-bore and microbore radio-HPLC systems. These are described in Table 10.1 and in the next section. The flow cell is placed between the two PMTs so that the two opposite side windows of the cell are in direct contact with the opposite faces of the PMTs. The orientation of the flow cell vis-à-vis the PMTs is illustrated in Fig. 10.2. HPLC stream splitting with linking of the FSA to a mass spectrometer and/or NMR spectrometer are not illustrated. The linking of the FSA to MS and NMR spectrometers is described further on in this chapter.

If a homogeneous flow cell is used, liquid fluor cocktail must be uniformly mixed with the HPLC effluent stream. Special low-viscosity nongelling fluor cocktails are recommended, which are described further on in this chapter. The liquid scintillator is added to the HPLC effluent stream by a variable volume scintillator pump (LS pump) and a static fluid mixer (mixing tee) before reaching the scintillation flow cell, as depicted in Fig. 10.1. Mixing the effluent stream with fluor cocktail renders the separated chemical components useless for any subsequent chemical or biological tests. If organic structural information is required on the compounds separated by the HPLC, as provided by MS or NMR spectroscopy or other tests on the effluent stream required, an electronically controlled stream splitter (digital stream splitter) can direct a portion of the HPLC effluent stream for online MS or NMR analysis (Shemesh et al., 2016, Draganov et al., 2015, Keller et al., 2015, Kiffe et al., 2008, L'Annunziata, 1984, L'Annunziata and Nellis, 2001a,b, Silva-Elipe, 2003a, and Wilson and Brinkman, 2003). An alternative approach is to fraction-collect the radio-HPLC effluent from a flow scintillation analyzer and subsequently analyze the collected fractions by MS or NMR spectroscopy (Gomes de Mello Martins et al., 2017; Keller et al., 2015, Peyronneau et al., 2012; Jacques et al., 2010a,b). Stream splitting and fraction-collecting after monitoring the HPLC effluent with a flow scintillation analyzer is discussed further on in this chapter. Certain scintillation flow cells, such as the solid (heterogeneous) cell, gamma cell, or PET cell (Table 10.1), do not use liquid scintillation (LS) fluor cocktail. When these cells are used, the stream splitter, scintillator pump, and static fluid mixer are not utilized obviously, and the HPLC

effluent can be split after FSA for direct online MS and NMR spectroscopy. The flow scintillation analyzer (FSA) is equipped with two PMTs, high voltage supply, coincidence and summation circuitry, pulse height analyzer, associated analog-to-digital converter, and multichannel analyzer (MCA) similar to the components of a modern LS analyzer. Modern flow scintillation analyzers are operated by a computer equipped with multitasking software, including automatic quench correction and efficiency determination, DPM measurements in the effluent stream, background reduction electronics, such as TR-LSC (see Chapter 6, Volume 1), multichannel analysis and spectral display, self-normalization and calibration, pulse height spectral display, preset and variable energy regions for activity analysis, dual independent counting regions for either automatic single or dual radionuclide analysis with update times from 1 to 120 s, software for radio-HPLC direct instrument control and data reduction, including three-dimensional and overlay display of activity peaks from different chromatogram traces (see Fig. 10.3), and instrument performance assessment (IPA) for monitoring

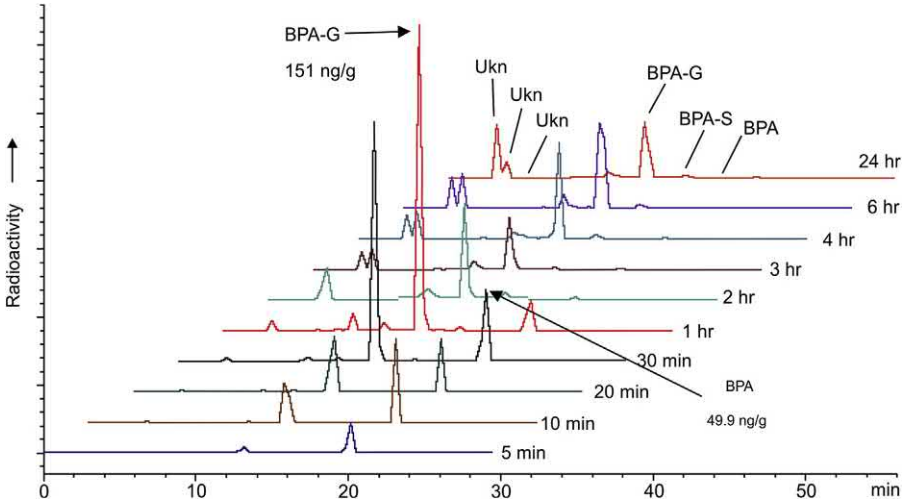

FIGURE 10.3 Three-dimensional analysis overlay of 10 flow scintillation analysis traces of HPLC separations (radioactivity vs. retention time in minutes) of ^{3}H-labeled BPA (bisphenol A) and metabolites after oral or subcutaneous administration of ^{3}H-BPA to mice. The traces are overlaid or offset into a three-dimensional display to provide a timeline comparison of metabolite anabolism and catabolism as illustrated. Units of radioactivity are not illustrated on the Y-axis, as the signal intensity for each chromatogram is scaled to the tallest BPA-G peak. Two metabolites identified by online mass spectrometry are BPA-glucuoride (BPA-G) and BPA-sulfate (BPA-S). *From Draganov et al. (2015); reprinted with permission from Elsevier © 2015.*

detection efficiencies, background, and Chi-square values with ^{3}H and ^{14}C standards. Detailed descriptions and the practical applications of most of these features are given in Chapter 6, Volume 1 "Liquid Scintillation Analysis." There is great similarity between the electronic components and radioanalytical capability of state-of-the-art flow scintillation analyzers and liquid or solid scintillation analyzers. The major difference between the two analyzers is the mechanism of detection, which in the case of FSA may be either liquid or solid scintillation, and the radionuclides are analyzed in a dynamic liquid stream.

In the example illustrated in Fig. 10.3, Draganov et al. (2015) used HPLC to separate radioisotope-labeled bisphenol A (^{3}H-BPA) and its metabolites after administration of the ^{3}H-BPA to mice. The separation of radioisotope-labeled compounds by HPLC, often referred to as radio-HPLC, is generally followed by radioactivity analysis with a flow-cell detector followed by online or offline analytical tests, such as MS or NMR spectroscopy to identify the chemical structure of the metabolites. The radio-HPLC of a radioisotope-labeled compound and its metabolites plotted with three-dimensional (3D) overlays over various periods of metabolism provide an excellent means of quantifying and recording the time course of the fate of organic compounds in living systems and the environment. In the example given by Fig. 10.3, the compounds separated by HPLC were quantified and plotted by a flow-cell detector through which the HPLC effluent passes. Metabolites were then identified by splitting the HPLC effluent sending 20% of the effluent to an electrospray ionization (ESI) tandem mass spectrometer (MS/MS) for the identification of metabolites and the remaining fraction (80%) of the HPLC effluent directly onto a homogeneous flow scintillation detector for the measurement of tritium activity in the various compounds separated on the HPLC column. Such direct online measurements are referred to hyphenated analytical techniques, which in this case would be abbreviated as HPLC-FSA-MS/MS.

Another example of the application of flow scintillation analysis to the time course measurement of a reaction by means of a three-dimensional overlay of HPLC runs can be taken from the work of Markham et al. (2004). The synthesis of the reduced form of ^{14}C-labeled β-nicotinamide adenine dinucleotide 2′-phosphate ([Ad-^{14}C]NADPH) from β-nicotinamide [U-^{14}C]adenine dinucleotide ([Ad-^{14}C]NAD^{+}) was measured by flow scintillation analysis of HPLC runs over a period of over 4 hours by Markham et al. (2004). They followed the course of the synthesis by HPLC analysis of reaction components in a centrifuge tube reaction vessel containing [Ad-^{14}C]NAD^{+}, ATP, glucose-6-phosphate, and NAD^{+} kinase. The HPLC analysis carried out over different time intervals provided a time course measurement of the progress of the synthesis of [Ad-^{14}C]NADPH. A three-dimensional display of the radioactivity label in the HPLC runs over a period exceeding 4 hours from the time of initiation of the reaction (t_0) to the complete synthesis (t_2) is illustrated in Fig. 10.4 together with the reaction scheme. The [Ad-^{14}C]NAD^{+} underwent 75% conversion after 3−4 hours (t_1), and the complete conversion to [Ad-^{14}C]NADPH is illustrated to occur at t_2 after the addition of glucose-6-phosphate dehydrogenase (glucose-6-P DH) and adjustment of pH.

B. Liquid (homogeneous) flow cells

A typical flow cell, whether it is a homogeneous liquid flow cell, a heterogeneous solid scintillator flow cell or a Cherenkov cell, consists of fine tubing (e.g., Teflon) coiled flat between two transparent windows at either side of the coiled tubing as seen in Fig. 10.5. The flow cell, illustrated in Fig. 10.5, is produced by Berthold Industries, and similar

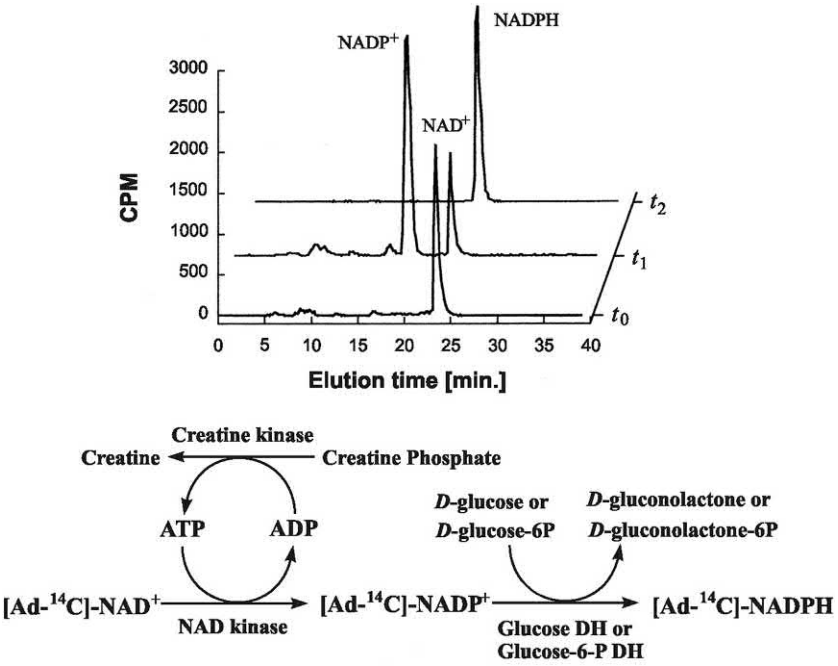

FIGURE 10.4 (Upper) HPLC flow detector radiograms produced with a PerkinElmer 500 TR radiomatic flow scintillation analyzer illustrated in a three-dimensional overlay following the time coarse of the enzymatic synthesis of [Ad-^{14}C]NADPH. t_0, reaction mixture before adding enzymes; t_1, reaction mixture at 75% conversion after adding the NAD$^+$ kinase; t_2, reaction mixture after completion of the reaction. FIGURE 10.5 Photograph illustrating the principle characteristics of a scintillation or Cherenkov flow cell (property of Berthold Technologies). Components identified are (A) the finger-tight inlet and outlet fittings for liquid chromatography system integration, (B) a SmartChip that automatically sets the cell-specific parameters, and (C) the sample area containing wound Teflon tubing. The component illustrated is inserted into a detector (Flowstar[1] LB 514) whereby the sample area illustrated above sits between the faces of two PMTs to optimize detection efficiency and low backgrounds with coincidence counting. The flow cells are easily interchangeable to accommodate liquid or solid scintillation cells, PET cells, microbore cells, gamma cells, and Cherenkov counting cells, among others (© 2018 Berthold Technologies (www.berthold.com); used under permission).

flow cells are available from other commercial suppliers such as Gammasonics and LabLogic Systems, Inc. (see Table 10.2). The cell (coiled tubing within windows) is inserted between two PMTs of the flow scintillation analyzer. The flow cell tubing is coiled so that it sits perpendicular to the planar faces of two PMTs. Because the liquid flow cell consists only of tubing, the detection of low- and intermediate-energy beta-emitting radionuclides (e.g., ^{3}H, ^{14}C, or ^{35}S) requires a prior mixing of the entire or a fractional part of the radioactive HPLC effluent with LS fluor cocktail, while the effluent stream is in motion and prior to the arrival of the effluent-fluor cocktail mixture at the orifice of a flow cell. This has traditionally been referred to as the homogeneous method because the effluent stream and fluor cocktail are homogeneously mixed, and the flow cell is referred to as a liquid cell.

The liquid homogeneous flow cell type provides the highest counting efficiencies for low-energy β emitters such as ^{3}H over the range of 20%–60% and intermediate-energy β emitters such as ^{14}C and ^{35}S with counting efficiencies in the range of 70%–95%. The high detection efficiencies are

1. Taken in part from L'Annunziata, M. F. and Nellis, S. W. (2001). Flow scintillation analyzer (FSA) interfaced with the HPLC and nuclear magnetic resonance (NMR) spectrometer. A state-of-the-art application of the Radiomatic FSA. *FSA Application Note FSA-004*. PerkinElmer, Inc. @ 2001 PerkinElmer; Reprinted with permission. All rights reserved. http://www.perkinelmer.com/CMSResources/Images/44-73061APP_FSAInterfacedHPLC.pdf, accessed October 31, 2018.

expected with the liquid (homogeneous) flow cells because a LS detection method is used where the radionuclides are in solution with fluor cocktail. Special fluor cocktails should be used that do not gel when mixing with HPLC effluents and suppress chemiluminescence, which can occur following the immediate mixing of cocktail with HPLC effluents.

The wide range of chemicals used as eluents in HPLC and the changing chemical characteristics of HPLC effluents when gradient elution is carried out and when particular compounds are eluted from the column will cause variable quench. As the percent counting efficiency of any radionuclide is a function of quench, a gradient quench correction curve is needed to convert online count rates to disintegration rates.

A disadvantage of the liquid (homogeneous) flow cell is that the separated compounds in the HPLC effluents are rendered useless for further chemical or biological tests due to their mixing with fluor cocktail. However, an effluent stream splitter can be used to divert a fraction of the HPLC effluent to the online analysis of FSA peaks via MS or NMR spectroscopy or onto a fraction collector to permit further studies on the HPLC-separated components. As in LS counting, radionuclides that emit low-energy gamma rays, Auger electrons, and internal conversion electrons can be measured also in the liquid flow cell with high counting efficiency. In the case of ^{125}I, counting efficiencies in the range of 60%−90% are possible. Alpha-emitting radionuclides are detected with high counting efficiencies (>95%) in the liquid flow cell.

C. Solid (heterogeneous) flow cells

The solid scintillator (heterogeneous) flow cell is manufactured with fine beads or particles of an insoluble solid scintillator placed within the Teflon tubing of the flow cell. The tubing is coiled flat between two transparent windows and placed between the faces of two PMTs. The HPLC radioactive effluent stream will flow through the cell and make intimate contact with the solid scintillator beads. This latter approach is referred to as the heterogeneous method because the effluent stream and scintillator do not mix, and the flow cell is called a solid cell. The PMTs will detect and measure the scintillation light photons emitted from the tubing, and the radioactivity determined during the sample residence time in the flow cell according to conventional LS technology described in Chapter 6, Volume 1 and further on in this chapter.

Various types of solid scintillators are used to make up the heterogeneous cell, including yttrium glass, polycrystalline cerium-activated yttrium silicate [YSi(Ce)], europium-activated calcium fluoride [CaF_2(Eu)], cerium-activated lithium glass, and plastic scintillator beads, among others. These will vary in their detection efficiency for various β and α emitters. The counting efficiencies are low for weak β emitters like ^{3}H (1.5−5%E) and good for the intermediate-energy β emitters such as ^{14}C (45−85%E). High-energy β emitters are detected as expected with yet higher counting efficiency. Kawano et al. (2011, 2015) describe a heterogenous flow-cell detector containing CaF_2(Eu) for the monitoring of tritium in water on a continuous flow-through basis. The flow-cell detector is equipped with dual PMTs for coincidence counting, a water flow pump, and multichannel monitoring pulse height analyzer, which would enable restricting counts to a low-level pulse height channel corresponding the tritium. With 5-mm diameter cells, Kawano et al. (2015) achieved detections levels of 2 and 10 Bq/mL of tritium in continuous flowing water with 10,000 and 600 s counts, respectively. Alton et al. (2018) used Monte Carlo code Geant4 and experimentation to determine the optimum geometries (scintillator particle radii) for maximum energy deposition in waterborne beta particle emitters with a CaF_2(Eu) flow-cell detector. Experimental measurements with tritium, carbon-14, and lead-210 indicate optimal radii of 10, 350, and 75 μm, respectively.

A major advantage of the heterogeneous flow cell is that the sample in the HPLC effluent is not destroyed because no fluor cocktail is used. The entire effluent stream can be analyzed by online MS and NMR spectroscopy, or it may be collected by a fraction collector and further chemical or biological tests can be carried out on the separated fractions. Also, chemical quench, which is a problem with the liquid homogeneous flow cells, does not occur with the solid (heterogeneous) cells. Therefore, high salt, buffer solutions, or pH gradients used in HPLC eluents will not affect counting efficiency. The only problem is that, due to the high surface area and structure of the solid scintillator packed in these flow cells, compounds undergoing separation in the HPLC may bind reversibly or irreversibly onto the scintillator. This can result in high backgrounds and peak broadening. Irreversible binding of sample onto the scintillator may require replacement of the flow cell. A solid heterogeneous flow cell containing monocrystalline SolarScint (trademark of PerkinElmer, Inc.) undergoes minimal sample binding. The inositol phosphates are one example of compounds that undergo adsorption onto yttrium silicate (YSi) scintillator, resulting in peak broadening. SolarScint flow cells operated in the pH range of 3−8 show minimal effects of compound binding, resulting in optimal peak resolutions. This is evidenced by Fig. 10.6, which illustrates the high resolutions of the HPLC-separated ^{3}H-labeled inositol phosphates detected with a 210-μL SolarScint heterogeneous flow cell.

Certain designs of heterogeneous flow cells are manufactured with relatively thick glass tubing to withstand high pressures of up to 3000 psi (200 bar) with fast flow rates. Soreefan et al. (2003) and Tan and DeVol (2003) carried out experimental and Monte Carlo investigations on the light collection efficiency of heterogeneous flow-cell detectors. They demonstrated with an alpha source that the light

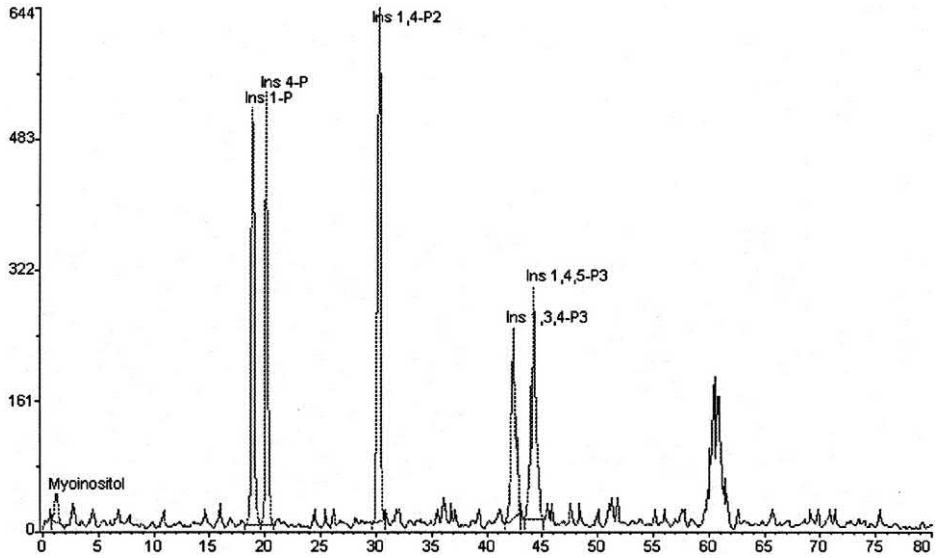

FIGURE 10.6 Activity peaks of ^{3}H-labeled inositol mono-, di-, and triphosphates separated by HPLC and measured with a 210-μL solid (heterogeneous) flow cell containing SolarScint solid scintillator, from the work of Dr. K. E. Nye at The Medical College, St. Bartholomew's Hospital, University of London, UK (© 1998 PerkinElmer, Inc. All rights reserved. Printed with permission).

collection efficiency decreased with increasing number of scintillator bead layers in the heterogeneous cell. Simulations extended to beta particle emissions with the PENetration and Energy Loss of Positrons and Electrons (PENELOPE) Monte Carlo code demonstrated that higher scintillator packing density (lower porosity) and smaller scintillator granule size would result in a higher fraction of electron energy deposited in the scintillator of the heterogeneous flow-cell detector. This effect was more pronounced for lower-energy electrons (<180 keV) than for higher-energy electrons (>550 keV).

D. Gamma and positron emission tomography flow cells

The gamma- and PET flow cells are made to provide highest detection efficiencies for gamma radiation. The cell types can be classified into those designed to provide optimum detection efficiencies for (1) high-energy γ emitters, (2) low-energy γ emitters, and (3) positron (β^{+}) emitters. The positron (β^{+}) emitters, which are principally those radionuclides used in PET, produce gamma radiation via annihilation (see Chapter 1, Volume 1). The low-energy gamma cell is also an efficient flow-cell detector for high-energy beta particle emitters, such as ^{32}P and ^{90}Y. Table 10.1 provides the main characteristics and detection properties of these scintillation flow cells.

1. High-energy gamma cell

The high-energy gamma flow cell will detect all γ emitters and high-energy β emitters; however, the high-energy gamma cell is designed specifically to provide optimum detection efficiencies for γ-emitting radionuclides of energy >70 keV. This type of flow cell (*e.g.*, Gamma-B flow cell, PerkinElmer, Inc.) consists of Teflon tubing coiled flat between two bismuth germanate (BGO) solid scintillator windows in between the faces of two PMTs, as illustrated previously in Fig. 10.2. A gamma ray emitted from a radionuclide in the flow cell tubing would interact with only one of the crystal scintillator windows on either side of the Teflon tubing. The scintillation light produced in one of the flow cell windows would be "seen" or detected simultaneously by the two PMTs and consequently registered as an event in coincidence according to the principles of coincidence scintillation counting. The scintillator BGO has a very high density (7.13 g/cm^3), high effective atomic number (high Z_{eff}), which provides this scintillator with a high "stopping power" for high-energy gamma radiation. At the same time, BGO has a high light output and short scintillation decay time, among other favorable properties for high-energy gamma ray detection. Thallium-activated sodium iodide [NaI(Tl)] solid scintillator is also used for the efficient flow-cell detection and measurement of gamma-emitting radionuclides (O'Hara et al., 2018; Trojanowicz et al., 2018; Kołacińska and Trojanowicz, 2014; Lindegren et al., 2014; Vitorge et al., 2014; Tsao et al., 2013).

Lindegren et al. (2014) designed a dual-flow cell consisting of coiled tubing of polyether ether ketone (PEEK), which fits within the well of a NaI(Tl) detector (62 mm o.d., 25 mm ID × 40 mm deep well illustrated in Fig. 10.7. The dual-flow cell consists of a reference cell and an analytical cell. The radio-HPLC flow starts from the injector to the reference cell for the detection and

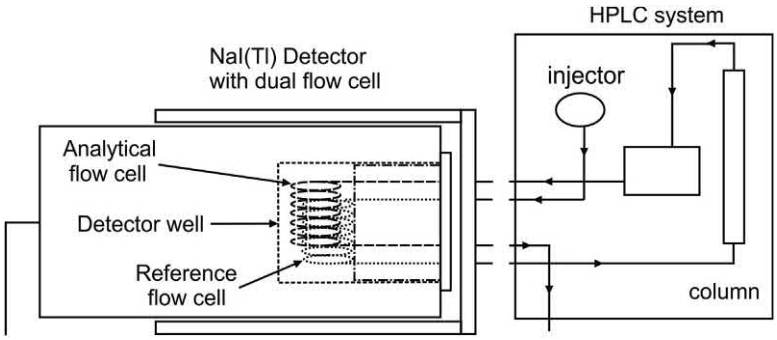

FIGURE 10.7 Schematic illustration of the dual flow-cell detector. The dotted line represents the reference flow cell, and the dashed line represents the analytical flow cell. *From Lindegren et al. (2014); reprinted with permission from Elsevier © 2014.*

measurement of the total sample activity prior to the sample entering the HPLC column. The radioactivity in the column effluent is then detected in the analytical cell. In this fashion, the sample serves as its own standard, before it is diluted in the HPLC column, permitting the online quantitative radioactivity analysis in the HPLC system. As described by Lindegren et al. (2014), both the loaded and eluted activity are measured in the same NaI(Tl) detector simplifying quantitative analysis of eluted activity, eliminating external calibration errors and internal system errors. The system was tested with the X-ray and gamma-emitting radionuclides ^{99m}Tc, ^{125}I, ^{131}I, and ^{211}At with X-ray and gamma photon emissions ranging between 27 and 364.5 keV. Such a flow-cell detector should be very suitable for short-lived positron-emitting radionuclides, which require a rapid activity analysis upon preparation.

2. Low-energy gamma cell

The low-energy gamma flow cell will detect all gamma photon, and X-ray photon, and high-energy beta emitters; however, the cell is designed generally to provide optimum detection efficiencies for gamma-ray energies $<$70 keV. This type of flow cell (e.g., Gamma-C flow cell, PerkinElmer, Inc.) consists of Teflon tubing coiled flat between two 4-mm-thick CaF_2(Eu) solid scintillator windows, as illustrated in Fig. 10.5. The CaF_2(Eu) scintillator has a much lower density (3.19 g/cm^3) and lower effective atomic number than the BGO scintillator employed in the previously described high-energy gamma cells. Therefore, the low-energy gamma scintillation flow cell has a lower gamma-ray stopping power than the previously described high-energy gamma flow cell. The high gamma stopping power of BGO is not needed for gamma rays of energy below 70 keV, and CaF_2(Eu) scintillator has a threefold higher scintillation conversion efficiency than BGO (L'Annunziata, 1987). Also, high-energy β particle emitters, such as ^{32}P ($E_{max} = 1710$ keV) and ^{90}Y ($E_{max} = 2280$ keV), emit beta particles of sufficient energy to penetrate the CaF_2(Eu) scintillator flow-cell windows of the low-energy γ flow cell detector and be detected with relatively high efficiency ($\sim$60% E). The mechanisms of coincidence scintillation detection with the use of two PMTs described in the previous section, however, are the same for both the CaF_2(Eu) and BGO detector windows.

The major advantages in utilizing the gamma cells for the measurement of γ or high-energy β emitters are that no liquid or solid scintillator is required in the cell tubing. The solid scintillator exists outside the flow-cell tubing, and therefore, no chemical or color quench is possible. After flow scintillation analysis, the entire HPLC effluent can be diverted to a mass spectrometer or NMR spectrometer for identification of HPLC peaks or collected by a fraction collector and further chemical and biological tests performed on the effluent fractions.

Heterogenous flow cells packed with CaF_2(Eu) are suitable for measuring low-energy beta emitters such as ^{3}H and ^{14}C (Alton et al., 2018; Magnussen et al., 2015), as the effluent is in intimate contact with the scintillator in this type of flow cell. The optimum radius of CaF_2(Eu) spheres or particles within the flow-cell tubing is a function of the track length of the beta particles within the scintillator. Alton et al. (2018) used Monte Carlo code Geant4 for the modeling and experimentation to determine the optimum CaF_2(Eu) radius for the detection of tritium, carbon-14, and lead-210 in heterogenous flow cells.

3. Positron emission tomography cell

PET scintillation flow-cell detectors are designed to detect all positron emitters generally in the effluent of a HPLC. These detectors are designed for the detection of the 0.511 MeV annihilation gamma photons when the emitted positrons undergo annihilation. Some flow-cell detectors may be designed exclusively for the measurement of positron emitters at highly reduced background count rates as described in the following paragraph. The positron emitters commonly analyzed by HPLC are short-lived

radionuclides (e.g., ^{11}C ^{18}F, ^{64}Cu, and ^{68}Ga) as isotope labels in radiopharmaceuticals used in PET in the field of nuclear medicine, which is described in previous texts by the author (L'Annunziata, 1987, 2007b, 2016). Numerous applications of PET scintillation flow-cell detectors to the radio-HPLC of positron emitters are available in the scientific literature; and a few examples are the following:

- **(i)** Carbon-11 (Collier et al., 2018; Kawamura et al., 2017; Hong et al., 2015; Kil et al., 2013; Peyronneau et al., 2012);
- **(ii)** Fluorine-18 (Kirjavainen et al., 2018; Xu et al., 2018; Wang et al., 2017; Hsu et al., 2016; Al-Momani et al., 2015; Kadirvel et al., 2014; Wyffels et al., 2014; De Leonardis et al., 2011)
- **(iii)** Copper-64 (Bergmann et al., 2013, Yim, 2013 and Jackson, 2012)
- **(iv)** Gallium-68 (Sivapackiam et al., 2018, 2016, Zha et al., 2018, Knetsch et al., 2015, Ebenhan et al., 2014, and Claesener et al., 2012
- **(v)** Zirconium-89 (O'Hara et al., 2018)

The emission of positrons during radionuclide decay is always accompanied by the 511-keV gamma rays due to the annihilation of a positron and electron, when the positron comes to rest in matter and eventually comes into contact with an electron, its antiparticle. Annihilation results in the simultaneous emission of two 511-keV gamma rays for each positron emitted by a radionuclide, and the two gamma rays are emitted in opposite directions or 180 degrees to each other. A detailed treatment of positron−electron annihilation and the gamma radiation produced by this phenomenon is given in Chapter 1, Volume 1. An illustration of two gamma-ray photons produced by positron annihilation within a detector of a PET flow cell is provided in Fig. 10.8. The two gamma rays are illustrated as traveling simultaneously in opposite directions from the flow cell. When annihilation radiation is produced in the flow cell, the two gamma ray photons will produce scintillation light in the two BGO crystal detector windows of the flow cell. The BGO windows have an opaque coating on the inner sides facing the flow-cell tubing. With such a detector design, the light produced in one BGO window can be "seen" or detected by only one PMT, that PMT facing the uncovered side of the BGO window. However, for any given pair of positron annihilation gamma rays originating from the sample in the flow cell, the two light flashes produced in the two BGO windows will be detected simultaneously by the two PMTs within the coincidence time of the instrument, and the two scintillation events (one in each window) will be registered and counted as a single coincident event. This detector design is intended to reduce background counts. Background events in the two BGO windows will not occur generally at the same time within the coincidence time of the scintillation analyzer, and these events will be rejected by the coincidence circuitry.

A similar flow-cell detector for the measurement of positron emitters eluted from HPLC utilized for the analysis of PET radiopharmaceuticals was designed by Takei et al. (2001). Flow cells of various volumes containing coiled Teflon tubing are accommodated between two BGO crystal detectors as illustrated in Fig. 10.9. The BGO detectors are housed in aluminum casings, whereby only gamma−photon pairs originating from positron annihilation are detected in coincidence. A 15-mm distance between the two aluminum housings for the BGO detectors allows for the easy insertion of flow cells of different volumes. Two counting window widths for the measurement of ^{11}C, namely, 400−600 keV and 90−680 keV, yielded detection efficiencies of $32 \pm 1\%$ and $43 \pm 1\%$, respectively (Takei et al., 2001). The narrower counting region yielded a fivefold higher figure of merit (FOM) (i.e., E^2/B) with a background count rate of 1.7 ± 1 cpm and detection limit of 0.3 Bq.

Background count rates in the PET scintillation flow cells are reduced to 1/10 the backgrounds encountered in the previously described high-energy gamma cells, which also employ BGO or NaI(Tl) crystal windows. The counting efficiencies of the PET scintillation flow cells are reduced by only a third of those obtained by the high-

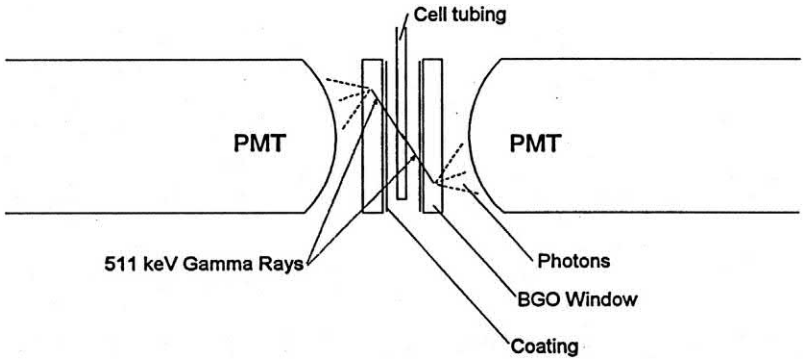

FIGURE 10.8 Basic diagram of a patented PET flow cell and photomultiplier tube (PMT) configurations used exclusively for the measurement of positron emitters. Annihilation gamma rays are illustrated interacting with the bismuth germanate (BGO) scintillator windows; however, the opaque coatings on the inner sides of the BGO detectors optically isolate the PMTs (© 1998 PerkinElmer, Inc. All rights reserved; printed with permission).

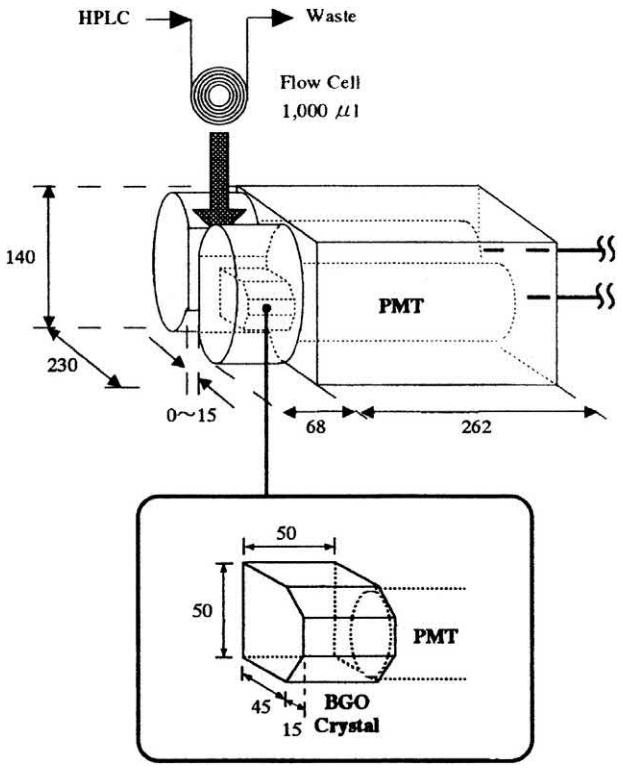

FIGURE 10.9 Block diagram of the sensitive positron detector. A pair of the BGO housings coupled to photomultipliers fixed in an aluminum frame. Dimensions are given in mm. *From Takei et al. (2001); reprinted with permission from Elsevier © 2001.*

energy gamma cells. Therefore, the PET flow cells provide considerably higher figures of merit (E^2/B) and lower detection limits for the measurement of positron emitters.

Not all scintillation detectors utilize PMTs. The PIN photodiode serves also as a suitable photomultiplier. Various types of photomultipliers are described in detail in Chapter 9, Volume 1. Carroll and Ramsey Associates produce an HPLC radioactivity flow detector consisting of a 1 cm^3 CsI(Tl) crystal detector coupled to a 1 cm^2 Si PIN photodiode and low-noise preamplifier built into a compact detector.

HPLC detector designs are not restricted to coiled Teflon tubing set between two detector windows as displayed previously in Fig. 10.9. Rather, the Teflon tubing, which houses the HPLC effluent, may be coiled around the scintillator crystal detector, as described by Huber et al. (2011). The tubing is coiled around the detector for higher sensitivity radio-HPLC applications, as this increases the length of time that the radioactivity peak spends near the detector by a factor of n, where n is the number of turns in the tubing and the sensitivity is increased by a factor of n. However, excessive length of tubing increases the duration that the radioactivity peak is near the detector, which results in peak broadening and thus reduced resolution for separating HPLC peaks.

A unique concept in the development of high-sensitivity radio-HPLC flow detectors for positron-emitting radionuclides arises from the work of Huber et al. (2010, 2011), who designed a detector by arranging conventional PET detector modules of BGO crystals into two parallel planes. Each of the BGO detector planes have an active detector volume of approximately $3 \times 3 \times 14$ cm, and the detector planes are separated at a distance of 3 cm providing a gap for the flow cell (e.g., coiled tubing). Coincidence counting of the annihilation γ ray photons is used with a 12 ns coincidence timing window to discriminate from background and improve the signal-to-noise ratio (SNR). As explained by Huber et al. (2011), the high-sensitivity radiation detector essentially takes a movie of the peak as it migrates through the flow cell; each frame of the movie is shifted (in space) so the centers of the peak are aligned, and then the frames are superimposed. The process provides the efficiency equivalent to a large area detector while reducing peak broadening. Straight or coiled tubing may be used. The use of a flow cell with the tubing coiled into a helix reduces the effective velocity (i.e., the velocity in the y-direction) of the radioactive compound passing through the detector. The helical flow cell thus increases the length of the active detector and the sensitivity for each activity peak. The gain in sensitivity is at the cost of some reduction in peak resolution; the peak width is broadened as a result of dispersion in the coiled flow cell. In comparison tests with a conventional HPLC flow cell with a 1 cm^3 CsI:Tl detector, Huber et al. (2011) demonstrate that the SNR for the high-sensitivity HPLC radiation detector signal was 28:1 for a single peak of 5.4 nCi of [^{18}F]fluorodeoxyglucose (FDG)-benzoic acid; whereas the SNR value for the conventional HPLC flow detector was estimated to be only 5:1.

Numerous radiopharmaceuticals labeled with short-lived positron-emitting nuclides, such as ^{11}C ($t_{½} = 20.38$ minutes), ^{18}F ($t_{½} = 109.7$ minutes), ^{64}Cu ($t_{½} = 12.7$ hours), and ^{68}Ga ($t_{½} = 68.3$ minutes), are synthesized and tested in radiochemical and clinical laboratories for specific applications in PET. Publications on the radiosynthesis and testing of PET radiopharmaceuticals are numerous. The short half-lives of the positron emitters produce minimal harm to patients while providing valuable imaging for medical diagnosis and monitoring the course of therapy.

Much work on the radiosynthesis of PET pharmaceuticals are focused on finding radiopharmaceuticals that can provide PET imaging for the diagnosis of specific diseases and the course of treatment. The radiosynthesis involves generally the use of HPLC and an online flow-cell detectors and mass spectrometer, which can provide immediate information on the course of reactions involved in synthesis. This immediate information is required due to the short half-lives of the PET radionuclides. For example, Bernard-Gauthier et al. (2013) synthesized 2-(4-[^{18}F]fluorophenyl)-7,8-dihydroxy-4H-chromen-4-one as a potential ^{18}F-PET pharmaceutical for brain imaging in the diagnosis of numerous neurodegenerative and psychiatric disorders,

such as Alzheimer's disease, Rett syndrome, Parkinson's disease, Huntington's disease, schizophrenia, traumatic brain injury, and major depressive disorder. Such a synthesis with a short-lived radionuclide requires fast HPLC separation with immediate online flow-cell analysis of reaction precursors and products and their identification by online MS. Fig. 10.10 illustrates an example of the online flow-cell analysis of ^{18}F bonded to reactants and products measured by HPLC and flow-cell analysis during the course of the synthesis of the ^{18}F-PET radiopharmaceutical. The flow-cell analysis, illustrated in Fig. 10.10, provides a record of how the reactions progress in the following sequence: Starting at 5 minutes, there is a small activity peak due to the preparation of ^{18}F-labeled dimethoxy precursors and a larger peak of $[^{18}F]F^-$ with Kryptofix-222 and K^+. After 25 minutes, the flow-cell analysis of the HPLC effluent shows the complete formation of the fluorinated dimethoxy precursor. After solid-phase extraction (SPE) and treatment with BBr_3, the flow-cell analysis after 15 minutes of reaction time shows a strong activity peak of the final ^{18}F-PET radiopharmaceutical due to a double methoxy deprotection of the precursor. Flow-cell analysis of HPLC effluents, such as the one illustrated in Fig. 10.10, can provide a quantitation of radiochemical yield of the reaction with flow-cell measurements of the radionuclide activities at the start and end of the reaction.

Due to the short half-lives of the positron emitters involved, the radiopharmaceuticals are most commonly prepared in large batches and transported to the PET imaging medical facilities; however, in the past few years, there has been increased interest in the decentralized production of these short-lived radiopharmaceuticals, including a dose-on-demand PET radiotracer synthesis oriented toward the imaging requirements for specific patients (Tarn et al., 2016). Research is thus focused into the development of rapid and efficient methods of synthesis and HPLC analysis of the radiopharmaceuticals. The testing of newly synthesized PET radiopharmaceuticals must be analyzed for purity and stability by HPLC with its effluent linked to a suitable radioactivity flow-cell detector. An example may be taken from the work of Knetsch et al. (2015), who synthesized the labeling of a trimeric fusarinine-C-RGD peptide with the PET radionuclide ^{68}Ga. The RGD peptide (L-arginyl-glycyl-L-aspartic acid) is responsible for cell adhesion to the extracellular matrix. Flow-cell radioactivity analysis of the ^{68}Ga-PET pharmaceutical in HPLC effluent, as illustrated in Fig. 10.11, provides quantitative evidence of the stability of the labeled compound in various chemical solutions and in human serum. The identity of the radioactivity peaks in the HPLC effluent can be confirmed by online MS or NMR spectroscopy.

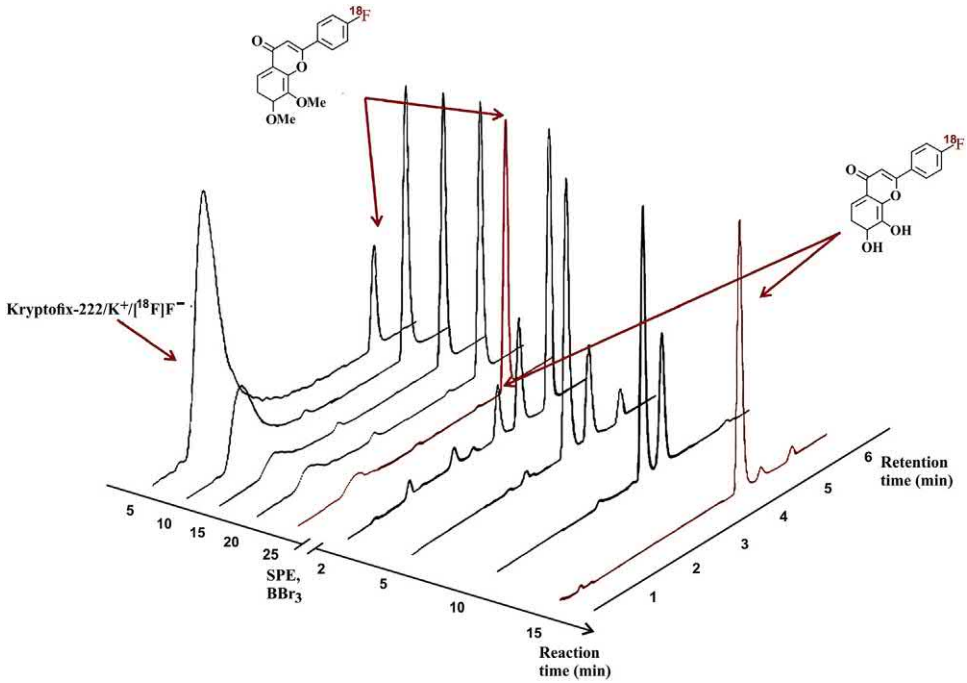

FIGURE 10.10 Analytical radiochromatograms for the advancement of the radiofluorination and BBr_3-promoted bis-deprotection reactions. At the far left, flow-cell analysis provides the time course for the labeling of a dimethoxy precursor with ^{18}F where after 25 minutes the free $[^{18}F]F^-$ peak drops to near background and the ^{18}F-dimethoxy precursors peak reaches a maximum. After solid-phase extraction (SPE) and BBr_3 reaction, the methoxy groups are cleaved, yielding the ^{18}F-dihydroxy final product after a 15-minutes reaction time. *From Bernard-Gauthier et al. E. Narrow-bore and microbore flow cells

Microvolume flow scintillation analyzer (FSA) cells are available, and these differ from the conventional flow cells mainly in their dimensions of inner-diameter (ID) and cell volume. The narrow-bore and microbore flow cells are made to accommodate narrow-bore (~2 mm ID) and microbore (~1 mm ID) HPLC systems that yield improved HPLC peak resolutions over the standard FSA systems. The standard or conventional FSA systems use larger cell volumes that accommodate wider HPLC columns (~5 mm ID). The major properties that distinguish narrow-bore and microbore FSA systems from the standard FSA systems are provided in Table 10.3. The high resolutions provided by the microbore HPLC-FSA systems yield improved molecular specie separations, which improves molecular identification via direct coupling to the ESI mass spectrometer (Johanns et al., 2017; Morris et al., 2017; Zeng et al., 2013; Onursal et al., 2011; Su et al., 2010). To demonstrate the potential of microbore flow cells, Schultz and Alexander (1998) tested a 1.2 μL volume on-column flow cell for use with 250-μm-ID HPLC columns capable of detecting < 200 DPM for a 1-minute-wide chromatogram peak with a PerkinElmer Radiomatic TR150 flow scintillation analyzer (see Fig. 10.12). They demonstrated that a solid scintillation cell packed with silanated lithium glass

TABLE 10.3 Characteristics of standard (conventional), narrow-bore, and microbore FSA systems.[a]

Characteristics	Standard FSA	Narrow-bore FSA	Microbore FSA
Cocktail pump	Digital	Digital	Precision syringe
HPLC columns	5 mm ID	2 mm ID	1 mm ID
Sample flow rate to FSA	333 μL to 2 mL/min	133 μL to 1 mL/min	25 −150 μL/min
LS cocktail flow rate (at 3:1 cocktail:sample ratio)	1−6 mL/min	400 μL to 3 mL/min	75 −450 μL/min
Mixing tee	>250 μL	10 μL	10 μL
Cell size	35 μL to 5 mL	15 −250 μL	3 −100 μL

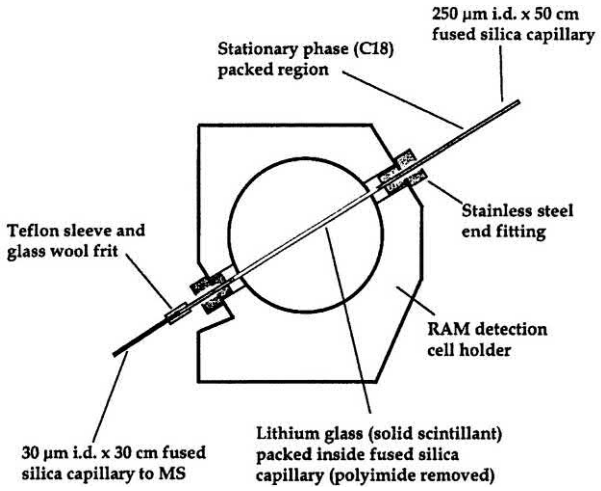

FIGURE 10.12 An on-column radioactivity monitor (RAM) flow cell for use with 250-µm-ID microcolumns. The flow cell volume is 1.2 µL. The detection window is 5 cm in length. *From Schultz and Alexander (1998), © 1998 John Wiley and Sons; Reproduced with permission.*

with a mean particle size of 9.6 ± 2.6 µm yielded a 24% increase in peak area compared with a cell packed with a mean particle size of 21.0 ± 2.5 µm. Also, they demonstrated that a 508-µm-ID cell yielded a 15% increase in peak area compared with a 762 µm-ID cell. As illustrated in Fig, 10.12, the microbore FSA cell is equipped with a 30-µm-ID tube for linkage directly to the inlet of an ESI chamber of a mass spectrometer.

F. Luminescence flow cell (fLumo)

The luminescence flow cell is a radio-HPLC detector (fLumo), which is only sensitive to positrons and insensitive to gamma rays for applications in the analysis and preparation of PET radiopharmaceuticals. The detector is identified as the fLumo by Berthold Technologies. The detector and its performance are reviewed in detail by Thonon et al. (2013), and only a brief description will be provided here.

The fLumo utilizes a flow cell modified with a solid melt-on scintillator that is sensitive to positrons and insensitive to the gamma photons that arise from positron annihilation. Thus, background from positron annihilation gamma photons can be ignored even without lead shielding. The detector is particularly useful in laboratories that are required to analyze positron-emitting radionuclides used for PET (e.g., ^{11}C. ^{18}F, ^{68}Ga, etc.), referred to as PET radionuclides. A schematic view of the Berthold LB 500 fLumo is illustrated in Fig. 10.13. The detector dimensions are $150 \times 350 \times 180$ mm^3 (w × d × h). Different flow-cell volumes (20, 50, and 100 µL) are interchangeable to accommodate diverse sample activities and flow rates. The scintillator is mounted onto the outside of the coiled tubing of the flow cell. Positrons emitted from within the flow cell volume interact with the scintillator, creating light photons that are captured by the PMT. The entire photon spectrum is captured by the PMT, which eliminates the need for a counting window.

As described by Thonon et al. (2013), the detector is connected to a high-energy radio monitor (HERM) electronics with dimensions of $210 \times 60 \times 120$ mm^3 (w × d × h). The HERM electronics component can provide radio-HPLC readout directly, or the HERM electronics can be connected to a personal computer (PC) via the use of a terminal program. The flow-cell data can be transferred via (1) a 0−1 V analog output, (2) a transistor−transistor logic (TTL) signal, or (3) via data transfer directly to a PC via a USB connection. Very high count rates of up to 1.0×10^7 cps can be measured by the PMT. Detector backgrounds of 10 cps are reported when no high-level source is available in the same room as the detector. In a hot cell where the PET radionuclides may be prepared in high-level batches, a detector background of 130 cps is reported when a 10 MBq ^{18}F source is at a distance of 20 cm from the cell. This background is reduced to 12 cps

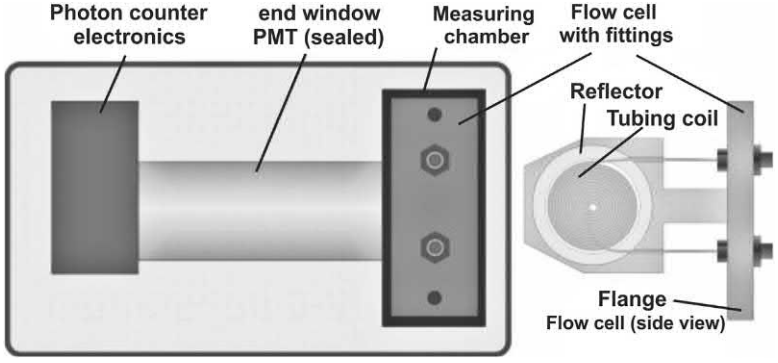

FIGURE 10.13 Schematic view of the Berthold LB 500 fLumo unshielded luminescence flow cell detector for positron-emitting radionuclides. *From Thonon et al. (2013); reprinted with permission from Elsevier © 2013.*

when the detector is shielded from the 10 MBq ^{18}F source with a 5 cm lead brick. At a signal-to-noise (S/N) ratio = 3, the detection limits are reported to be 0.2 MBq/mL per 10 μL injection volume (0.1 MBq/mL per 20 μL injected, HPLC system) for fluorine-18 and 0.04 MBq/mL for gallium-68 per 10 μL injected into the HPLC (Thonon et al., 2013). The higher limit of detection for fluorine-18 over that of gallium-68 is due to the differences in the energy maxima (E_{max}) of the positrons emitted by ^{18}F ($E_{max} = 0.634$ MeV) and ^{68}Ga ($E_{max} = 1.90$ MeV).

Linearity of response of a detector over a long range of activity is important in radionuclide analysis. The linearity of the fLumo flow-cell detector response measured by HPLC peak integration HPLC runs over a wide range of activity concentration 0.2 or 2500 MBq/mL is reported by Thonon et al., 2013) with a correlation coefficient $r^2 > 0.995$. A typical radio-HPLC of [^{18}F]FPRGD2 is illustrated in Fig. 10.14. The [^{18}F]FPRGD2 is an abbreviation for an efficient PET imaging agent [^{18}F]FB-E [c(RGDyK)]$_2$, which belongs to a series of RGD peptides (arg-gly-asp) labeled with [^{18}F] to improve the efficiency of tumor targeting and pharmacokinetics. The peak is symmetrical with a small width (~0.35 minutes) and similar to the peak of the nonradioactive compound, which is measured by a UV detector upstream from the fLumo radioactivity flow-cell detector.

Some examples that describe the utilization of the Berthold LB 500 fLumo for the radio-HPLC measurement of positron-emitting radionuclides are the radio-HPLC measurement of ^{18}F radiopharmaceuticals by Cardinale et al. (2017), Bertrand et al. (2016), and Perreault et al. (2016) and of ^{68}Ga-labeled pharmaceuticals by Isal et al. (2018), Azzouna et al. (2017, 2015) , and Asti et al. (2014a,b).

For the HPLC measurement of compounds labeled with radionuclides that decay by isomeric transition (e.g., ^{99m}Tc) or electron capture (e.g., ^{125}I) with the emission of gamma and X-ray photons, the Berthold LB 500 Herm with either a fLumo gamma-measuring cell or a separate NaI(Tl) flow-cell detector may be employed, as demonstrated in the works of Gaonkar et al. (2018, 2016), Nayak et al. (2015), and Baishya et al. (2014) in the radio-HPLC of ^{99m}Tc pharmaceuticals and Gevaert et al. (2016),Verbeken et al. (2015), Wynendaele et al. (2015), and Stalmans et al. (2014) in the radio-HPLC measurement of ^{125}I-labeled pharmaceuticals.

The Berthold LB 500 fLumo detector would be sensitive to high-energy negatron emitters; however, other detectors, such as the Berthold FlowStar^2 LB 514 with specific liquid and solid flow cells and dual PMT detection with coincidence counting, among others available from commercial suppliers listed previously in this chapter in Table 10.2, are much more efficient for low- and high-energy beta emitters, such as ^{3}H, ^{14}C, ^{35}S, ^{32}P, and ^{90}Y.

G. Hybrid silicon pixel flow cell

The Medipix2 and Timepix chips are hybrid silicon pixel sensors, which have been demonstrated by Tarn et al. (2016) and Maneuski et al. (2017) to be efficient detectors of positrons. They demonstrated that the Medipix2 and Timepix chips can be implemented in a microfluidic platform for positron counting in flow analysis assays of PET radiopharmaceuticals.

The Medipix2 sensor was developed by the Medipix2 Collaboration, which is an international research effort of numerous institutes and universities with the European Organization for Nuclear Research (CERN). The objective of the Medipix2 Collaboration was the development of a single photon counting pixel detector readout chip using a 25 μm CMOS (complementary metal–oxide–semiconductor process, https://medipix.web.cern.ch/collaboration/medipix2-collaboration, accessed June 26, 2018). The collaboration at CERN produced the Medipix2, resulting in a 65K single photon counting pixel array with a square pixel size of 55 μm on a 14 × 14 mm^2 detection area whereby the sensor can act as a real-time camera and counter of positrons (Tarn et al., 2016).

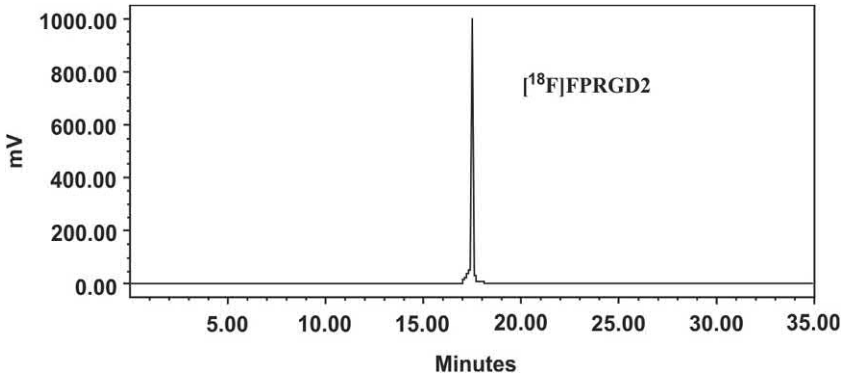

FIGURE 10.14 HPLC radiochromatogram of [^{18}F]FPGRDD2 (100 MBq/mL, 20 μL injected, calvolt 10,000 counts/s/volt). *From Thonon et al. (2013); reprinted with permission from Elsevier © 2013.*

The Timepix chip evolved at CERN from the development of the Medipix2. The pixels of the Timepix are of identical size as those of the Medipix2, but the functionality within each pixel was changed. In the Timepix chip, each pixel can be programmed to count particle hits like Medipix2 or to record Time-Over-Threshold (TOT) or to measure the arrival time of the first particle to impinge onto the pixel (https://medipix.web.cern.ch/collaboration/medipix2-collaboration, accessed June 26, 2018). As described by Maneuski et al. (2017), the Timepix chip can be set up to operate in two modes of interest for the measurement of positrons in a flow-cell arrangement on a microfluidic platform:

(i). In counting (or Medipix) mode, a threshold is set on the discriminator, and pulses above this value are counted on a 14 bit counter (maximum count is 11,810).

(ii). In TOT mode, the pulse triggers a local clock, and the clock ticks are counted while the pulse remains over threshold. This yields a value of the pulse width (which is proportional to pulse height) for each individual pulse, hence providing a measure of the energy of incident particle.

Tarn et al. (2016) tested the properties of the Medipix2 chip as a detector for positrons, which could serve as a detector for the analysis of PET pharmaceuticals in a microfluidic platform. They utilized solutions of ^{68}Ga-citrate, which is commonly used in PET imaging, and passed the ^{68}Ga solutions through a silica-based monolithic column designed for the purification and chromatographic separation of compounds in future microfluidic quality control platforms. An illustration of the first microfluidic arrangement for the HPLC analysis of positron emitter with the Medipix2 positron detector is provided in Fig. 10.15. The porous silica monolith column was prepared by Tarn et al. (2016) with a thin and flat shape (14 mm length × 4 mm width × 1.5 mm thickness). This length of the monolith corresponds with that of the Medipix2 chip positron detector, and the thin dimension of the monolith improves positron detection by minimizing monolith positron absorption, whereas the attachment of the monolith to the Medipix2 chip maximizes positron capture and

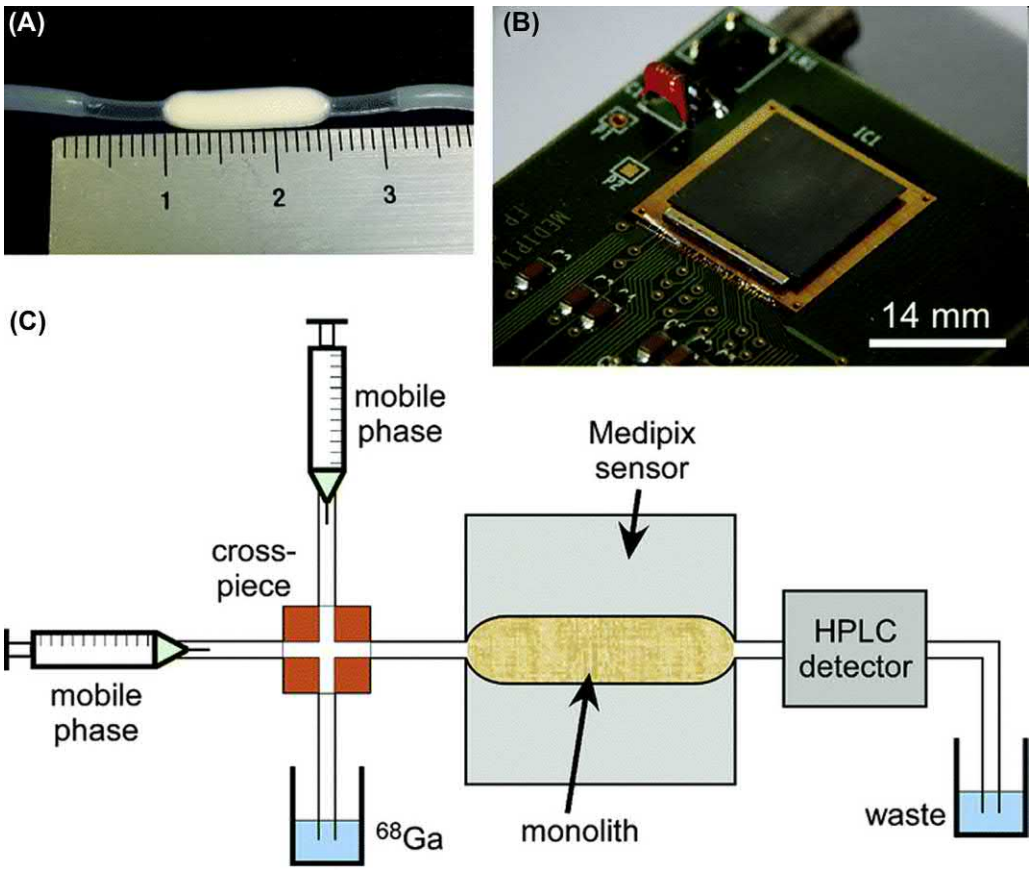

FIGURE 10.15 (A) Silica-based monolithic column encased in heat-shrink tubing, (B) Medipix positron detector, featuring 14 × 14 mm^2 sensor area. (C) Schematic of the experimental setup, with the monolith column placed above the Medipix sensor, and featuring a cross-injection system and a standard sodium iodide radio-HPLC detector. *From Tarn et al. (2016).*

detection. The monolith is connected at one end to a sample injection system and at the other end to a NaI(Tl)/PMT flow-cell. The NaI(Tl) flow-cell detector measures the ^{68}Ga activity via the measurement of the 0.511 MeV annihilation gamma photons after the ^{68}Ga exits the silica-based monolithic column and Medipix2 positron flow detector. The NaI(Tl) flow-cell response provides a measure of ^{68}Ga activity that can be compared with the ^{68}Ga activity measured by the Medipix2 chip.

The Medipix2 chip was demonstrated to be highly superior to a standard NaI(Tl) flow cell for radio-HPLC measurement of ^{68}Ga in a microfluidic platform, as illustrated in Fig. 10.16. Tarn et al. (2016) underscore that the Medipix detector shows a substantial increase in detection signal for the ^{68}Ga-citrate peak as illustrated, with a measured signal-to-noise (S/N) ratio of 14 for the Medipix positron detector and 3 for the standard NaI(Tl) radio-HPLC flow cell detector. Images of positron tracks detected by the Medipix chip at two different time points, namely, when the ^{68}Ga citrate passes through the monolithic column and after it has been eluted from the column, are illustrated in Fig. 10.16.

A measure of the linearity of response of a detector to differing levels of radionuclide activity that need to be measured in practical situations is a vital property. Tarn et al. (2016) tested varying ^{68}Ga citrate activity levels through the monolithic column with a record of 100 frames of the Medipix detector response with 1.0 second integration time. The linearity of the detector response is

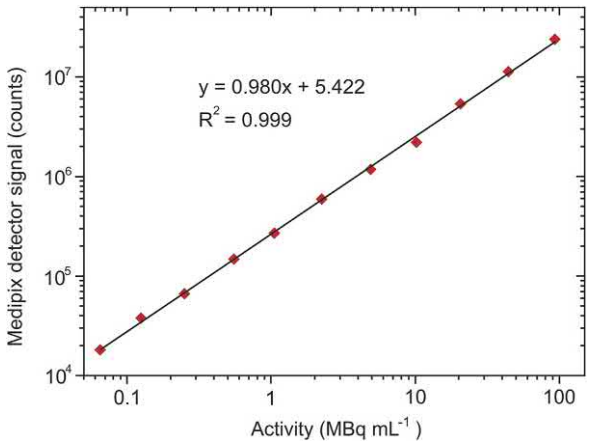

FIGURE 10.17 Plot illustrating the linearity of the Medipix2 positron detection signal with varying activity levels of ^{68}Ga citrate on a log scale. *From Tarn et al. (2016).*

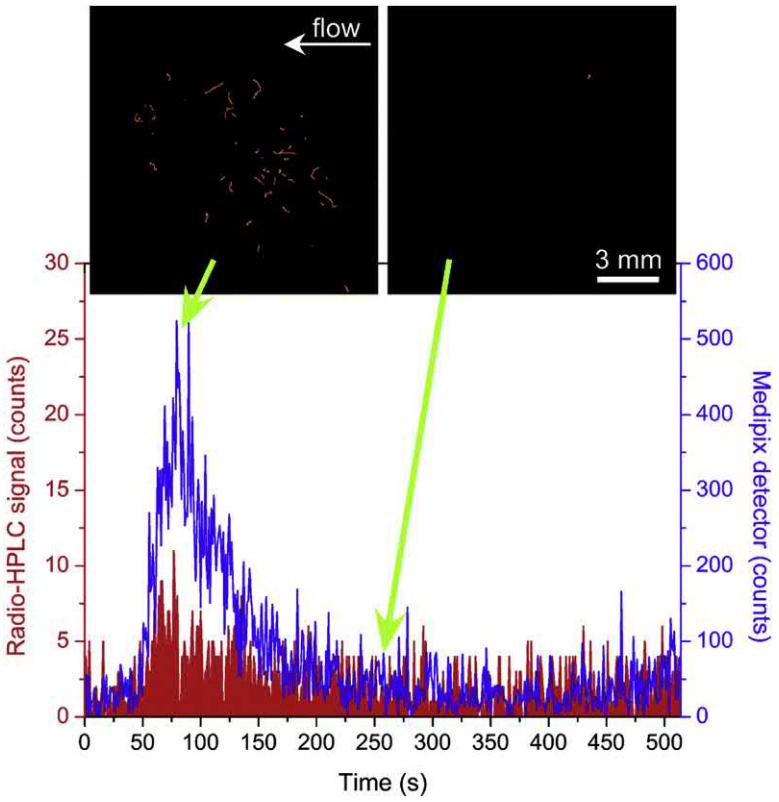

FIGURE 10.16 Plot of ^{68}Ga citrate radioactive emissions as it passed through the monolithic column (200 μL/min of a 15 MBq/mL solution). The blue (upper) signal shows the signal from the positron Medipix detector, whereas the red (lower) signal was taken from a flow-through NaI/PMT radio-HPLC detector. Note that the plots are on different scales. Inset are images (14 × 14 mm^2) taken from the Medipix detector at different time points. Color is visible in the electronic version of the book. *From Tarn et al. (2016).*

illustrated in Fig. 10.17. They note that a clinical PET scan typically requires ~370 MBq (10 mCi), and with a maximum injection volume to a patient of 10 mL, the expected radionuclide activity levels during the purification and quality control of the radiopharmaceutical would be a minimum of 37 MBq/mL. Thus, Tarn et al. (2016) note that the Medipix detector would be able to detect clinically relevant levels of radioactivity in volumes of hundreds of nanoliters.

Maneuski et al. (2017) tested the counting capability of the Timepix chip for the potential radioassay of positron emitters in the production of radiopharmaceuticals for PET. They utilized a positron detection system consisting of a 300-μm-thick silicon detector with a 256 × 256 array of pixels, each of 55 μm on a side, providing a total detector active area of 1.96 cm^2. The detector was bump bonded to a Timepix readout chip, which processes individually the signal output from each pixel. As noted earlier in this section, the Timepix chip has more than one mode of operation, which permits a measurement of the total energy deposited by each positron. This prevents the double counting of positron hits by individual pixels at low activities, which can yield optimum minimum detectable activities (MDAs). To enable high sample count rates of positron emitters generally encountered in the synthesis and preparation of PET pharmaceuticals, Maneuski et al. (2017) employed an amplifier shaping factor of ~1 μs to assure little double pulsing if the pixel count rate is kept below 1 MHz per pixel, which would yield a maximum count rate of 40 MHz/mm^2 with linear detector response. The linearity of the Timepix/Medipix detector response compared with that of a CsF crystal scintillation detector coupled to a PMT is illustrated in Fig. 10.18. The sensitivity of the Timepix was demonstrated to be superior to a BGO detector with measureable positron signals down to the background level of the laboratory. Maneuski et al. (2017) demonstrate that the detection of positrons in lieu of annihilation gammas with the Medipix/Timepix detector in a very small setup (the entire detector system fits in the palm of a person with USB cable link to a PC) provides high position resolution as well as a high sensitivity and activity range with linearity of response all of which open the door to the application of the Medipix/Timepix detectors to the microfluidic analysis of pharmaceuticals for PET.

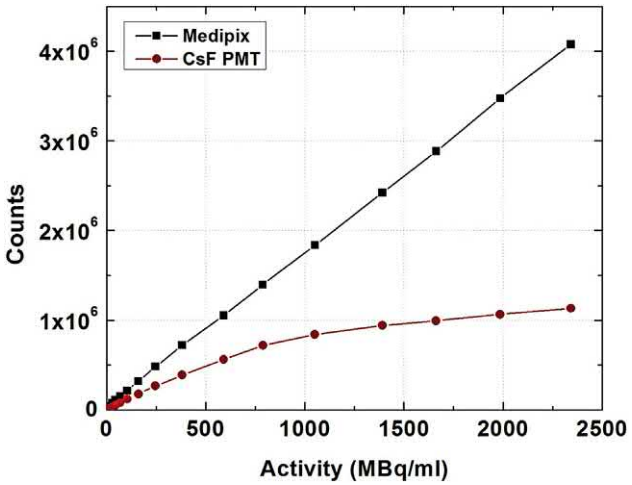

FIGURE 10.18 Comparison of a CsF scintillator PMT and the Timepix detector for measuring different concentrations of ^{18}F-solution injected on to an HPLC system. The counting of single positrons is inherently linear in the absence of any saturation effects. *From Maneuski et al. (2017); reprinted with permission from Elsevier © 2017.*

An excellent review of progress toward the microfluidic quality control testing of radiopharmaceuticals is provided by Ha et al. (2017), and reviews on the development of silica monoliths and various microfluidic columns for chromatographic separations in microfluidic platforms are provided by ALOthman and Wabaidur (2019), Konala and Tetala (2018), Masini and Svec (2017), Mattrey et al. (2017), Shalliker (2017), Groarke and Brabazon (2016), and Hong et al. (2016).

H. Criteria for flow-cell selection

When making a decision on which type of scintillation flow cell would be best for a particular application, several factors should be considered among which are (1) the detection efficiency of the flow cell for the radionuclide of interest, (2) the flow-cell detector background when the MDA is an important factor, (3) the level of radioactivity of the sample components, that is, the sensitivity required, which takes into account the previous items (1) and (2) and the FOM defined by E^2/B, which would be a measure of detector sensitivity, (4) the costs involved in using scintillation fluor cocktail with a liquid (homogeneous) flow cell, (5) the chemical composition of the HPLC eluent used, and (6) whether further analysis of the HPLC effluent is required (i.e., Must the compounds separated and detected in the HPLC effluent be analyzed by online MS or NMR spectroscopy, or must the components be isolated and other chemical and biological tests be performed on the separated components?). Data listed in Tables 10.1 and 10.4 are helpful in the selection of a scintillation flow cell to use for a particular application. Some examples will be cited to illustrate the use of the data in these tables. The data listed in Table 10.4 refer to flow cells that have specific detector geometries for BGO and CaF_2(Eu) scintillator crystals and specific counting window regions. Flow-cell detectors with these specific geometries may or may not be available currently on the commercial markets. Nevertheless, the data provided in Table 10.4 can serve to provide a general idea of the potential for using a BGO or CaF_2(Eu) flow cell for the measurement of the radionuclides listed.

The highest counting efficiencies for all β or α emitters are obtained with the liquid scintillator (homogeneous) flow cell. However, a special low-viscosity nongelling LS fluor cocktail must be mixed with the HPLC effluent stream with a controlled pump and static fluid mixer. The separated compounds or molecular entities in the HPLC effluent are thereby rendered useless for any other chemical or biological tests that may be required. A stream splitter could be employed to separate part of the HPLC effluent for online MS, online NMR spectroscopy, or fraction-collecting prior to the mixing with the scintillation fluor cocktail. Stream splitting permits only a portion of the HPLC-separated components of the sample to be collected or analyzed online by the mass and NMR spectrometers. In the case of ^{3}H measurements when the separated ^{3}H-labeled components are of low activity (close to background), there is no alternative but to use the liquid homogeneous flow cell.

If sample activities are well above background, ^{3}H can be detected with a solid (heterogeneous) cell containing the solid scintillator such as the YG-150 solid cell (Berthold Technologies) or monocrystalline SolarScint (PerkinElmer, Inc.) among others. See Fig. 10.6 for an example of the detection of ^{3}H-labeled inositol phosphates by a heterogeneous flow cell containing SolarScint. The advantages in this case are no fluor cocktail is used, no chemical quench problem exists, and the entire effluent stream can be utilized for online MS or NMR spectroscopy or other subsequent chemical or biological tests or even isolated from solution following fraction collection. All other beta emitters (e.g., ^{14}C, ^{35}S, ^{33}P, ^{32}P) or alpha emitters are detected with relatively high counting efficiencies with the heterogeneous flow cell (also referred to as solid cells), such as the YG-150 (yttrium glass) solid cell for standard flow rates, YG-40-x6M solid microbore cell or the YG 50-S5P solid prep cell for preparative HPLC with higher sample activities and flow rates $>$ 3 mL/min (Berthold Technologies). The only disadvantage of the heterogeneous cell is the possible reversible and sometimes irreversible adsorption of the sample molecules (e.g., peptides, lipids, proteins) onto the solid scintillator that cause peak broadening and increased background from one HPLC run to another. Berthold Technologies and possibly other suppliers provide solid (heterogeneous) flow cells for samples with such molecular sticking problems, such as the YG 150-S6D for standard flow rates and activities, the YG 400 solid cell for higher flow rates or lower activities, and the YG xx-S6M for the solid microbore cell at standard flow rates and activities or the YG 75-x6M for the solid microbore cell at higher flow rates or lower activities.

The solid scintillator (heterogeneous) flow cell is particularly applicable to radioactivity measurements when very high pressure (up to 3000 psi) and high flow rates are required. Table 10.1 lists some solid scintillator (heterogeneous) cells used for high pressure/high flow rate conditions.

The gamma cells are classified into two types: (1) the high-energy gamma cell, which yields optimum detection efficiencies for radionuclide X-ray or gamma emissions $>$ 70 keV energy, and (2) the low-energy gamma cell, which provides higher counting efficiencies for radionuclides with X-ray or gamma emissions of energy $<$ 70 keV. Table 10.4 provides the counting efficiencies (*%E*), background count rates, and calculated FOMs for a number of gamma-emitting radionuclides with both the high-energy Gamma-B and low-energy Gamma-C scintillation flow cells, which are trademarks of PerkinElmer, Inc. The Gamma-B and Gamma-C flow cells may no longer be available commercially, and the data listed in Table 10.4 refer to flow cells that have specific detector geometries for BGO and CaF_2(Eu) scintillator crystals. Nevertheless, the data provided in Table 10.4 can serve to provide a general idea of the potential for using a BGO or CaF_2(Eu) flow cell for the measurement of the radionuclides listed.

The counting regions, listed in Table 10.4, from which the counting efficiencies and backgrounds were determined, are defined by lower level (LL) and upper level (UL) discriminator settings of a MCA with pulse height equivalents in keV. The most abundant X-ray and gamma-ray emissions of each radionuclide are also listed in Table 10.4 to help the reader interpret the efficiencies provided by the two types of gamma cells. From Table 10.4, it can be seen that ^{55}Fe, ^{125}I, and ^{109}Cd are more efficiently measured with the low-level Gamma C flow cell manufactured with CaF_2(Eu) scintillator windows, which is evidenced by the superior *%E* and FOM values. A flow-cell equivalent to the Gamma C is the Iodine Cell (I 100−1000) produced by Berthold Technologies. The FOMs for the measurement of ^{201}Tl with the Gamma-B and Gamma-C flow cells are very close, and either of these cells would be appropriate. Akhlaghi et al. (2008) provides an excellent example of the use of FSA for the measurement of ^{201}Tl. The remaining nuclides listed in Table 10.4 in order of increasing gamma ray energy are detected more efficiently with the high-energy Gamma-B flow cell, which is manufactured with the higher density and thicker BGO scintillator windows. A flow cell equivalent to the Gamma-B cell is the Gamma cell BGO-X produced by Berthold Technologies.

The reader should notice that varying the counting region LL and UL discriminator settings will govern the counting efficiency and background for any particular radionuclide to be measured and flow cell used. By adjusting the region settings, an optimum FOM can be found, which is calculated as

$$\mathrm{FOM} = E^2/B \tag{10.1}$$

TABLE 10.4 Performance characteristics of high-energy (BGO) and low-energy [CaF_2(Eu)] Bremsstrahlung and gamma scintillation flow cell detectors for the detection of radionuclides listed in order of increasing photon radiation emission energies.[a,c]

		High-energy Gamma-B, BGO[d]				Low-energy Gamma-C, CaF_2(Eu)[d]			
Radionuclide	Radiation energy (keV)[b]	Region (keV)	%E	Background	FOM (E^2/B)	Region (keV)	%E	Background (CPM)	FOM (E^2/B)
^{55}Fe	Bremsstrahlung up to 23.2 keV	0–35	0.2	5	0.008	0–10	14.2	40	5.0
^{125}I	27.4-keV (30%) and 31-keV (>100%) X-rays, 35-keV gamma (7.0%)	0–120	27.1	48	15.3	10–85	81.1	108	60.8

[b]The most abundant radiations are given, and in parenthesis the approximate intensities or relative abundances of the radiations are provided as a percentage, that is, radiation emissions per 100 disintegrations.
[c]The data listed refer to flow cells that have specific detector geometries for BGO and $CaF_2(Eu)$ scintillator crystals and specific counting window regions. Flow-cell detectors with these specific geometries may or may not be available currently on the commercial markets. Nevertheless, the data provided can serve to provide a general idea of the potential for using a BGO or $CaF_2(Eu)$ flow cell for the measurement of the radionuclides listed.
[d]Flow cells similar to the Gamma B and Gamma C cells are the Gamma Cell BGO-X and the Iodine Cell 1 100–1000, respectively, of Berthold Technologies.

where E is the percent counting efficiency and B is the background count rate. An optimum FOM can provide higher sensitivity for radionuclide detection by reducing the MDA as described further on in this chapter. In Table 10.4, counting region settings can be compared with the X-ray and gamma emissions of each radionuclide. Limiting the counting region settings will limit the radiation energies that can be detected by the flow cells; however, the limited region settings will also reduce background count rates. The FOM, therefore, is a good means of calculating the optimum tradeoff of highest counting efficiency and lowest background. An interesting example may be taken from the radionuclide ^{51}Cr listed in Table 10.4. Its 320-keV gamma ray emission has only a 10% intensity or relative abundance, which is defined as the number of emissions per 100 radionuclide disintegrations. In the case of ^{51}Cr, there are only 10 gamma rays emitted per 100 ^{51}Cr radionuclide disintegrations. Therefore, with the selected counting region of 200–500 keV (Table 10.4), a maximum counting efficiency of only 10% can be achieved, if all gamma rays could be detected without loss. The reported counting efficiency is 3% for the high-energy Gamma-B flow cell. A significantly higher counting efficiency for ^{51}Cr could be obtained by increasing the counting region to 0–500 keV to include detection of the 5-keV X-rays; however, this would result in a much higher background count rate.

The high-energy and low-energy gamma cells have the advantage that the HPLC effluent is not mixed with any fluor cocktail, as the X- or gamma radiation emissions are detected outside the Teflon tubing of the flow cell by the external BGO or CaF_2(Eu) cell windows. Also, there is no adsorption of radioactive sample onto scintillator as would occur in the heterogeneous flow cell types. After measurement of radioactivity in the separated components of the HPLC effluent, the entire effluent stream can be analyzed online by MS or NMR spectroscopy or collected in fractions with the traditional fraction collector to permit subsequent chemical and biological studies on fractions of interest.

The reader should also note from Table 10.1 that high-energy beta particle emitters, such as ^{32}P and ^{90}Y, can be detected by the low-energy gamma cells at a significantly high counting efficiency (~60%). Therefore, if samples are not near background and the MDA is not of concern, the gamma cell could be the flow cell of choice for these high-energy beta particle emitters because no fluor cocktail is required and there is no adsorption of sample in the gamma cell. Even for the intermediate-energy β emitters, such as ^{14}C, ^{35}S, and ^{33}P, where counting efficiencies with the low-energy Gamma-C flow cell may be very low (~0.1%), the low-energy gamma cell may be the cell of choice when radioactivity levels are very high, such as in the μCi or mCi levels, commonly encountered in laboratories involved in the preparation or synthesis of radioisotope-labeled compounds or sources. The low counting efficiencies of the low-energy gamma cell for the intermediate-energy β emitter are an advantage in this case because sample activities are high, count rates are reduced to useable levels due to the low counting efficiency, and the labeled compounds or sources can be fully recovered with a fraction collector.

III. Principles of flow scintillation counting

A. Count rates

As noted in Chapter 8, Volume 2 on Radioactivity Counting Statistics of this book, the sample counting time is an important factor in the measurement of sample radioactivity. Longer counting times provide statistically more accurate measurements of the true count, that is, the standard deviations of the count determinations are reduced as counting time is increased. In flow counting, however, the sample counting time is a function of the flow rate and flow-cell volume, as the sample consists of a stream, which passes through a tube (flow cell) situated perpendicular to the faces of the photon detectors (PMTs) as illustrated in Fig. 10.2. The photon detectors, therefore, will see the radioactive sample only for the time that the sample resides in the flow cell. This period of time is referred to as the residence time (T_R), which is calculated as

$$T_R = \frac{V}{F} \tag{10.2}$$

where V is the cell volume in mL and F is the sample flow rate in mL/min. When a liquid (homogeneous) flow cell is used, the flow rate (F) is a function of the sum of the HPLC and cocktail flow rates. Therefore, the calculation of the flow rate for a homogeneous cell must include the mix ratio of the HPLC mobile phase to cocktail. For example, for a 3:1 cocktail/mobile phase ratio, the flow rate is calculated as

$$F = \text{HPLC flow rate} + \text{Cocktail flow rate} \tag{10.3}$$

or

$$F = 1.0\ \text{mL/min} + 3.0\ \text{mL/min} = 4.0\ \text{mL/min}$$

Because the sample flows through the cell at a given rate, sample will enter and leave the cell simultaneously. Therefore, the flow scintillation analyzer will measure the flowing sample in segments according to the sample residence time. The instrument will automatically calculate the count rates according to the calculations illustrated subsequently. The following example illustrates the calculation of residence time and count rate:

Example 10.1 If we have a flow cell of 600 μL volume and a flow rate of 4.0 mL/min and the counts collected (observed

counts) were 1200, we can calculate the residence time and count rate as follows:

$$T_R = \frac{0.6 \text{ mL}}{4.0 \text{ mL/min}} = 0.15 \text{ min}$$

The count rate (CPM) can be calculated by dividing the observed counts by the residence time, as in this example,

$$\text{Count rate} = \frac{\text{Counts}}{T_R} \tag{10.4}$$

$$\text{Count rate} = \frac{1200 \text{ counts}}{0.15 \text{ min}} = 8000 \text{ CPM}$$

or more easily the count rate is calculated as described previously by the author (L'Annunziata, 1979) by multiplying the counts collected by the inverse of the flow equation ratio (Eq. 10.2) or

$$\text{Count rate} = c\frac{F}{V} \tag{10.5}$$

where c is the total observed number of counts. From Eq. (10.5) and the above example, we can calculate the count rate as

$$\text{Count rate} = 1200 \text{ counts} \cdot \frac{4.0 \text{ mL/min}}{0.6 \text{ mL}} = 8000 \text{ CPM}$$

The observed sample counts and count rate calculations on a flowing sample are repeated or "updated" by the instrument during fixed or variable update periods, which can be set by the operator. The update times can be adjusted to any value over the range of 1−120 s in modern flow scintillation analyzers. Both observed sample counts and background counts are, therefore, calculated per update time and net count rates calculated as described in the subsequent section.

B. Background and net count rate

The computer programs of the flow scintillation analyzer are designed to subtract random background events from sample radionuclide decay events to provide a net sample count rate according to the equation:

$$\text{Net CPM} = \frac{\text{observed counts} - \text{background counts}}{T_R} \tag{10.6}$$

The background counts are subtracted from the gross sample counts before dividing by the residence time. Otherwise, as explained by Kessler (1986), the background counts are amplified by the residence time of the sample in the flow cell. Reich et al. (1988) also explain that the true background of the system is the result of external cosmic radiation and electronic noise, which are independent of the flow. Therefore, the "static" (nonflow) background must be eliminated before the flow equation is applied. If not, the background would be overstated by a multiple of the flow rate.

In the calculation of the net count rate according to Eq. (10.6), both the observed counts and the background counts are per update time. If the update time selected is 6 s, then the counts accumulated during a 6-s update time are inputted into the equation. Also, the background counts subtracted in the above equation, whether determined by the system or entered into the software by the operator, are divided from a background CPM into the equivalent of an update time worth of background counts before being entered automatically into the equation. Hence, the net count rate is calculated each update time by subtraction of the background before dividing by the residence time.

Example 10.2 If a radionuclide standard is injected into a flow-cell detector via the inlet line of the liquid scintillator pump, the cell volume is 400 μL, the flow rate is 4.0 mL/min, an update time of 6 s is selected, a background count rate of 25 counts per minute is entered into the software program, and the observed counts in a given update time is 400, then the Net CPM is calculated according to Eq. (10.6) as

$$\text{Net CPM} = \frac{400 \text{ counts} - 2.5 \text{ counts}}{0.4 \text{ mL}/4.0 \text{ mL/min}}$$

$$= \frac{397.5 \text{ counts}}{0.1 \text{ min}}$$

$$= 3975 \text{ CPM}$$

Note that both the observed sample counts and background counts in the above calculation are per update time. In the above example, the background represents less than 1% of the net count rate. However, when either the update counts get lower, background increases, or residence time is reduced, the background becomes more significant and an accurate measurement and proper subtraction of background may be necessary.

The background is determined obviously without radioactive sample; however, the homogeneous flow cell must contain the fluor cocktail and HPLC eluent used for a particular HPLC run, and the heterogeneous cell must contain the HPLC eluent when background is determined. If a homogeneous cell is used, the background is determined by filling the cell with the same ratio of cocktail to HPLC mobile phase as will be used during the HPLC runs. A background run is then carried out for 10 minutes or more with a minute scalar time

for the summary. The statistical method used to calculate the background is as follows:

$$\mathrm{BKG} = \left[\frac{B_s}{N} + 2\frac{\sqrt{B_s}}{\sqrt{N}}\right](N) \tag{10.7}$$

where BKG is the background subtracted in the calculation of net count rate, B_S is the measured background expressed in counts in one scalar minute, and N is the number of samplings per minute. In the previous example, where the update time was 6 s, the calculation is carried out every 6 s or 0.1 minutes. Therefore, N in this case would be equal to 10 samplings. The division and multiplication by the number of samplings (N) is required because the calculation is based on an update time, whereas the background is given in counts each minute.

C. Counting efficiency and disintegration rates

The counting efficiency (E) is the ratio of the net sample count rate (i.e., background-subtracted count rate) as measured by the instrument and the actual disintegration rate or activity of the measured sample. The ratio, when multiplied by 100, is expressed as the percent counting efficiency or

$$\%E = \frac{\text{net CPM}_\text{S}}{\text{DPM}_\text{S}}(100) \tag{10.8}$$

where net CPM_S and DPM_S are the measured net sample count rate (i.e., background-subtracted count rate) and the actual sample disintegration rate, respectively. The counting efficiency is a function of the radionuclide emissions and the energies of the particles emitted, the type of liquid or solid flow cell detector used, counting region selected, and the level of quench in the sample, which is governed, in turn, by the chemistry of the HPLC mobile phase and scintillator. To express the flow scintillation analysis results in DPM, it is necessary, therefore, to determine the counting efficiency for a particular application or HPLC run.

The counting efficiency can be determined with a radionuclide standard in the flow cell while under a static (isocratic) or gradient (dynamic) mode.

When quenching is constant in an HPLC run, that is, the HPLC sample components and mobile phase (i.e., eluent) have no changing effect on the counting efficiency, a static efficiency correction can be used. Under this type of correction, the counting efficiency is constant throughout the entire HPLC run.

When the HPLC sample components and eluent are not constant and thus have a changing affect on the counting efficiency, it is necessary to carry out a gradient counting efficiency run to determine the counting efficiencies at different points in time during the HPLC run as the sample components elute from the HPLC column.

1. Static efficiency runs

There are two ways of performing the static efficiency runs. When the sample components have absolutely no quenching effect on the counting efficiency of the scintillation system, it is possible to determine the counting efficiency *independent of the HPLC system*. When the sample components do have a quenching effect on the counting efficiency, but the effect is constant throughout the length of the HPLC run, it is necessary to determine the counting efficiency *dependent on the HPLC system.* The two methods are subsequently described. The detailed procedures are available from Anonymous (1997).

a. Independent of the high-performance liquid chromatography system

This method requires spiking a volume of the flow scintillation cocktail with a radionuclide standard and filling the scintillation flow cell with the standard in cocktail. Solid (heterogeneous) flow cells and gamma cells obviously do not use scintillation cocktail; and counting efficiency determinations with these types of cells require only an eluent solution of the radioactivity standard. An outline of the procedure used for liquid (homogeneous) flow cells is as follows:

(1) The normal background of the system is determined first.

(2) A known activity (DPM) of the radionuclide of interest is added to an accurately measured volume of the flow scintillation cocktail. A minimum volume of 25 mL is used for each radionuclide to be measured. To ensure sufficiently high count rates and good counting statistics, the activity of the standards used can be estimated by taking into account the flow cell volume and estimated counting efficiency of the flow cell. For example, the final activity concentrations of standard should be at least approximately 10,000 DPM/mL for ^{14}C and approximately 25,000 DPM/mL for ^{3}H.

(3) The counting parameters for the particular radionuclide and efficiency run parameters are set in the flow scintillation analyzer, including the DPM in the flow cell, which is calculated as

$$\text{DPM in cell} = (\text{DPM/mL})(\text{flow cell volume in mL}) \tag{10.9}$$

(4) The inlet line for the LS pump is placed into the container holding the solution of radionuclide standard in flow scintillation cocktail. A separate inlet line and line filter are used to avoid possible contamination of the LS cocktail source used during normal runs.

(5) The LS pump is kept running for at least 5 minutes to assure the complete filling of the flow cell.
(6) After filling the flow cell, the LS pump is stopped, and the efficiency run program of the computer-controlled flow scintillation analyzer is initiated. The counting efficiency is calculated according to the basic Eq. (10.8) as

$$\%E = \frac{\text{net CPM in cell}}{\text{DPM in cell}}(100) \tag{10.10}$$

(7) The efficiency run is saved, and flow scintillation cocktail containing no radionuclide is pumped through the cell until background levels are reached.
(8) When dual radionuclide analysis is required (e.g., $^{3}H-^{14}C$), the procedure is repeated with the second radionuclide with the counting efficiency run set to a second counting region.

b. dependent on the high-performance liquid chromatography system

When the sample components have a quenching effect on the counting efficiency, but the effect is constant, it is necessary to spike a volume of the flow scintillation cocktail with a known activity of radionuclide standard. The flow cell is then filled with a mixture of the spiked LS cocktail and HPLC eluent. This method and the previously described procedure are static methods, and the procedures are quite similar with the exception that step (6) in the previous procedure will, in this case, include running both the LS pump and the HPLC to fill the flow cell with a mixture of spiked scintillation cocktail and HPLC eluent. Both pumps are turned off when the flow cell is filled, and the efficiency run program is initiated as described in the previous static procedure.

^{3}H and ^{14}C are low- and intermediate-energy β-emitting radionuclides, respectively, and the LS yields for these radionuclides are easily quenched. Phosphorus-32 is not easily quenched, as described in Chapter 6, Volume 1 of this book. One can expect, therefore, that HPLC eluent will have an effect on the counting efficiency of ^{3}H and ^{14}C in most flow scintillation systems. The preceding counting efficiency determination procedure, which includes HPLC eluent, is recommended when low- to intermediate-level radionuclides are used and when the HPLC eluent components have a constant quench effect on the counting efficiency.

2. Gradient efficiency run

When the HPLC eluent consists of a gradient mixture, quench will vary during the HPLC run and the counting efficiencies will, therefore, not be constant. In this case, a gradient efficiency run is required. The setup procedure for the gradient efficiency run is similar to the previously described efficiency run (dependent on the HPLC system) with the exception that the efficiency run is a dynamic one. The dynamic run requires that both the LS pump and the HPLC gradient run simultaneously during the efficiency run. The computer program linked to the flow scintillation analyzer may construct a gradient efficiency correction curve or table, which can be used to correct for counting efficiency changes during a specific gradient HPLC run.

When the counting efficiency of the detection system is known, the scintillation analyzer can convert the count rates of the eluting components in the HPLC effluent by use of the following converted form of the basic Eq. (10.8):

$$\text{DPM} = \frac{\text{net CPM}}{\%E/100} \tag{10.11}$$

where net CPM is that defined by Eq. (10.6), whereby the above equation can be written in detail as follows:

$$\text{DPM} = \frac{(\text{observed counts} - \text{background counts})/T_R}{\%E/100} \tag{10.12}$$

Eq. (10.12) can also be expressed as

$$\text{DPM} = \frac{\text{net counts}}{(T_R)(E)} \tag{10.13}$$

where net counts is the background-subtracted counts and E is the decimal equivalent of the percent counting efficiency. For the column chromatographic separation of radionuclides, Grate et al. (1996) and Grate and Egorov (1998a,b) take Eq. (10.13) further to include the efficiency of recovery (E_{rec}), which is the ratio of the activity of a particular radionuclide recovered from a separation column (e.g., HPLC column) compared with the activity of that nuclide loaded on the column. They quantify radionuclides eluted from separation columns according to flow scintillation peak areas described by the equation:

$$\text{DPM} = \frac{C_n}{(E_d)(E_{rec})(T_R)} \tag{10.14}$$

where DPM is the radionuclide activity, C_n is the background-corrected peak area or, in other words, the net counts, that is, the observed counts minus the background counts determined in a blank run, E_d is the decimal equivalent of the % detection efficiency, and E_{rec} and T_R are the radionuclide efficiency of recovery and sample residence time in the flow cell, described previously. Radionuclide recovery efficiencies can sometimes be measured during a run with the use of a tracer nuclide, such as the gamma-emitting nuclide ^{85}Sr as a tracer for the beta-

emitting nuclide ^{90}Sr. If a known activity of ^{85}Sr is added to a sample, separated on a column, and collected and analyzed for its gamma activity, the recovery efficiency for radiostrontium can be calculated.

D. Minimal detectable activity

In many forms of chromatography, peaks that are sharp, detectable above the baseline, and well defined or proportioned are easier to detect than a broad peak or one that displays tailing and lack of form. In radio-HPLC, the MDA is a calculated activity of a peak from a flow-cell detector expressed in disintegration per minute (DPM) or disintegrations per second (Bq) based on the relative peak height and the presumption that the limit of detectability or MDA is twice the count rate of the background (Reich et al., 1988; Anonymous, 1990), which is calculated as the

$$\mathrm{MDA} = (B)(W)/(T_R)(E) \tag{10.15}$$

where B is the background count rate, W is the width of the peak in minutes, T_R is the residence time defined by Eq. (10.2), and E is the decimal equivalent of the % counting efficiency or $\%E/100$.

As explained by Reich et al. (1988), the MDA of a flow-cell detector is not directly related to the total amount of radioactivity in any given peak but rather to the specific activity of any flow segment residing in the detector at any given time. Therefore, flow rate, cell volume, and peak width in addition to the obvious background and detection efficiency all play a key role in defining the MDA. Borai and Mady (2002) measured the MDA or lower limit of detection (LLD) in Bq units for ^{238}U and ^{232}Th separated on ion exchange chromatograph columns. They used the expression of Currie (1968) where

$$\mathrm{LLD} = K\left[2.71 + 4.65(B)^{1/2}\right] \tag{10.16}$$

where K is a proportionality constant relating the flow scintillation detector response to the activity and B is the number of background counts for a given counting period. The value of K has units of reciprocal time and is calculated according to the following:

$$K = W/(T_R)(E)(V) \tag{10.17}$$

where W is the peak width in units of volume, T_R is the sample residence time in the flow cell, E is the detector counting efficiency, and V is the flow-cell detector volume (Reeve and Crozier, 1977). Using a 0.4-mL heterogeneous flow cell consisting of Ce-activated glass scintillator in an IN/US flow scintillation analyzer (now LabLogic Systems, Inc.) and a Dionex 2000 ion chromatographic system, Borai and Mady (2002) measured LLDs of 3.0 ± 0.1 Bq for ^{238}U and 6.0 ± 0.1 Bq for ^{232}Th.

The variables of flow rate, cell volume, and peak width should now be considered as factors governing the optimization of flow scintillation analysis in a radio-HPLC system. The following section will describe these variables in terms of sensitivity, speed of analysis, and resolution.

E. Sensitivity, flow rate, and resolution

The sensitivity of a flow detector in a given radio-HPLC run is another term reflecting the MDA, that is, the sensitivity is increased when the MDA is decreased. The sensitivity can be increased by (1) reducing the flow rate, which will increase the residence time (T_R), or (2) increasing the size of the flow cell, which increases the detection efficiency. Reducing the flow rate would increase the HPLC run time, but it could also diminish the resolution of the HPLC-separated sample components because flow rate is a key factor in the chromatographic separation of sample components. On the other hand, increasing the size of the flow cell would also reduce resolution. The term resolution refers to the ability to distinguish between activity peaks that are in close proximity to each other. Increasing the flow cell size will lower the resolution. When compounds or molecules are difficult to separate, it is best to use a flow cell size that will give the best resolution although at a diminished sensitivity. On the other hand, when radioactivity levels are low and activity peaks are well separated, it is recommended to sacrifice resolution for increased sensitivity. Therefore, the selection of cell size will depend on the characteristics of any particular HPLC separation run.

As a general rule, the best flow-cell volume for a given HPLC application would be a cell with a volume of one-half to one-fourth the volume of the smallest peak of interest. As described by Anonymous (1990), the following equations can be used to estimate the optimum flow-cell size for two basic cell types:

For solid (heterogeneous) cells or gamma cells:

$$V_C = K(V_P) \tag{10.18}$$

where V_C is the cell volume, K is a constant between ¼ and ½ where smaller values yield higher resolution and larger values yield higher sensitivity, and V_P is the volume in mL of the smallest peak of interest. The value of V_P is calculated as

$$V_P = (W)(F) \tag{10.19}$$

where W is the peak width in minutes and F is the flow rate in mL/min.

For the liquid (homogeneous) cells:

$$V_C = K(V_P + V_S) \tag{10.20}$$

where V_S is the volume of liquid scintillator for the same duration as the peak.

As demonstrated by Kessler (1986), the resolution of HPLC activity peaks from flow detectors is dependent not only on the flow rate and flow cell size as described but also on the update time, which is the time interval in seconds over which the detector pulses are summed. Kessler demonstrated that, maintaining the flow rate and flow cell size constant, two very close and overlying peaks can be separated into two clearly defined peaks by reducing the update time. This may be intuitively obvious as the activity peaks are plotted on a time scale (activity vs. time in minutes). Reducing the pulse summation update time would provide activity changes over shorter time intervals. In summary, we can conclude that the higher sensitivity (lower MDA) of a flow detector is highly dependent on the residence time of the sample in the flow detector, cell volume, and update time; however, a trade-off must be made where sensitivity is sacrificed for resolution by controlling flow rate, cell size, and update time.

F. Precision

As described in Chapter 1, Volume 1 and Chapter 8, Volume 2, radioactivity decay is a random event, that is, it cannot be predicted when a given radionuclide would decay. However, we could predict that one-half of the nuclei of a given radionuclide in a sample would decay in one half-life. In view of the random character of radioactivity decay, we can say that the precision of a count rate determination is a function of the total number of counts collected and the counting time, as the count number will be greater for longer counting times.

The precision of a given count determination is expressed in terms of its standard deviation, which is calculated as

$$\mathrm{SD} = \sqrt{\text{total counts}} \tag{10.21}$$

In the case of flow-cell detectors, we can look at some specific examples.

Example 10.3 If a flow rate of 4.0 mL/min and a flow-cell detector of 250 μL volume were used for a particular HPLC application, we could calculate that the radioactivity from the sample in the flow cell would be observed for 3.75 s determined as follows:

$$T_R = V/F = 0.25\ \text{mL}/4.0\ \text{mL min}^{-1} = 0.0625\ \text{min} = 3.75\ \text{seconds}$$

If the count rate for the 3.75-s period was 20,000 CPM, the standard deviation according to Eq. (10.21) would be calculated as

$$\mathrm{SD} = \sqrt{(20{,}000\ \text{cpm})(0.0625\ \text{min})} = \sqrt{1250\ \text{counts}} = 35.4$$

or the counts collected can be expressed as 1250 ± 35.4 counts at one standard deviation and the percent standard deviation (% SD) would be

$$\frac{35.4}{1250}(100) = 2.8\%$$

and the results expressed as 1250 counts ± 2.8%.

If we take the same flow rate and flow-cell volume but detect a lower count rate of 2000 CPM, the standard deviation could be calculated as

$$\mathrm{SD} = \sqrt{(2{,}000\ \text{cpm})(0.0625\ \text{min})} = \sqrt{125} = 11.2$$

and the percent standard deviation (% SD) would be calculated as

$$\frac{11.2}{125}(100) = 8.9\%$$

The percent standard deviation calculation can be simplified to the following:

$$\%\mathrm{SD} = \frac{100}{\sqrt{\text{total counts}}} \tag{10.22}$$

Example 10.4 If we take the above example 10.3 and increase the cell volume from 250 to 500 μL and keep the flow rate (4.0 mL/min) and the two observed count rates (20,000 and 2000 CPM) the same, we can calculate the new percent standard deviations (%SD) as follows to see how increasing cell volume will improve sensitivity and precision, albeit at an expected loss of resolution:

The residence time or the duration that the radioactivity in the cell would be observed can be calculated as

$$T_R = V/F = 0.50\ \text{mL}/4.0\ \text{mL min}^{-1} = 0.125\ \text{min} = 7.5\ \text{seconds}$$

The percent standard deviation for the example taken for a count rate of 20,000 CPM is calculated as

$$\%\mathrm{SD} = \frac{100}{\sqrt{(20{,}000\ \text{cpm})(0.125\ \text{min})}} = \frac{100}{\sqrt{2500\ \text{counts}}} = 2.0\%$$

and that for the count rate of 2000 CPM is

$$\%\mathrm{SD} = \frac{100}{\sqrt{(2000\ \text{cpm})(0.125\ \text{min})}} = \frac{100}{\sqrt{250\ \text{counts}}} = 6.3\%$$

Examples 10.3 and 10.4 illustrate that increasing the flow-cell volume from 250 to 500 μL increased the residence time, and consequently, the precision of the measurement was improved by reducing the %SD of the observed counts. However, larger flow-cell volumes will reduce activity peak resolutions as described previously.

Eq. (10.22) can be used to calculate the percent standard deviation (%SD) for any count rate (CPM) or total counts collected, that is, (CPM·T_R) of any flow-cell detector. The residence time (T_R) in minutes required to achieve a desired %SD can be calculated by manipulation of Eq. (10.22) as follows:

$$\sqrt{\text{total counts}} = \frac{100}{\%\text{SD}} \tag{10.23}$$

or

$$\text{total counts} = \left(\frac{100}{\%\text{SD}}\right)^2 \tag{10.24}$$

or

$$(\text{CPM})(T_R) = \left(\frac{100}{\%\text{SD}}\right)^2 \tag{10.25}$$

and

$$T_R = \frac{1}{\text{CPM}}\left(\frac{100}{\%\text{SD}}\right)^2 \tag{10.26}$$

which is similar to the equation described by Kessler (1986).

G. Detection optimization

Major advances in real-time flow-cell analysis have been made in detection optimization, which was achieved by including technology currently available to modern scintillation analyzers (Anonymous, 1996; Wasyl and Nellis, 1996). This technology includes (1) multichannel analysis for counting region optimization, (2) time-resolved liquid scintillation counting (TR-LSC) for background reduction, (3) detection and correction of chemiluminescence, which can be a significant interference when fluor cocktail and HPLC eluate are mixed, and (4) operation software, such as RadioStar and Chromeleon Driver (Berthold Technologies), Win-Flow (IN/US Systems/LabLogic Systems, Inc.), and FLO-ONE or ProFSA (PerkinElmer, Inc.), among others, which facilitate flow scintillation analysis setup, optimization, control, performance assessment, and result reporting.

1. Multichannel analysis

The application of the MCA in flow scintillation analysis as in LSA will sort all signals according to pulse height into individual channels calibrated in keV. Visual observation of the pulse height spectra from the MCA facilitates counting region optimization for a flow sample at a given quench level. Region optimization is achieved by setting the lower-level discriminator (LLD) and upper-level discriminator (ULD) to provide the highest FOM calculated as E^2/B, where E is the percent counting efficiency and B is the background count rate. The term FOM is analogous to the term signal-to-noise (S/N) ratio, as the sample activity peak is the signal of interest and the background radioactivity is equivalent to the noise we must reduce.

The pulse height spectral display offered by the MCA will also permit visualization of the sample pulse height spectrum originating from more than one radionuclide. If two radionuclides are present in the sample, the pulse height spectrum of the MCA can be used to select the LLD and ULD settings for two counting regions. This will enable the activity analysis of two radionuclides in the same sample as described in Section X of this chapter and in more detail in Chapter 6, Volume 1.

2. Chemiluminescence detection and correction

The chemiluminescence pulse height spectrum can be observed via the MCA. Chemiluminescence can occur only when the liquid homogeneous flow cell is used; and it could occur when the HPLC mobile phase is mixed with scintillation fluor cocktail prior to continuing on to the flow-cell detector. Chemiluminescence is treated as an interference like background; however, unlike background, chemiluminescence can be eliminated altogether from the sample count rate. The occurrence of chemiluminescence can be tested easily by mixing nonradioactive sample with HPLC eluent through a flow-cell detector and observation of the MCA pulse height spectral output. The chemiluminescence pulses are found in the region of 0–6 keV. For high-energy β emitters (e.g., ^{32}P), this portion of the pulse height spectrum can be excluded from the sample counting region, if chemiluminescence is of concern. When analyzing low-energy β emitters, such as tritium, the chemiluminescence detection and correction, available in the operation setup of the flow scintillation analyzer software (e.g., FLO-ONE), can be enabled.

See Section IV of this chapter, which describes flow scintillation cocktails. Scintillation cocktails are available, which can suppress the occurrence of chemiluminescence.

3. Time-resolved liquid scintillation counting

TR-LSC provides yet a further means of optimizing detection in the flow scintillation analyzer by reducing background. TR-LSC (PerkinElmer, Inc.) is a patented method of reducing backgrounds by discriminating against sample and background pulses by means of counting the number of afterpulses that occur following an initial pulse event (Bhade et al., 2012; Rónai et al., 2006; Mavon et al., 2004). Afterpulses are more numerous in nonquenchable events, which are pulse

events origination from outside the scintillation solution, such as cosmic radiation, which might strike the flow cell or face of one of the PMTs. Quenchable events are pulse events originating in the scintillation fluor cocktail of the flow-cell detector, and these have few if any distinguishable afterpulses. By counting afterpulses, the instrument circuitry and software discriminate between quenchable pulses originating from the scintillation solution in the flow cell and nonquenchable pulses originating from outside the flow cell. The instrument circuitry can, therefore, reject pulses that do not originate from within the flow cell as background radiation. A guard scintillator also surrounds the sample chamber but does not come in contact with the low-energy β emissions originating from within the flow cell. External radiation of cosmic origin or external radiation in the laboratory environment can strike or pass through the scintillator guard. The pulse events occurring from external radiation interactions with the guard detector are nonquenchable pulses, and these have numerous afterpulses compared with sample events in the flow cell. The combination of the scintillator detector guard surrounding the flow cell and TR-LSC results in the virtual elimination of nonquenchable background with a dramatic reduction in background count rate of up to 75%. Typical TR-LSC backgrounds are 2−3 CPM for ^{3}H and 4−5 CPM for ^{14}C with region optimization for these radionuclides.

The combined effect of region optimization and TR-LSC is seen in Fig. 10.19, which illustrates an HPLC run of ^{14}C-labeled drug metabolites. In the upper trace of Fig. 10.19, the counting region (0−156 keV) is not optimized, and TR-LSC is not enabled (background = 30 CPM). Only three activity peaks are discernible. When the counting region is optimized to the highest FOM (E^2/B) by adjusting the LLD and ULD settings to 4−100 keV respectively, and TR-LSC is enabled, the background is reduced to 2 CPM and as many as nine activity peaks can be identified as illustrated in the lower trace of Fig. 10.19. The concept and practice of region optimization is discussed in Chapter 6, Volume 1.

H. Instrument performance assessment

Commercial flow scintillation analyzers are equipped with software and radionuclide standards that will assist the operator in setting up the IPA. The performance of the flow scintillation analyzer can be carried out on a routine basis to provide assurance that the instrument is operating within acceptable parameters and to have a standing record of the instrument performance over a period of time. To maintain good laboratory practice (GLP) and, at times, to satisfy regulatory agencies, it is necessary to have records of the instrument performance on a routine basis, for example, daily, weekly, or monthly, whichever may satisfy our needs

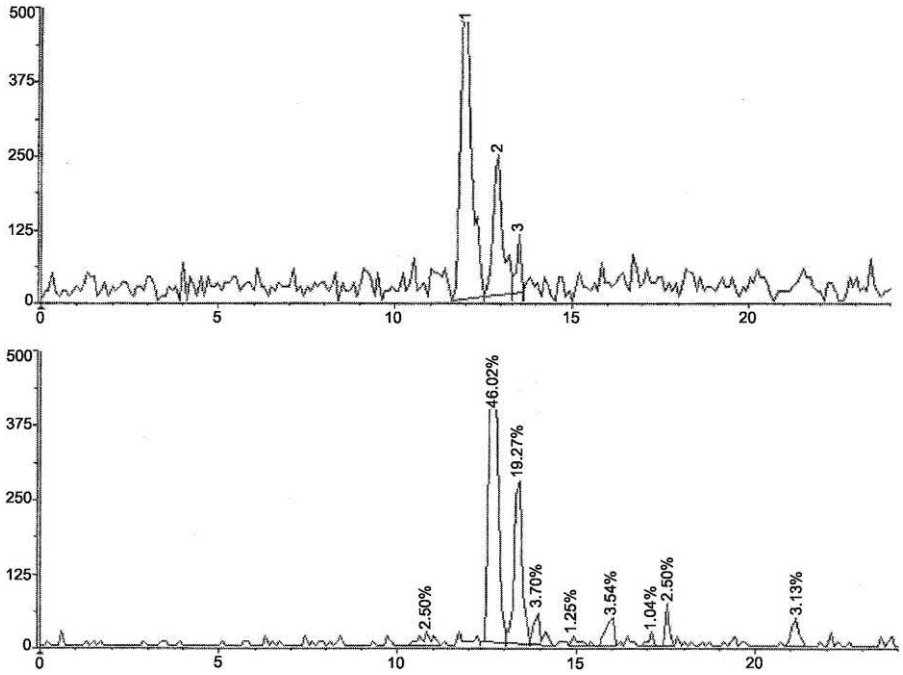

FIGURE 10.19 Flow scintillation analysis trace of ^{14}C metabolites separated via HPLC. (Upper): A wide-open counting region of 0−156 keV is used without TR-LSC background rejection. (Lower): An optimized counting region of 4−100 keV is used with TR-LSC background rejection. [Courtesy of Paul Riska, Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT.] *From Anonymous (1996), reprinted with permission ©1996 PerkinElmer, Inc. All rights reserved.*

as evidence that deviations in instrument performance do not have any effect on the analytical results. The IPA can be carried out with ^{3}H and ^{14}C and background standards. The radionuclide standards are NIST traceable. The standards are in sealed vials, which can be mounted in a vial holder that duplicates the mounting characteristics of a flow cell.

Eight parameters can be assessed using ^{3}H and ^{14}C standards. These are (1) ^{3}H efficiency, (2) ^{3}H background, (3) ^{3}H FOM, (4) ^{3}H chi-square, (5) ^{14}C efficiency, (6) ^{14}C background, (7) ^{14}C FOM, and (8) ^{14}C chi-square. The parameters are discussed in more detail in Chapter 6, Volume 1. The results are stored and printed in tabular and/or graphic form with a time and date stamp. Data points for each of the above parameters can be stored in memory as a binary file (unchangeable by the user) and plotted. The data can be displayed, stored in computer memory, and printed whenever needed. In any given graph for each of the eight parameters listed above, an average line is calculated as illustrated in Fig. 6.168a of Chapter 6, Volume 1. The one, two, and three sigma values are calculated to help the user evaluate any trends or outlying points. If a value of any of the parameters fails the limits test set for that parameter, a warning message can be received on the computer monitor with suggestions that the user can follow to assess the problem further and to take preventive action if any parameters are obtained too frequently outside of the recommended limits.

IV. Flow scintillator selection

Among the scintillation flow cells described previously in this chapter, the liquid (homogeneous) flow cell is the type most commonly utilized for the detection of low- and intermediate-energy β emitters (e.g., ^{3}H, ^{14}C, ^{35}S, ^{33}P) in HPLC effluents. The popularity of the liquid cell is due to the highest detection efficiencies and absence of adsorption of radionuclide-labeled compounds onto solid scintillator. The latter characteristic is a major concern in the use of solid (heterogeneous) flow cells.

Homogeneous flow-cell counting requires special cocktails. The development and characteristics of modern flow scintillation cocktails are described in reviews by Thomson (1994, 1997) and in Chapter 7, Volume 1. Because the flour cocktail must be added mechanically and mixed readily with the HPLC effluent, it must possess certain physical and performance characteristics. These characteristics outlined by Thomson (1997) are the following:

- Low viscosity
- Rapid and easy mixing with the HPLC eluate
- High sample acceptance capacity
- Compatibility with complex samples and HPLC gradients
- No gel formation
- Good counting performance
- Low background contribution
- Chemiluminescence resistance
- Safe to handle
- High flash point
- Biodegradable

Obviously, not all of these characteristics can always be achieved to the optimum; however, all of these characteristics can be achieved to a certain degree with most circumstances by modern flow scintillation cocktails.

The older generation or classical flow scintillation cocktails, still used by researchers, have relatively low flash points and are less safe to handle. Modern research for improved flow cocktails has provided now safer high-flash-point cocktails, which are biodegradable and capable of mixing readily with a wide range of sample types and gradients used in HPLC. A major advance was the patented development of a flow-scintillation cocktail with the chemical components capable of removing luminescence while simultaneously minimizing background without sacrificing counting efficiency (Hegge and ter Viel, 1986; Thomson, 1993).

Some of the classical flow cocktails, such as the Flo-Scint I, II, III, and IV, are based on pseudocumene or trimethylbenzene solvents with flash points of about 48°C (118°F). Flo-Scint A is compatible with acetonitrile/water gradients, polar organic solvents, and dilute salt solutions. It has a 50% sample holding capacity for aqueous solutions, resistant to chemiluminescence, and nongelling. New-generation flow-scintillation cocktails are readily biodegradable and have a high flash point of 120°C (248°F).

Some of the new generation of flow scintillation cocktails available commercially, their properties and applications, and their suppliers are listed in Table 10.5. The table is not exhaustive, and other flow cocktails and suppliers may exist.

V. Dual-functionality flow-cell detectors

The analysis of radionuclides in the environment or in nuclear process streams generally involves the determination of the activities of radionuclides in an aqueous medium. In environmental analysis, radionuclide activities are generally low and the radionuclides are found in complex mixtures, which require a preliminary chemical cleanup to isolate the radionuclide of interest and preconcentration to achieve limits of detection. Preliminary chemical cleanup is particularly necessary to isolate the radionuclide of interest in the analysis of α- and β-emitting radionuclides, and even γ emitters, to avoid interferences due to the overlap of broad scintillation spectra. Although α particles are emitted with discrete lines of energy, they undergo variable loss of energy as they travel through liquids (see Chapter 1, Volume 1) and display broad scintillation spectra, as discussed

TABLE 10.5 New generation of flow-scintillation cocktails and suppliers.[a]

Flow cocktail	Properties and applications[b]
Flow Safe 2	Compatible with polar solvents and rapid mixing capability with eluates, low odor high flash point (105°C), nontoxic, biodegradable, low chemiluminescence, nonflammable
Flow Plus	Formulated to prevent the formation of gels or a high viscosity liquid stream designed for typical solvent/water gradients and also compatible with solutions of lower ionic strength, nonjellying, low viscosity, low chemiluminescence, low quench
Berthold Technologies: https://www.berthold-bio.com/	
FlowLogic U	Low viscosity and compatible with a wide range of HPLC gradients at a 1:1 ratio; miscible with 0.1N NaOH yielding a clear nonviscous emulsion
FlowLogic HA	Designed for highly aqueous samples with ratios of up to 2:1 scintillator to sample
FlowLogic HS	Formulated to accommodate high salt and buffer samples; biodegradable, low viscosity, and nongelling
SoFieScint	A very-low-viscosity cocktail with high sample uptake capacity, compatible with a wide range of HPLC gradients at a 1:1 ratio, excellent for use with a stop-flow system where very low levels of activity are measured
LabLogic: https://lablogic.com/	
ProFlow G+	Designed for general eluents and water/methanol and water/acetonitrile gradients, safe, high flash point, and free of nonylphenol ethoxylate (NPE) and thus in accord with the EEC directive 2003/53/EC; high flash point (147°C), biodegradable, and can be drain disposed without breaching EEC regulations
ProFlow P+	Designed for eluents with ammonium phosphate gradients, safe, high flash point, and free of NPE and thus in accord with the EEC directive 2003/53/EC; high flash point (147°C), biodegradable, and can be drain disposed without breaching EEC regulations
Meridian Biotechnologies Ltd., http://www.meridian-biotech.com/	
Ecoscint Flow	Designed for aqueous flow samples, biodegradable, high sample holding capacity (1: 1 sample to cocktail) with a wide range of HPLC gradients even 0.1N NaOH samples yield a clear nonviscous emulsion, low viscosity, and non-gelling.
Uniscint BD	Designed to accommodate high salt and buffer samples for HPLC flow measurements; can accommodate all concentrations of ammonium phosphate up to 2M at a 3:1 scintillator to sample ratio accepting ammonium phosphate gradients in the range of 0–2M, biodegradable, high flash point (>150°C), low viscosity, nongelling, reduced toxicity solvent
Monoflow 5	Nonhazardous and biodegradable scintillator with low toxicity useful for HPLC effluents in flow detectors at ratios of 3:1 scintillator to sample; disposable in most cases as a normal liquid waste
Monoflow 1	Designed for organic flow samples; traditional cocktail with high sample holding capacity
National Diagnostics, https://www.nationaldiagnostics.com/	
Ultima-Flo M	Designed for multipurpose flow counting applications with high sample-holding capacity for a wide range of HPLC gradients, including aqueous gradients, water/methanol gradients and water acetonitrile gradients, low viscosity capable of rapid mixing, nongelling, biodegradable and safer cocktail, resistant to chemiluminescence, and high flashpoint (~120°C)
Flo-Scint II	Formulated for polar solvents and dilute buffers yielding good sample holding capacity with low viscosity; a pseudocumene-based flow-scintillation cocktail excellent with methanol and acetonitrile gradients, resistant to chemiluminescence and nongelling
Ultima-Flo AP	Designed to accept up to 2.0 M ammonium phosphate with fast and facile mixing, excellent for use with ammonium phosphate buffers as HPLC eluents with high sample acceptance over entire gradient, other gradients up to 1.0 M PBS and 1.0 M NaOH are easily accepted at good mixing ratios, quench resistant over a wide range of sample types, nongelling, low viscosity, biodegradable and safer cocktail, and high flash point (~120°C)
Flo-Scint III	A classical pseudocumene-based classical flow cocktail designed as an excellent scintillator for methanol and acetonitrile gradients and moderately buffered solutions, including phosphates, resistant to chemiluminescence, and nongelling
Flo-Scint A	A classical pseudocumene-based flow cocktail formulated for acetonitrile/water gradients, polar organic solvents and dilute salt solutions, excellent water-holding capacity up to 50%, resistant to chemiluminescence, and nongelling
PerkinElmer Inc., http://www.perkinelmer.com/

TABLE 10.5 New generation of flow-scintillation cocktails and suppliers.[a]—cont'd

Flow cocktail	Properties and applications[b]
ProFlow G+	Designed for general eluents and water/methanol and water/acetonitrile gradients, safe, high flash point, and free of NPE and thus in accord with the EEC directive 2003/53/EC (https://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2003:178:0024:0027:en:PDF, accessed July 2, 2018); high flash point (147°C), biodegradable, and can be drain disposed without breaching EEC regulations
ProFlow P+	Designed for eluents with ammonium phosphate gradients, safe, high flash point, and free of NPE and thus in accord with the EEC directive 2003/53/EC; high flash point (147°C), biodegradable, and can be drain disposed without breaching EEC regulations
Gold Flow	A diisopropylnaphthalene (DIN)-based cocktail for aqueous and organic flow systems, flash point (140°C)
Triskem International, http://www.triskem-international.com/	
Quickzint Flow 302	Recommended for flow cell counting of hydrophilic solvent, such as methanol and acetonitrile aqueous gradients, suitable with low ionic strength aqueous solutions, including buffer gradients, low viscosity, nongelling, flash point (35°C)
Quicksafe Flow 2	Designed as a safe flow cocktail with high flash point (>100°C), has an exceptionally low viscosity, ideal for polar solvents (methanol and acetonitrile) and their aqueous gradients, rapid mixing, nontoxic solvent with low odor
Zinsser Analytic, https://www.zinsser-analytic.com/	

[a]Suppliers are listed in alphabetical order and below the flow cocktails listed that they supply. The list is not exhaustive. Other flow cocktails from the above suppliers are available, and other suppliers not listed may be available.
[b]More detailed information on the properties and applications of the flow cocktails are available from the websites provided.

in Chapters 5 and 6 of Volume 1. Likewise, β particles lose energy according to their path length in water, and they are emitted from radionuclides with a broad spectrum of energies. The scintillation pulse height spectra are broad and will overlap with spectra of other alpha and beta nuclides. Although γ ray photons undergo minimal energy loss when traveling through water, they display broad spectra in scintillator crystal detectors due mainly to Compton scattering. The classical methods of analysis are specific for each radionuclide of interest; they involve specific procedures of sample preparation and cleanup to isolate the radionuclide from other interfering nuclides; they are time-consuming; and they are carried out generally in specific laboratories equipped for such analysis. For over a decade, much research has been focused on the relatively rapid automated radiochemical separation and analysis of radionuclides in the environment, which can be carried out by any laboratory, including mobile on-site laboratories. These procedures are discussed in detail in Chapter 11, Volume 2. The radiation flow-cell detectors or sensors that are utilized in these automated methods will be discussed in this section. The concepts and techniques are provided in more detail in comprehensive papers by Trojanowicz et al. (2018), Watson et al. (2018), Duval et al. (2016a), Seliman et al. (2013), Grate et al. (2005, 2008), and Fjeld et al. (2004), and additional information may be obtained from Chapter 11, Volume 2. These radionuclide flow detectors are classified into two types (Fjeld et al., 2004), which are the following:

(1) A flow radiation detector simultaneous with radionuclide separation or *dual-functionality* detector. This type of detector would contain a scintillating extraction chromatographic resin or a combination of scintillating beads and selective extracting chromatographic resin within a flow cell, which is capable of concentrating the radionuclide of interest. Such a flow radiation detector has a dual functionality, that is, it enables the simultaneous concentration and detection of the radionuclide of interest. An illustration of the principal of dual functionality in a flow cell is illustrated in Fig. 10.20,

(2) A flow radiation detector sequential to radionuclide separation. This type of detector would be a flow cell, which would detect and analyze the radionuclides after they are separated by ion chromatography.

The first of the two detector types listed above is recognized as a very sensitive detector for the preconcentration and analysis of α- and β-emitting radionuclides in water, and these are referred to as preconcentrating mini-column radionuclide sensors or detectors. A schematic

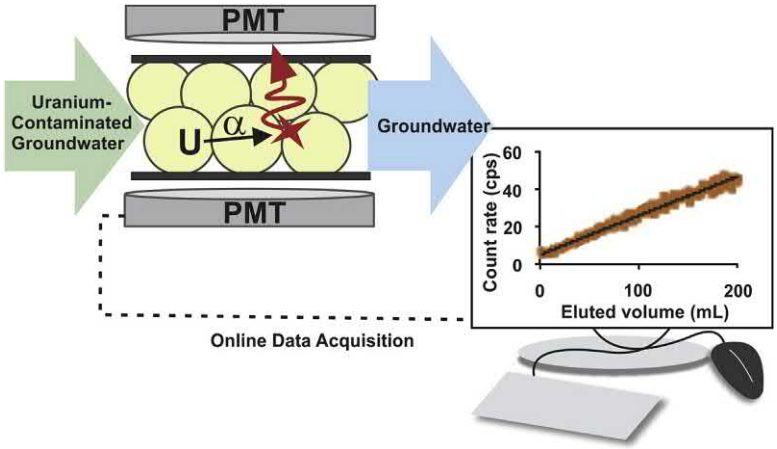

FIGURE 10.20 A dual-functionality flow-cell detector. The flow cell contains an extractive scintillating resin, which contains covalently bound fluor and ligand. Uranium in groundwater at low activity near the limits of detection is made to pass through the flow cell. The uranium binds to the scintillating resin and concentrates within the flow cell where it is counted with an activity well above the limits of detection. *From Duval et al. (2016a); reprinted with permission from Elsevier © 2016.*

diagram of such a flow cell is illustrated in Fig. 10.21. It is a dual-functionality column, as the column contains a selective sorbant or chromatographic resin capable of concentrating the radionuclide of interest, and it contains a scintillator embedded within the selective sorbant or resin or in intimate contact with it, thereby serving the dual purpose of concentrating the radionuclide and its detection. One of the major advantages of a dual-functionality flow-cell detector is the capacity of analyzing relatively large volumes of sample (up to a liter of water in some circumstances) whereby the radionuclide of interest is concentrated on an extractant in the flow detector, and at the same time, it is detected by the scintillator with which the extractant is in intimate or close contact. The concentration of radionuclide in this fashion permits the analysis of low levels of radionuclides in water below the limits set for drinking water standards, and it permits the analysis in situ or in the field without the need for a specialized laboratory. These detectors and the theory and principles of their operation and application are reviewed in detail by Trojanowicz et al. (2018), Watson et al. (2018), Duval et al. (2016a), Seliman et al. (2013), and Grate et al. (2008). The subsequent paragraphs will describe the various types of dual-functionality flow-cell detectors used in radionuclide analysis.

A. Scintillating extractive resins

A scintillating extractive resin consists of an intimate combination of a scintillator medium and an ion selective absorbent medium (extractant) on a solid support (e.g., macroporous styrenic polymer) packed into a single

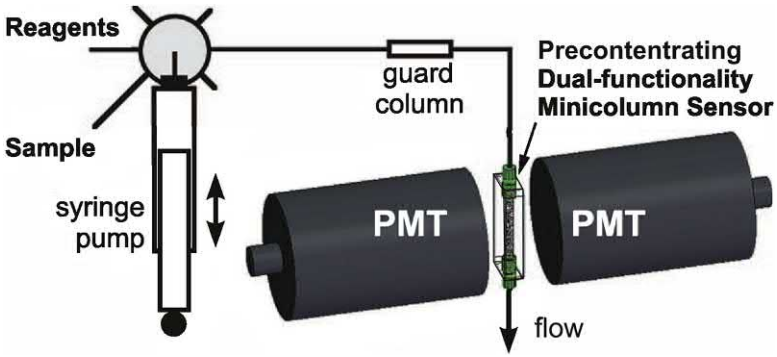

FIGURE 10.21 Preconcentrating minicolumn radionuclide detector based on dual-functionality materials in a preconcentrating minicolumn sensor. The sensor consists of a transparent flow cell containing a packed bed of dual-functionality materials placed between two photomultiplier tubes. The column may also be a coil within the detection zone. The sensor assembly is shown connected to an automatic fluidic system. The guard column contains hydroxylapatite to absorb organic matter. *From O'Hara et al. (2009a); reprinted with permission © 2009 American Chemical Society.*

column of tubing (e.g., Teflon tubing of ~0.15 cm ID and up to ~15 cm length). Other dimensions are used, and these are available from the references cited in this section. The tubing can be coiled into a loop (~2.5 cm dia.) to fit optimally in the detection region of the two photomultipliers. Other shapes (e.g., U-shaped tubing) are used. The minicolumn of tubing can be inserted into a suitable holder between the PMTs of a commercial flow scintillation analyzer (FSA). See Table 10.6 for a listing of various scintillating extractive resin formulations tested for the environmental analysis of various radionuclides.

The intimate combination of scintillator and extractant is prepared by several techniques, which may include, for example, the diffusion of scintillator into macroporous polymer beads followed by polymer coating. The coating provides physical and chemical stability to the combined scintillator and polymer. Subsequent to the polymer coating, residual chloromethyl groups of the polymer-coated resins are aminated, which provides a chemically stable scintillating resin with covalently bound ligand groups (Seliman et al., 2011). Alternatively, the resin may be synthesized to provide for a combination of extractive and scintillating properties via a sequence of copolymerization reactions of fluor molecules with polymer substrate (e.g., methyl styrene) together with chemical transformation of molecular groups to provide extractive power (i.e., ion exchange ligands) to the resin (Watson et al., 2018; Duval et al., 2016a; Seliman et al., 2013). Procedures used for the preparation of the various types of scintillating extractive resins are available from the references cited in Table 10.6.

It is important that the scintillating extractive resin have a capacity to selectively absorb the radionuclide of interest even in waters of relatively high ionic strength. In synthetic groundwater (GW) containing 33 Bq/L of ^{99}Tc (the US maximum contaminant level encountered in waters as pertechnetate, $^{99}TcO_4^-$) at elevated anion concentrations of 100 and 250 ppm Cl^-, NO_3^-, SO_4^{2-}, and HCO_3^-, and 1200 ppb Cr(VI), Seliman et al. (2011) demonstrated the linear response of triethylamine (TEA) and methyldioctylamine (MDOA)-bonded scintillating resins to the application of various volumes of the groundwater. Following the synthesis of new dual-functionality anion exchange resins via the copolymerization of fluor molecules with styrene and other aromatics together with amination reactions to form an anion exchange resin, Seliman et al. (2013) demonstrated the selective property of the resin for $^{99}TcO_4^-$ over up to 1000 ppm of potentially interfering anions such as Cl^- and $Cr_2O_7^{2-}$, among others in natural freshwaters with constant flow-cell counting efficiency.

An important property of scintillating extractive resins used for flow cells is that they retain their detection response (i.e., scintillating property) even after repetitive use. The detection response to the scintillating extractive resins prepared by Seliman et al. (2013) was tested as a function of the successive loading of different well water samples without regeneration. The response of the extractive resin in a flow cell to successive column loadings with various activities of ^{99}Tc

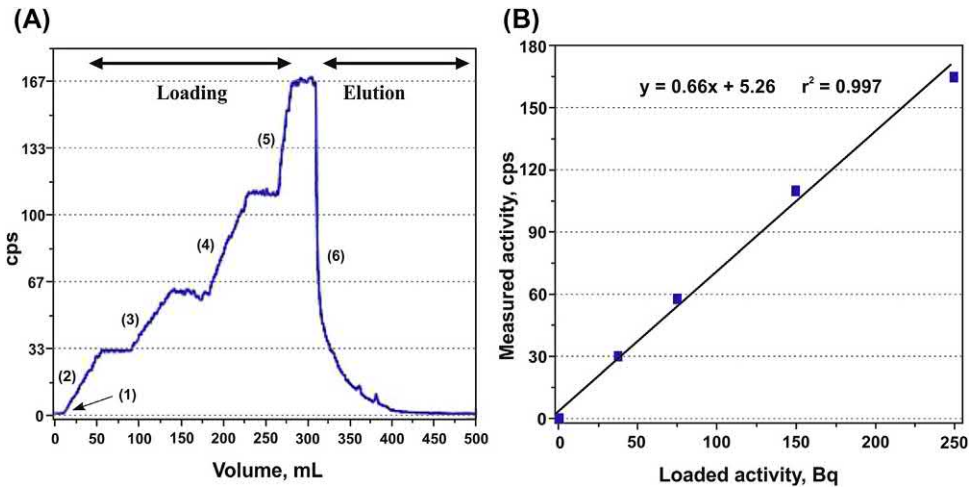

FIGURE 10.22 Optical flow-cell detector response to the scintillating extractive resin with the retention of pertechnetate ($^{99}TcO_4^-$) standards in well water matrix, using the following successive loading technique: (A) Data were obtained by pumping at 0.75 mL/min flow rate of (1) 15 mL of blank sample; (2) 50 mL of 37.5 Bq ^{99}Tc; (3) 50 mL of 37.5 Bq ^{99}Tc (total 75 Bq); (4) 50 mL of 75 Bq ^{99}Tc (total 150 Bq); (5) 50 mL of 100 Bq ^{99}Tc (total 250 Bq); and (6) elution by 200 mL 5 M nitric acid after pumping 50 mL of blank sample. (B) Resulting calibration curve from the responses. Numbering (1) to (6) in Fig. 10.22A was added by the writer to identify the responses to the successive sample and elution loadings. *From Seliman et al. (2013); reprinted with permission from Elsevier © 2013.*

and various quantities of anions is illustrated in Fig. 10.22A and B. The linearity of response of the scintillating extractive resin after successive analysis of natural waters with varying radionuclide activities and anion concentrations is a crucial test for the applicability of these resins to satisfy practical analytical requirements. An example is illustrated in Fig. 10.22A and B where the extraction capacity and scintillating response is illustrated to remain with a linear correlation coefficient ($r^2 = 0.997$ of Fig. 10.22B) and flow-cell detection efficiency constant (66%) after successive loadings with increasing ^{99}Tc activities and anion concentration (loadings 1 through 5 of Fig, 10.22A).

The application of scintillating extractive resins to quantitatively concentrate low levels of radionuclides over and above limits of detection and in solutions, such as natural groundwater and well water containing competitive ions, must be demonstrated, such as that described above for ^{99}Tc. Another example is the testing of a scintillating extractive resin for uranium in simulated groundwater by Duval et al. (2016a), with the continuous pumping of ^{233}U at a concentration of 50 Bq/L through a flow-cell detector containing the scintillating extractive resin. Fig. 10.23 illustrates the linear response of the flow-cell detector to the accumulated activity of ^{233}U with a flow-cell detection efficiency of 17% and the continuous pumping of up to 500 mL of water with a total ^{233}U activity of 25 Bq. Similar testing of a scintillating extractive resin to concentrate a total activity of only 6.6 Bq of $^{99}TcO_4^-$ in 200 mL of well water by Seliman et al. (2013), which is equivalent to a concentration of 33 Bq/L, is illustrated in Fig. 10.24. The concentration of $^{99}TcO_4^-$ on the scintillating resin accumulates the activity in the flow cell to levels well above the detection limit (DL) of the flow-cell detector for ^{99}Tc. Such a test demonstrates the practicality of the method because the US maximum contaminant level (MCL) of $^{99}TcO_4^-$ in well water is reported to be 33 Bq/L.

Several radionuclides have been analyzed with the dual-functionality scintillating extractive resins in flow-cell detectors, and these are listed in Table 10.6. The detection efficiencies obtained depend on α and β emission of the radionuclide, the scintillation extractive resin used, and the flow detector design. Some examples of detection efficiencies obtained for various radionuclides are the following:

- **(i)** ^{nat}U, 60%*E* (DeVol et al., 1996; Ayaz and DeVol, 2003; Hughes and DeVol, 2003);
- **(ii)** ^{89}Sr, 60%*E* (DeVol et al., 2001b); ^{90}Sr, 46%*E* and ^{90}Y, 99%*E* (Egorov et al., 1999b);
- **(iii)** ^{99}Tc, 66%*E* (Egorov et al., 1999b, DeVol et al., 2001a, DeVol et al., 2002, Ayaz and DeVol, 2003 and, Seliman et al., 2011, 2013);
- **(iv)** ^{129}I, 50%*E* (Grogan and DeVol, 2011);
- **(v)** ^{233}U, 97%*E* (Roane and DeVol, 2002; Duval, 2016a);
- **(vi)** ^{239}Pu, 78%*E* (DeVol et al., 1997; Roane and DeVol, 2002); and
- **(vii)** ^{241}Am, 97%*E* (Hughes and DeVol, 2003 and Roane and DeVol, 2002, 2005).

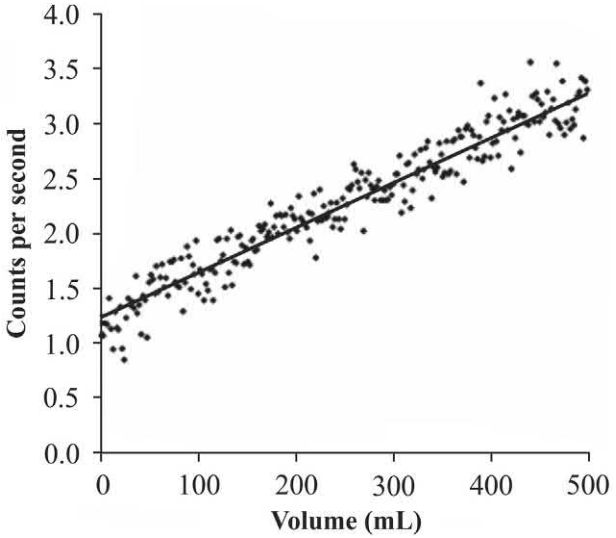

FIGURE 10.23 Simultaneous concentration and detection of uranium-233 at a concentration of 50 Bq/L from groundwater by a flow-cell detector containing a scintillating extractive polymer. *From Duval et al. (2016a); reprinted with permission from Elsevier © 2016.*

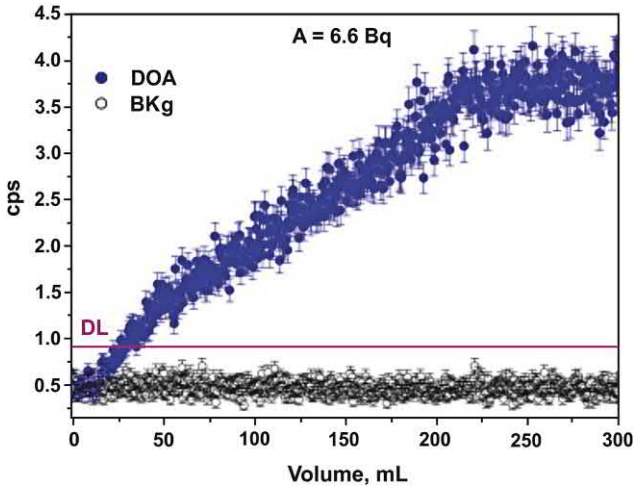

FIGURE 10.24 Online quantification with a scintillating extractive resin (synthesized with amination reaction with dioctylamine, DOA) in a U-shaped flow cell using 200 mL of acidified well water containing 33 Bq/L of $^{99}TcO_4^-$ and a total activity A = 6.6 Bq on the resin. The magenta-colored horizontal bar indicates the detection limit (DL). Color is visible in the electronic version of the book. *From Seliman et al. (2013); reprinted with permission from Elsevier © 2013.*

An advantage of the dual-functionality resins is the capability in many circumstances to concentrate and analyze radionuclides at or below the limits set for drinking water standards.

Other scintillating extractive resins have been prepared by Barrera et al. (2016) for the extraction and concentration of ^{99}Tc in seawater and urine and by Lluch et al. (2016) for the extraction of ^{210}Pb from river water. The techniques are demonstrated to be practical; however, off-line LS analysis was used rather than online real-time measurements.

B. Composite bed of scintillating and extracting particles

The composite-bed scintillating dual-functionality column detector consists of a composite heterogeneous mixture of scintillating particles and chemically selective particles. The dual functionality of radionuclide concentration and detection is achieved with an intimate mixture of separate extraction beads and nonporous scintillating beads (Grate et al., 2005, 2008). The mixture of beads is packed into fine inert tubing (e.g., ~1.6 mm I.D. × ~ 140 mm long) coiled into a loop to a diameter of ~2.5 cm and placed between PMTs of a flow-cell radiation detector. The minicolumn of fine tubing can be inserted into a suitable holder between the PMTs of a commercial flow scintillation analyzer (FSA) among those listed previously in Table 10.2. See Table 10.7 for the composition of the various combinations of scintillating particles and chemically selective particles applied to the analysis of various radionuclides.

The scintillating component in the mixed beds is, in most cases, Bicron BC-400 (see Table 10.7), which consists of 100–250 μm scintillating plastic (polyvinyltoluene) beads. These beads are nonporous, and they have a high chemical stability in sample solutions and regeneration reagents. The stability of these beads offers the advantage of constant detector response after repetitive use, as there is no possibility of fluor loss from the column. The composite bed of intimately packed extraction and scintillating beads is an excellent arrangement for the detection of radionuclides that emit β particles of intermediate and high energy, such as ^{99}Tc ($E_{max} = 0.249$ MeV), ^{90}Sr ($E_{max} = 0.546$ MeV), and ^{90}Y ($E_{max} = 2.28$ MeV). If we consider ^{99}Tc, which emits β particles of lower energy among the three radionuclides listed, it emits β particles with an energy maximum of 0.249 MeV; however, according to the distribution of β particle energy spectra in general, there are very few β particles that possess the maximum energy (see Fig. 1.45 of Chapter 1, Volume 1). In general, most beta particles are emitted at approximately ⅓ E_{max}. The range of the β particles of highest energy (0.249 MeV) emitted by ^{99}Tc in water is 740 μm, found on the range-energy curve of Fig. B.3 of the Appendix, However, considering that most of the β particles are emitted with an average energy of approximately ⅓E_{max} or 0.098 MeV, these β particles would have a range in water of ~150 μm, according to the range-energy curve of Fig. B.3 of Appendix B.3 of this book. The range of the β particles in the plastic BC-400 scintillating beads (1.03 g/cm^3) would be similar to that of water (1.00 g/cm^3), as their densities are very close. The ~150 μm range for the average number of ^{99}Tc β particles and a maximum range of 740 μm for β particles of highest energy from ^{99}Tc assure that a large proportion of the β particles emitted by

^{99}Tc, adhered to the chemically selective resin particles, will have sufficient energy to reach and penetrate the 100−250 μm scintillator beads with which they are closely packed in the minicolumn of the flow detector.

The composite bed method facilitates the use of existing extraction chromatographic, ion exchange, or solid-phase extraction materials used for the chemically selective sorbent component of the mixed bed (see Table 10.7), as described by Grate et al. (2008). Also, other radionuclides present in the samples do not interfere with the proper chemically selective sorbent component of the mixed bed. For example, tests with the addition of ^{137}Cs, ^{90}Sr, and ^{239}Pu as interfering nuclides resulted in transient activity peaks that present, after washing, no interference in the measurement of ^{99}Tc (Grate et al., 2008). Detection efficiencies obtained with the composite-bed dual-functionality method for various radionuclides are the following: ^{89}Sr, 81%*E*; ^{90}Sr, 47%*E* (DeVol et al., 2001b); ^{90}Sr, 63%*E* (Egorov et al., 2006; Grate et al., 2008); ^{99}Tc, 34%*E* (DeVol et al., 2001a, and Egorov et al., 2002); and ^{237}Np, 5.6%*E* (Hughes and DeVol, 2003). The lower detection efficiency achieved for ^{237}Np is due to the shorter range of travel in water of the α particles emitted by ^{237}Np compared with β particles. Another advantage of the composite-bed minicolumn detector is the ^{99}Tc(VII) selective composite bed can be regenerated with a small volume of 2 M HNO_3, resulting in a rapid elution of the ^{99}Tc(VII) without loss of the scintillation properties of the composite bed (Egorov et al., 2002, 2003; Grate et al., 2008). The measurement of ^{99}Tc(VII) in groundwater below the regulatory drinking water level of 33 Bq/L has been demonstrated with a prototype groundwater probe device that integrates the flow-cell detector, data acquisition, and instrument control components in a single functional instrument (Egorov et al., 2005a).

C. Equilibrium-based bed

The equilibrium-based dual-functionality flow cell consists of a composite bed of scintillating particles and chemically selective particles (e.g., 1:4 w/w ratio of AG 4-X4:BC-400 or 1:1 w/w ratio of SuperLig 620:BC-400) packed into a minicolumn (e.g., 4 mm I.D. × 29 mm length). The column may be contained in Teflon tubing (Grate et al., 2007), or it may be machined in a block of Bicron BC-800 (Saint-Gobain Crystals), which is cast from ultraviolet transparent methyl methacrylate monomer (Egorov et al., 2006; O'Hara et al., 2009a). The column dimensions machined in the block are the same as with Teflon tubing (i.e., 4 mm I.D. × 29 mm length) providing a bed volume of 0.365 cm^3. The block with column is fitted into a PerkinElmer TR Radiomatic flow scintillation analyzer.

The operation of the equilibrium-based detection functions when the sensing material in the column achieves equilibration with the analyte concentration in solution, that is, the analyte concentration exiting the column is the same as the analyte concentration entering the column. The impetus behind the development of this new technique is the search for "reagentless" measurements, that is, the possibility of repetitive analysis without the need to use reagents to regenerate the detector column after each analysis.

The principle and theory behind the operation of the equilibrium-based dual-functionality flow-cell detector is described by Grate et al. (2005, 2007, 2008, 2009), Egorov et al. (2006), and O'Hara and Nivel (2014) and O'Hara et al. (2009a). In brief, the method is based on the chromatography principle where the magnitude of analyte

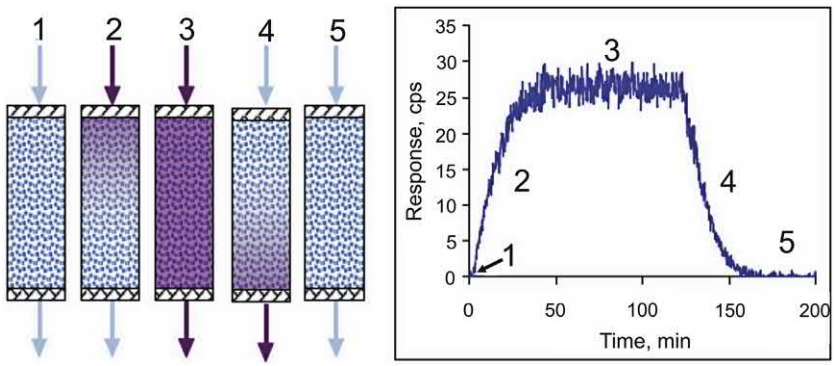

FIGURE 10.25 Equilibrium sensing conceptual schematic showing inflow of a β emitter in groundwater (left) and simultaneous sensor response to β decay events (right). The following steps are depicted: (1) groundwater containing no above-background radionuclide enters and exits the column, (2) groundwater contaminated with a beta-emitting radionuclide enters the column, (3) the groundwater contaminated with a beta-emitting radionuclide enters and exits the column where the activity of the radionuclide entering and exiting the column is equal, (4) groundwater containing no above-background radionuclide enters the column, and (5) the groundwater containing no above-background radionuclide enters and exits the column resulting in the elution of all of the analyte radionuclide from the sensor, once again returning the column to the background condition of step 1. *Figure from O'Hara and Niver (2014), https://www.pnnl.gov/main/publications/external/technical_reports/pnnl-23131.pdf.*

retention on the column sorbent beads is a function of the analyte distribution coefficient, D, defined as

$$D = C_s/C_a \tag{10.27}$$

where C_s is the equilibrium analyte concentration in the sorbent layer (stationary phase) and C_a is the equilibrium analyte concentration in the aqueous (mobile) phase (Grate et al., 2005). The method entails delivering the water sample to the column until complete breakthrough has occurred. Complete breakthrough exists when an equilibrium concentration occurs throughout the entire length of the column. This occurs when no additional analyte preconcentration of the sorbent in the column is possible, and the concentration of analyte added to the column is the same as that exiting the column. The principle is illustrated in Fig. 10.25.

This approach to the analysis of radionuclides has the following key features, which are reviewed by Grate et al. (2008): (1) the response of the detector is a steady state once the sorbent phase is equilibrated, (2) the response varies with the analyte activity or concentration, and (3) reversibility of the response can occur because it is based on a dynamic equilibrium. The variable response is observed when an analyte of different activity or concentration is added to the column because the analyte will reequilibrate and the detector response will increase or decrease according to the new activity. Likewise, if the sample is a blank containing no analyte, the detector signal will drop as if the column were regenerated with a reagent (Grate et al., 2008; O'Hara and Niver, 2014, See Fig. 10.25). Thus, in principle, the equilibrium-based method requires no chemical reagents.

A typical minicolumn assembly for the equilibrium-based analysis of ^{99}Tc in groundwater as the pertechnetate anion ($^{99}TcO_4^-$) is illustrated in Fig. 10.26. The sensor module designed by O'Hara and Niver (2014) consists of a syringe pump (not illustrated) driven by a step motor to deliver sample to the ^{99}Tc sensor inlet line. The ^{99}Tc sensor inlet is affixed with a 13 mm diameter, 2.7 μm glass microfiber filter disc to ensure no particulate matter is transported to the inlet frit of the ^{99}Tc sensor. The sensor is housed in a light tight canister situated between two PMTs to produce coincidence counts for background discrimination. The column body is composed of a heterogeneous mixture of selective sorbent media (orange dots of Fig. 10.26) and organic scintillating particles (green dots). The column is enclosed at both sides with quartz windows (blue windows in Fig. 10.16), which are transparent to UV and visible photons. At both sides of the windows, two PMTs fit within a crevice to capture the photons emitted by the minicolumn sensor. The column is packed with a mixture of a strong anion exchange resin (Toyopearl QAE-550C, 50−150 μm particle size) and BC-400 scintillating beads (250−500 μm particle size) in a ~0.13:1, v/v ratio.

The method can be applied to the measurement of ^{99}Tc and ^{90}Sr in groundwater at levels below the MDA limits required for water quality. Various responses to a ^{99}Tc equilibrium-based flow-cell detector are illustrated in Fig. 10.27. As underscored by Grate et al. (2008), the

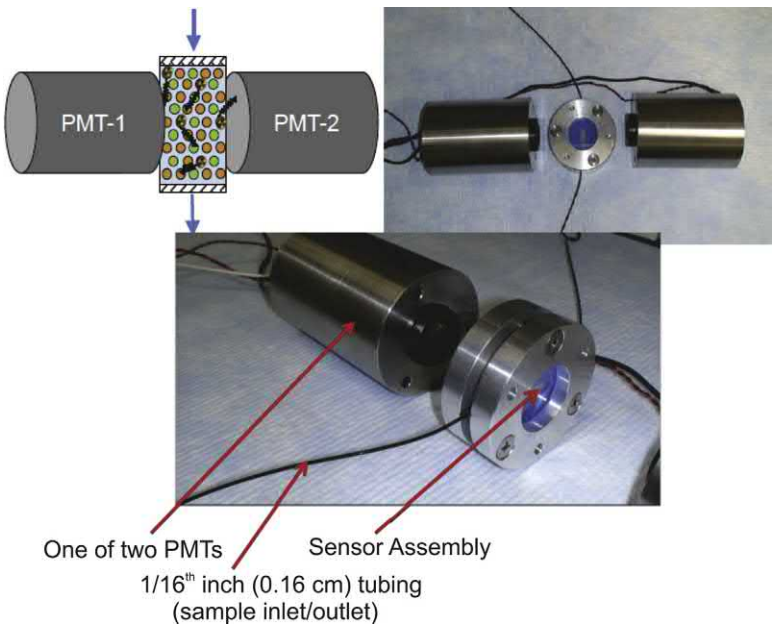

FIGURE 10.26 Schematic of minicolumn sensor (top left). Photos of equilibrium sensor (partially disassembled) for ^{99}Tc monitoring are shown in top right and bottom. *From O'Hara and Niver (2014), https://www.pnnl.gov/main/publications/external/technical_reports/pnnl-23131.pdf.*

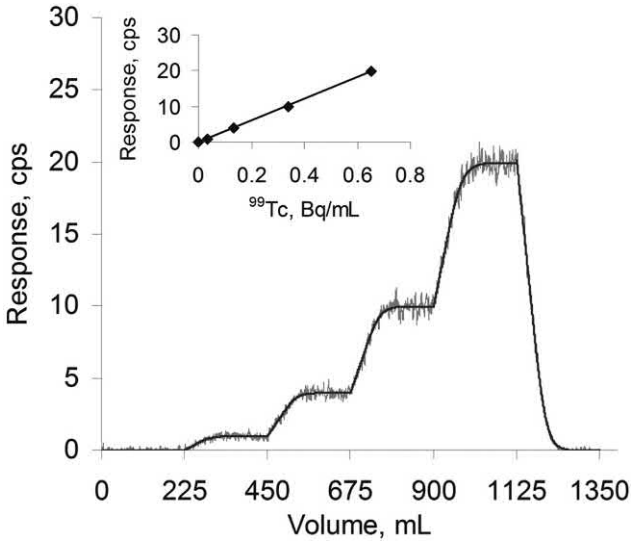

FIGURE 10.27 Responses of a composite bed (1:4 w/w ratio AG 4-X4:BC-400) preconcentrating minicolumn sensor to samples at increasing activities of ^{99}Tc standards (in 0.01 M nitric acid) in the pertechnetate form, followed by a final blank sample. The data were obtained by delivering 225-mL aliquots of the following solutions at 2-mL/min syringe pump flow rate: (1) blank sample, (2) 0.033 Bq/mL, (3) 0.13 Bq/mL, (4) 0.34 Bq/mL, (5) 0.65 Bq/mL, (6) blank sample. The calibration curve (slope 30.4 counts (Bq/mL)) from the average equilibrium count rate is shown in inset. The activity of the lowest level standard is equivalent to the drinking water standard for ^{99}Tc. *From Egorov et al. (2006); reprinted with permission © 2006 American Chemical Society.*

response of the equilibrium-based detector, illustrated in Fig. 10.27, manifests the three key features of the method described in the previous paragraphs, namely, (1) steady-state responses are obtained while pumping 225-mL samples through the column, (2) the detector response level and the calibration curve in the inset of Fig. 10.27

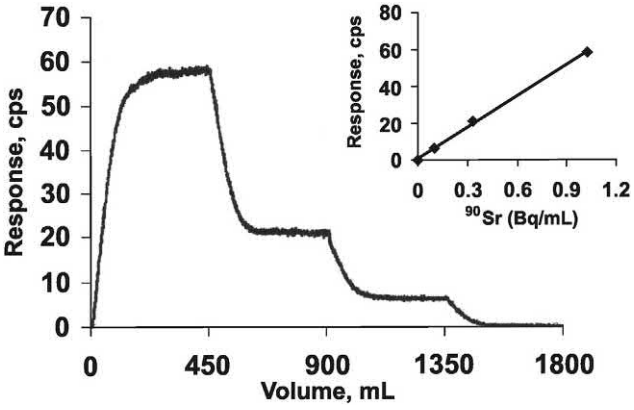

FIGURE 10.28 Responses of a ^{90}Sr equilibrium-based detector consisting of a mixed bed (1:1 w/w ratio of SuperLig 620:BC-400) to ^{90}Sr standards in Hanford groundwater acidified to pH ~2.1 with nitric acid: (1) 1.02 Bq/mL; (2) 0.33 Bq/mL; (3) 0.10 Bq/mL; (4) blank sample. *From Egorov et al. (2006); reprinted with permission © 2006 American Chemical Society.*

illustrate how the detector signal varies with the sample activity, and (3) the final blank sample shows how the detector response drops to zero demonstrating the reversibility of the response.

In the case of ^{90}Sr analysis, the solid-phase extraction sorbent consisted of SuperLig 620, which is a silica support with covalently bound crown ether ligands. The column bed consists of a 1:1 w/w mixture of SuperLig 620 with BC-400 scintillating plastic beads. When groundwater acidified to a pH of 2 is passed through the column bed, the sorbent component will retain the ^{90}Sr, whereas the ^{90}Y passes through unretained. The responses of the equilibrium-based column to 450-mL sample volumes of acidified groundwater containing ^{90}Sr are illustrated in Fig. 10.28. The figure illustrates the repetitive and linear lower response of the detector to lower activities of ^{90}Sr pumped through the column.

The detection efficiencies with the equilibrium-based flow detectors designed for ^{99}Tc and ^{90}Sr are reported to be 38% and 63%, respectively (Egorov et al., 2006; Grate et al., 2007, 2009; O'Hara et al., 2009a). The technique has been demonstrated for the measurement of ^{99}Tc in groundwater via a sensor probe in well bore holes (Grate et al., 2008), and there is no reduction or change in flow detector response after testing with numerous samples. As described by O'Hara and Niver (2014), the net (background subtracted) sensor count rate is converted to radionuclide activity per unit volume (A_{Tc}, Bq/mL) according to the equation:

$$A_{Tc} = \frac{R_{eq}}{E_m} \tag{10.28}$$

where R_{eq} is the net count rate (cps) of the sensor at equilibrium with ^{99}Tc, and E_m is the measurement efficiency in units of cps/(Bq/mL). They note that in situations of analyzing groundwater where the chemistry (i.e., distribution of anions) can change over time, it is necessary to utilize the method of matrix spike in addition to determining the measurement efficiency according to the equation:

$$E_m = \frac{R_{eq,sp} - \left(\frac{V_s - V_{sp}}{V_s}\right) R_{eq}}{A_{matrixsp}} \tag{10.29}$$

where $R_{eq,sp}$ is the net count rate of the spiked sample (i.e., sample spiked with radionuclide standard) at equilibrium, R_{eq} is the net count rate of the unspiked sample, V_s is the sample volume, V_{sp} is the volume of the ^{99}Tc spike, and $A_{matrixsp}$ is the activity of the ^{99}Tc matrix spike in the mixed sample. The value of $A_{matrixsp}$ is calculated according to

$$A_{matrixsp} = \frac{A_{sp} V_{sp}}{V_s} \tag{10.30}$$

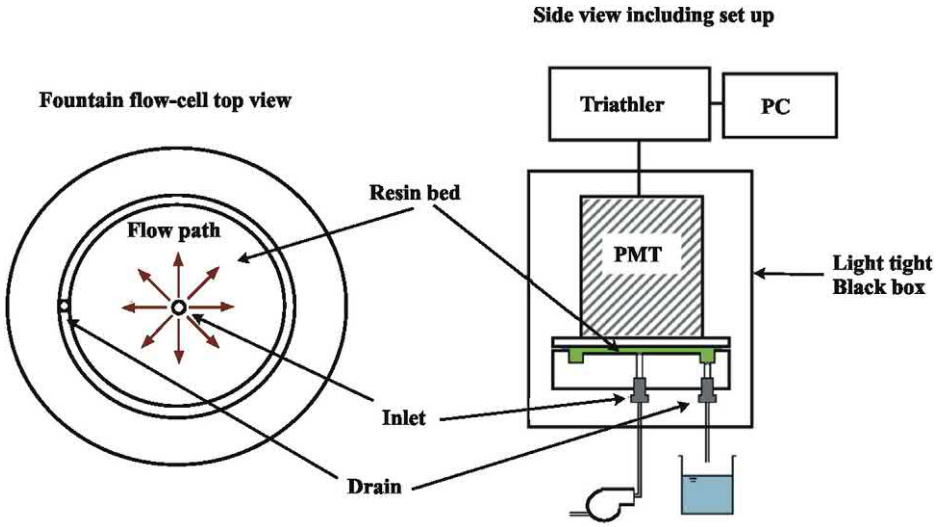

FIGURE 10.29 Planar fountain flow cell schematic and setup with PMT, Triathler counter, personal computer, and pump for a dual-functionality preconcentrating radiometric detector. The left image illustrates the radial solution flow through a packed resin bed. *From Hughes and DeVol (2006a); reprinted with permission © 2006 American Chemical Society.*

D. Planar mixed-bed flow cell

A fountain-flow cell design based on a radial solution flow through a mixed dual-functionality resin bed of inorganic scintillator particles (CaF_2:Eu) and anion exchange resin (Dowex 1 × 8−400(Cl^-)) was designed by Hughes and DeVol (2006a). The flow is directed from the center of the mixed scintillator and resin bed to the periphery. The dual-functionality mixed bed is interfaced with a single PMT through a polycarbonate window as illustrated in Fig. 10.29. The mixed bed was operated in a quantitative-capture mode rather than the equilibrium-based mode described in the previous Section C. The capture efficiency of the resin for ^{99}Tc was greater than 98%, and the detection efficiency was 50.2%. A flow cell with a coil geometry containing the same mixed bed yielded the highest sensitivity with a detection limit of 3.78 Bq/L for a 100 seconds count time and a 200-mL sample, which is well below the regulatory level of 33 Bq/L for drinking water (Hughes and DeVol (2006a). The planar cell geometry offers several advantages, including effective capture and reasonable detection efficiency, flexibility in the geometry of the selective and transducing materials, and the possibility of placing a permeable membrane between the sample and the separation/transducing materials allowing diffusion of the sample ions to the mixed bed while stopping suspended particles (Grate et al., 2008).

E. Planar detectors based on semiconductor diodes

The planar dual-functionality flow-cell detectors may have the following design formats: A planar detector with bis(2-ethylhexyl)phosphonic acid (HDEHP) extractant and plasticizer in a PVC film on the surface of a passivated ion-implanted planar silicon (PIPS) semiconductor diode (Egorov et al., 2004a,b and Addleman et al., 2005) or preconcentration of analyte on Dowex 1x8-400(Cl^-) anion

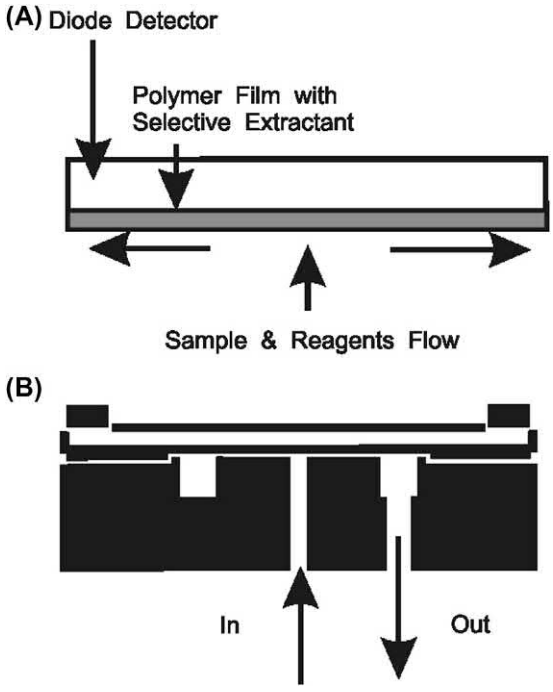

FIGURE 10.30 Preconcentrating diode flow detector modified (A) with analyte selective film, and (B) schematic of a "fountain"-flow cell for the diode detector. *From Egorov et al. (2004a); reprinted with permission © 2004 American Chemical Society.*

exchange resin on a Teflon-coated PIPS semiconductor detector (Hughes and DeVol, 2006a).

The semiconductor diode designs described by Egorov et al. (2004a) consisted of (1) a semiconductor diode flow detector coated with a combined polymer film with actinide-selective organic extractants, such as HDEHP and bis(2-ethylhexyl)methane-diphosphonic acid (DIPEX) used as plasticizers, and (2) a fountain-flow design with the diode coated with HDEHP-plasticized film. These films have high actinide uptake chemistries, which provide these detectors with the capacity of actinide preconcentration on a thin-film geometry on the semiconductor diode surface. The two flow-cell detector designs are illustrated in Fig. 10.30.

The deposition of the thin film of actinide-selective organic extractant on the surface of the diode provides the flow-cell detector with the capacity to concentrate actinides in water samples depositing the actinides in close proximity to the diode detector separated only by a thin film of 0.5−3 μm thickness. The fountain-flow design illustrated in Fig. 10.30B enables the passage of water over the planar diode assembly illustrated in Fig. 10.30A whereby the actinides in the water concentrate on the polymer film containing the selective extractant. As described by Egorov et al. (2004a), the diode detector offers the following advantages: (1) diode detectors yield energy resolution much superior to that of scintillation detection, providing energy spectral information useful for the identification of radionuclides, (2) the background noise levels of diode detectors are orders of magnitude lower than scintillation detectors, and (3) diode detectors designed for the measurement of alpha radiation provide excellent discrimination against beta and gamma radiation.

The combined polymer film with actinide-selective organic extractant used to coat the semiconductor diode of the flow detector, described in the previous paragraphs, enables the concentration of actinides on the thin film of the detector while, at the same time, facilitating the measurement of α particle energy spectra with high resolution. The resolution of the α particle energy spectra is dependent on the thickness of the polymer film. Excellent resolutions of <100 keV FWHM are obtained with the polymer film thickness <0.5 μm, and energy resolution is degraded significantly with >2-μm-thick films (Egorov et al., 2004a; Addleman et al., 2005). Typical α particle energy spectra with an actinide selective film thickness of 0.5 μm is illustrated in Fig. 10.31.

Egorov et al. (2004a) tested the feasibility of using a diode packed in a fountain-flow cell with ^{241}Am standard and with the diode coated with an HDEHP-plasticized film of 3 μm thickness. The detection efficiency was 30%, and the detector traces, illustrated in Fig. 10.32, show the preconcentration of the ^{241}Am on the surface of the HDEHP-plasticized film on the diode surface. Also, from Fig. 10.32, it can be seen how the HDEHP extractant of the diode detector is regenerated with 4 M nitric acid. The findings demonstrate the robustness of the PIPS diode coated with actinide extractant in contact with aqueous solution.

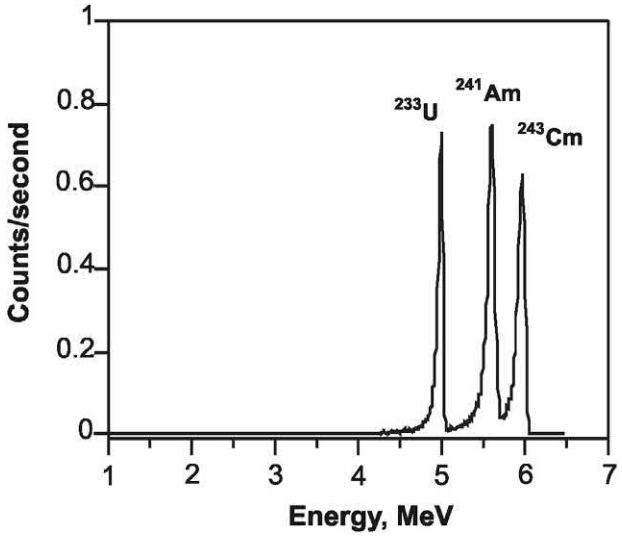

FIGURE 10.31 Alpha energy spectra illustrating feasibility of chemically modified diode detectors for in situ detection of alpha emitters in solution. Spectra measured in a static contact regime. Sample volume is 3 mL. High-resolution alpha spectroscopy in solution was demonstrated using a sample containing 1000 dpm/mL of ^{233}U, ^{241}Am, and ^{243}Cm. FIGURE 10.33 Schematic of the flow cell. During the preconcentration step (left), the resin is suspended in solution, as radioactive solution enters the flow cell at the bottom port. The solution leaves the flow cell through the outflow port, but the radioactivity is retained on the resin. The schematic on the right shows the data collection step, as the flow is stopped and the resin has settled on the detector surface. *From Hughes and DeVol (2006b); reprinted with kind permission from Springer Nature © 2006.*

A quite different approach to the use of diode-based flow cells was devised by Hughes and DeVol (2006b) with a flow cell designed to mix water samples with 40−80 μm Dowex 1x8-400(Cl^-) strong basic anion exchange resin in chloride form. This ion exchange resin exhibits a selective bias for binding with pertechnetate ($^{99}TcO_4^-$) over other anions encountered in groundwater. The ion exchange resin concentrates the ^{99}Tc from the water, which is passed through the flow cell, and the resin is then allowed to settle to the bottom of the cell onto the surface of a Teflon-coated 300-μm-thick PIPS semiconductor detector (see Fig. 10.33). Hughes and DeVol (2006b) selected the smallest diameter ion exchange resin available to achieve the highest interaction probability of the ^{99}Tc decay radiation with the semiconductor diode when attached to the resin beads at the bottom of the flow cell. The semiconductor detector measured 450 mm^2 in diameter, which formed the base of the flow cell, as illustrated in Fig. 10.33. The walls of the flow cell consisted of a cylindrical piece of 2.4 cm ID, 3.2 cm OD, 5 cm H polyethylene pipe providing a cell volume of ~20 mL.

Hughes and DeVol (2006b) demonstrated that passing incremental 20-mL volumes of groundwater spiked with 33.99 Bq/L of ^{99}Tc would result in a quantitative capture of

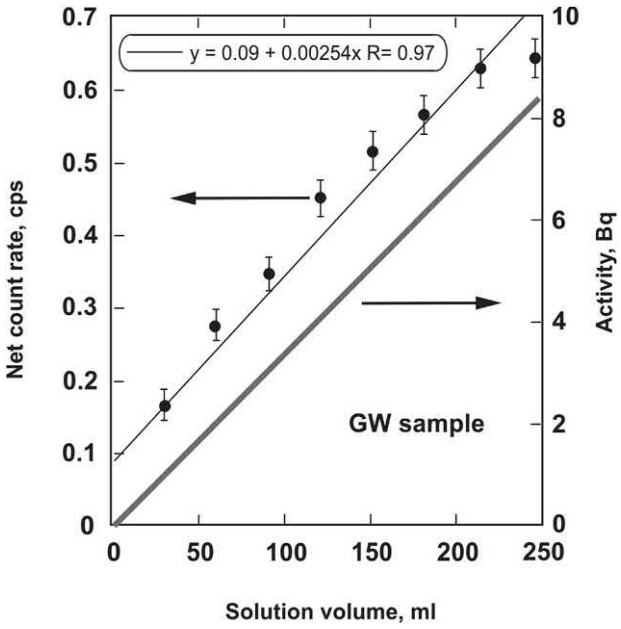

FIGURE 10.34 Flow profile of a groundwater sample. The thin black line is the regression fit to the data, and the error bars represent one standard deviation based on counting uncertainty. ^{99}Tc by the ion exchange resin for each 30-mL increment of groundwater passed through the flow cell and a linear concentration of the ^{99}Tc with total water volumes up to 250 mL illustrated in Fig. 10.34. An average detection efficiency of 17.66% ± 3.20% and background of 0.35 cps was reported. This flow-cell technique could measure ^{99}Tc levels in 30-mL groundwater samples below the limits of 33 Bq/L set for pertechnetate in drinking water.

F. Whole-column detector

A dual-functionality flow-cell detector consisting of a chromatographic column of Dionex C14 chromatographic stationary phase contained within a Bicron BC400 plastic scintillator detector was devised by Link and Synovec (1999) for the HPLC separation and measurement of low levels of beta-emitting analytes. The detection of low levels of the radioisotope is achieved by encompassing the entire column of chromatographic media within the detector volume, that is, the chromatographic column is also the detector. In this case, the dual functionality of separation and scintillation is not achieved with a mixed bed of resin and scintillator, as in the examples cited in the previous paragraphs; rather, the dual functionality is obtained with a chromatographic stationary phase contained within the scintillating column. A schematic diagram of the column is illustrated in Fig. 10.35. The column was constructed of two pieces of $2.5 \times 6.4 \times 0.8\ cm^3$ of BC400 plastic scintillator. A shallow hexagonal region was milled out of each piece of plastic scintillator to create a cavity measuring 0.78 cm wide × 4.1 cm long × 0.05 cm deep to contain the chromatographic stationary phase bordered by a 0.125-cm-deep O-ring groove. The two pieces of plastic scintillator with their respective cavities were joined together with screws and sealed with an O-ring to form the planar chromatography column of 1-mm thickness. The O-ring seal kept the mobile liquid phase within the column. The planar column was coupled with silicone optical coupling to two PMTs. A flow-cell detector without chromatographic medium was coupled downstream to the dual-functionality column to compare its effectiveness with a conventional flow-cell detector.

The approach used by Link and Synovec (1999) with the whole-column detector is the following: The radioisotope-labeled organic compounds are injected into the column, and all of the compounds reside on the column at one time, i.e., the compounds are detected together on the column until each compound is eluted sequentially from the column. As the compounds are eluted from the column, the detection signal is reduced according to the activity of the labeled compound eluted. The planar geometry of the whole-column detector minimizes the distance between the chromatography medium and the scintillation detector. Link and Synovec (1999) tested the detector with ^{11}C-labeled pharmaceuticals. The radionuclide ^{11}C undergoes positron decay with a maximum energy (E_{max}) of 0.961 MeV and a range calculated by Link and Synovec (1999) to be 3.5 mm. The maximum distance of travel for a beta particle in the cavity of the whole-column detector is only 0.005 mm before reaching the plastic scintillator. The continuous detection of the isotope-labeled compounds in the whole-column detector provides an increased radiation SNR, and the recorded chromatographic separation of the labeled-compounds is maintained without the characteristic resolution loss via postcolumn flow-cell detector band broadening. The simulated and experimental responses of

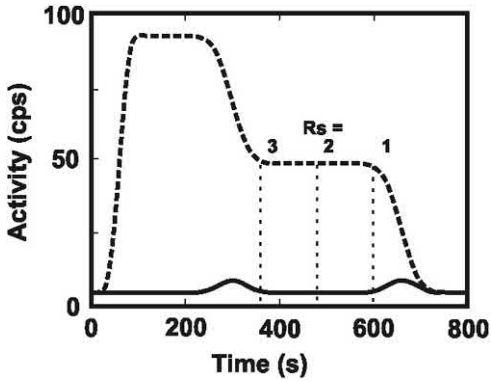

FIGURE 10.36 Simulated whole-column (- - -) and flow-through (—) detector signals for a two-analyte system. Detector response is equal for the two detectors. Analyte retention times are 300 and 660 seconds. *From Link and Synovec (1999); reprinted with permission © 1999 American Chemical Society.*

the whole-column detector to the HPLC separation of isotope-labeled compounds are illustrated in Figs. 10.36 and 10.37, respectively. Link and Synovec (1999) calculated simulated responses of the whole-column detector and a flow-through detector for the chromatographic separation of two ^{11}C-labeled analytes of equal activity, which is illustrated in Fig. 10.36. The signal from whole-column detection is at a maximum when the entire sample is injected into the column. Once the entire sample of a mixture of radioisotope-labeled compounds is loaded into the column, an appropriate mobile phase is pumped through the column, and the signal drops as labeled compounds are separated and eluted from the column. Fig. 10.36 illustrates the signals from a whole-column detector and of a flow-through detector during the chromatographic separation of two radioisotope-labeled compounds of equal activity. As described by Link and Synovec (1999), the signal from the whole-column detection is the total amount injected on the column at time t past injection time minus the total amount, which has eluted up to that time. This is illustrated in the simulation of Fig. 10.36 where the activity drops to one-half as one of the two compounds of equal activity is eluted from the column. The signal from the flow-through detector is weaker, as only a portion of the analytes is detected at any given time.

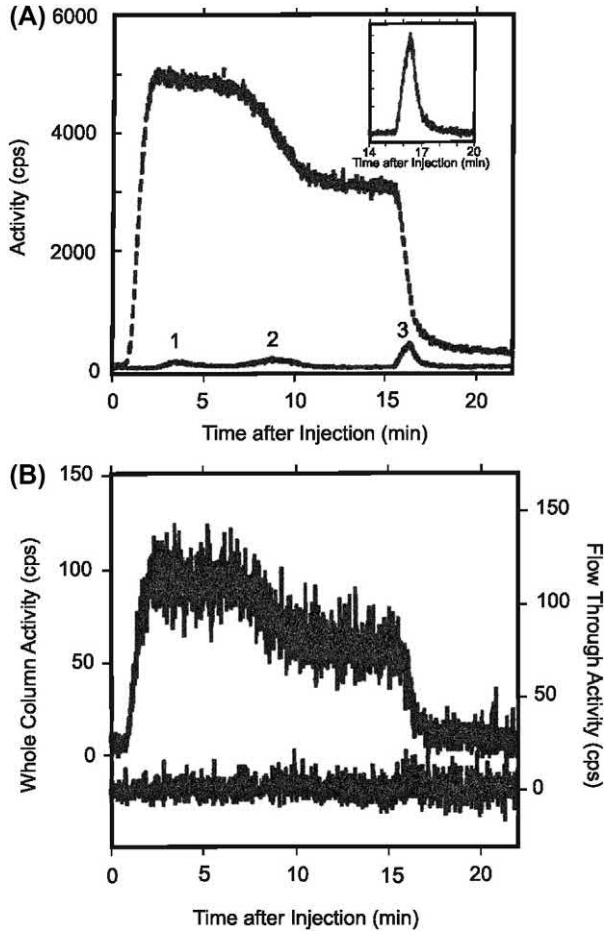

FIGURE 10.37 Sample radioactivity chromatograms to illustrate the difference between whole-column and flow-through detection: (A) injection of 9250 Bq; (B) injection of 185 Bq. The peaks are denoted by number: analyte 1, a trace impurity; analyte 2, [^{11}C]-α-methylepinephrine; analyte 3, [^{11}C]-*m*-hydroxyephedrine. Traces: - -, whole-column detection; —, flow-through detection. The inset in (A) shows the [^{11}C]-*m*-hydroxyephedrine flow-through peak amplified fourfold to illustrate column resolution. In (B), plotting of the two signals is offset vertically for clarity. The left y-axis is whole-column activity with the 0 value offset by 50 counts/s (cps) from the x-axis; the right y-axis is for flow-through detection with the 0 value offset 30 counts/s from the x-axis. The data were decay corrected to time of injection for accuracy in presentation. *From Link and Synovec (1999); reprinted with permission © 1999 American Chemical Society.*

Link and Synovec (1999) demonstrated the relative sensitivities of the whole-column and flow-through column methods with an experimental comparison of detector responses to two samples of relatively high and low activities. The two samples contained a total activity of 9250 and 185 Bq of a mixture of ^{11}C-labeled compounds, and the whole-column and flow-through column detector responses to the two samples, as the compounds were eluted from the column, are illustrated in Fig, 10.37. Both whole-column and flow-through column detection were sufficiently sensitive to measure the ^{11}C-labeled organic compounds of relatively high activity, as they are eluted from the column; however, only the whole-column detector was sufficiently sensitive to measure the activity of the major analytes of the low-activity sample. The whole column detection efficiency reported for ^{11}C was 96%. A limit of detection (L_D) for analytes of 2 Bq (54 pCi) was measured for whole-column detection, which is a 50-fold improvement in L_D compared with the flow-through detection.

G. Tritiated water vapor in air detector

The monitoring of tritium in air is important in facilities where relatively high levels of tritium may exist, such as in laboratories where tritium fuel is used in research on nuclear fusion, and in fission nuclear power plants particularly in power plants that use D_2O as a moderator. Tritium in air can take on two forms, namely, gaseous tritium (HT, DT, and T_2) or in the form of water vapor (HTO, DTO, and T_2O) where H, D, and T refer to the three isotopic forms of hydrogen, ^{1}H, ^{2}H, and ^{3}H, respectively. Carnpi et al. (1998) developed a detector consisting of a disk of zeolite, which has a high absorptive capacity for moisture (i.e., water vapor in air) and acts as a scintillator with increased efficiency when activated with Eu^{3+}. The scintillation efficiency properties of zeolites doped with Eu^{3+} and other lanthanides or metal ions are thoroughly researched (Saini et al., 2018; Taiji et al., 2018; Li et al., 2017; Rong gui et al., 2014; Gong et al., 2013; Rocha et al., 2013; Flores-Acosta et al., 2005; Joly et al., 2007; Lezhnina and Kynast, 2010). The detector developed by Carnpi et al. (1998) consists of a disk of Eu-doped zeolite coupled to a PMT and an

air flow system capable of monitoring the zeolite-trapped water vapor in air. The flow-cell detector is classified as a dual-functionality flow detector because it simultaneously concentrates and detects the radionuclide of interest. Gaseous tritium is not trapped by the zeolite, and thus, the detector could discriminate between the chemically oxidized form of tritium in air (i.e., tritiated water vapor) and the tritium gas. Tritiated water vapor is the most hazardous form of airborne tritium. The derived air concentration limit is 8×10^5 Bq/m^3 for the gaseous form of tritium, which is 25,000 times higher than the air concentration limit for the oxidized form (Carnpi et al., 1998). In 1 hour of operation, the flow detector is reported to reveal HTO concentrations 40 times below the derived air concentration, and a level equal to the derived air concentration could be revealed within the first minute of counting. The flow cell may be operated continuously for a 5-hour duration.

VI. Flow-cell radionuclide analysis sequential to separation

The previous section in this chapter dealt with dual-functionality flow detectors, which have the capacity to simultaneously separate and detect radionuclides with the aim of concentrating the radionuclide of interest on the column while simultaneously providing a measurement of the radionuclide activity. This section will focus on the flow-cell detectors that are used to measure radionuclide activities subsequent to or sequential to their chromatographic separation.

A. ^{99}Tc in nuclear waste and process monitoring

The analysis of ^{99}Tc in nuclear waste has been given much attention due to its high activities in waste, its long half-life (2.6×10^6 years), and its high mobility in the environment. Methods developed by Egorov et al. (2004b, 2005b) and O'Hara et al. (2008a,b) include robotic and automated handling steps that perform sample oxidation, the separation of ^{99}Tc(VII) as pertechnetate ($^{99}TcO_4^-$) from interfering radionuclides with an anion exchange column, and the delivery of the separated pertechnetate to a flow detector followed by the automated computed-controlled ^{99}Tc activity analysis.

For the automated analysis of ^{99}Tc, a heterogeneous flow-cell detector has been used such as a 1-mL pore volume Li-doped glass scintillator flow cell with a Beta Ram detector system (LabLogic, Inc.) reported by Egorov et al. (2004b, 2005b) and O'Hara et al. (2008a,b). A flow-cell detection efficiency of ~55% for the ^{99}Tc is reported. These researchers processed the detector output to obtain an instrument response in cpm/mL followed by calculations yielding the sample activity in dpm/mL. The flow-cell

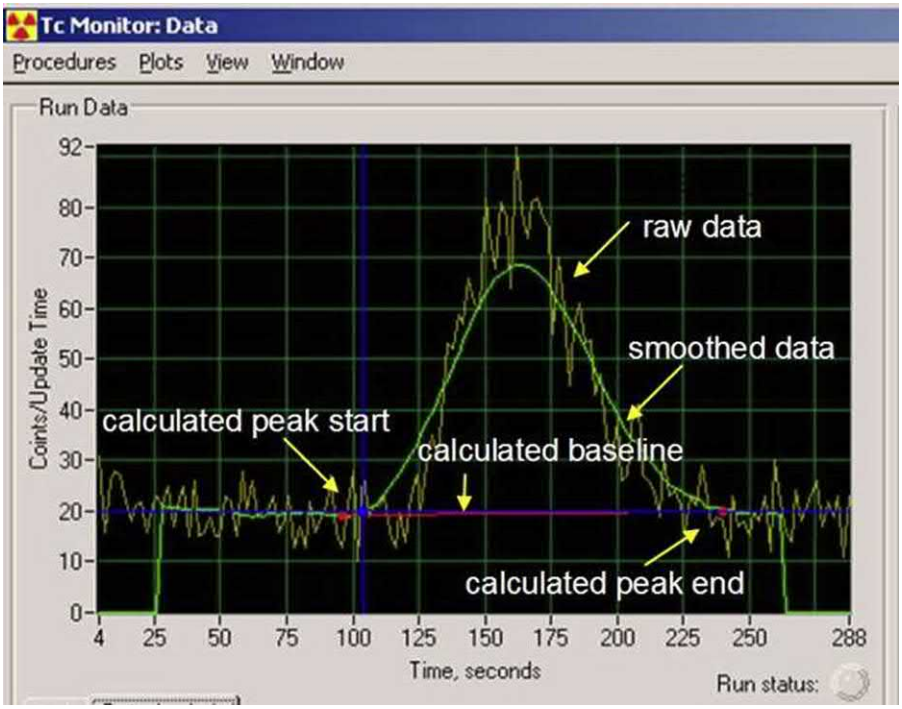

FIGURE 10.38 Detector data display of ^{99}Tc as it passed through the detection cell (yellow). Green trace shows smoothed data, which were used to determine baseline (blue/red horizontal line) and subsequently the net counts under the peak. Color in this figure is visible in the electronic version of this book. *From O'Hara et al. (2008a); reprinted with permission ©2008 by the American Nuclear Society, La Grange Park, Illinois.*

detector response is a peak of the ^{99}Tc radiation counts, as the radionuclide in the ion exchange column eluate enters and exits the flow-cell detector. A typical peak is illustrated in Fig. 10.38. The raw data from the flow-cell detector are a peak corresponding to a time series of counts per update time, which is smoothed with a moving-average algorithm, including a baseline determination. Subsequently, a peak search and integration algorithm is used to determine the peak start and peak end positions and a calculation of the integrated peak area in counts.

Once the peak area in counts is obtained, the count rate of the radionuclide in the original sample is calculated, as described by O'Hara et al. (2008a), according to the following:

$$C_{cpm/mL} = \frac{(N_{cts}/t_r)}{V_s \times D} \tag{10.31}$$

where N_{cts} is the net (background-subtracted) peak area in counts, t_r is the counting (or residence) time in the flow-cell detector, V_s is the original sample volume in mL, and D is the sample volume dilution factor resulting from the automated sample preparation and measurement. The dilution factor D is thus the fraction of the digested sample loaded onto the separation column versus the total volume of the digestate. A calibration factor, which provides a value to the overall efficiency of the measurement, including the chemical yield and the flow-cell detection efficiency, is determined by spiking the automated sample preparation and analysis system with a standard of the radionuclide under analysis (e.g., ^{99}Tc), and the calibration factor is then calculated according to the following:

$$E = \frac{C_{sp} - C_u}{V_{sp} \times A_{sp} \times D_{sp}} \tag{10.32}$$

where E is the calibration factor in units of cpm/dpm, C_{sp} and C_u are the net detector peak areas in cpm for spiked and unspiked samples, respectively. Spiking involves the injection of a precise volume of radionuclide standard (known activity) into the automated sample preparation and analysis system. V_{sp} of Eq. (10.32) and previously described in Eq. (10.29) is the volume (mL) of radionuclide standard (spike) added to the sample, A_{sp} is the activity concentration (dpm/mL) of the radionuclide standard, and D_{sp} is the spiked-run dilution factor, which is calculated in the same manner as D of Eq. (10.27). The activity concentration, A_{Tc}, of the radionuclide (e.g., ^{99}Tc) in units of dpm/ml is then calculated, as described by O'Hara et al. (2008a), as

$$A_{Tc} = \frac{C_{cpm/mL}}{E} \tag{10.33}$$

where $C_{cpm/mL}$ and E are the count rate of the radionuclide in the original sample and calibration factor, respectively, as previously defined.

Automated methods for the analysis of radionuclides, including ^{99}Tc in nuclear waste and process streams, are discussed in detail in Chapter 11, Volume 2, and many of these methods include the use of a flow detector for the analysis of radionuclides, as these are separated on the ion exchange column of the automated flow—based instrumental setup. Automation in the separation and analysis of radionuclides can involve ion exchange chromatographic columns described and flow-cell detectors in this chapter as well as other methods of analysis such as radioisotope MS. Automated methods, such as flow injection and sequential injection fluidics, are beyond the scope of this chapter. The reader will find a review of the principles and practice of these techniques in radionuclide analysis in Chapter 11 of Volume 2 "Automated Radiochemical Separation, Analysis and Sensing" of this book. Other excellent reviews on automating radiochemical analysis including the use of flow-based detectors, as well as other methods including MS, are provided by Trojanowicz et al. (2018), Rodríguez et al. (2016), and Cerdà et al. (2014). Table 10.8 from Trojanowicz et al. (2018) provides a compilation of automated flow methods applied to the analysis of radionuclides in nuclear wastes and reactor coolants. See also Rodríguez et al. (2016) for a comprehensive review of automated flow analysis methods applied to the radiochemical analysis of a wide range of environmental samples, including drinking water, milk, soil, sludge, radwaste urine, hospital residue, seawater, and vegetable matter.

B. Actinides and ^{90}Sr in soil

The combined extraction of actinides and ^{90}Sr from soil followed by chromatographic radionuclide separation and flow-cell analysis is possible, as demonstrated by Roane et al. (2003); however, the analysis requires the removal of interfering ions that influence the chromatographic retention times of the radionuclides, which is a key to their identification. Prior to the separation of the radionuclides by ion chromatography and flow-cell analysis, the soil is subjected to acid digestion and leaching followed by cleanup by processing soil extract through Sr resin and TRU resin columns as illustrated in Fig. 10.39. The identification and activity analysis of the radionuclides is carried out by ion chromatography and comparison of radionuclide retention times with those of known radionuclide standards followed by flow-cell analysis. Roane et al. (2003) used a Beta RAM flow-cell scintillation detector (LabLogic, Inc.). Flow-cell detector responses to the ion chromatographic separation of radionuclides extracted from soil and those of known radionuclide standards are illustrated in Fig. 10.40.

Radionuclide activity is determined from the flow-cell detector response or radionuclide peak by integrating the peak to determine its net area, N, which represents the background-subtracted counts of the peak. The counts are

divided by the count time t (seconds). A calibration factor CF (Bq/cps) for each radionuclide was calculated from the relation:

$$CF = \frac{Af}{(N/t)} \tag{10.34}$$

where A is the loaded activity of standard, and f is the branching ratio for charged particle decay. Roane et al. (2003) found the calibration factors to range from 0.761 for ^{241}Am to 1.088 for ^{233}U. The calibration factor (CF) in this case has units of dps/cps, which is the inverse in units of the calibration factor (E) of Eqs. (10.32) and (10.33), described previously. Thus, the radionuclide count rates per unit volume of sample ($C_{cps/mL}$) are converted to sample activities per volume ($A_{dps/mL}$) by the relation:

$$A_{dps/mL} = CF \cdot C_{cps/mL} \tag{10.35}$$

which is the inverse of the previously described Eq. (10.33). The relation given in the above Eq. (10.35) was used by Egorov et al. (2005a,b) to convert count rates per sample volume to disintegration rates per sample volume.

Roane et al. (2003) demonstrated that the radionuclides extracted from soil required dilution to prevent interference from ions that would alter the ion chromatography retention times of the radionuclides compared with the retention times of the radionuclide standards. Improvements in radionuclide concentration and cleanup will allow for increased concentration of radionuclides extracted from soil to permit the measurement of low activity levels.

C. Alpha/beta discrimination

The possibility of analyzing α- and $\beta(\gamma)$-emitting radionuclides in the same sample by pulse shape discrimination (PSD) and reporting these as gross α and gross β activities has widespread applications in the environmental measurement of radioactivity. See Chapter 6, Volume 1 and Chapter 2, Volume 2 for additional information on this subject. Because the radionuclides are often extracted in mixtures, high-performance ionic chromatography (HPIC) linked to flow scintillation analysis with alpha/beta discrimination facilitates

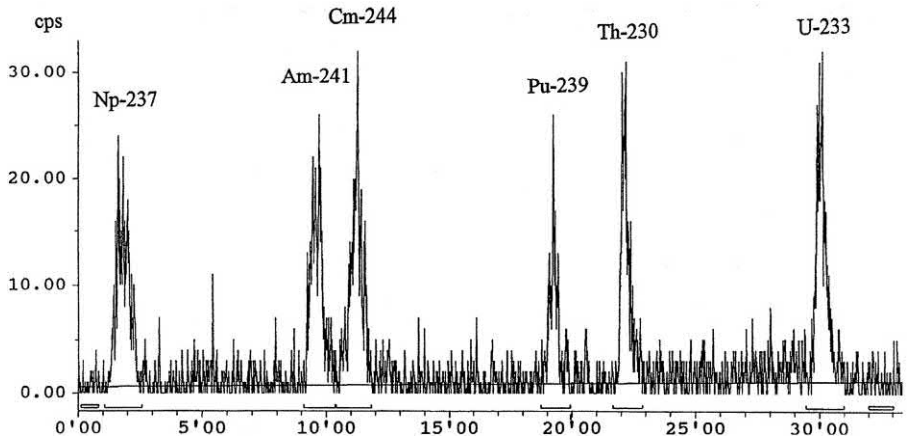

FIGURE 10.41 A typical chromatogram of select actinides using cationic elution. *From Reboul and Fjeld (1995); reprinted with permission © 1995 Wolters, Kluwer Health, Inc.*

the environmental analysis of mixtures of α- and β-emitting radionuclides. Separation procedures for fission products utilizing HPLC and HPIC have been developed (Bradbury et al., 1990; Reboul and Fjeld, 1994). The separation procedure for six common actinides by HPIC is reported by Reboul (1994); Reboul and Fjeld (1995). Fig. 10.41 from the work of Reboul and Fjeld (1995) provides an excellent illustration of actinide separation by HPIC and online flow-cell measurements of the separated nuclides. Such excellent (clean) radioisotope separations may preclude the need for α and β activity discrimination by pulse shape analysis (PSA). However, PSA can offer advantages in addition to the α/β discrimination, such as lower background count rates for the detection of alpha versus beta particles and thus, lower limits of detection for alpha-emitting radionuclides. For example, with a flow-cell detector equipped with a Parlene C-coated CsI(Tl) detector and alpha–beta discrimination, Fjeld et al. (2005) obtained a background count rate of 8 cpm for alpha particles and 17 cpm for beta particles in the measurement of alpha- and beta-emitting radionuclides separated by ion chromatography.

As described in detail in Chapters 6, Volume 1 and Chapter 2, Volume 2, it is possible to use pulse decay analysis (PDA) or PSA to discriminate between α- and $\beta(\gamma)$ decay events in the same sample. Events originating from alpha particle interactions with scintillator have 35–40 ns longer decay lifetimes than events originating from beta particle or gamma interactions. This is a result of the longer deexcitation and light emission processes in LS fluors after α particle interactions. In PSA or PSD, the area of the tail of a pulse is compared with the total pulse area, which provides a method of assigning a pulse to that of an α pulse (long pulse) or β/γ pulse (short pulse). Such pulse discrimination for α/β analysis requires two MCAs, where pulses of longer decay times originating from α events are registered in the α-MCA and those of shorter decay times are registered in the β-MCA as originating from β or $\beta(\gamma)$ events.

Various methods of PDA with solid scintillators are described in Chapter 9, Volume 1. Usuda and Abe (1992) and Usuda et al. (1992) tested several solid scintillators including CsI(Tl), NaI(Tl), CaF_2(Eu), BaF_2, BGO, NE102A, and stilbene for the PSD of events arising from α and $\beta(\gamma)$ interactions. Planar solid scintillators were coupled to a single PMT. They used a flow cell consisting of a spiral channel (not tubing), because tubing will absorb all of the α emissions. Solutions of the $\alpha + \beta(\gamma)$ sources flow along the spiral channel in contact with a Au-coated Mylar film, which protects the solid scintillator. The surface of the planar solid scintillator is also protected with Au-coated Mylar film. The α count rate obviously is a function of the thickness of the Au-Mylar protective layers, and the system suffers from low α detection efficiency. Their work demonstrated the potential of solid scintillators for the simultaneous analysis of $\alpha + \beta(\gamma)$ sources using PSD; and CsI(Tl) crystal scintillator was found to provide the best discrimination between α and $\beta(\gamma)$ rays. The scintillator CsI(Tl), however, is water soluble as well as hygroscopic. Thus, without some means of protection from moisture, CsI(Tl) cannot be applied as a scintillator in a solid (heterogeneous) flow cell where the radioactive solution would flow through cell tubing containing a fine powder of solid scintillator. With this in mind, Chotoo et al. (1997) developed a polymer-coated CsI(Tl) scintillation flow cell for simultaneous alpha and beta analysis, which is discussed further on in this section.

DeVol and Fjeld (1995) tested three solid heterogeneous flow cells consisting of 63–90 μm particles of CaF_2(Eu), glass scintillator (GS-20) and BaF_2 packed into translucent Teflon tubing as potential flow cells, which can be coupled to HPIC systems for on-line α/β discrimination

for the routine on-line analysis of alpha-emitters. The contribution from beta-emitters in the chromatograph effluents can be removed by time discriminator settings of a pulse-shape analyzer. By selecting the optimum time discriminator setting, the $\beta(\gamma)$ contribution to the background count rate was reduced by a factor of 4.1 with a BaF_2 heterogeneous flow cell at the expense of only a slight $< 9\%$ loss in α detection efficiency. An alpha detection efficiency of $\sim 50\%$ for ^{233}U is reported by DeVol and Fjeld (1995) providing MDAs of 0.6 Bq for flow cells containing CaF_2(Eu) and BaF_2 and 1.1 Bq for the cell containing GS-20. Like most heterogeneous flow cells, the lack of inertness and intrinsic contamination of the scintillator remains a problem.

Lochny et al. (1998) and Wenzel et al. (1999) devised a plastic scintillator flow cell for the on-line measurement of alpha- and beta-emitting radionuclide mixtures in high-level waste. The detector consisted of the plastic scintillator Meltilex (PerkinElmer, Inc.) and transparent perfluoroalkoxy (PFA) tubing (Dupont, USA). Meltilex is a meltable plastic containing the fluors PPO (diphenyloxazole) and MSB (methylstyrylbenzene). The inner walls of the flow cell tubing were coated with Meltilex permitting detection of both alpha and beta particles. With the use of appropriate energy windows and varying the flow-cell geometry the detector is able to suppress beta particles to a great extent; and the detector is capable of monitoring the decontamination of radioactive waste.

A series of research studies by Chotoo et al. (1997), Hastie et al. (1999), DeVol et al. (1999), Tan et al. (2000), Tan and DeVol (2002) and Fjeld et al. (2005) at Clemson University's Department of Environmental Engineering and Science Department has culminated in a very efficient flow-cell detector for alpha/beta PSD. The detector reported by Tan et al. (2000) consisted of a flow cell containing granular 63–93 μm Parylene C polymer-coated CsI:Tl scintillator situated between two PMTs in coincidence detection mode. The scintillation pulses were analyzed by PSD using the charge integration technique (see Chapters 6 and 9 of Volume 1 for detailed treatments on PSD). PSD is achieved by comparing the fast decay component (pulse integrated over a short period of time, I_f) to the total integrated current from the pulse, I_{tot}, that is, I_f/I_{tot}, as described in Chapters 6 and 9 of Volume 1. Excellent PSD of alpha and beta events was achieved by Tan et al. (2000), who report a spillover of 2.1% for α events to β and 1.4% spillover of β events to α at a pulse-shape discriminator setting $I_f/I_{tot} = 72$ for a mixture of ^{233}U and $^{90}Sr(^{90}Y)$ yielding alpha and beta detection efficiencies and backgrounds of 31.3% and 26.4%, and 0.84 and 0.31 cps, respectively. Tan and DeVol (2002) utilized pulse-shape analysis for alpha/beta determinations with a flow cell containing particles of CsI:Tl encapsulated with a 10% layer (ratio of coating to particle mass) of Parylene C polymer; and in lieu of photomultiplier detectors, they used silicon PIN-photodiodes. For pulse-shape analysis and discrimination of alpha- and beta-events, Tan and DeVol (2002) utilized two timing gates. The first gate was set to measure the leading edge of the pulse; while, the second gate was set to measure the tail of the pulse. The gates were set to maximize the pulse-shape numerical value difference for alpha and beta scintillation pulse events from the CsI:Tl detector. The spillover of beta events into the alpha region of interest was $\sim 3.9\%$; while the background counts in the alpha region of interest was 0.1 cps. Fjeld et al. (2005) measured alpha- and beta-emitting radionuclides with ion chromatography and pulse-shape analysis employing a heterogeneous flow cell containing Parylene C-coated CsI(Tl) in Teflon tubing. The pore volume of the flow cell was 0.15–0.20 mL; and with a flow rate of 1 mL/min an effective counting time of 10 seconds was obtained. They inferred the identification of radionuclides by their characteristic elution time. An example of typical flow-detector responses to eluted radionuclides separated into alpha- and beta chromatograms following alpha/beta discrimination are illustrated in Fig. 10.42. A small spillover (*i.e.*, misclassification) of alpha events as beta, results in the small peak of ^{244}Cm in the beta chromatogram.

Radionuclides activities were determined by Fjeld et al. (2005) integrating the areas under the chromatogram peaks, which would provide the total counts and then dividing by the counting time and detection efficiency. Net count rates are used by subtracting the background count rates, which were 8 cpm for alpha-particle events and 17 cpm for beta-particle events. The detection efficiencies were calculated according to the following:

$$\varepsilon = \frac{N}{At} \tag{10.36}$$

where N is the net (background subtracted) counts determined by peak integration, t is the count time, and A is the activity (Bq) of radionuclide standard loaded onto the column.

Minimal detectable concentrations of the radionuclides are reported by Fjeld et al. (2005) according to whether the analysis is performed on-line via the flow scintillation analyzer, or off-line by counting the separated radionuclides with a conventional LS analyzer equipped with alpha/beta discrimination. The minimal detectable concentrations calculated according to the method of the Currie (1968) equation for paired blanks are listed in Table 10.9 for a 0.2 L aqueous sample or 0.5 g solid sample for on-line and off-line counting. Alpha/beta PSD generally yields much lower backgrounds in the alpha MCA compared with the beta MCA, and thus, lower minimal detectable concentrations can be expected for the alpha emitters.

A unique application of alpha/beta PSD reported by Wierczinski et al. (2001a) was applied to the first online separation and detection of a subsecond α-decaying nuclide. Subsecond ^{224}Pa ($t_{1/2} = 0.85$ seconds) was produced by the ^{209}Bi(^{18}O,3n)^{224}Pa reaction at the 88-inch cyclotron at the Lawrence Berkeley National Laboratory. After production, the nuclide was transported via a gas-jet system to a fast centrifuge system followed by online extraction with trioctylamine/scintillation solutions and online flow scintillation counting with PSD to minimize beta events.

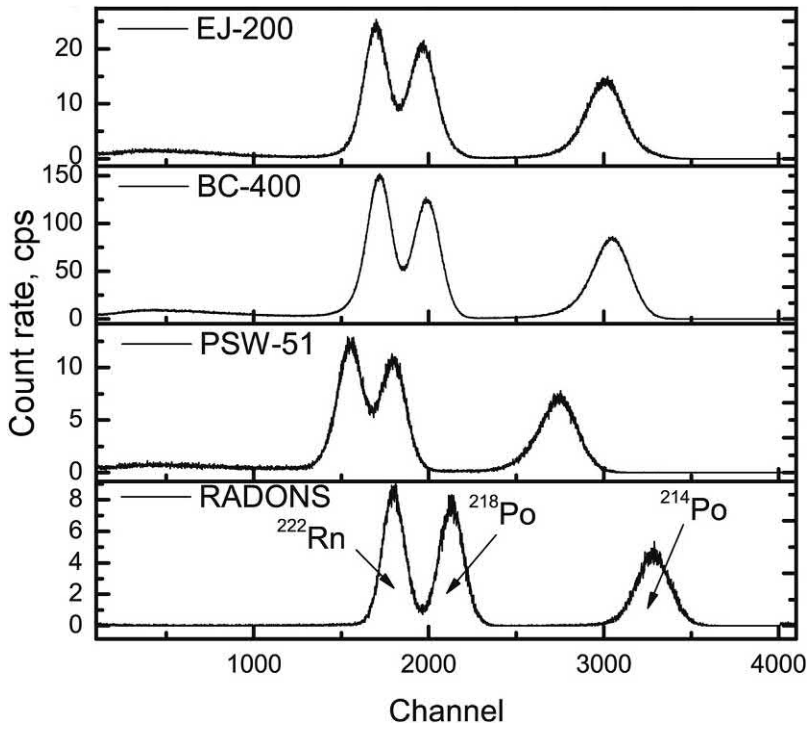

FIGURE 10.43 PERALS pulse height spectra of ^{222}Rn and progeny absorbed in EJ-200, BC-400, PSW-51 plastic scintillator, and as a reference, an optimal case where ^{222}Rn is dissolved in RADONS (ETRAC, USA) LS cocktail. *From Mitev (2016); reprinted with permission from Elsevier © 2016.*

Plastic scintillating microspheres (PSMs) together with alpha/beta discrimination subjected to the continuous flow of river water were demonstrated by Tarancón et al. (2016) to be a robust detector for ^{3}H and ^{90}Sr/^{90}Y. The scintillating microspheres are packed into 6 mL plastic scintillation counting vials. The top and bottom of the vials are drilled to provide inlet and outlets for the pumping of river water through the scintillating microspheres for optimum periods from 6 to 100 hours. Off-line analysis with a Quantulus LS spectrometer demonstrated the capabilities of the plastic scintillation microspheres for alpha/beta discrimination and analysis of ^{3}H and ^{90}Sr/^{90}Y. Detection efficiencies for ^{3}H and ^{90}Sr/^{90}Y reported are 0.53% and 182%, respectively, with a mean background count rate of 1.56 cpm. Limits of detection are 740 Bq/L for ^{3}H and 2.1 Bq/L for ^{90}Sr/^{90}Y with a 5 hour counting time and 1.52 mL sample volume. Improved detection limits are reached by increasing the sample volume (i.e., cell volume) and the counting time.

Mitev (2016) demonstrated the potential of using PSMs or plastic scintillator microspheres packed in polyethylene foils (PS foils) for the continuous monitoring of ^{222}Rn. Plastic scintillators, including EJ-200, BC-400, and PSW-51, were shown to absorb ^{222}Rn and provide excellent alpha/beta PSD with excellent resolutions of ^{222}Rn and

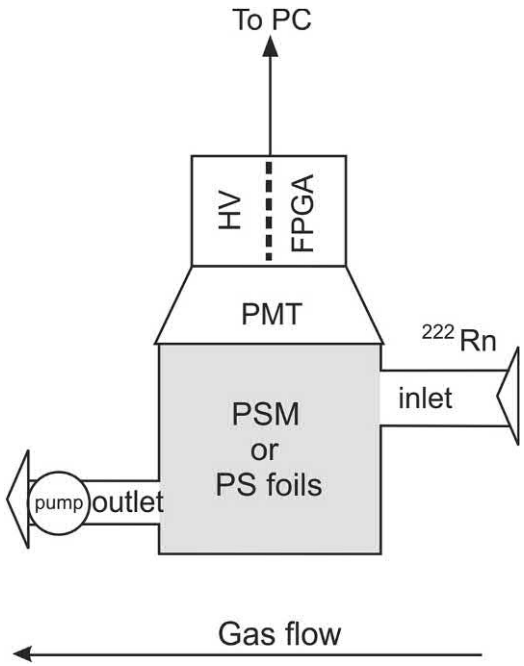

FIGURE 10.44 A potential continuous online radon monitor based on the absorption of ^{222}Rn in plastic scintillator. *From Mitev (2016); reprinted with permission from Elsevier © 2016.*

progeny permitting the quantitative analysis of ^{222}Rn. For example, the alpha peak resolution of ^{222}Rn absorbed into the plastic scintillators is sufficient to permit the separation of the 5.489 MeV peak of ^{218}Po from that of the 6.002 MeV peak of ^{222}Rn, as illustrated in Fig. 10.43. The alpha/beta PSD by the plastic scintillating spheres was performed off-line with a PERALS or a conventional LS spectrometer; however, Mitev (2016) demonstrates the potential for the future design of a flow-through radon monitoring device (Fig. 10.44) using field programmable gate array electronics.

D. ^{89}Sr and ^{90}Sr(^{90}Y) analysis

Since the nuclear atmospheric weapons tests in the 1960s, there has been great concern over the levels of ^{90}Sr in the environment as a serious threat to internal contamination in the human body. This is due mainly to the relatively long half-life of ^{90}Sr ($t_{1/2} = 28.8$ years) and the similarities in the chemistry of calcium and strontium whereby ^{90}Sr will accumulate in the body by residing with a long biological half-life in the human skeleton along with calcium (L'Annunziata, 1967; L'Annunziata and Fuller, 1968). A paper by Desmartin et al. (1997) underscores the continuing concern for ^{90}Sr residues in the environment, as it is produced in a relatively high yield (5.8% from ^{235}U) during the fission of heavy elements. Thus, high levels of ^{90}Sr are found in spent nuclear fuel and reprocessing plants. The classical method of analysis of ^{90}Sr involves precipitation of its daughter ^{90}Y as a carbonate or oxalate followed by counting of the precipitated ^{90}Y (L'Annunziata, 1971; Piltingsrud and Stencel, 1972).

Current techniques in the analysis of ^{90}Sr in the environment involve the combination of HPIC and flow scintillation analysis (FSA) also referred to as online liquid scintillation counting (OLLSC) when homogeneous flow-cell counting is involved [Knöchel and coworkers (see Alfaro et al., 1995; and Desmartin et al., 1997)]. Automated methods of flow analysis to the analysis of ^{90}Sr among other radionuclides in nuclear wastes and reactor coolants and in the environment are reviewed by Trojanowicz et al. (2018), Rodríguez et al. (2016), and Kołacińska and Trojanowicz (2014). These automated methods may include the online flow-cell radiometric measurement of ^{90}Sr among numerous other radionuclides as well as the various MS methods of analysis, which can provide multicomponent analysis and improved limits of detection of transuranic isotopes.

Desmartin et al. (1997) describes the coupling of HPIC to separate ^{90}Sr from natural or power plant reactor water and online flow scintillation analysis before the daughter radionuclide ^{90}Y has time to grow to any significant level following ^{90}Sr separation. They used an HPIC Dionex 2010i system (Dionex Corporation, Sunnyvale) coupled to a radiomatic flow scintillation analyzer with FLO-ONE operation software (PerkinElmer Inc., Waltham, MA, USA) equipped with a 2.5 mL homogeneous flow cell operated with an eluent flow rate of 1 mL/min and a scintillator flow rate of 2.5 mL/min.

Desmartin et al. (1997) set the pulse height discriminators to provide two counting regions of the flow scintillation analyzer, which is equipped with an MCA, to measure the ^{89}Sr and ^{90}Sr simultaneously. Synthetic reactor water containing various concentrations of $^{134}Cs^{+}$, $^{90}Sr^{2+}$($^{90}Y^{3+}$), $^{60}Co^{2+}$, $^{133}Ba^{2+}$, and $^{135}I^{-}$ was easily separated by HPIC to isolate radiostrontium. Trivalent ions such as $^{90}Y^{3+}$ are stopped at the top of the HPIC column. Therefore, the ^{90}Sr(^{90}Y) parent–daughter radionuclides are separated during the chromatography run. The reported MDAs, calculated according to Eq. (10.15) in Section III.D of this chapter, are 480 DPM for ^{89}Sr and 60 DPM for ^{90}Sr.

Grate et al. (1996, 1998a) and Grate and Egorov (1998a) automated the analysis of ^{90}Sr in nuclear waste based on sequential injection analysis, which rapidly separates ^{90}Sr from ^{90}Y, ^{137}Cs, among other radionuclides. They used a sorbent extraction microcolumn containing Sr-Spec resin (EiChrom Industries, Darien, IL) that selectively binds ^{90}Sr as a crown ether complex under acidic conditions. The ^{90}Sr is analyzed online with a flow scintillation analyzer, which can be operated in the continuous- or stopped-flow modes described subsequently in Section VII of this chapter. More information concerning the automation techniques are described in Chapter 11, Volume 2.

Several extractive scintillation sensor materials were tested by DeVol et al. (2001a,b) for either off-line or online monitoring of radiostrontium. Online separation techniques offer the advantage of more automated and rapid analysis cited in the previous paragraph and discussed in detail in Chapter 11. The most effective extractive sensor found by DeVol et al. (2001a,b) consisted of a bed of strontium-specific resin marketed under the trademark Sr-Spec Resin (100–150 μm from EiChrom Industries) and BC-400 scintillating beads (100–200 μm from Bicron, Inc.) combined together 1:2 by weight as a mixed bed. The Sr-Spec Resin consists of an inert, porous organic polymer support impregnated with a solution of bis-4,4′(5′)-tert-butyl-cyclohexano-18-crown-6 (DtBuCH18C6) in 1-octanol. It displays a high selective affinity to strontium at low pH while excluding alkali and alkaline earths. For online tests, DeVol et al. (2001a,b) packed <0.5 g of the Sr-Spec Resin/BC-400 mixture into 3 mm OD × 1.6 mm ID × 140 mm long polytetrafluoroethylene tubing yielding an approximate pore volume (PV) of 200–400 μL, which was 60%–70% of the total void volume. The flexible tubing was coiled in an approximate diameter of 2.54 cm and placed between two PMT tubes of the flow scintillation analysis detector (Beta Ram of LabLogic Systems). The column was loaded with 1–5 PVs of sample in 4M HNO_3 and the column washed with additional ~25 PVs of 4M HNO_3, and the adsorbed ions were eluted with 50 PVs of distilled–deionized water. The detection efficiency reported

was 76% for ^{89}Sr ($E_{max} = 1.49$ MeV). The detection efficiency for ^{90}Sr, which was not tested, should be slightly lower since the beta particle emissions from ^{90}Sr are of lower energy ($E_{max} = 0.546$ MeV).

Interferences in the separation and flow-cell analysis of radionuclides were studied by Roane et al. (1999). These interferences are of two types: (1) radiological interferences and (2) chemical interferences. The radiological interferences are found when other radionuclides are present in the sample, which require their removal by the use of a selective ion exchange or preconcentrating column. Chemical interferences occur when certain ions present in the sample or their ionic strength (i.e., sample load) can affect the performance of an ion exchange column and thus affect the elution times and separations of the radionuclides of interest. Borai and El-Sofany (2004) separated ^{90}Sr and ^{90}Y in the presence of interfering ^{234}Th on a Dionex 2000 ion chromatographic system with 0.2 M ammonium sulfate in 0.3 M HCl eluent. They used a 0.4 mL heterogeneous flow-cell detector with Ce-activated glass scintillator and obtained quantitative recoveries for ^{90}Sr and ^{90}Y in the presence of 17−262 Bq/mL of ^{234}Th.

High-level nuclear waste contains significant ^{137}Cs whereby its daughter ^{137m}Ba is a potential interfering nuclide in the ion exchange separation in the analysis of ^{90}Sr. O'Hara et al. (2008b) and DeVol et al. (2009) found SuperLig 620 solid-phase extraction resin (230−420 mesh) from IBC Advanced Technologies, American Fork, UT, as a suitable extraction chromatographic resin for the separation of interfering nuclides. They determined optimal separations using 2 M nitric acid for the elution of radiocesium and yttrium, a radiostrontium elution step with ~0.49 M ammonium citrate followed by a barium elution step with ~1.8 M ammonium citrate. Quantitative analysis of ^{90}Sr in high-level nuclear waste was achieved with an automated sequential injection analysis microfluidics system (see Chapter 11) coupled to a flow-cell detector. A Beta Ram (LabLogic Systems) heterogeneous flow-cell detector was used consisting of a 1 mL volume Li-glass scintillator. The solid scintillator heterogeneous flow cell was preferred because it yielded adequate detection efficiencies (56% for ^{90}Sr) for the relatively high levels of radioactivity encountered and there is no generation of organic waste, which occurs when homogeneous detectors are used. The linear response of the flow detectors to ^{90}Sr activities injected into the chromatographic system is illustrated in Fig. 10.45. The average recovery for ^{90}Sr was reported to be 98%.

Flow-cell analysis of low levels of radionuclides separated by column chromatography can be achieved by the use of specific resins that can concentrate the radionuclides of interest and the use of stopped-flow detection whereby the residence time of the sample in the flow-cell detector can be increased indefinitely, as described in Section VII of this chapter.

Under conditions of transient continuous flow, Plionis et al. (2009) demonstrated the low-level analysis of ^{90}Sr in urine and other aqueous media by the use of Sr-spec resin (EiChrom Industries, Inc., Darren, IL) and a homogeneous flow-cell detector. The homogeneous flow cells yield the highest detection efficiencies for beta-emitting radionuclides (see Table 10.1), and these flow cells require the mixing of liquid scintillator fluor cocktail with the column effluent stream, as illustrated in Fig. 10.46. They used a Beta Ram (LabLogic Systems, Brandon, FL) 2500 µL liquid flow cell. An internal cocktail pump mixes the LS cocktail with the effluent stream before it enters the flow cell. A low-viscosity LS cocktail was used (in-flow 2:1, LabLogic Systems) together with ScintFlow SA and LauraLite 3.4 software run on a desktop PC to control flow-cell counting parameters. A

detector integration time of 6 s was selected to allow sufficient counts to accumulate for each data point.

In a transient flow system, as used by Plionis et al. (2009), the residence time, T_R, of the eluted sample in the flow cell is defined by Eq. (10.2) described earlier in this chapter. Plionis et al. (2009) used a flow cell with a 2500 μL volume and a combined scintillator effluent flow rate of 3 mL/min. Thus, the residence time, according to Eq. (10.2), is calculated as 50 seconds or 0.83 minutes. The peak area produced by the flow-cell detector response was summed and the background count subtracted by Plionis et al. (2009) to derive a net number of counts for the peak according to Eq. (10.6). With the use of a radionuclide standard, the detection efficiencies were determined according to Eq. (10.8). The counting region for the ^{90}Sr pulse height spectrum was optimized, and a counting window of 2−600, which defined the channel lower- and upper-level discriminators, was selected. Background pulse events are more prevalent at the low end of the pulse height spectrum, and those occurring in the region between 0 and 2 are not counted. The background was reported to be only 4.1 cpm, with a ^{90}Sr detection efficiency of 102.5 ± 6%. The LS detection efficiency of ^{90}Sr, which has a beta spectrum energy maximum at 546 keV, can approach 100% (see Fig. 6.19 of Chapter 6, Volume 1 illustrating the LS

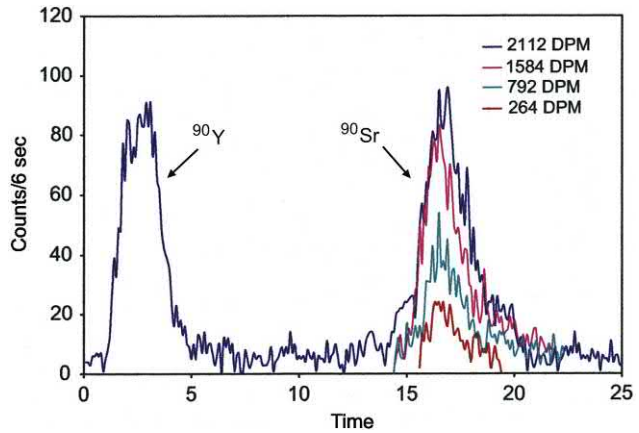

FIGURE 10.47 Flow-cell detector traces for various activities of ^{90}Sr as determined by transient-flow counting and a 3-cm column. Traces, as low as 264 dpm, are visually apparent. Computer-aided peak finders are helpful for determining lower activities of ^{90}Sr. For clarity, only the highest concentration sample is shown for the first peak. The color-coded traces are visible in the electronic version of this book. *From Plionis et al. (2009); reprinted with permission from Elsevier © 2009.*

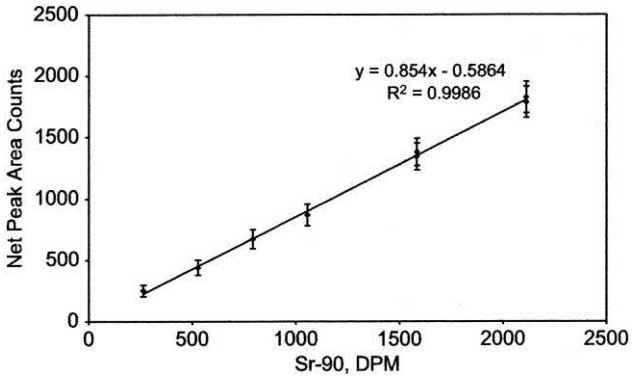

FIGURE 10.48 A calibration curve of flow-cell detector response to various levels of ^{90}Sr activity as determined by transient-flow counting. The fact that the R^2 is close to unity and that the intercept is near zero indicates that there is a highly linear detector response for this analyte. Error bars represent 3σ. *From Plionis et al. (2009); reprinted with permission from Elsevier © 2009.*

detection efficiencies of several beta-emitting radionuclides of widely differing beta spectrum energy maxima). Plionis et al. (2009) explain the small portion of the detection efficiency > 100% as possibly due to diffusion of sample zone within the flow cell or luminescence. The lower level of detection was estimated to be 47 dpm and the lower level of quantification to be 156 dpm. An example of flow-cell detector traces for various levels of ^{90}Sr activity is illustrated in Fig. 10.47. Recoveries of ^{90}Sr in urine sample were quantitative, and a typical calibration curve illustrating a linear detector response to various levels of ^{90}Sr is illustrated in Fig. 10.48.

E. Cherenkov flow-cell analysis

There are commercially available flow cells, called "Cherenkov cells." These consist of coiled Teflon tubing sandwiched between scintillator windows, as described in Table 10.1. These cells are designed for the detection of high-energy beta-emitting radionuclides in HPLC effluents, such as ^{32}P, ^{90}Y, and ^{86}Rb. The E_{max} of the beta particle emissions should be >> 263 keV, which is the threshold energy for the production of Cherenkov photons in water (see Chapter 6, Volume 2). In these flow cells, Cherenkov photons are produced in the narrow aqueous phase and wall of the Teflon tubing; however, most of the photons detected are produced in the scintillator that sandwiches the coiled Teflon tubing. Thus, the beta particle energies must be sufficient to penetrate the Teflon tubing and dissipate energy within the solid scintillator. Although such a cell may be called a "Cherenkov cell," the photons detected are not exclusively Cherenkov photons. The main advantages of these cells are (1) no organic scintillation cocktails are used and (2) no solid scintillator is used inside the Teflon tubing. Some examples of the applications of these cells in the measurement of radionuclides in liquid chromatography effluents are (1) the measurement of ^{32}P (E_{max} = 1710 keV) reported by Waters et al. (1999), Wierczinski et al. (2001b), and Poljaková et al. (2009), (2) the measurement of ^{86}Rb (E_{max} = 1770 keV) reported by Marks et al. (2004, 2009) and Grady et al. (2010), and (3) the measurement of ^{62}Cu (E_{max} = 2926 keV) reported by Yue et al. (2006).

A large Cherenkov cell measuring 12 cm in diameter × 10 cm in length with a 1 L sample volume was designed by Fujii et al. (2002) to measure high-energy beta-emitting radionuclides, such as ^{89}Sr, ^{90}Y, and ^{32}P, as a liquid waste monitor for nuclear medicine. High-energy beta-emitting nuclides are used commonly in nuclear medicine, and the Cherenkov cell was designed for the rapid measurement of these radionuclides in liquid waste. The waste is pumped into the 1-L cell, and the Cherenkov photons are detected by two PMTs on opposite sides of the cell. A coincidence circuitry is utilized to reduce

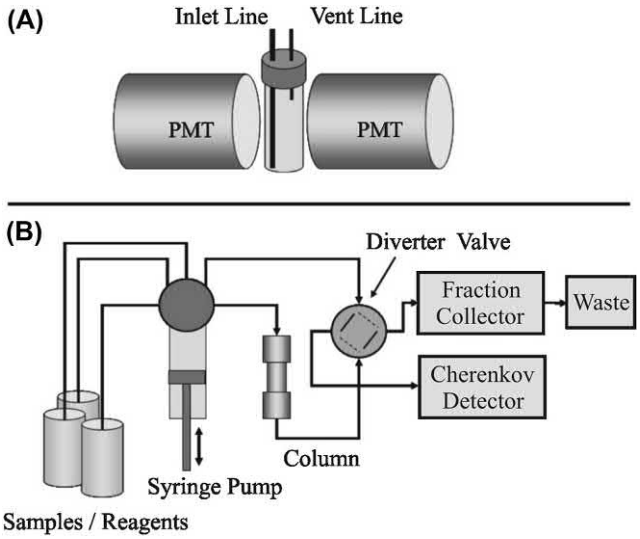

FIGURE 10.49 (A) Cherenkov detection flow cell configured between dual photomultiplier tubes (PMTs). (B) Fluidic layout for automated ^{90}Sr analytical system, including the Cherenkov flow-cell detector. *From O'Hara et al. (2009b); reprinted with permission © 2009 American Chemical Society.*

noncoincident background events. Measurements are made in a "stopped-flow" mode, that is, the flow is stopped for 5–20 minutes for Cherenkov photon counting. Detection efficiencies were sufficient to yield detection limits of 0.003–0.007 and 0.001–0.003 Bq/mL for 5- and 20-minutes measurements, which is more than sufficient for the monitoring of the liquid waste.

O'Hara et al. (2009b) constructed in-house a simple online Cherenkov flow-cell detector consisting of a 2-dram glass vial and cap, which allowed a 5.0 mL volume of column effluent containing ^{90}Y to be delivered and aspirated from the base of the vial via an inlet line illustrated in Fig. 10.49A. A second shorter line was placed just within the cap to allow for the displacement of air during the transfer of sample into and out of the cell. The Cherenkov flow cell was placed between two PMTs of a flow scintillation analyzer; and counting data were acquired using Flo-One software with a laptop computer. The objective of such an arrangement is the analysis of ^{90}Sr in environmental water samples via the Cherenkov counting of ^{90}Y daughter nuclide. Relatively large samples of water up to 0.5 L are loaded onto a SuperLig 620 column, which enables the preconcentration of the ^{90}Sr and the removal of interfering components of the sample matrix as well as other radionuclides, including the elution of its ^{90}Y daughter. Following a period of ^{90}Y ingrowth with the preconcentrated and purified ^{90}Sr, the newly ingrown ^{90}Y is eluted from the column into the Cherenkov flow-cell detector. The ^{90}Sr activity is then calculated from the measured ^{90}Y

daughter activity and the time of ingrowth of the daughter nuclide. O'Hara et al. (2009b) coupled the Cherenkov flow-cell detector to a fully automated liquid handling system illustrated in Fig. 10.49B. Chapter 11 in this volume provides a detailed description of the principles and operation of such fully automated radioanalytical systems.

The Cherenkov flow-cell detector described by O'Hara et al. (2009b) provided a Cherenkov counting detection efficiency of 42.6% for ^{90}Y. With the preconcentration of ^{90}Sr from 0.35 L of water, they demonstrated a detection limit of 0.057 Bq/L, which is below the drinking water limit (DWL) of 0.30 Bq/L. The MDAs for the ^{90}Sr are dependent generally on the volume of sample analyzed, the ^{90}Y yield or recovery efficiency, the sample counting time, background count rate, detection efficiency, and in the counting of its ^{90}Y daughter nuclide, on the ingrowth time of the ^{90}Y. O'Hara et al. (2009b) determined, for an ^{90}Y ingrowth time of 72 hours, Cherenkov flow-cell background of 0.153 cps, ^{90}Y Cherenkov detection efficiency of 0.426, and recovery efficiency of 0.789, that the method could measure ^{90}Sr at the DWL of 0.30 Bq/L within ~9, ~3, and ~1.5 hour detection intervals for 0.2, 0.35, and 0.5 L, respectively, of groundwater samples.

VII. Stopped-flow detection

In Section III.E of this chapter, the relationship of flow detector sensitivity or efficiency and flow rate was discussed. In summary, it was concluded that higher sensitivity (lower MDA) of a flow detector could be achieved by increasing the residence time of a sample in the flow detector (T_R) and the cell volume. Increasing the cell volume would, however, reduce HPLC peak resolutions. During the normal continuous flow of an HPLC run, the residence time of a sample (radioactivity peak) in the detector is generally short (<5 minutes). If the sample activity is low (near background), it may be difficult or impossible to distinguish the sample radioactivity from background with the short sample residence times of continuous-flow runs. This is obvious because longer counting times are required to reduce counting error (Eq. 10.22) and lower limits of detection (see Eq. (6.157) of Chapter 6, Volume 1). If we stop the flow of an HPLC run when the radionuclide is detected by the flow detector at its highest count rate (HPLC peak maximum), the sample residence time can be increased indefinitely at its highest count rate. This is referred to as stopped-flow detection, whereby longer counting times can be selected to achieve acceptable counting statistics and lower limits of detection.

The theory and practice of stopped-flow detection are described by Grate et al. (1996), Grate and Egorov (1998a,b), and Egorov et al. (1998a,b). Under the assumption of no secondary mixing or phase separation in the flow cell under stopped-flow conditions, Egorov et al. (1998a,b) note that the fraction of the sample zone present in the detector flow cell at the peak maximum, D_m, is obtained from the transient continuous-flow peak signal using the equation:

$$D_m = \frac{(C_{max})(T_R)}{(T_i)(C_n)} \tag{10.37}$$

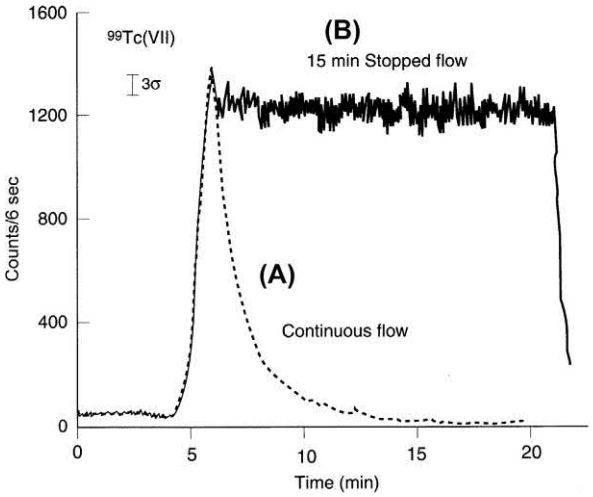

FIGURE 10.50 Comparison of continuous-flow (curve A) and stopped-flow (curve B) detection of ^{99}Tc. The error bar indicates three standard deviations of the peak maximum counts. *From Egorov et al. (1998a), reprinted with permission © 1998 American Chemical Society.*

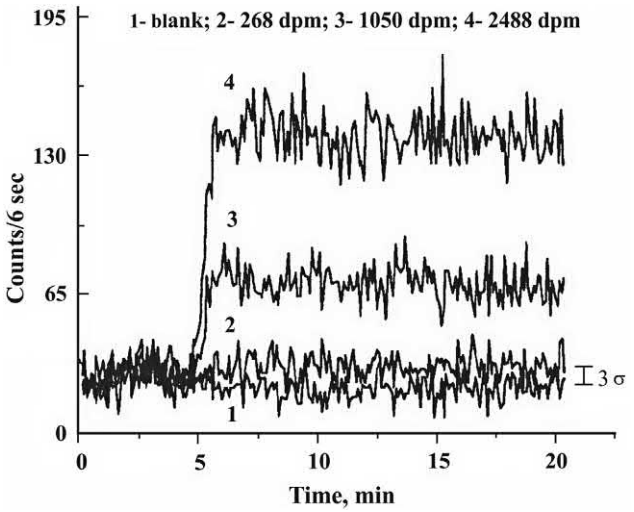

FIGURE 10.51 Selected detector traces from the analysis of ^{99}Tc(VII) standards using 15-minutes stopped-flow detection. The activities of the standards are listed. The error bar corresponds to three standard deviations of the background count rate. *From Egorov et al. (1998a), reprinted with permission © 1998 American Chemical Society.*

where C_{max} is the number of net counts at the peak maximum, T_R is the sample residence time as previously defined (Eq. 10.2), T_i is the pulse summation update time, and C_n is the net peak area counts. If the flow is stopped at the peak maximum, the background-subtracted (net) count rate, C_{cpm}, of the radionuclide is related to the sample activity A_{dpm} according to the following equation of Egorov et al. (1998a,b):

$$C_{cpm} = (D_m)(E_d)(E_{rec})(A_{dpm}) \tag{10.38}$$

where E_d and E_{rec} are the detection efficiency and sample recovery efficiency, respectively, described previously (Eq. 10.14).

Stopped-flow detection was tested by Grate and Egorov (1998a,b) and Egorov et al. (1998a) for the analysis of ^{99}Tc in a 2.5 mL flow cell. Using a ^{99}Tc standard in the continuous-flow detection mode establishes the time position of the peak maximum, as illustrated in Fig. 10.50 (curve A). At the time position of the peak maximum, the instrument is programmed to direct the eluate diverter valve to waste and simultaneously stop the cocktail pump initiating a stopped-flow mode. The detector traces (B) in Fig. 10.50 illustrate a duplicate 15-minutes stopped-flow analysis demonstrating reproducibility of the stopped-flow detection. Stopped-flow analysis of ^{99}Tc at three activity levels is illustrated in Fig. 10.51. The lowest activity of the standard (268 DPM) (trace 2, Fig. 10.51) would not be statistically distinguishable from the background (trace 1, Fig. 10.51) in a continuous-flow measurement. However, a 15-minutes stopped-flow measurement provided sufficient signal accumulation (counts) to yield a reliable analysis of the ^{99}Tc activity (268 DPM) with 8% (3σ) counting error (Egorov et al., 1998a).

VIII. Flow-cell effluent water monitors

A. ^{3}H effluent water monitors

A characteristic of heavy water reactor operation is the production of tritium in the moderator. Consequently, as reported by Sigg et al. (1994) and Hofstetter (1995), the potential release of tritium into the environment through aqueous effluents is of concern at CANDU reactors and at other tritium handling facilities. Developments in flow scintillation analysis have provided a rapid online detection system, which can monitor continuously tritium levels in effluents permitting corrective action to mitigate unwanted tritium release into the environment.

The first flow cells used at the Savannah River Site (SRS), Aiken, South Carolina, were of the heterogeneous type containing solid scintillator beads, such as yttrium silicate, reported by Hofstetter (1991). Continuous monitoring of tritium levels in the aqueous effluents of selected SRS heavy water purification facilities makes use of a heterogeneous flow cell containing plastic scintillator coupled with coincidence electronics providing a sensitivity of ~25 kBq/L (670 pCi/mL). The system requires a water purification pretreatment process, which includes microfiltration, ultraviolet sterilization, activated charcoal and ion exchange resin columns, and a phase separator before continuation of the aqueous stream to the flow cell at a rate of 3 mL/min. The solid scintillators provide limited detection sensitivity with a counting efficiency of only 0.18% for ^{3}H but adequate for the needs of the facilities where they are employed (Hofstetter and Eakle, 1993; 1995).

Tritium effluent water monitors reported by Sigg et al. (1994) and those utilized at CANDU systems (Cutler et al., 1993) make use of a homogeneous 2.5 mL LS flow cell containing coiled Teflon tubing installed in a modified PerkinElmer Radiomatic A250 flow scintillation analyzer. The effluent monitoring method requires water pretreatment, and the LS (homogeneous) cell system provides tritium quantification as well as rapid detection at several pCi/mL. Sensitivities of 16 and 1 pCi/mL are reported for 5-min and daily averages of counting data, respectively, which is reported to provide approximately 200 times greater sensitivity than similar methods utilizing the solid scintillator heterogeneous flow cells. As described by Sigg et al. (1995), a centrifugal pump moves environmental water to be monitored at about 10 L/min from the sampling location to the instrument position where it passes across the surface of a cross-flow filter. Sample water at only 2 mL/min is drawn through the filter for further pretreatment by flash distillation. A 0.25-mL static mixer blends 0.15 mL/min of LS cocktail with the sample water before passing through the 2.5 mL flow cell. It is reported that, at the lowest flow rates, full response to changes in environmental tritium is possible in 30 minutes, and LS cocktail consumption is less than 7 L a month. Flow rates are increased by as much as sixfold if increased response time is needed. Ultima Gold XR (PerkinElmer, Inc.) LS cocktail was used for low flow rates. Sigg et al. (1995) report that other fluor cocktails with lower viscosity are available when higher flow rates are required. A tritium counting efficiency of 36% is reported with the LS homogeneous flow cell system, which is many orders of magnitude more sensitive than the plastic solid scintillator heterogeneous flow cell. As noted earlier, the plastic solid scintillator flow cell could provide a tritium counting efficiency of only 0.18%. The flow scintillation analyzer was equipped with an external ^{241}Am standard with a 3-mm-thick tungsten shutter assembly to expose the flow cell to the 59.5-keV gamma rays for the production of a quench-indicating parameter.

Monitoring of tritium release at fusion research facilities and fission power plants is necessary to provide evidence that a facility is conforming to limits set by regulatory commissions on the release of tritium into the environment.

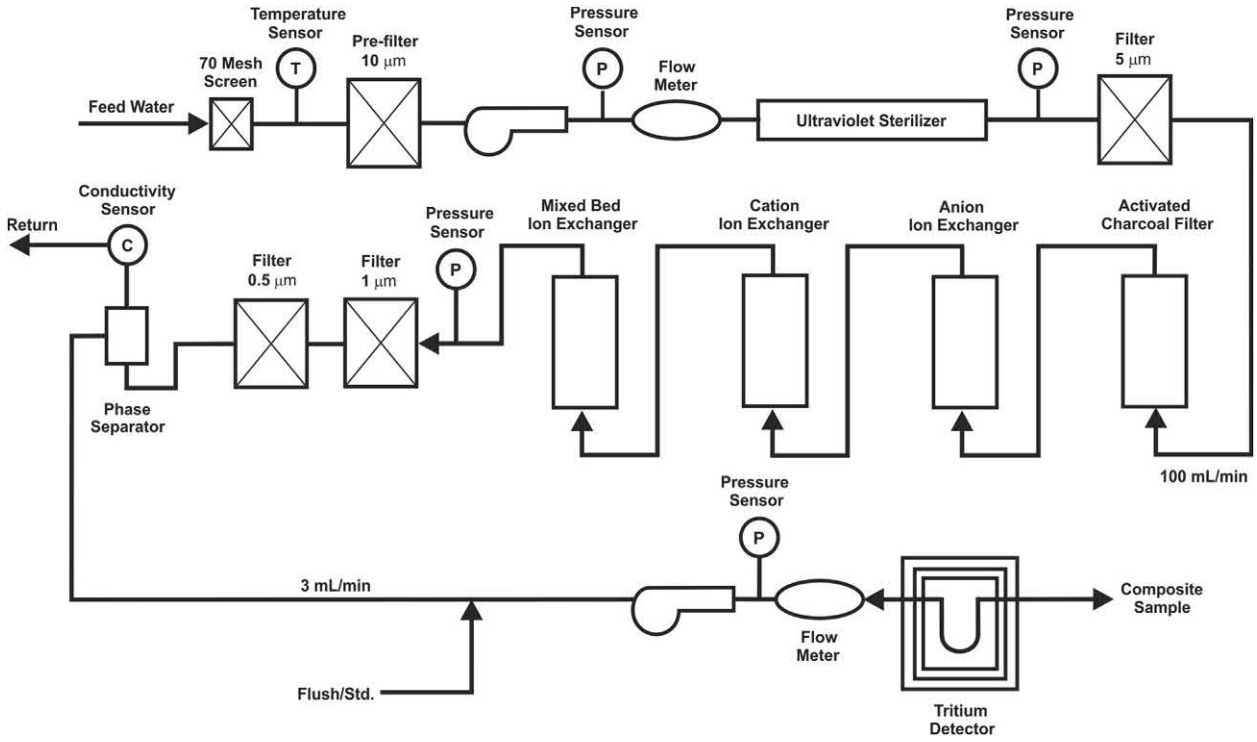

FIGURE 10.52 Sketch of a tritium in water monitor. *From Bruyere and Cadwallader (2012); reprinted with permission from Elsevier © 2012.*

It is also of political importance that a facility can demonstrate that it is not releasing any hazardous levels of tritium into the environment.

Bruyere and Cadwallader (2012) describe the function and practical application of a continuous monitoring system for aqueous tritium. The technique, which was first developed at the Savannah River National Laboratory (Hofstetter, 1991; 1995), involves the diversion of a small stream of effluent water through a flow-cell detector containing plastic solid scintillant and PMTs to detect and measure the scintillation photons in coincidence to reduce background. The flow-cell detector is equipped with an alarm system, which can be set whenever a specific level of tritium activity is detected. A sketch of the tritium in water monitor is illustrated in Fig. 10.52. As described by Bruyere and Cadwallader (2012) and illustrated in Fig. 10.52, the feed water is pumped at a rate of 100 mL/min through rough (10 μm) and polishing filters (5 μm), and a small portion of the water is collected in a 1-L surge tank. An ultraviolet light is used to sterilize the water sample together with biocide to reduce algal growth. The surge tank provides the monitor with a reserve of 8 hours of hold time to allow for continuous water monitoring during filter changeouts and maintenance. Thus, the water monitor need not be turned off during maintenance. A displacement pump moves the surge tank water through a series of charcoal filters and ion exchange resins that would reduce interfering organic contaminants, metal ions, and hydroxides to provide only tritium radionuclide through the U-shaped flow-cell detector. The ion exchange resin beds are changed at less than once a week. The flow-cell detector senses tritium at 56 Bq/mL (1514 pCi/mL) and the alarm set at 3000 pCi/mL.

B. Heterogeneous ($\alpha-\beta$) and γ discriminating cell

A flow cell with dual detectors capable of discriminating alpha and beta emissions against gamma emissions was developed by Tarancón et al. (2005). The flow cell was designed with two detectors, one for the measurement of alpha and beta emissions and the other detector for the measurement of gamma emissions. The flow cell contained BC-400 plastic scintillator beads (250−500 μm in diameter) as receptor for α and β radiation within the inner volume of the flow cell and an outer layer of BC-408 plastic scintillator completely surrounding the flow cell inner chamber as receptor of γ radiation. Only gamma radiation could penetrate the walls of the inner chamber and reach the outer plastic scintillator.

Tarancón et al. (2005) demonstrated the flow cell by measuring activity levels of different volumes of contamination pulses of $^{90}Sr/^{90}Y$, ^{134}Cs, and ^{240}Pu in continuous streams. Detection efficiencies reported were 107.7% for

$^{90}Sr/^{90}Y$ by the $\alpha-\beta$ receptor, 3.2% for ^{240}Pu by the $\alpha-\beta$ receptor, 18.3% for ^{134}Cs by the $\alpha-\beta$ receptor, and 0.89% for ^{134}Cs by the γ receptor. The advantages of such a flow-cell detector are (1) the detector may be applied to the analysis of alpha-, beta-, and beta−gamma-emitting radionuclides in liquid effluents, (2) the sensor is designed for providing online and continuous information on the specific activity and volume of a radioactive contamination, and (3) the flow cell can provide remote and continuous information on the presence of different radionuclides in a liquid stream for contamination in volumes > 5 mL and specific activities up to 1 Bq/mL.

IX. Single radionuclide analysis in high-performance liquid chromatography

Flow-cell radionuclide analysis has been traditionally and remains a routine technique in the biosciences, including research in biochemistry, molecular biology, drug research and metabolism, and radiopharmaceutical research, among other related fields, when used in conjunction with HPLC. Flow-cell radionuclide analysis is more common in the biosciences than any other branch of science. These studies generally involve the flow-cell measurement of radionuclide-labeled (e.g., ^{3}H, ^{11}C, ^{13}N, ^{14}C, ^{18}F, ^{35}S, ^{33}P, ^{32}P, etc.) bioorganic molecules separated by HPLC, which is one of the most popular chromatographic methods used for molecular separations and characterization. The method provides the means for further structural analysis by methods such as MS and NMR spectroscopy. Current methods involve the flow-cell analysis of radioisotope-labeled bioorganic molecules separated by HPLC combined with online MS and NMR spectroscopy. Examples will be provided in this chapter.

Many applications of flow-cell radionuclide analysis of HPLC effluents in studies of anabolic and catabolic reactions in the biological sciences are found in the journal literature, and these research reports number in the hundreds. The significance of radioisotope labeling in metabolic studies in the life sciences was underscored by Koppen et al. (2014) with the following note:

> *"Radiotracer technology (^{14}C or ^{3}H) is still the method of choice to study the in vivo disposition of a new drug as it allows making up a mass balance and enables the quantitative detection of the parent drug and all of its metabolites in complex matrices without the need for authentic standards."*

Among the many reports available from the literature, a few examples of flow-cell radionuclide analysis in various fields of study are listed in Table 10.10.

X. Dual radionuclide analysis

Commercially available flow scintillation analyzers (FSAs) are equipped with a MCA, computer display of the sample pulse height spectrum, and pulse height discriminators, which can be set to define two counting regions. The proper setting of these counting regions will permit the activity analysis of two different radionuclides in the sample (e.g., HPLC effluent) provided their beta energy maxima (E_{max}) are significantly different as described in detail in Chapter 6, Volume 1. It is necessary only that the counting efficiencies of the two radionuclides (lower energy and higher energy emitter) in the two counting regions be determined as described previously in Chapter 6, Volume 1. The flow scintillation analyzer will automatically determine the activities of the two radionuclides in the flow cell. An example of simultaneous ^{3}H and ^{14}C traces of the same HPLC run of a $^{3}H/^{14}C$ dual-labeled precursor (drug-agonist) and its metabolites in animal and human liver measured by Shaffer and Langer (2007) can be seen in Fig. 10.53. Dual labeling with ^{3}H and ^{14}C can be a helpful tool in the elucidation of metabolite reaction mechanisms and structure when combined with MS and NMR spectroscopy (Nassar et al., 2003, Silva-Elipe, 2003, Chowdhury, 2005; and L'Annunziata, 1984, 2007a, 2013). Fig. 10.54 illustrates the metabolic pathway proposed by Shaffer and Langer (2007) following online flow scintillation analysis of the ^{3}H- and ^{14}C-drug agonist and online MS.

Some examples of the flow scintillation analysis of dual radionuclides in HPLC effluents are the following: ^{3}H-^{14}C (Dayhuff et al., 1986; Kusche and Lindahl, 1990; Sabourin et al., 1988; Seidegård et al., 1990; Shaffer and Langer, 2007; Shirley and Murphy, 1990; Wells and Digenis, 1988); ^{3}H-^{33}P (Morgan et al., 1987); ^{3}H-^{32}P (Balla et al., 1987; Guillemette et al., 1989; Nolan and Lapetina, 1991; Rubiera et al., 1990; Sasakawa et al., 1990); and ^{3}H-^{35}S (Hughes et al., 1992; Lyon et al., 1994; Mays et al., 1987); and ^{89}Sr-^{90}Sr (Desmartin et al., 1997).

XI. Online HPLC-FSA and mass spectrometry[2]

In the biological sciences, MS is one of the most popular methods employed for the determination of the molecular weights, molecular formulae, and structures of metabolites. The popularity of MS is due to the high sensitivity of the analytical method and the possibility of

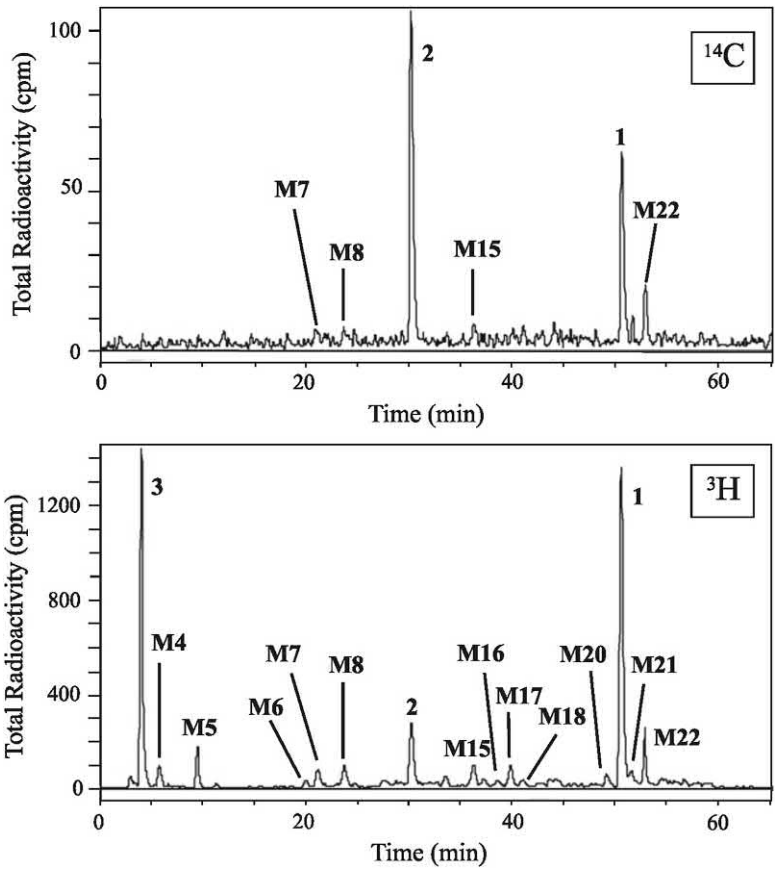

FIGURE 10.53 Online HPLC radiochromatograms of dual radiolabeled incubations in rat liver microsomes with [^{14}C/^{3}H]1 after 60 minutes measured with an IN/US Beta RAM radiometric flow cell detector. Top: ^{14}C channel; bottom: ^{3}H channel. Chromatogram radioactivity peaks are labeled according to compound or metabolite number. Not all metabolites are labeled with radioisotope because the radioisotope labels were located at only one carbon atom of the parent compound assigned number 1. *From Shaffer and Langer (2007); reprinted with permission from Elsevier © 2007.*

determining the structure of metabolites directly from HPLC effluents without further sample treatment. The traditional and more time-consuming methods of structure analysis, including chromatography of metabolites, followed by chromatogram fraction collection, and purification prior to submission of isolated metabolites to MS, have been applied for many years (L'Annunziata, 1970, 1984; L'Annunziata and Fuller, 1971a). Advanced techniques include the online mass spectral structural analysis of metabolites directly off the HPLC column after detection of peaks of interest. This section describes the state-of-the-art of online MS of radioisotope-labeled metabolites following HPLC separation and flow scintillation analysis (FSA) detection of chromatogram peaks of interest, also referred to as hyphenated radio-HPLC-FSA-MS analysis. This hyphenated analytical method may also be written as LC-RI-MS to signify the online hyphenated sequence "liquid chromatography—radioisotope detection—mass spectrometry."

A. HPLC-FSA-MS instrumentation and interfacing

When the metabolism of a radioisotope-labeled compound is studied and the metabolites are separated by HPLC, flow scintillation analysis (FSA) can provide the quantitative analysis of metabolites in terms of percentage of total recovered radioactivity. For example, when a parent compound labeled with a radioisotope, such as ^{3}H, ^{14}C, ^{32}P, ^{33}P, or ^{35}S, is administered with a known radioactivity to a test animal or medium and the metabolites separated by HPLC, the percentage of the total radioactivity administered is automatically measured by the FSA prior to MS. Consequently, the use of FSA prior to MS provides advantages over the UV detector, which include (1) irrefutable evidence that a certain HPLC peak is one of interest, i.e., it is labeled with radioisotope and thus a confirmed product of the radioisotope-labeled precursor, (2) the measurement of radioactivity from the isotope label is performed by the FSA without a miss, unless the isotope label is near or essentially at background levels, (3) the FSA reports the radioactivity of

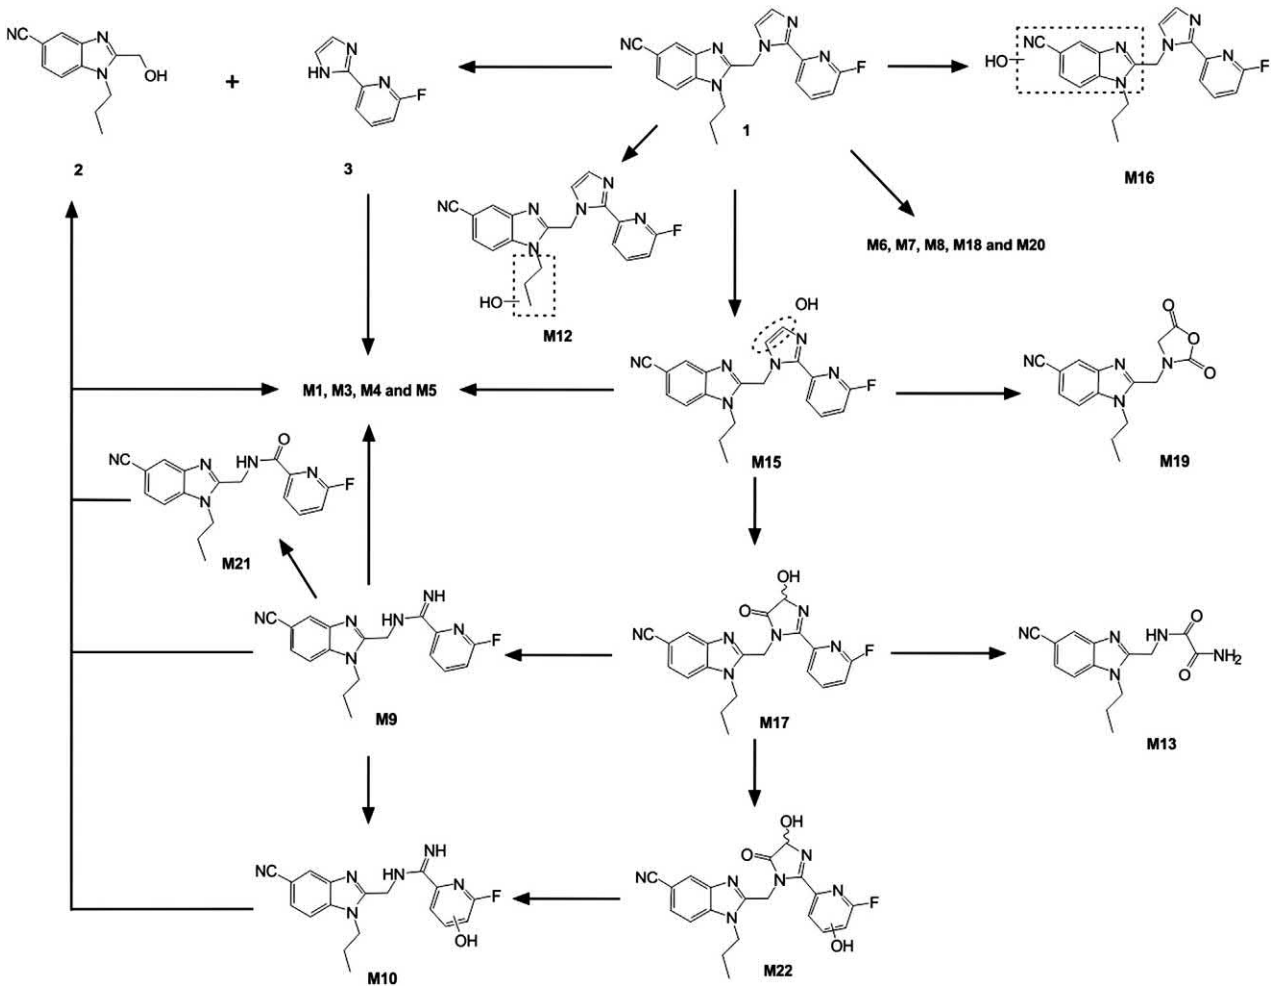

FIGURE 10.54 Proposed metabolic pathways for molecule 1 in cross-species hepatic microsomes determined with the aid of radioisotope labeling and online HPLC and mass spectrometry. *From Shaffer and Langer (2007); reprinted with permission from Elsevier © 2007.*

the HPLC-separated parent compound and metabolite fractions in quantitative units of disintegrations per minute (DPM) providing valuable data for the quantitative percentages of total radioactivity administered to a test organism, and (4) the FSA can store quantitative data on metabolites over a series of HPLC runs carried out over a time span to determine the time course of a metabolism study (see Fig. 10.3 illustrated earlier in this chapter).

The FSA provides the real-time radioactivity levels of metabolites as these are eluted from the HPLC column, and the radioactivity peaks from the FSA can provide the signal to initiate MS analysis. The FSA is connected directly to the MS if using a heterogeneous (solid) flow cell (see Fig. 10.12). If a homogeneous (liquid) flow cell is used, the flow is split to both the FSA and MS. The homogeneous flow-cell arrangement requires HPLC eluate splitting because scintillation cocktail is mixed with eluate for radioisotope analysis. Stream splitting is often set to provide most of the stream to the FSA and a small portion to the mass spectrometer because of the high sensitivity of mass spectrometers (pg/μL) that utilize ESI techniques for sample introduction. The degree of HPLC stream splitting to the flow scintillation analyzer (i.e., flow-cell detector) and the mass spectrometer may depend on the activity of the radioisotope label and the need to maximize the sensitivity of radioisotope detection. Thus, a larger portion of the HPLC stream will go to the radioisotope detector, and the remaining smaller fraction to the more sensitive mass spectrometer. For example, Ubukata et al. (2011) and Shaffer and Langer (2007) split the HPLC eluate stream according to the ratio of 1:9 between the mass spectrometer and radioactivity flow detector. In a similar fashion, Ramanathan et al. (2007) used a stream splitter that diverted 15% of the HPLC eluate to the mass spectrometer and 85% to the radioactivity flow-cell detector, whereas Athersuch et al. (2008) used a dead-volume T-piece to divert 150 μL/min of the HPLC eluate to the mass spectrometer and 450 μL/min of the eluate to the flow scintillation analyzer.

Other examples of steam splitting of HPLC effluent ratios to the mass spectrometer and radioisotope detector are 1:6 by Glaenzel et al. (2018), 1:5 by Geenen et al. (2013), and 1:4 by Dymond et al. (2016), Liu et al. (2016) and Tozuka et al. (2011).

The homogeneous flow-cell setup provides higher detection efficiencies (up to 45% for ^{3}H and 88% for ^{14}C) depending on the quench level of HPLC solvents. Stream splitting of HPLC eluate to the flow scintillation analyzer and mass spectrometer is a common practice (see also Edlund and Baranczewski, 2004; Ghosal et al., 2005; Prasad et al., 2011; Singh et al., 2001; Vickers et al., 2001; and Yuan et al., 2002). In most cases, most of the eluate is directed onto the FSA, and only a small fraction diverted to the mass spectrometer. When a heterogeneous flow-cell detector is used, the entire HPLC eluate or any convenient fraction of the eluate may be used for spectroscopic analysis because the eluate is not mixed with liquid scintillator before entering the flow scintillation analyzer. For example, Pedras et al. (2003) used a heterogeneous flow-cell detector containing SolarScint solid scintillator for the measurement of ^{14}C-labeled metabolites before directing the HPLC eluate on to the mass spectrometer. The HPLC analysis of radiopharmaceuticals containing ^{99m}Tc are best detected with a gamma flow cell that utilizes NaI(Tl). These entire HPLC eluates or any convenient fraction of the eluate can be diverted on to online spectrometers (Vanbilloen et al., 2003; Vanderghinste et al., 2003).

Interfaces with the HPLC effluent and mass spectrometer must liberate the biochemical or bioorganic molecular species of interest (e.g., metabolite) from the aqueous solvent molecules and ionize the molecular species prior to mass spectrometric separation of the molecular ions and molecular ion fragments. This is performed most commonly by spray ionization (SI) techniques, which involve a combination of processes including spraying the HPLC effluent from a fine capillary into minute droplets, pneumatic heating with a drying gas, applied electric potential, and in some cases chemical ionization. Common MS interfaces used in conjunction with HPLC are ESI and atmospheric pressure chemical ionization (APCI) of which published applications number in the hundreds. A few examples of recent applications of ESI may be found in Lu et al. (2018), Gobo et al. (2018), Murakami et al. (2018), Tung et al. (2018), and Xiao et al. (2018), and applications of APCI are described by Etzbach et al. (2018), Gorassini et al. (2017), Oldekop et al. (2017), Rybin et al. (2017), Tessema et al. (2017), and Wang et al. (2018).

In the ESI method, a nebulizer gas and electric field is introduced at the interface to produce charged droplets of the HPLC effluent. The combination of electric field energy and pneumatic heating via a warm concurrent dry gas stream causes the charged droplets of the HPLC effluent to subdivide and yield eventually single ionized molecules. Fig. 10.55 illustrates the interface between the effluent of a microbore HPLC chromatograph effluent or flow-cell radionuclide detector to an ESI source of the mass spectrometer. APCI is a chemical ionization technique, which employs a mechanism similar to ESI. The differences exist in the establishment of a plasma of the nebulized HPLC effluent by a DC discharge at atmospheric pressure. Reactions between ions and molecules occur in the plasma to produce molecular ion species of the biochemical or bioorganic compounds present, which are then introduced via vacuum into the mass spectrometer. SI techniques yield high ionization efficiencies and consequently mass spectral detection limits as low as the pg/μL level. Also, SI

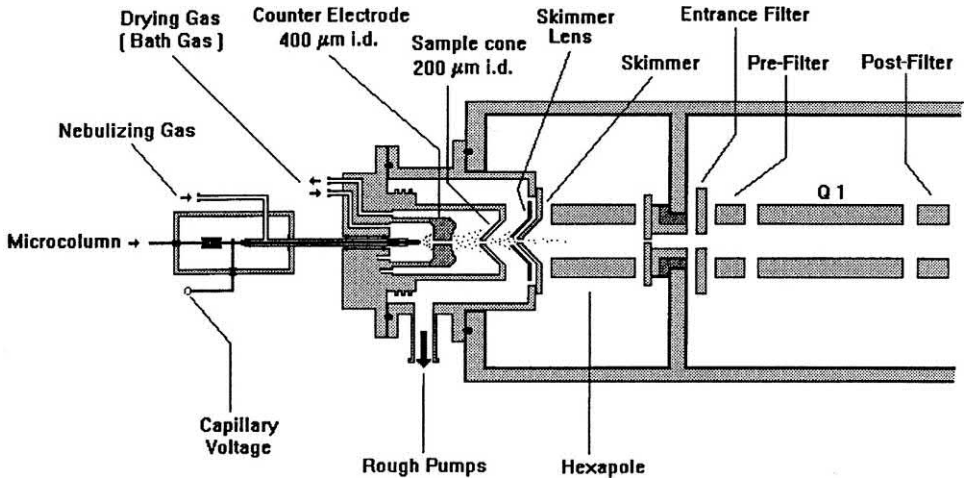

FIGURE 10.55 Schematic of a modified electrospray ion source for the Quattro I mass spectrometer. techniques are soft, which yield relatively minor molecular ion fragmentation providing accurate molecular weight determinations in the mass range up to 10^5-10^6 Da, the sensitivity depending on the specific type of mass spectrometer used. The theory and principles of ESI and APCI are described in detail in a book by Gross (2017) on MS; and special treatments on ESI and APCI are provided by Tang et al. (2017) and Pasilis and Van Berkel (2017), respectively.

The molecular ions and molecular ion fragments produced via the SI interface are separated in the mass spectrometer according to their mass-to-charge ratios (m/z) using electric and/or magnetic fields. Several types of mass spectrometers are available for use online with HPLC, including time-of-flight analyzers, quadrupole ion filters, quadrupole ion trap instruments, and orbitrap systems. The characteristics of these instruments are described in detail by Gross (2017), and a comparison of the key features of the various types of mass spectrometers in terms of their application to HPLC-MS metabolite identification is given in a thorough review by Niessen (2017).

A tandem mass spectrometer is used often online with HPLC in metabolism studies, which may include online flow-cell detectors (Abdel-Khalik et al., 2017; Farlin et al., 2018; Geng et al., 2018; Jensen et al., 2017; Maltais et al., 2018; Sato-Nakai et al., 2017 and Sharma et al., 2017). Tandem MS is abbreviated as MS/MS because it consists of dual mass analyzers coupled in a tandem instrument useful in selectively separating the parent molecular ions from the product ion fragments. Dual mass analysis with the tandem analyzer is accomplished by first selecting the parent molecular ions after initial ionization with a sector magnet, and the molecular ions are further dissociated via collision with a gas such as He, Ne, N_2, or Ar referred to as collision-induced dissociation (CID). The ion fragmentation products of CID are analyzed subsequently in the second mass analyzer according to their m/z and abundance.

B. Representative data

Numerous research papers employing online HPLC-FSA-MS have appeared in the scientific journals, including works by Abdel-Khalik et al. (2017), Chillar et al. (2011), Glaenzel et al. (2018), Huskey. (2016), Jensen et al. (2017), Koitka et al. (2010), Lenz et al. (2011), Narita et al. (2018), Okarvi and Al Jammaz (2016), Prasad et al. (2010), Sato-Nakai et al. (2017), Scheible et al. (2016), Shaffer and Langer (2007), Sharma et al. (2017), Shemesh et al. (2016), Su et al. (2010), and Suddaby et al. (2016). Some examples of representative data will be described in this section.

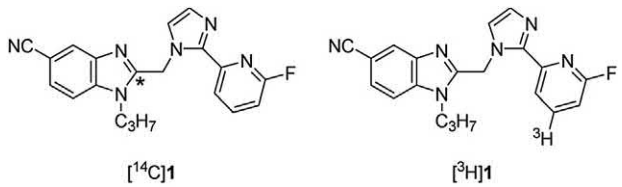

FIGURE 10.56 Chemical structures for [^{14}C]1 (symbol '*' denotes ^{14}C) and [^{3}H]1. *From Shaffer and Langer (2007); reprinted with permission from Elsevier © 2007.*

An interesting example can be taken from the work of Shaffer and Langer (2007), who studied the in vitro metabolism of a drug labeled with the radioisotopes ^{3}H and ^{14}C at specific sites of the molecule, illustrated in Fig. 10.56. The metabolism studies were executed by incubation of the radioisotope-labeled drug in hepatic microsomes. The radioisotope-labeled compounds were diluted with non-labeled compound to yield 10 μM incubation concentrations with 0.25 μCi of [^{14}C]1 or 2.5 μCi of [^{3}H]1 (see Fig. 10.56) and a combination of the two for dual-radiolabel studies. The number "1" denotes the precursor compound where metabolites of "1" are numbered consecutively according to the proposed sequence of metabolite formation as illustrated previously in Figs. 10.53 and 10.54.

Shaffer and Langer (2007) separated the precursor drug from its metabolites by HPLC, which was interfaced directly with a Beta Ram (LabLogic, Inc.) flow scintillation analyzer (FSA) flow-cell detector and a PerkinElmer tandem quadrupole mass spectrometer (PerkinElmer, Inc.). The effluent from the HPLC was split 1:9 between the mass spectrometer and the FSA with LS cocktail flowing at the rate of 3 mL/min to the radiometric flow-cell detector. Radioactivity in the HPLC effluent is measured by the FSA and plotted against time in minutes, as illustrated previously in Fig. 10.53. The activity peaks corresponding to metabolites separated by HPLC are numbered in Fig. 10.53, and some metabolites are labeled only with ^{3}H and others only with ^{14}C, which aided in the confirmation of the molecular origin of a particular metabolite. The flow-cell radioactivity detector provides additional information on the quantities of each metabolite relative to the precursor drug, as listed in Table 10.11. Depending on the origins of the metabolites relative to the molecular structure of compound 1, some metabolites are labeled with only ^{14}C, only ^{3}H, with both ^{14}C and ^{3}H, or without any radioisotope label.

Determinations of the molecular structures of the metabolites are facilitated by the mass spectra of each of the compounds, as these are eluted from the HPLC. A mass spectrum will yield the molecular weight (*m/z*) of the parent ion of a metabolite, and the ion fragments will provide evidence of the molecular structure. For example, Shaffer and Langer (2007) used characteristic fragment ions produced in the collision-induced dissociation (CID) mass spectrum, illustrated in Fig. 10.57, together with radiochromatographic data as starting points in the elucidation of the structure of metabolites and the metabolic scheme,

TABLE 10.11 Quantitative inline generated profile of [^{14}C]metabolites, [^{3}H]metabolites, and total metabolites after a 60-minute monoradiolabeled incubation with either [^{14}C]1 or [^{3}H]1 in rat liver microsomes.[a]

which was illustrated previously in Fig. 10.54. The characteristic ion fragments, illustrated in the mass spectrum of Fig. 10.57, illustrate the protonated parent ion at *m/z* 361 and fragment ions at *m/z* 319, 198, 170, and 156. The ion fragment at *m/z* 319 is due to the loss of the C_3H_7 group, illustrated in the upper left-hand portion of the spectrum. The ion fragment at *m/z* 198 is due to the loss of a neutral fragment of mass 163 as illustrated, which undergoes further fragmentation to ions at *m/z* 170 and 156. Other illustrative examples of the determinations of metabolic pathways by means of the hyphenated technique of HPLC-FSA-MS can be found in the references cited previously in this section.

XII. Online FSA and nuclear magnetic resonance[2]

As described previously in this chapter, flow scintillation analysis (FSA) is commonly used to quantify the radioisotope label on organic compounds, such as biochemicals, drugs, and metabolites separated from complex mixtures by

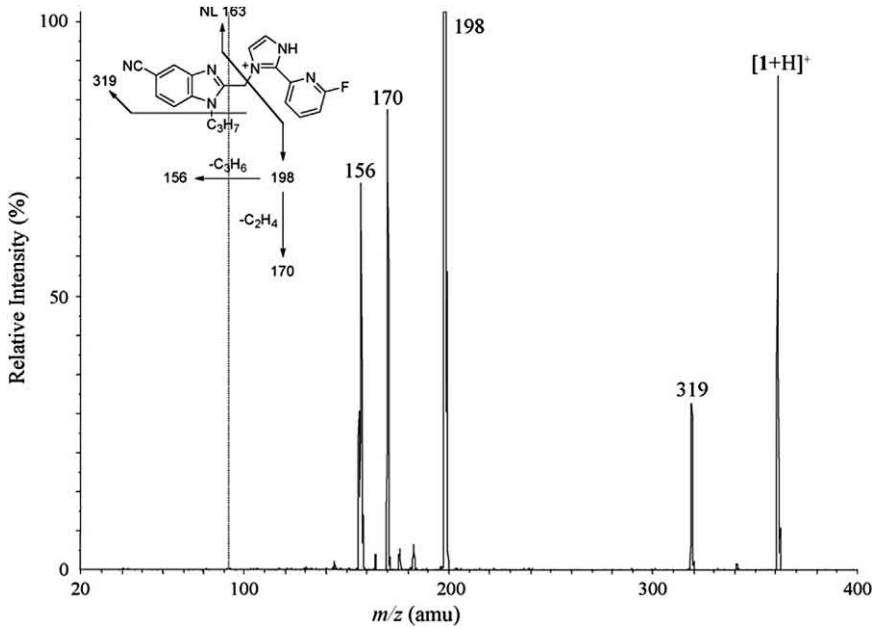

FIGURE 10.57 Collision-induced dissociation mass spectrum of protonated 1 (*m/z*) 361 and its proposed fragmentation pathways. FIGURE 10.58 Proton NMR spectrum of L-chiro-inositol, and in the inset to the right, the proton NMR spectrum corresponding to myo-inositol for comparison, in D_2O solvent. The only protons yielding a resonance absorption signal are the protons attached to the cyclohexane ring. The protons attached to the hydroxyl groups do not display a resonance absorption signal because they exchange with deuterium from the D_2O solvent. The two stereoisomers differ in structure only at one carbon atom marked by the circle drawn over the two structures. The chemical shifts are measured here in δ (cpm) or τ (cpm) where $\tau = 10.0 - \delta$. *From L'Annunziata (1970), Ph.D. Dissertation, https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum.*

HPLC. The subsequent task of determining the molecular structure of the separated substances can be challenging. Traditional methods of structure determination involve collecting the radio-HPLC separated fractions that correspond to activity peaks measured by the flow scintillation analyzer. The collected fractions are then isolated, further purified, and then submitted to spectroscopic methods of analysis such as MS and NMR spectroscopy. Both MS and NMR methods provide complementary information that can be used to derive a molecular structure. MS, described in Section XI of this chapter, can provide the molecular weight, molecular formulae, and structure from ion

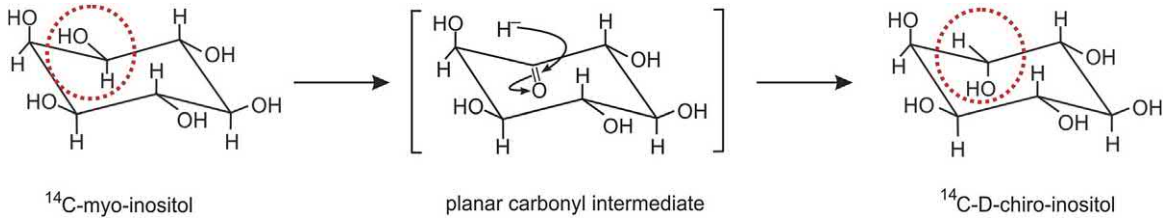

FIGURE 10.59 Soil microbial epimerization of uniformly labeled ^{14}C-myo-inositol to ^{14}C-D-chiro-inositol. The dotted circle surrounds the only carbon atom where the stereochemistry differs between the two isomers. The reaction was demonstrated with the use of uniformly labeled ^{14}C-myo-inositol incubation in soil in the work of L'Annunziata et al. (1977). The brackets illustrate the proposed intermediate. *From L'Annunziata (1970), Ph.D. Dissertation, https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum.*

fragmentation patterns, whereas NMR can provide additional complementary structural information, including the spatial orientation (i.e., stereochemistry) of atoms in the molecular structure. A good example of this can be taken from early work of the writer concerning the mass and NMR spectra of the inositol diastereomers, all of which produce virtually identical electron-impact mass spectra, but different NMR spectra (L'Annunziata, 1970; L'Annunziata and Fuller, 1971a, b; 1976). In the case of the inositol diastereomers, they differ only by the orientation of one proton and hydroxyl group on a single carbon atom (see Fig. 10.58). The writer (L'Annunziata, 1970 and L'Annunziata and Fuller, 1971a,b) demonstrated that these inositol stereoisomers, isolated as inositol phosphates in soils, can be identified by their NMR spectra. The NMR spectroscopic analysis of molecular structure was at the very early stages of development in the late 1960s and early 1970s; however, currently NMR is used generally online with HPLC and flow-cell detectors for the structural elucidation of radioisotope-labeled organic compounds, which is described in the following section of this chapter. As illustrated in Fig. 10.58, the myo-inositol and chiro-inositol, isolated as soil inositol phosphates and separated by chromatography, differ only by the orientation of the proton and hydroxyl group at a single carbon atom, and their NMR spectra are unique. From this work, the writer (L'Annunziata, 1970; L'Annunziata and Fuller, 1971a) postulated that the D-chiro-inositol and its phosphates in soils could originate via the epimerization of the most abundant soil myo-inositol. By incubating uniformly labeled ^{14}C-myo-inositol in soil, the writer and coworkers (L'Annunziata et al., 1977) demonstrated the soil microbial epimerization of the ^{14}C-myo-inositol to ^{14}C-chiro-inositol, illustrated in Fig. 10.59.

An increasing popular approach to drug metabolism and natural product studies involves the online measurement of the NMR spectra of compounds directly off the HPLC column obviating the need for compound isolation. This section will describe developments in linking the flow scintillation analyzer (i.e., flow-cell detector) from the HPLC to the NMR spectrometer to provide online (in situ) molecular structure analysis of radioisotope-labeled compounds.

A. Principle of nuclear magnetic resonance spectroscopy

NMR spectroscopy is used to derive the molecular structure of organic compounds from the magnetic properties of the atomic nuclei (e.g., ^{1}H and ^{13}C) and the surrounding molecular electrons of an organic compound since the first commercial NMR spectrometer appeared in 1960. Nuclei of certain atoms of odd mass such as ^{1}H and ^{13}C, or even mass and odd charge, have a net charge and a spin. The spinning charge of the nucleus creates a magnetic dipole (μ). If one places spinning proton nuclei, which are a component of most organic compounds, in a magnetic field (*H*), the axis of the magnetic dipoles of these nuclei will precess at an angle (θ) with respect to the magnetic field axis, as illustrated in Fig. 10.60. The precession of the nuclei with respect to the applied magnetic field axis occurs somewhat like the way a spinning top precesses under the force of the earth's gravitational field. The angular velocity of this precession is a function of the strength of the applied magnetic field (*H*) and the affects of *shielding* caused by spinning electrons in the molecular environment of the proton nuclei within the organic compound.

Spherical nuclei of odd mass, such as ^{1}H, ^{13}C, ^{15}N, ^{19}F, and ^{31}P, possess a spin of ½, and when subjected to the external magnetic field, the nuclei can possess two orientations, namely, an orientation in the direction of the magnetic field (+½), as illustrated in Fig. 10.60, or an orientation against the magnet field (−½), i.e., opposite to the orientation illustrated. While under the forces of a stable magnetic field (*H*) of the NMR spectrometer, the proton nuclei are irradiated with a radio frequency energy tunable over a narrow range. When the variable frequency is attuned to the precessional angular velocity of a given proton nucleus within a molecule, the two frequencies are in *resonance*. The applied energy at this resonance frequency is absorbed by the proton nucleus, and the nucleus is caused to flip or become aligned against the applied magnetic field (*H*). The energy absorbed by the proton nucleus, which causes it to reach the higher energy spin state (*i.e.*, flipped or −½), is the energy measured by the NMR spectrometer.

An auspicious circumstance characteristic of NMR spectroscopy is the following: the resonance absorption by proton

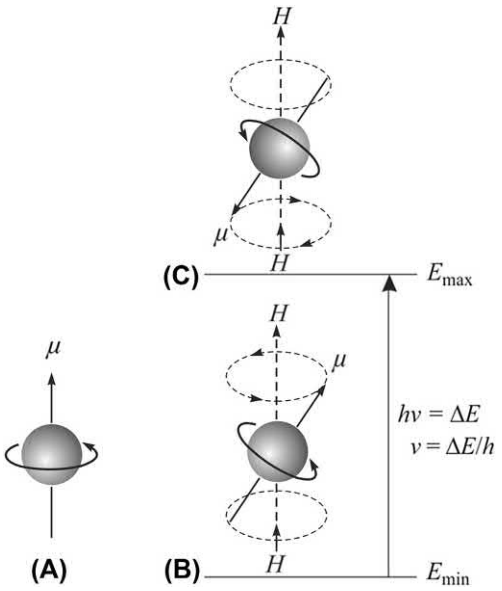

FIGURE 10.60 An atomic nucleus of spin quantum number ½ with magnetic moment μ in (A) the absence of an external magnetic field and (B) the presence of an external magnetic field (H). At E_{min}, the nucleus maintains a spin aligned with the external magnetic field and precesses with a frequency (ν) in accord with the strength of the external magnetic field. The nucleus makes a quantum jump ($h\nu$) to a higher energy state E_{max} aligning its spin against the magnetic field after exposure to a radio frequency (ν) coinciding with the frequency of precession. Atomic nuclei of spin ½ have only two possible quantum spin states, one aligned and the other against the external magnetic field. Examples are nuclei of odd charge and odd mass, such as ^{1}H, ^{7}Li ^{13}C, ^{15}N, ^{19}F, ^{29}Si, ^{31}P, ^{35}Cl, and ^{37}Cl. *From L'Annunziata (2016); reprinted with permission from Elsevier © 2016.*

nuclei is complicated by the shielding effect of electron clouds of varying densities in the environment of organic molecules. The electron cloud, surrounding a nucleus, also has charge and spin and therefore produces its own characteristic magnetic field, which apposes or shields the externally applied field. The degree of *shielding* is a function of the electron cloud density, which will differ from nucleus-to-nucleus in the organic molecule, because of the differing electronegativities of neighboring atoms. Therefore, protons in a molecule will absorb different resonance frequencies depending on their location in the molecule. This effect is referred to as the *chemical shift*. A proton, which is highly shielded, absorbs at a lower resonance frequency than a proton with reduced shielding. The presence of atoms of differing degrees of electronegativity (electron-withdrawing ability) in molecules as well as the differing three-dimensional orientation of atoms within molecules will cause a wide spectrum of shielding effects on neighboring protons. This gives rise to a wide spectrum of resonance absorption frequencies for protons depending on the structural group to which the protons are attached, their neighboring atoms, and their spatial orientation in the molecule. Therefore, the differing resonance absorption frequencies or chemical shifts of protons in NMR spectroscopy provide an absorption spectrum, which serves as a means for identifying chemical groups and their spatial positions in organic molecules.

The chemical shift of a particular proton nucleus in a molecule is recorded with respect to the chemical shift of the protons on a reference molecule, e.g., tetramethylsilane or $(CH_3)_4Si$ most often referred to as TMS (see Fig. 10.58). The difference in chemical shifts of a proton or group of protons in a molecule with respect to that of TMS is recorded and calculated in units of Hz, whereas the magnitude of the applied frequency is in the order of magnitude of MHz, a million-fold greater. The difference in chemical shift of a proton nucleus with respect to that of the reference (e.g., TMS) in Hz is divided by the applied frequency in MHz to record chemical shifts in convenient units of parts per million (ppm). Nuclei of even mass (e.g., ^{2}H and ^{12}C) in a molecular structure do not possess a magnetic moment, and these nuclei are inert to the previously described effects of an external magnetic field. Thus, deuterated solvents are used generally in the measurement of NMR spectra of water-soluble compounds.

For additional reading on the principles of NMR as well as MS, see works by Goldenberg (2016), Günther (2013), and Simpson and Simpson (2014).

B. HPLC-FSA-NMR system

Because time is money, the trend is to analyze samples as fast as possible with as much automation that current technology will permit. This has led to advances in metabolism studies where the molecular structure of isotope-labeled metabolites must be determined. A major advance in this field has been the direct linking of the NMR spectrometer to the HPLC. Several papers on this technology serve as excellent examples (Albert, 2014; Anonymous, 2012; Bailey et al., 2000; Brkljača and Urban, 2015; Brkljača et al., 2017; Hall et al., 2016; Hansen et al., 1999; Hehn et al., 2013; Johansen et al., 2013; Kim et al., 2011; Larsen et al., 2009; Lee et al., 2012; Lenz et al., 2007; Li et al., 2010; Martin et al., 2003; Provera et al., 2010a,b; Ren et al., 2017; Scarfe et al., 2000; Seger et al., 2013; Shi et al., 2009; Shockcor, 2017; Shockcor et al., 1996; Silva et al., 2013; Silva-Elipe, 2003; Silva-Elipe et al., 2003; Singh et al., 2001; Smith et al., 1999; Sweeny et al., 2000; Timmers and Urban, 2012; Timmers et al., 2012; and Wilson and Brinkman, 2003).

When the metabolism of a radioisotope-labeled compound is studied and the metabolites are separated by HPLC, flow scintillation analysis provides for the quantitative analysis of metabolites in terms of percentage of total recovered radioactivity (see Table 10.11). For example, when a parent compound labeled with a radioisotope, such as ^{3}H, ^{14}C, ^{32}P, ^{33}P, or ^{35}S, is administered with a known radioactivity to a test animal and the metabolites separated by HPLC, the percentage of the

total radioactivity administered is automatically measured by the FSA prior to NMR spectroscopy. In addition, the FSA provides irrefutable evidence of radioisotope label on the structure of the metabolite, which can provide information as to the pathways and mechanisms of metabolism of radioisotope-labeled precursor compounds. This was illustrated previously in Table 10.11. Consequently, the use of FSA prior to NMR spectroscopy provides information on the radioisotope label in the HPLC effluent, whereas the UV detector may provide only information on the presence of a molecular component in the HPLC effluent be it labeled or not with radioisotope. Thus, the FSA and UV detector linked to the HPLC effluent stream will provide information on molecular components as they are eluted off the HPLC column.

Radioisotope tracers are commonly used in metabolic studies, and there remains the need to quantify the isotope label on the metabolites eluted from the HPLC prior to their molecular structure analysis by NMR spectroscopy. The FSA (i.e., flow-cell detector) provides the real-time radioactivity levels of metabolites as these are eluted from the HPLC column, and the radioactivity peaks from the FSA can provide the signal to initiate NMR spectroscopic analysis. This will allow the researcher using HPLC-FSA-NMR to accurately stop the flow and capture the HPLC peak of interest in the NMR flow probe for molecular structure analysis. The FSA is connected between the UV detector and NMR if using a heterogeneous (solid) flow cell. If a homogeneous (liquid) flow cell is used, the flow is split to both the FSA and NMR. The heterogeneous flow cell (see Table 10.1) uses a solid scintillation detector and yields relatively high detection efficiencies for ^{14}C (70%–85%) providing full recoveries of the HPLC eluate for subsequent NMR analysis. The homogeneous flow cell arrangement requires HPLC effluent splitting because scintillation cocktail is mixed with effluent for radioisotope analysis. The latter homogeneous flow cell setup is most appropriate for ^{3}H analysis with detection efficiencies of up to 45% depending on the quench level of the HPLC solvents.

A specially designed flow probe is inserted into the NMR sample chamber. The probe is constructed to permit the sample to flow into the NMR spectrometer and the resonance spectra obtained while either flowing through, or more commonly stopped (i.e., stopped-flow analysis) and analyzed for a required period of time. The following site provides information on flow probes for NMR: https://www.bruker.com/products/mr/nmr/hyphenation/lc-nmr/overview.html, accessed October 31, 2018. The NMR flow probe placed in the bore of the magnet holds the sample with a commonly employed cell volume of 120 μL. It contains the antennae for sample radio frequency energy irradiation and the receipt of the weak radio frequency resonance signal. A stop-flow mode is commonly employed for measurement of the NMR spectra because of the low sample concentrations in the HPLC peaks. Suitable NMR spectra are obtained with samples as small as 1 μg (or even submicrogram) depending on sample molecular weight and analysis time (Beery, 2000; Silva-Elipe, 2000). Sample analysis times can vary from 1–2 hours to 1–2 days. Stopped-flow NMR measurements of single peaks of the liquid chromatogram are governed by the signal from the UV absorbance detector or the signal from the FSA radioactivity detector. A signal from the radioactivity detector also confirms a metabolite of a radioisotope-labeled parent compound, and it can be used to quantify the radioisotope label in that metabolite, whereas peaks observed from the UV detector, which do not coincide with radioisotope peaks, will demonstrate the absence of radioisotope label. The FSA detector, therefore, not only can be used to trigger stopped flow for NMR analysis, but it may also provide valuable quantitative data for metabolic studies as seen previously in Table 10.11.

C. HPLC-FSA-NMR representative data

Applications of FSA to online HPLC-NMR setups for the chromatographic separation, radioactivity analysis, and molecular structure analysis of isotope-labeled metabolites are found in the scientific journals. The following are illustrative examples: Bailey et al. (2000), Berry et al. (2014), Byon et al. (2016), Dockens et al. (2000), Glaenzel et al. (2018), Hansen et al. (1999), Huskey et al. (2016), Kumar et al. (1999), Lenz et al. (2007), Mamidi et al. (2014), Martin et al. (2003), Maurizis et al. (1998), Paulson et al. (2000), Sato-Nakai et al. (2017), Scarfe et al. (2000), Scheible et al. (2016), Sharma et al. (2017), Shockcor (2017), Silva-Elipe (2003), Singh et al. (2001), Sweeny et al. (2000), Takahashi et al. (2015), and Vickers et al. (1998). Researchers will use commonly the stopped-flow method described above, where the signal of a liquid chromatogram peak from the FSA radioactivity detector or UV detector will trigger the stopped flow needed for in situ NMR spectroscopy in the HPLC eluate. Others will utilize the same FSA or UV signal to collect the entire peak in a suitable vial (i.e., fraction collection) and then submit the sample to further purification prior to off-line NMR analysis in a suitable solvent. A representative example of the application of online HPLC-UV-FSA-NMR spectroscopic analysis will be cited subsequently.

In a study on the metabolism of the drug ZD6126 developed for the treatment of colorectal, lung, breast, and prostate tumors, Lenz et al. (2007) studied the metabolism of [^{14}C]-ZD6126 in test animals. The [^{14}C]-ZD6126 was administered to the test animals, and samples were collected from the animals after various time intervals between 6 and 48 hours after dosing. Urine and bile samples were freeze-dried, reconstituted in MeOH to remove excessive salts, and again freeze-dried and reconstituted in 400–800 μL of D_2O:ACN (acetonitrile) 50:50, v/v

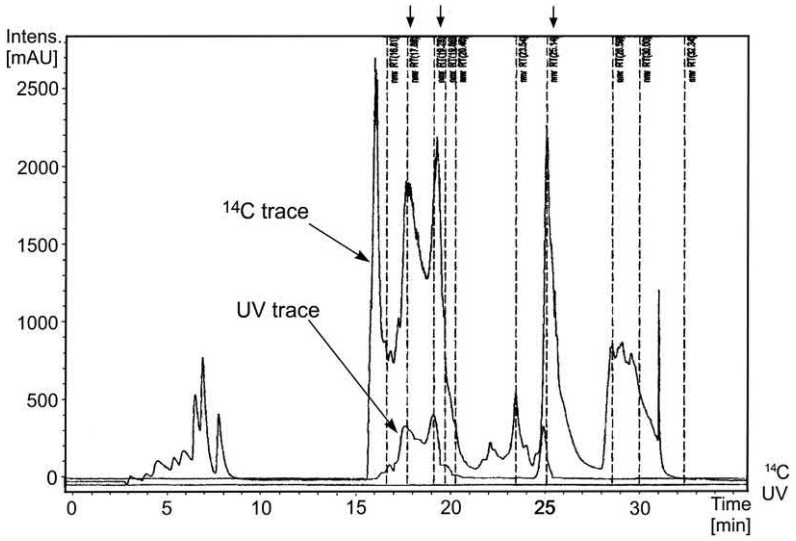

FIGURE 10.61 UV and ^{14}C traces of the HPLC separation of [^{14}C]-ZD6126 metabolites in pooled bile samples from male rats (6−12 hours collection, 6 mL total volume). Arrows indicated peaks of interest eluting at 17.88, 19.28, and 25.14 minutes for the stopped-flow measurement of ^{1}H NMR spectra. *From Lenz et al. (2007); reprinted with permission from Elsevier © 2007.*

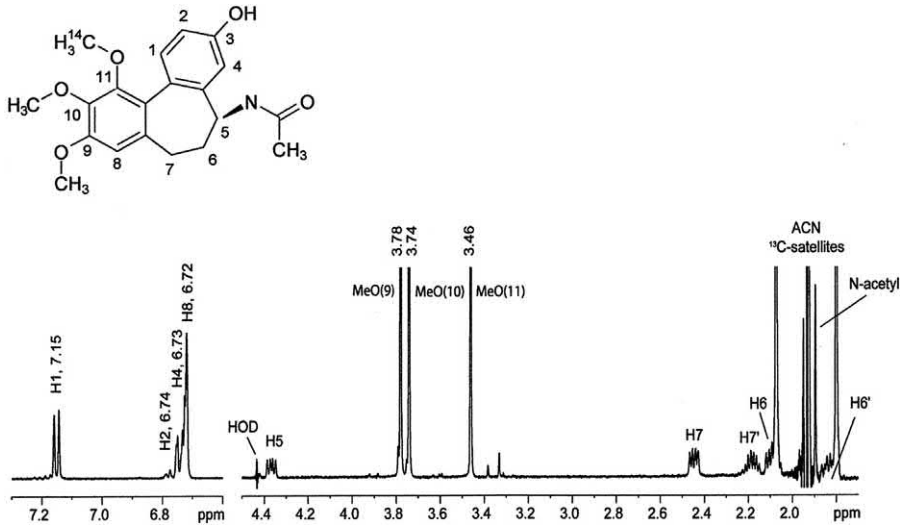

FIGURE 10.62 Structure of [^{14}C]-ZD6126 phenol and its stopped-flow ^{1}H NMR spectrum. Key: HOD, residual water. *From Lenz et al. (2007); reprinted with permission from Elsevier © 2007.*

containing 1% formic acid-d_2. After centrifugation, the sample was injected directly into an HPLC column for direct ^{1}H HPLC-NMR analysis. It is critical that the dried sample be reconstituted in deuterated solvents and that the HPLC mobile phase also contain deuterated solvents to avoid interference from extraneous solution protons during the online determinations of the ^{1}H NMR spectra of the metabolites. The HPLC mobile phase in this case contained D_2O and ACN buffered with 0.1% formic acid-d_2.

A Berthold LB507A radioactivity monitor was interfaced with the HPLC prior to a Shimadzu UV diode array detector (DAD). The radioactivity detector was equipped with a 150 μL solid flow cell. The HPLC peaks of ^{14}C radioactivity and UV absorption from the two detectors were used by Lenz et al. (2007) for the signaling of the initiation of the stopped flow for the determination of the ^{1}H NMR spectra. Typical ^{14}C radioactivity and UV absorption traces of the HPLC effluent are illustrated in Fig. 10.61. The arrows at the uppermost part of the traces indicate peaks of interest, labeled with ^{14}C, where stopped flow permitted the online determination of ^{1}H-NMR spectra.

An example of a typical online stopped-flow ^{1}H NMR spectrum is that of [^{14}C]-ZD6126 phenol, illustrated in Fig, 10.62, and diagnostic signals for various metabolites

provided by the online HPLC-NMR determinations are listed in Table 10.12. Included with the ^{1}H NMR spectrum of [^{14}C]-ZD6126 phenol of Fig. 10.62 are the specific assignments to the proton resonance signals at various chemical shifts (δ ^{1}H, ppm). For example, proton assignments at carbon atoms numbered 1, 2, 4 … are designated as H1, H2, H4 … at the top of the peaks in the NMR spectrum followed by the values of the chemical shifts (e.g., H1, 7.15 ppm). Signals assigned to the methoxy groups at carbon atoms numbered 9, 10, and 11 are also assigned at 3.78, 3.74, and 3.46 ppm, respectively. Table 10.12 lists the proton chemical shifts of standards and various metabolites measured by Lenz et al. (2007) with online HPLC-NMR, which provided evidence for their structural determinations. Online HPLC-MS provided additional evidence for the identifications of metabolites.

Measurements of ^{14}C activities permitted quantitative measurements of radioactivity recoveries in extracts of the various test animals.

XIII. Online HPLC-FSA-MS-NMR

Multiple hyphenation techniques refer to the combination of a chromatographic system (i.e., online) with more than one detector for the spectroscopic determination of the structure of compounds separated by the chromatographic system. For example, LC-MS and LC-NMR refers to the combination of liquid chromatography with MS or NMR spectroscopy, respectively, as discussed in previous sections of this chapter. A multiple hyphenation technique abbreviated as LC-MS-NMR includes the combination of MS and NMR spectroscopy online by means of a liquid chromatography effluent splitter. If a radioisotope-labeled compound and its metabolites are separated by HPLC, a flow scintillation analyzer (FSA) will be linked to the HPLC effluent stream to detect the radioisotope-labeled compounds as they are eluted from the chromatographic column, and, in addition, an ultraviolet (UV) detector may be added for the detection of unlabeled as well as labeled compounds. Such a system may be hyphenated as online HPLC-UV-FSA-MS-NMR. As reported by Hansen et al. (1999), these techniques can cut the time needed to carry out such complex studies to short durations from 1 day to a few weeks compared with the span of months required when traditional techniques of compound isolation, purification, and subsequent spectroscopy are undertaken. Multiple hyphenation techniques are reviewed by Shockcor (2017), Silva-Elipe (2003), and Wilson and Brinkman (2003). The combination of more than one spectroscopic analysis in a single HPLC run offers advantages as noted by Silva-Elipe (2003) as follows.

> *NMR and MS data on the same analyte are crucial for structural elucidation. When different isolates, such as metabolites, are analyzed by NMR and MS, one cannot always be certain that the NMR and MS data apply to the same analyte. To avoid this ambiguity, LC-MS and LC-NMR are combined. MS data should be obtained initially since with NMR, data collection in the stopped-flow mode can take hours or days depending on the complexity of the structure and the amount of sample. This is why it is preferable to designate this operation as LC-MS-NMR rather than LC-NMR-MS.*

The HPLC-MS-NMR technique is not always favorable. As pointed out by Silva-Elipe (2003), the inclusion of NMR in the hyphenation is not always an advantage, particularly when the structural problem is very complex, the separation of the chromatographic peak is not suitable, or the volume of the chromatographic peak with respect to the volume of the NMR flow cell is not compatible. Silva-Elipe (2003) underscores that there will always be situations where the traditional isolation and purification of the analyte(s) will be required, and it is up to the analyst to choose the correct approach in determining the molecular structure of the analyte(s).

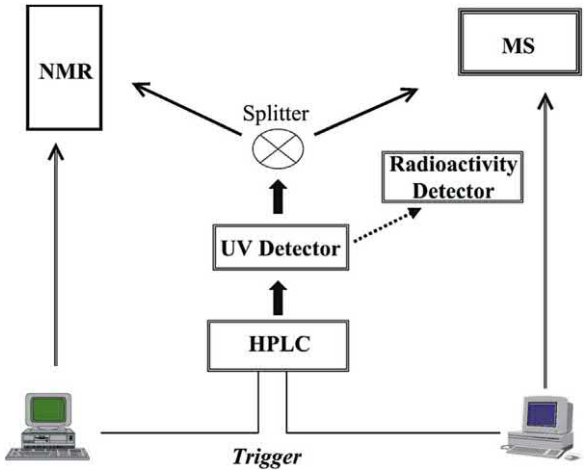

FIGURE 10.63 Schematic setup for the LC-MS-NMR system. A dashed arrow pointing to the radioactivity detector (i.e., FSA) is set to one side, as it would be coupled with the effluent steam of the HPLC only when radioisotope-labeled compounds are separated on the HPLC column. *From Silva-Elipe (2003); reprinted with permission from Elsevier © 2003.*

Online HPLC-UV-FSA-MS-NMR instrumentation is reported by several researchers. For online spectroscopic analysis of natural products, Bailey et al. (2000), Hansen et al. (1999), Scarfe et al. (2000), and Shockcor et al. (1996) split the HPLC effluent in the proportions of 95% to the NMR spectrometer and the remaining 5% of the effluent to the mass spectrometer in light of the relative sensitivities of the two spectrometers. The NMR spectra are obtained using the stopped-flow method with resonance signal acquisitions varying from several minutes to hours with a 500.13 MHz Bruker DRX-500 NMR spectrometer. The various acquisition times are dependent on compound concentrations that eluate off the HPLC column. Smith et al. (1999) also report the use of a splitter of HPLC effluent to the MS and NMR spectrometers. The proportions of HPLC effluent splitting will depend on the sensitivities of the MS and NMR spectrometers to the compounds eluted from the chromatography column. Silva-Elipe (2003) reports the use of a 1:100 splitting ratio, that is, 1% of the column effluent was directed to the MS spectrometer and the remaining 99% on to the NMR spectrometer. At a flow rate of 1.0 mL/min, this translates to 0.010 mL/min to the MS and 0.990 mL/min to the NMR spectrometers, respectively. Shockcor (2017) provides an excellent summary of the state-of-the art of these hyphenated chromatographic and spectroscopic methods, including advances such as stopped flow, time-sliced stopped flow, HPLC peak collection into capillary loops

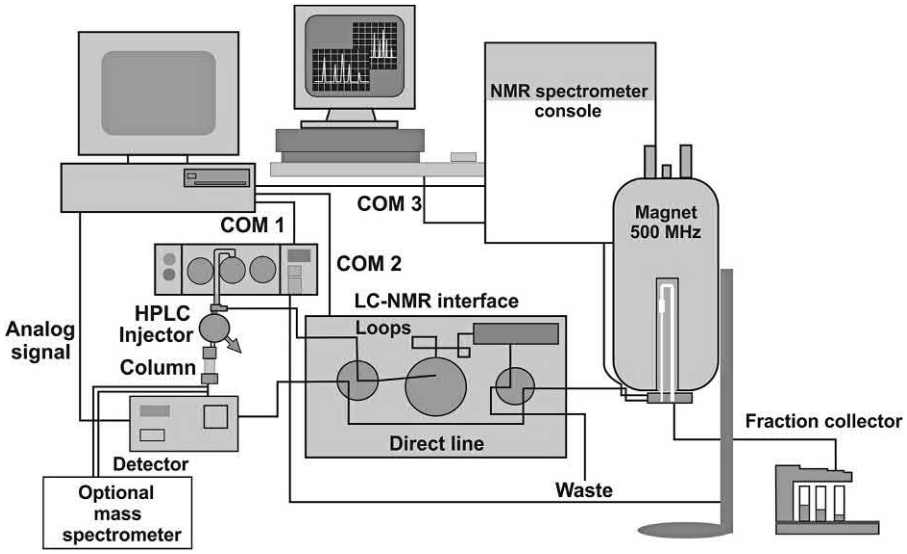

FIGURE 10.64 Instrumental setup of the HPLC-UV-FSA-MS-NMR apparatus. Three computer communications (COM 1, 2, and 3) control the HPLC and HPLC detector, the HPLC-NMR interface, and the NMR readout, respectively. The detector may be a UV detector or an FSA. A splitter at the HPLC column effluent can divert part of the LC stream to a mass spectrometer and the remaining part to the NMR. A direct line from the UV or FSA detector (i.e., flow-cell radionuclide detector) leads on to the 500 MHz NMR spectrometer, or eluted fractions may be stored in capillary loops for stopped-flow NMR or subsequent off-line NMR. The fraction collection of HPLC peaks provides the ability of isolating the separated compounds for further studies and more thorough NMR spectroscopy. *From Shockcor (2017); reprinted with permission from Elsevier © 2017.*

for postchromatographic NMR, deuterated solvent selection for HPLC, and NMR solvent suppression to avoid costs associated with deuterated solvents.

Schematic illustrations of the instrumental setup for the hyphenated HPLC-UV-FSA-MS-NMR analysis of HPLC effluents for the online separation, radioisotope label analysis, and molecular structural elucidation of complex mixtures are illustrated in Figs. 10.63 and 10.64. When ^{14}C-labeled compounds are eluted from the HPLC, a solid heterogeneous scintillation flow cell, such as one containing SolarScint or CaF_2(Eu) scintillator, may be used (see Table 10.1), allowing for the entire effluent to pass through the radioactivity flow-cell detector before reaching the splitter.

Michael F. L'Annunziata

Michael F. L'Annunziata, PhD, is the founding editor and coauthor of the *Handbook of Radioactivity Analysis* now in its Fourth Edition. His graduate thesis research at the University of Arizona, Tucson, AZ, United States, in the 1960s, financed by the then US Atomic Energy Commission, dealt with the analysis of ^{89}Sr and ^{90}Sr in the event of nuclear fallout. During 1970–1971, he worked in the chemical industry (Amchem Products, Inc., Ambler, PA, United States) as a ^{14}C-tracer chemist. Michael was then appointed a professor at the Postgraduate College, Chapingo, Mexico (1972–75), and a senior research scientist and graduate thesis advisor at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico City during (1975–77). Michael served as a scientific officer in the Department of Research and Isotopes and Department of Technical Co-operation of the International Atomic Energy Agency (IAEA) in Vienna, Austria during 1977–91 and head of IAEA Fellowships and Training during 1987–91. Michael F. L'Annunziata was first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as the chemical pathway and origin of the various inositol phosphate stereoisomers in soils (PhD dissertation, 1970, https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum =) and in 1975 (*SSSA Journal* 39(2), 377–379), and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–736, https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733). From 1977 to 2007, he served as IAEA expert in peaceful applications of nuclear energy in more than 50 countries of the world in Europe, Asia, Africa, Latin America, and the Middle East. His book entitled *Radioactivity: Introduction and History*, First Edition, published by Elsevier, was on the Best Sellers List in Physics (*LibraryJournal Academic Newswire* in 2008), and his much expanded Second Edition entitled "Radioactivity: Introduction and History, From the Quantum to Quarks" published by Elsevier in 2016 (https://www.sciencedirect.com/book/9780444634894/radioactivity) was awarded an Honorable Mention in the 2017 PROSE AWARDS in the category of Chemistry and Physics.

I. Introduction

Destructive analysis, complete with radiochemical separation of the radionuclide(s) of interest from the sample matrix and potential interferences, is a fundamental and often critical component of radioanalytical measurements. In this regard, radiochemistry has been described as "inconvenient but indispensable" (Bickel et al., 2000). Faster automated methods are needed to support analytical laboratories that make measurements on environmental samples; International Atomic Energy Agency (IAEA) laboratories involved in safeguards; and on-site laboratories at nuclear facilities. In addition, automation is required to move destructive analysis methods from the laboratory to online monitoring applications at nuclear facilities, and to sense radionuclides in the environment, at-site or in situ.

Destructive analysis is normally carried out in fixed laboratories using manual sample preparation, separation, and measurement techniques. Classic separation methods such as liquid–liquid extraction and ion exchange are well known and have been reviewed in the past (Choppin, 1984–85; Nash et al., 2006; Rydberg et al., 2004). For mass spectrometric measurement methods, the analyte must be separated from matrix components that may generate

Handbook of Radioactivity Analysis: Volume 2. https://doi.org/10.1016/B978-0-12-814395-7.00011-8

isobaric or molecular interferences. For radiometric methods, the analyte should be radiochemically purified prior to measurement to address matrix effects, spectral interferences, and prepare thin sources. Although gamma-emitting radionuclides may be determined by nondestructive analysis in some measurement scenarios, separations may still be required in many cases if the gamma emissions are weak and/or the sample matrix is radiologically complex.

Automation in radiochemical analysis offers many significant advantages, including reduced worker exposure to radioactivity, increased reliability, improved safety, and more consistent analytical protocols, as well as shorter analysis times, higher throughput, and lower costs. Instruments and sensors are required that perform all the functions previously carried out as sequential manual steps in the laboratory, yet achieve this rapidly and efficiently in an automated analyzer or sensor. "Fortunately, the convergence of digital instrumentation for preprogrammed fluid manipulation and the development of new separation materials for column-based isolation of radionuclides has enabled the development of automated radiochemical analysis methodology" (Grate et al., 2010).

In addition, automation can enable measurements that are not currently considered feasible because they are too costly and time-consuming for manual laboratory analysis or too difficult to deploy online or at-site. The ability to automatically separate radionuclides of interest from the background and from each other may allow radiation detection techniques currently used only for nondestructive analysis to be more informative or accurate.

Currently, radiochemical automation is either practiced or under development in the following areas:

- IAEA laboratories have automated aspects of the analysis of spent fuel using robotic arm technology in radiological glove boxes (Beugelsdijk and Hollen, 1998; Brandalise et al., 1994; Zahradnik and Swietly, 1996; Ziegler and Mayer, 1999).
- Automated methods have been developed to support the analysis of samples related to environmental management of US DOE sites, linking automated radiochemical separations to radiometric or mass spectrometric detection (Egorov et al., 1998b, 2001, 2004b; Grate and Egorov, 1998a; Grate et al., 1996, 1999b, 2004, 2010; Murray, 1994).
- Automation methods are under development to support analyses of environmental samples related to nuclear nonproliferation (Auer et al., 2010; Bowyer et al., 1999; Zähringer et al., 2009).
- Requirements for the laboratory analysis of large numbers of potentially contaminated samples have motivated research into the automation of radiochemical analysis. These samples may be from contaminated environmental sites or bioassay samples from an accidental or intentional nuclear event (Lariviere et al., 2008a,b).
- Automated process monitoring instrumentation has been developed for nuclear waste processing. An instrument for determination of ^{99}Tc in Hanford nuclear waste can perform sample preparation, separation, and detection all in less than 15 minutes for online analysis (Egorov et al., 2004a, 2005a, 2012; Grate et al., 2004).
- Radiochemical sensors have been developed for detection and determination of radionuclides in water and process samples (Egorov et al., 2006; Grate et al., 2004, 2008; Hofstetter and Wilson, 1992; O'Hara et al., 2009a,b).
- Radiochemical analysis as needed to support nuclear power reactors, reactor wastes, and the environment around reactors (Kolacinska et al., 2017, 2018; Trojanowicz et al., 2018).
- Heavy element researchers automate the rapid separation and measurement of short-lived heavy isotopes generated from target samples (Gaggeler, 1997; Schaedel, 2007; Zvara, 1999).
- Isolation and purification of radioisotopes for medicine requires separation of short-lived daughter products from their longer-lived parent isotopes. Interest in new isotopes and the desire to perform this separation at site are leading to increasing interest in automated radiochemical separation units (Boschi et al., 2013; Bray et al., 2000; Egorov and O'Hara, 2005; Egorov et al., 2000; Fisher, 2008; Krasikova, 2007; McAlister and Horwitz, 2009; Nagatsu et al., 2011; O'Hara et al., 2009d, 2017a,b, 2018a,b,c; Troyer and Schenter, 2009).

One may anticipate additional needs for radiochemical analysis in the following areas, which will lead to additional needs for automated methods:

- Decommissioning of nuclear reactors leads to additional analytical requirements as well as new types of samples (Hou, 2005a,b, 2007; Hou et al., 2005, 2007). An analysis approach for Pu from concrete, with automated flow-based separation, has been demonstrated (Qiao and Hou, 2010).
- Nuclear accidents such as Chernobyl and Fukushima lead to extensive sampling and analysis efforts, where automation may become advantageous (Bu et al., 2014; Cao et al., 2016; Chen et al., 2017; Hou et al., 2013; Ketterer and Szechenyi, 2008; Maxwell et al., 2014; Men et al., 2018; Xu et al., 2013, 2015, 2016a,b). The Fukushima accident has stimulated a new focus on radionuclides in seawater. Reprocessing plants also lead to anthropogenic environmental radionuclides in seawater (Qiao et al., 2017).

II. Radiochemical separations

A. Separation requirements

The requirements for radiochemical separations and other sample preparation steps in radiochemical analysis are determined largely by the detection method, which defines the acceptable characteristics of the sample presented to the detector.

There are four primary means of detection used in radiochemical analysis: radiometric detection of gamma rays, beta particles, or alpha particles, and mass spectrometry. Nondestructive analysis is possible primarily for those radionuclides that can be analyzed directly by high-resolution gamma spectroscopy. In almost all other cases, separations are required to separate the radionuclides of interest from other matrix components or other radionuclides that interfere with the detection method. Beta particles are emitted with a broad range of energies, and individual radionuclide species cannot be readily discerned using scintillation detection techniques. For example, radiometric detection of ^{99}Tc in nuclear waste matrixes requires complete separation from other interfering radioactive species. Although alpha particles are emitted with characteristic energies, a number of important radionuclides have unresolvable alpha energies, including ^{241}Am/^{238}Pu and ^{237}Np/^{234}U. In addition, matrix effects on the energy resolution of alpha spectroscopy necessitate extensive sample purification and preparation.

An alternative detection technique that has become increasingly important in modern radiochemical analysis is inductively coupled plasma mass spectrometry (ICP-MS). This approach to radiochemical analysis has been reviewed in detail (Kim et al., 2007; Lariviere et al., 2006) and critically compared (Hou and Roos, 2008). The trade-offs between radiation counting and atom counting have been described previously (Lariviere et al., 2006; Ross et al., 1993; Smith et al., 1992). In general, short-lived fission products are best detected with radiation detection, whereas long-lived (low specific activity) radionuclides can oftentimes be detected with more sensitivity using ICP-MS.

ICP-MS is also a selective detector since particular mass-to-charge ratios can be monitored. Nevertheless, separations are desirable prior to introducing a sample into the ICP-MS so that the sample is always introduced into the system in a consistent matrix (Colodner et al., 1994; Denoyer, 1992; Thompson and Houk, 1986). Matrix components can affect quantification. Moreover, detection by mass spectrometry is subject to interferences involving isobars and molecular ions, and tailing of peaks when one isotope is at much higher concentration than an isotope with an adjacent mass number (Crain and Alvarado, 1994; Garcia Alonso, 1995; Garcia Alonso et al., 1993, 1995; Kim et al., 2007; Lariviere et al., 2006; Smith et al., 1995; Tan and Horlick, 1986). Examples include ^{99}Tc/^{99}Ru, ^{151}Sm/^{151}Eu, ^{91}Zr, ^{16}O/^{107}Pd, ^{238}UH/^{239}Pu, ^{238}U/^{238}Pu, and ^{241}Pu/^{241}Am (Crain and Alvarado, 1994; Garcia Alonso et al., 1995; Smith et al., 1995). In addition, the possibility of interference from a large excess of ^{238}U in the measurement of ^{237}Np has been noted (Egorov et al., 2001).

In summary, chemical separations are carried out in radiochemical analysis to separate radionuclides with interfering radiation energy spectra for radiometric detection (Vajda and Kim, 2011) or to remove species, leading to isobaric, molecular, or spectral interferences in mass spectrometric detection (Kim et al., 2007; Lariviere et al., 2006). In many cases, it is also necessary to enable preconcentration and/or separation of radionuclides of interest from stable matrix components that affect subsequent analysis (Kim et al., 2000b). Whenever chemical separations are required, there may also be a requirement for additional sample preparation steps to control the speciation of the radionuclides prior to separation.

B. Radiochemical separation approaches

Separations in conventional radiochemical analysis have been carried out by a variety of classical and chromatographic methods, including precipitation, liquid−liquid extraction, and ion exchange. Often sequential combinations of these methods are used, and in some cases, individual steps must be repeated. Classic separation methods have been reviewed in the past (Choppin, 1984−85; Nash et al., 2006; Rydberg et al., 2004). Such classical methods have limited suitability for use in automated radiochemical analysis and have many disadvantages even for laboratory analyses.

Two column separation formats are generally considered for automated separations in radiochemical analysis. The first involves high-performance chromatographic techniques coupled with online flow-through scintillation detection for intermittent sampling and quantification of actinides and fission products in water (Desmartin et al., 1997; Reboul and Fjeld, 1994, 1995). Smith et al. (1995) described the use of high-performance ion chromatography (HPIC) with online radiometric detection for qualitative analysis of Hanford waste samples. Long separation times (40 minutes to several hours), matrix effects on the reproducibility and reliability of the separation procedure, limited capacity of the separation material, and speciation problems are significant issues with these chromatographic approaches that limit their applicability for rapid automated radiochemical analysis on difficult sample matrixes.

The second approach uses selective separation chemistries in extraction chromatographic or solid-phase extraction formats to rapidly and selectively isolate species of interest from stable matrix and radiological interferences (Cortina and Warshawsky, 1997; Dietz and

Horwitz, 1993; Grate and Egorov, 1998a; Izatt et al., 1996). The species of interest are strongly and preferentially retained by the column material under the solution conditions selected for the separation. Following a wash step (or sequence of wash steps) to remove unretained or slightly retained sample components, the species of interest are abruptly released by creating a large drop in the affinity factors via changes in the mobile phase composition or even by doing reaction chemistry on the retained species. Thus, this separation format relies on selective uptake and release properties rather than on the chromatographic efficiency of a long separation column, where analytes separate by migrating at different rates down a column due to (often small) differences in distribution ratios. This overall approach is shown in Fig. 11.1.

In general, radiochemical separations using extraction chromatographic materials can be accomplished rapidly using small columns operated under low pressures. Because of the selective analyte capture during sample loading step, analyte preconcentration can be achieved to improve analysis sensitivity. Compared with the high-performance chromatographic format, selective chemical separations are more tolerant of complex sample matrixes, and the columns have greater capture capacity (Cortina and Warshawsky, 1997). And unlike conventional chromatography, this approach can use reaction chemistry in addition to simple eluent delivery. Based on these considerations, selective chemistries on solid phases are particularly well suited for automation of radiochemical analysis.

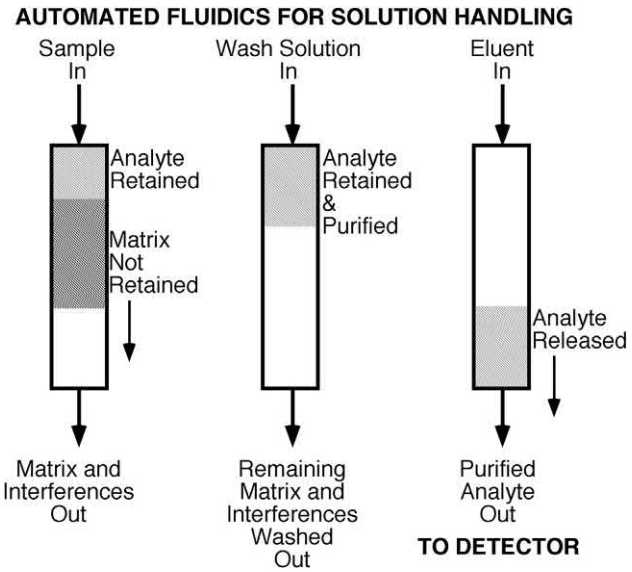

FIGURE 11.1 Schematic diagram of the separation approach whereby the analyte is selectively retained on the solid phase, whereas the matrix and interfering species are removed in the sample load and wash steps. Then an eluent is added that abruptly changes the retention of the analyte, releasing it in purified form for detection. Automated fluidic systems deliver sample, wash solutions, and eluents as per operator-specified computer code.

C. Modern radiochemical separation materials

A number of solid-phase materials have been developed to simplify analytical separations of heavy metals and radionuclides, using the separation approach shown in Fig. 11.1. These materials are based on either extraction chromatographic or solid-phase extraction materials, and they have made a significant contribution to the development of automated radiochemical analyzers and radionuclide sensors. Here, we use solid-phase extraction to refer to materials where the selective chemistry is covalently bound to the solid support.

A variety of solid-phase extraction materials dubbed "AnaLig" or "SuperLig" have been developed using "molecular recognition" ligands on solid supports and commercialized by IBC Advanced Technologies (American Fork, Utah) (Izatt, 1997; Izatt et al., 1994, 1996). These ligands are covalently bound to various polymeric or silica gel supports. The materials have been developed and investigated mainly for wastewater or effluent cleanup processes and have not been extensively used or characterized for analytical applications. Fundamental metal ion uptake studies of these are not available in the published literature. Nevertheless, AnaLig materials selective for Sr, Ra, and Tc were incorporated in Empore Rad Disks marketed by 3M for use in analysis of water samples (Fiskum et al., 2000; Schonhofer and Wallner, 2001).

Materials using selective or semiselective extractants impregnated on porous polymer and silica gel supports have been called solvent-impregnated resins and are more generally known today as extraction chromatographic materials (Dietz and Horwitz, 1993; Dietz et al., 1999; Horwitz, 1998; Horwitz et al., 2006). Early developments in extraction chromatography and relevance to radiochemistry were noted in an article in *Nature* in 1965, using organophosphorous extractants on silica gel support particles (Mikulski and StroŃSki, 1965). Modern extraction chromatographic materials use porous polymer support beads and have been commercialized by Eichrom Technologies, Inc. (Darien, Illinois) and Triskem International (Bruz, France). In most cases, they use chemistry from well-established liquid–liquid extraction separations. Extractant-impregnated beads are packed in a column and used to separate species from aqueous solutions by extraction chromatography (Cortina and Warshawsky, 1997). The uptake properties and chemical selectivities of these materials are well characterized in the literature. Extraction chromatographic methods generally tolerate high levels of potential interferences and complex sample matrixes; use columns with high capacities; work at low

pressures; and provide flexibility in sample loading conditions. These features are well suited for automated radiochemical separations.

III. Automation of radiochemical analysis using flow injection or sequential injection fluidics

A. Flow injection and sequential injection fluidics

The requirements for fluid handling in automation include a means to select samples, reagents, and eluents, bring them into the fluidic system, and deliver them to flow cells, separation columns, and detectors with precise control over volumes, flow rates, and timing. Sequential injection (SI) techniques from the field of flow injection (FI) analysis provide a versatile fluid handling approach for meeting these requirements (Fang, 1993; Ruzicka, 1994; Ruzicka and Hansen, 1988). Unlike conventional FI methodology or chromatography, which are based on a continuous forward flow paradigm, SI involved fluid flow in both directions and programmed flow reversals (Cerda et al., 1999, 2001; Christian, 1994; Grudpan, 2004; Ivaska and Ruzicka, 1993; Lenehan et al., 2002; Ruzicka, 1994, 2005; Ruzicka and Marshall, 1990; Taljaard and van Staden, 1998). The pump(s) and valve(s) of an SI system are fully controlled by a computer. FI and SI methods are compared in Fig. 11.2. These terms are actually used fairly loosely throughout the literature. We will use FI to mean flow injection as shown in Fig. 11.2A with an injection valve for sample introduction. We will use SI as shown in Fig. 11.2B and C to mean sequential injection in which solutions are pulled into a holding coil via a multiposition valve and pushed out through this valve to a reactor or separation system. Fluid handling approaches for radiochemical separations have been reviewed in detail, including several schematics, in an article (Grate et al., 2010). A comparison of fluidic and robotic approaches has been published (Grate et al., 2011). A number of recent articles describe the use of flow injection and sequential injection techniques in radiochemistry (Fajardo et al., 2010; Kolacinska and Trojanowicz, 2014; Trojanowicz et al., 2018).

The preferred fluid drive for SI is a modern digital syringe pump. A multiposition selection valve is used to select samples, reagents, or eluents that are pulled into a holding coil located between this valve and the pump. Precise control of the flow rate and the timing determine the volume of the solution pulled into the system. After changing the position of the selection valve, the solution or solutions in the holding coil are pushed out of the holding coil (away from the pump) and toward the reactor, separator, and/or detector downstream. Solutions can be pulled into the holding coil and delivered to the flow system downstream one at a time, or multiple solutions can be pulled into the holding coil in sequence and "stacked" there prior to pushing them forward into the flow system. Sequential injection systems are mechanically simple yet quite versatile. Reagents, eluents, samples, and standards can all be nested around the multiposition valve and sequentially selected for delivery into the system. The volume of each solution introduced into the holding coil can be varied simply by computer control, rather than by physically reconfiguring the system (e.g., by installing a larger injection loop as in conventional flow injection or chromatography). When utilizing a holding coil of adequate volume, the pump does not contact either reagent solutions or samples (but rather a carrier solution such as distilled water), and it can be located remotely from the remainder of the system.

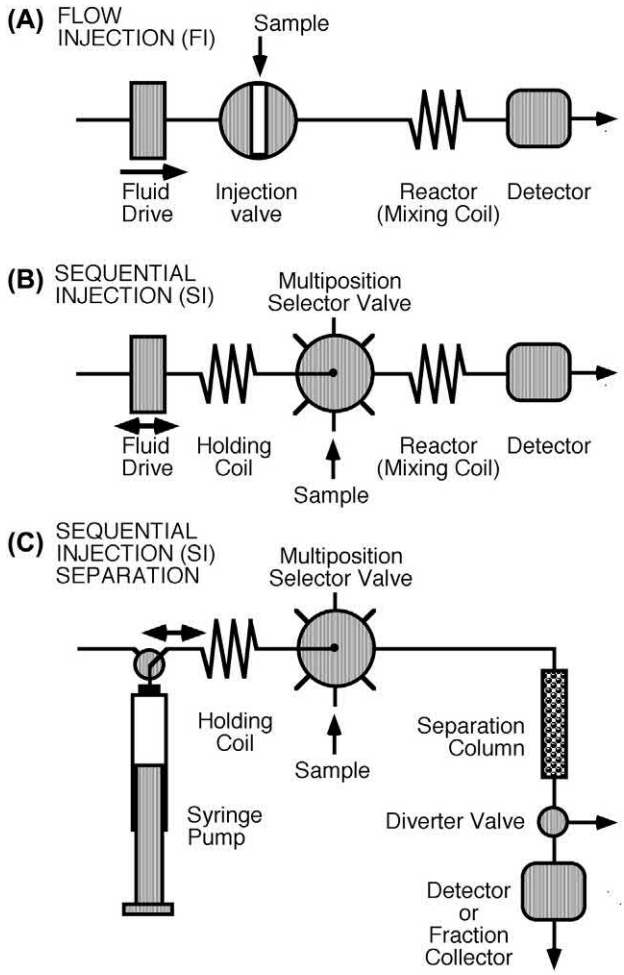

FIGURE 11.2 Schematic diagrams comparing (A) flow injection and (B) sequential injection fluid handling methods. The key components of a sequential injection separation system are shown in (C). *Adapted with permission from Grate and Egorov (1998a). Copyright 1998 American Chemical Society.*

Typical colorimetric sequential injection analysis (SIA) procedures stack zones of sample and reagent(s) in a holding coil with a narrow internal bore. When the stacked zones are propelled toward the detector, mixing occurs by dispersion, yielding a detectable product.

B. Sequential injection separations

Use of SI instrumentation for automating radiochemical analysis (Egorov et al., 1998a,b, 1999a,b, 2001; Grate and Egorov, 1998a,b; Grate et al., 1996, 1999a,b) typically involves use of a separation column, as shown in the apparatus in Fig. 11.2C. A suitable detector or fraction collector follows the column. A diverter valve is useful for directing sample matrix and wash solutions to waste without passing them through the detector; radionuclides released from the separation column can then be directed to the detector. Various diverter valve configurations can be used (Grate et al., 2010), including four-port two-position valves (Egorov et al., 1998b, 2012; O'Hara et al., 2018a) or six-port two-position valve (Mateos et al., 2000). These enable the diversion of column wash solutions to waste; bypassing the column to wash the detector flow cell; and reversal of flow through the column. With flow reversal, the sample can be loaded from one end of the column and then eluted back off of that end without going through the whole-column packing.

When using SI instrumentation and methodology to automate column-based separations, the approach must be modified to accommodate larger solution volumes; milliliter quantities of multiple solutions may be necessary to wash separation columns and elute species of interest. Pulling these solutions into the holding coil at typical SIA flow rates is excessively time-consuming. However, increasing the flow rate can cause outgassing of solutions in the holding coil due to reduced pressure as the pump pulls the solution in. This is unacceptable, but it can be resolved by using a larger bore holding coil, e.g., 1.6 mm ID. However, a larger holding core bore leads to increased dispersion between the solution being pulled in and the carrier fluid already in the coil.

To prevent dispersion and mixing of these solutions, an air segment can be aspirated into the coil prior to the reagent solution ("Reagent" refers generically to reagents and eluents.) Then the reagent solution is delivered to the column. This approach is shown in Fig. 11.3. The air segment is expelled to waste, a new air segment is pulled in, and a new reagent solution is pulled into the holding coil, ready to be delivered to the column. In this way, several different solutions of varying volumes and composition can be delivered to the separation column. The holding coil functions as a zero dispersion volumetric extension of the syringe pump. The use of a large bore holding coil and air segment in this way for sequential injection separations has been referred to as separation-optimized SI (Egorov et al., 1998b; Grate and Egorov, 1998a; Grate et al., 1999a,b).

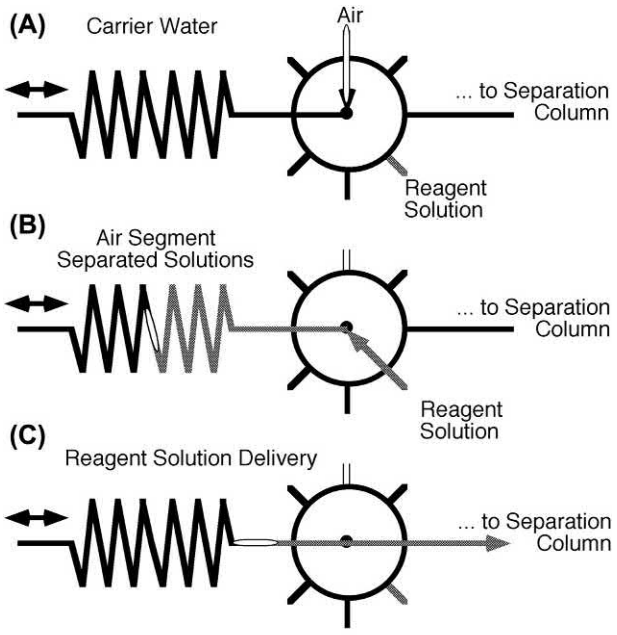

FIGURE 11.3 Schematic diagram for the use of an air segment in the holding coil for separation-optimized sequential injection fluid handling. The air segment is pulled into the holding coil prior to the reagent solution (A). This keeps the reagent solution separated from the carrier fluid (typically water) in the holding coil during reagent aspiration (B). After injecting a fixed amount of the reagent solution past the multiposition selection valve (C), the remainder of the reagent solution and the air segment are discarded to waste (not shown).

C. Alternative fluid delivery systems

The choice of the basic fluid handling approach is not necessarily limited to the SI paradigm using a multiposition valve and holding coil. For example, dedicated syringe pumps can be used for sample handling and reagent delivery in an approach typically used in robotic workstations. In addition, modern digital syringe pumps with zero dead volume syringes and multiposition selector valves have become available from IMI Precision Engineering (Littleton, CO). In this design, a single syringe pump can be used for sequential delivery of multiple solutions with minimal cross-contamination. Thus, the syringe pump can serve as both the fluid drive and the holding coil. Finally, in some instrument designs and procedures, a combination of digital syringe pumps and positive displacement high-performance liquid chromatography (HPLC) pumps can be used to automate solution handling tasks required in the sample preparation and separation procedure.

Given this range of possibilities, several additional configurations have been developed and, in some cases,

given names (Grate et al., 2010). A "multisyringe flow injection" approach has been described using up to four syringe pumps in parallel (Cerda et al., 1999; Fajardo et al., 2004, 2005; Miro et al., 2002a). When using flow reversals and a holding coil with each syringe, "multisyringe flow injection" can actually be regarded as a modified SI system. Solutions can be selected using a series of three-port solenoid valves instead of the conventional multiposition valve in SI. The multisyringe approach has been further reviewed as a technique for spectroanalytical methods of analysis (Cerda et al., 2018).

Commercial flow injection accessories have been adapted for radiochemical column separations, especially in the mass spectrometry community as a front end to ICP-MS (Grate et al., 2010). The PerkinElmer Model FIAS-400 is a flow injection system that has been used to automate extraction chromatographic separations for actinide analyses (Benkhedda et al., 2005a,b; Epov et al., 2005a,b, 2007; Hollenbach et al., 1994). The PrepLab liquid handling system for ICP-MS has also been adapted for extraction chromatographic separations (Kim and Kim, 2002; Kim et al., 2000a, 2004; Ohtsuka et al., 2005, 2006). HPIC systems have also been adapted with columns, although some columns described have been much longer than those normally used for extraction chromatography (Hang et al., 2004; Peterson et al., 2007). Recently, sample preparation instrumentation by Elemental Scientific has been used to automate column-based separations. The prepFAST-MC system performed separations for the analyses of Ca and Sr, and separately, for Cu in biological samples, achieving high throughputs (Enge et al., 2016; Romaniello et al., 2015). In further advances, a prepFAST-SR system was developed for tandem extraction chromatographic separations where the TEVA and UTEVA separation materials were automatically loaded into the column bodies and used in sample preparation for the analyses of U and Pu isotopes (Metzger et al., 2018).

An alternative to the use of syringe pumps is to control the air pressure over the solvent in bottles, creating an automated pressurized injection (PI) system (Guerin et al., 2013). This approach can be advantageous with corrosive or viscous solvents and when solutions may generate gases themselves. This approach has been developed for extraction chromatographic separations of actinides (Guerin et al., 2013).

D. Column configurations

Columns containing the solid-phase separation medium can be included in the system directly downstream from the multiposition selection valve, as shown in Fig. 11.2C. However, other configurations are advantageous in some analysis protocols. For example, the column can be configured with a four-port two-position valve as shown in Fig. 11.4A so that the analyte captured on the "top" of the column is eluted in the opposite direction so that it need not travel through the remainder of the column material (Egorov et al., 2012; O'Hara et al., 2018a). Similarly, using a six-port two-position valve as the diverter valve can also enable column flow reversal (Mateos et al., 2000).

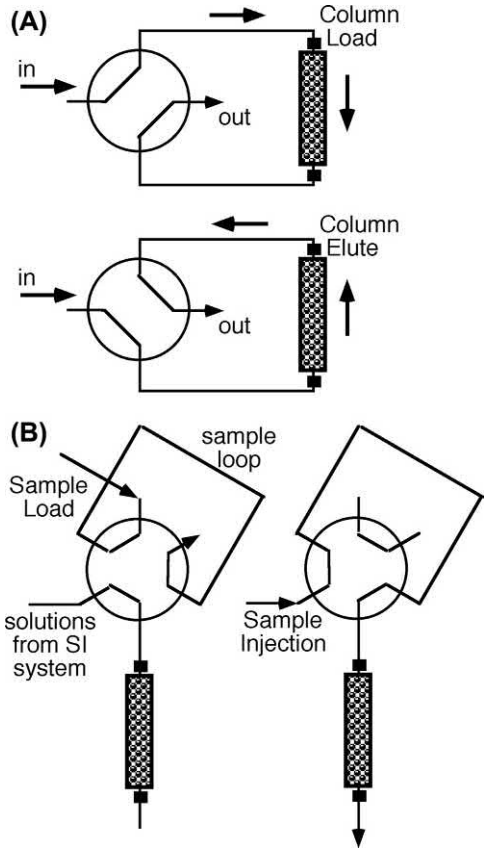

FIGURE 11.4 (A) Schematic illustration of a column coupled to a two-position valve so that the sample can be loaded in one flow direction and analytes can be eluted in the opposite direction. (B) Schematic illustration of a sample injection valve and loop directly upstream from the separation column.

Another configuration that is useful in some cases is to add a sample injection valve after the multiposition valve and immediately before the separation column, as shown in Fig. 11.4B (Egorov et al., 2001). In this way, hot radioactive samples are injected directly upstream from the column via a sample loop; the multiposition valve and the holding coil of the sequential injection system are never exposed to the sample. This type of sample injection is similar to conventional FI, and the sample volume is determined by hardware, not by time and flow rate parameters under software control as in SI systems that use the holding coil as part of the sample injection method.

Yet another useful configuration is to set up column switching capabilities (Grate et al., 1999a). A partial column switching system is shown schematically in

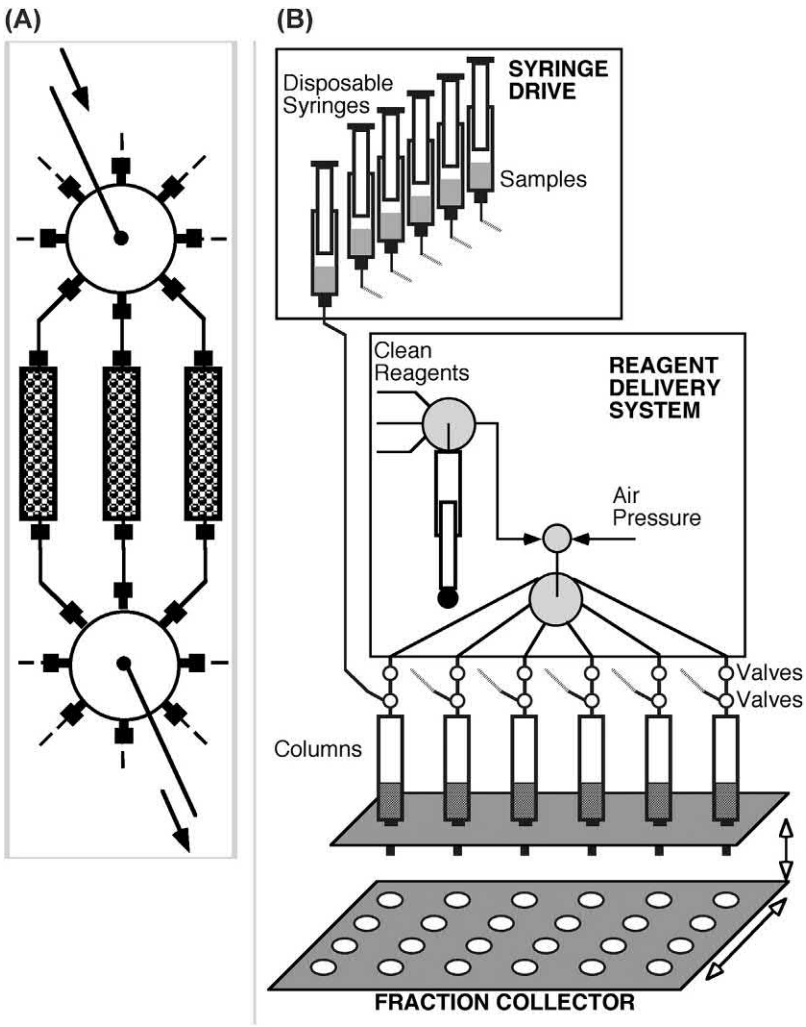

FIGURE 11.5 (A) Schematic diagram of a column switching system, where the columns are placed between two multiposition selection valves. Only three columns are shown for simplicity, although the valves shown will accommodate eight. (B) Schematic diagram of the key components and layout of the PNX system to perform column-based separations. Samples are delivered to columns via a three-port valve positioned above each column and downstream from the clean reagent delivery system. Subsequently, eluents are delivered from the clean reagent delivery system, and fractions are collected by a fraction collector that can translate among fixed positions horizontally and vertically to raise vials to surround the column outlets. *(B) Reproduced with permission from Grate et al. (2011). © 2011 Oldenbourg Wissenschaftsverlag GmbH.*

Fig. 11.5A. Multiple fresh columns can be set up prior to beginning a set of samples. Each sample can be directed to a fresh column for rapid throughput without column wash steps between samples. This approach has been used to set up a rapid automated separation workstation for processing of ^{90}Sr-containing samples along with quality control samples, including standards, spiked samples, and blanks (Grate et al., 1999a). Column switching has also been described for delivering clean solutions to multiple columns that are mounted in parallel in a rack above a fraction collector, as shown schematically in Fig. 11.5B (Grate et al., 2011). Then, each column delivers its separated fractions to a different section of a fraction collector; hence, effluents from different columns do not travel the same flow paths downstream from the columns, eliminating cross-contamination concerns. The design shown in Fig. 11.5B is an automation system for column-based separations that the authors called PNX, for Pacific Northwest eXtraction system (Grate et al., 2011). In a subsequent version, PNX-II, six syringe pumps in the clean reagent delivery system deliver eluents to each of six columns simultaneously for rapid parallel separations.

Four parallel columns have also been implemented in an FI system with peristaltic pumps for the efficient analysis of anthropogenic radionuclides from seawater (Qiao et al., 2014). Both ion exchange and extraction chromatographic methods were implemented for separations, and radiometric and ICP-MS methods were used for quantification. The replacement of the peristaltic pumps with a multichannel syringe pump was discussed.

E. Renewable separation concepts and methods

The separation column for automated radiochemical analyzers is shown in Fig. 11.2C as a fixed column. The practical life of such fixed columns is determined by the sample type, the separation media, and the separation chemistry involved. With suitable column cleanup steps

between samples, and sufficiently robust column media, such separation columns may be used tens or possibly even hundreds of times. Such columns can then be manually replaced as necessary.

An alternative approach is to automatically pack separation material into the column body online and release it automatically after use. This approach results in "renewable separation columns," and SI systems using them have been referred to as SI-RSC systems. Originally, renewable surface techniques were developed by Ruzicka and coworkers to trap chemically selective particles and beads for observation by microscopic or optical techniques while perfusing with sample (Egorov and Ruzicka, 1995; Mayer and Ruzicka, 1996; Pollema and Ruzicka, 1994; Ruzicka, 1994; Ruzicka and Ivaska, 1997; Ruzicka and Scampavia, 1999; Ruzicka et al., 1993; Willumsen et al., 1997). Changes in the bed properties (e.g., absorbance, reflectance, fluorescence, etc.) induced upon the introduction of the sample solution provided the basis for an analytical measurement. In this approach, particles serve as sensing surfaces for chemical or biological detection. After use, the beads were released to waste, and a new microbed was packed. This process renews the interactive surface for the next measurement.

When the flow cell that captures the beads is not associated with a detector, it serves primarily as a separation medium. This approach can be scaled to handle bed volumes from 1 microliter to a milliliter or more. Renewable surface methods were introduced to the field of radiochemistry using extraction chromatographic radiochemical separation materials in SI-RSC systems (Egorov et al., 1999a). Slurries of the extraction chromatographic material were captured in a flow cell (column) of well-defined volume, and this packed bed was used to carry out separations. Afterward, the column bed material was released from the flow cell, and fresh suspensions of beads were introduced and captured for subsequent sample assay. The SI-RSC method has been demonstrated for ^{90}Sr analysis using Sr resin, ^{99}Tc analysis using TEVA resin, and ^{241}Am analysis using TRU resin. Recently, a commercial sample preparation system, the Elemental Scientific prepFAST-SR system, was developed to implement a renewable column separation approach for the analysis of U and Pu isotopes (Metzger et al., 2018). Automatic loading and unloading of the TEVA and UTEVA extraction chromatographic resin materials provided fresh column material for each sample. This provided a commercial off-the-shelf (COTS) system for processing samples for IAEA-related analyses.

Several approaches exist for capturing and releasing particles in RSC flow cells.

The original flow cells for renewable surface techniques were "jet ring cells," where beads were trapped in the end of a tube in contact with a planar surface. The roughened end of the tube allowed fluid to pass but retained beads (Ruzicka, 1994; Ruzicka and Scampavia, 1999; Ruzicka et al., 1993). Beads were removed from the cell either by reversing the fluid flow or by lifting the tube away from the detector surface under forward flow conditions. Flow cells were also designed to trap beads with a solid rod intersecting the cylindrical channel of a machined flow cell at right angles (Dockendorff et al., 1998; Holman et al., 1997). This rod precluded escape of the beads; a leaky tolerance allowed fluid to flow around it. Beads were released by an axial motion of the rod that withdraws the rod end from the flow channel. By contrast, a rotating rod design has been developed where the end of the rod is angled; in one rotation position, the angled end blocks beads from exiting the outlet channel while allowing fluid flow around a leaky tolerance (Bruckner-Lea et al., 2000; Grate et al., 2003, 2009; Ozanich et al., 2007, 2009). A 180° rotation opens the outlet channel for bead release. This design in shown in Fig. 11.6A. Frit-based renewable separation flow cells have also been developed (Egorov

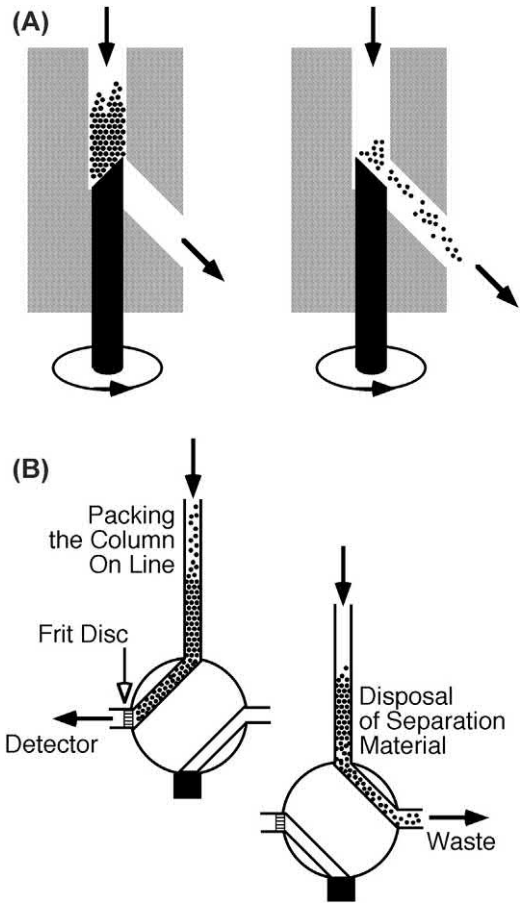

FIGURE 11.6 Two approaches for renewable separation columns: (A) the rotating rod flow cell and (B) a frit restricted method incorporated into a two-position valve. *(B) Adapted with permission from Egorov et al. (1999a). Copyright 1999 American Chemical Society.*

et al., 1999a). In these systems, a bead suspension is directed through a frit to trap beads or to an open channel to discard beads. This approach has been applied to radiochemical separations. The valve for determining which fluidic path is open can be downstream, or it can be integral to the design as shown in Fig. 11.6B.

F. Lab-on-valve

Column separation approaches can also be implemented with a lab-on-valve (LOV) approach (Erxleben and Ruzicka, 2005; Luque de Castro et al., 2008; Ruzicka, 2000; Wang and Hansen, 2003). The LOV system is typically configured as an SIA system, with a syringe pump providing reversible flow, a holding coil, and multiposition valve. However, the multiposition valve is configured with a custom plastic head that integrates functional components of the analytical method in direct communication with the ports of the valve. Plastics such as acrylic, ULTEM, and PCTFE are used, and various custom configurations have been developed. One such configuration is shown in Fig. 11.7.

For column separations, a column body that is either integrated into the monolithic valve head or in close proximity with the valve head communicates directly with one of the valve port positions; the beads of separation material are loaded into the column body automatically. This close proximity of the column with the switching actuation of the multiposition valve is advantageous for loading beads of separation material in and out of the column body. The column is effectively part of the LOV system, instead of being placed downstream from a multiposition valve as in Fig. 11.2C. When the separation material is freshly loaded and unloaded for each sample, the LOV platform provides a renewable separation column technique. The concept of loading beads and retaining them in a flow cell was included as part of the original concept for the LOV published by Ruzicka (2000) and demonstrated as part of an optical measurement system. This bead injection approach was adapted to create affinity chromatography columns (Erxleben and Ruzicka, 2005), and microcolumns for trace metal separations were discussed in a review (Wang and Hansen, 2003; Wang et al., 2003). LOV platforms have been used to perform extraction chromatographic separations for analysis of radionuclides, such as

- ^{90}Sr (Beltran et al., 2013; Kolacinska et al., 2017; Mola et al., 2014; Rodriguez et al., 2012),
- ^{99}Tc (Kolacinska et al., 2017; Rodriguez et al., 2015b; Villar et al., 2013, 2017),
- ^{226}Ra (Rodriguez et al., 2016b),
- plutonium (Qiao et al., 2013c), and
- uranium/thorium (Avivar et al., 2011, 2012).

G. Extractant liquids and particles

Thus, there are many ways to implement renewable surface columns, and these can be used for either the automated radiochemical analysis methods or the radionuclide sensors to be described below. Additional approaches with liquids and particles for radiochemical separations are noteworthy.

Miro et al. (2002b) have shown, for example, that an extraction coil can be used to replace the column-based approach, creating a liquid–liquid extraction in which the extractant is immobilized as a wetting film on the walls of a tubing coil, instead of immobilizing it in a porous polymer as in extraction chromatography. This method was implemented as part of an SI separation system. After coating the coil with extractant solution, the sample was loaded and the extractant was washed. Captured ^{90}Sr in the extractant film was recovered by using an organic solvent that stripped the extractant from the coil (Miro et al., 2002b). The separation material, a liquid extractant, is automatically renewable.

Additional approaches for liquid extraction were described recently (Maya et al., 2014; Rodriguez et al., 2015a, 2016a; Villar et al., 2015). Radionuclide separations by liquid–liquid extraction were critically compared with solid-phase extraction techniques in a review (Rodriguez et al., 2016a). Automated in-syringe extractions were described (Maya et al., 2014) and applied to analysis of species such as ^{99}Tc and uranium (Rodriguez et al., 2015a; Villar et al., 2015). Detection approaches for these applications were off-line scintillation counting (^{99}Tc) and spectrophotometric detection using arsenazo dye and a long path length liquid waveguide capillary cell (uranium).

An extractant for radionuclides was coated on magnetic particles for magnetically assisted chemical separations (Shaibu et al., 2007). The actinides of interest were captured from aqueous solutions into the extractant

followed by a magnetic solid–liquid separation. The extractant-loaded particles could be stripped for reuse. This approach has been demonstrated with a number of extractants for separating actinides that are relevant to nuclear waste process streams (Shaibu et al., 2006a,b, 2007). Magnetic separation processes are suitable for automation.

H. Detection

Detection of the separated radionuclides can be done in a variety of ways, broadly classified as radiometric (i.e., radioactivity detection) techniques and mass spectrometry techniques. These methodologies have been critically compared (Hou and Roos, 2008).

Flow-through liquid scintillation detection represents a radiometric method that integrates well with flow-based separation and analysis systems. This approach combines the output of the SI separation system with liquid scintillation cocktail and delivers it into the flow cell of the detector. This flow cell typically consists of a length of photon-transparent tubing in a compact coil that is placed between two photomultiplier tubes (PMTs). A schematic diagram of the flow-through liquid scintillation detection approach is shown in Fig. 11.8. Many of the detector traces in this chapter were obtained by this method.

Flow-through scintillation detectors also exist that use particles of a solid scintillator packed into the flow cell. This avoids the use of the liquid scintillation cocktail and the associated waste. The fully automated process analyzer for total Tc in nuclear waste, to be described below, used this type of scintillation detection.

Other flow-based detectors are used for monitoring the passage of gamma- or positron-emitting radionuclides such as ^{89}Zr. The flow gamma detector is generally comprised of a gamma detector (e.g., NaI(Tl) scintillation spectrometer) and a detection coil, both of which are housed within radiation shielding. Column effluents (frequently the purified radioanalyte fraction) are passed through the detection coil (tubing), passing across the face of detector. As with the flow-through scintillation detectors described above, the gamma detector provides a radiochromatogram of the eluting analyte (O'Hara et al., 2018a, b, c). These gamma detectors are likewise employed in radio-high performance liquid chromatography (radio-HPLC) systems.

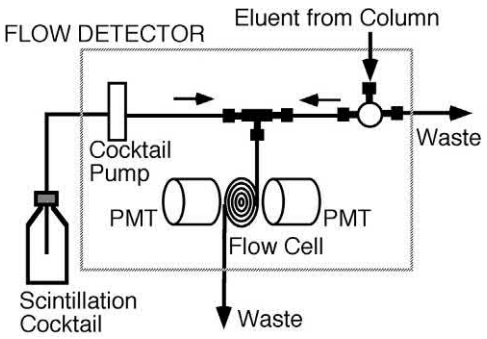

FIGURE 11.8 Schematic diagram of a flow through liquid scintillation detection system.

Mass spectrometry represents a detection method that is advantageous for radionuclides with low specific activity or where mixtures of radionuclides are eluted. Mass spectrometry can provide separate signals for each isotope according to their mass-to-charge ratios. ICP-MS has been used as the online detector for actinide separations and will be described below. Indeed, the separation of radionuclides prior to ICP-MS (Egorov et al., 2001; Kim et al., 2007; Lariviere et al., 2006) has become a major driver in the automation of radiochemical separations (Grate et al., 2010).

Recently, accelerator mass spectrometry (AMS) has been applied to the analysis of samples where actinides such as plutonium and uranium were first purified using automated fluidic methods (Qiao et al., 2013d, 2015).

Finally, automation of radiochemical separations represents a significant savings in cost and labor even when the output of the instrument is delivered to a fraction collector for separate off-line counting or mass spectrometry (Grate et al., 1999a,b). In addition, some labs may already be set up to handle radiochemical separations and counting operations separately. Automated radiochemical separations with fraction collection can provide efficiencies for the separation lab without altering the overall work flow from separations to detection.

A recent review discusses a variety of detection techniques relative to a variety of flow techniques for the analysis of environmental samples (Fajardo et al., 2010).

IV. Selected radiochemical analysis examples

A. Strontium-90

Strontium-90 is a high yield fission product in nuclear waste that decays by beta emission to ^{90}Y, which is also a beta emitter. The half-lives of these isotopes are 28.9 years and 64 hours, respectively. The determination of ^{90}Sr is important in the characterization of stored nuclear wastes from nuclear weapons production and in process streams associated with spent fuel reprocessing. Analytical determination of ^{90}Sr, a pure beta emitter, requires that it be separated from inactive matrix constituents and a variety of interfering radionuclides prior to quantification by counting methods. A variety of classical and chromatographic methods can be used to achieve the required chemical separations, including precipitation, liquid–liquid extraction, ion exchange, thin-layer chromatography, and electrophoresis (Alfaro et al., 1995; Amano and Yanase, 1990; Borcherding and Nies, 1986; Cobb et al., 1994; Fourie and Ghijsels, 1969; Gattavecchia and Tonelli, 1991; Kramer

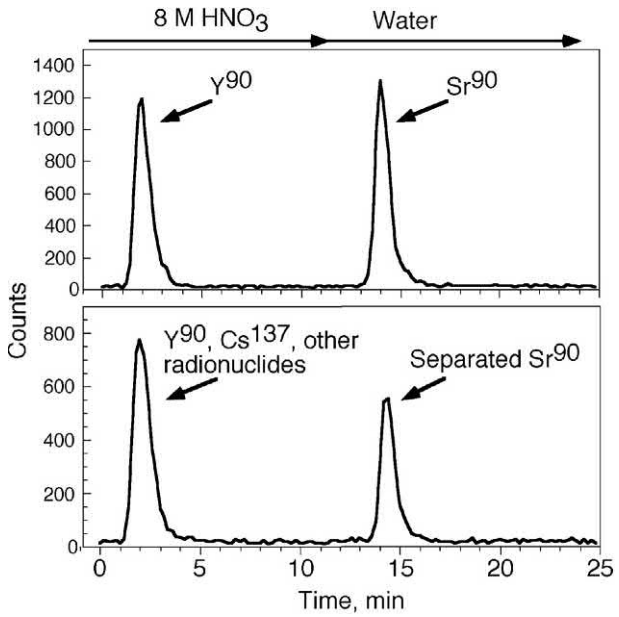

FIGURE 11.9 Detector traces for the separation of a ^{90}Sr and ^{90}Y containing standard in the upper plot and separation of ^{90}Sr from other radioisotopes in a nuclear waste sample. *Reproduced with permission from Grate et al. (1996). Copyright 1996 American Chemical Society.*

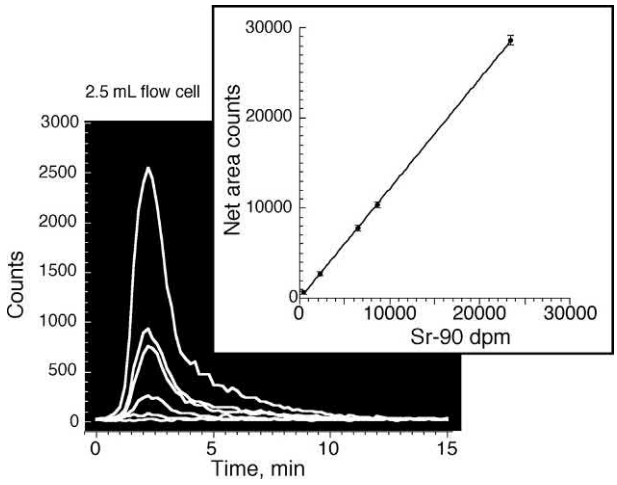

FIGURE 11.10 Quantification of ^{90}Sr illustrating linearly increasing peak areas with increasing standard activity. *Adapted with permission from figures in Grate et al. (1996). Copyright 1996 American Chemical Society.*

and Davies, 1982; Kremliakova et al., 1990; Kuno et al., 1993; Lamb et al., 1989; L'Annunziata, 1971; Noshkin and Mott, 1967; Porter et al., 1967; Smulek and Lada, 1979; Wilken and Joshi, 1991; Wilken and Diehl, 1987; Wood et al., 1993). Currently, extraction chromatography using Sr resin (Eichrom Technologies, Inc., Darien, Illinois) is the preferred separation method (Dietz et al., 1991; Horwitz et al., 1991, 1992a,b).

Detector traces from the automated SI separation of ^{90}Sr, using flow-through liquid scintillation counting, are shown in Fig. 11.9. This analytical separation was first automated using conventional SI methods with stacked zones and subsequently with separation-optimized SI (Grate et al., 1996, 1999a). The sample in 8 M nitric acid (HNO_3) solution is loaded on Sr resin, which contains a crown ether in 1-octanol immobilized on a porous polymer support; the crown ether stationary phase retains Sr from 8 M HNO_3 with a retention volume of $\sim$100 (Horwitz et al., 1991, 1992a,b). Other radionuclides (including the ^{90}Y daughter) and sample matrix components are unretained and are removed by washing the resin with additional 8 M nitric acid. Then, the purified ^{90}Sr is released from the column by eluting with water or weak acid (e.g., 0.05 M nitric acid), where the retention volume is less than one.

The peak area of the eluted ^{90}Sr is used for quantification. Fig. 11.10 shows detector traces for different activity standards and the linear calibration curve obtained from peak areas. The theory of flow-through scintillation detection has been described previously in Chapter 10, Volume 2 of this book. In evaluating the analytical quantification of radionuclides, a number of figures of merit are relevant. The separation or recovery efficiency indicates the fraction of the analyte delivered to the column that is recovered after the separation. The detection efficiency indicates the number of counts observed compared with the number of radioactive decays from the sample in the detector flow cell. These two efficiencies are given as E_{rec} and E_d, respectively, in Chapter 10 and used in Eq. (10.14). The total effective efficiency is the product of the recovery efficiency and the detection efficiency.

The automated separation of ^{90}Sr represents a simple load, wash, and elute procedure for the separation of a species that is present at high activities in nuclear waste samples. The procedure can be implemented either with online detection, as just described, or by delivering the eluted Sr to a fraction collector. Using the separation-optimized SI method, it has been demonstrated that complete separation and analysis can be carried out in just over 20 minutes.

The "multisyringe flow injection" approach has also been used for automating Sr resin column separations (Fajardo et al., 2004), using off-line counting and ICP-OES to determine radioactive and total Sr, respectively. More recently, a number of LOV methods for strontium analyses have been developed and investigated (Beltran et al., 2013; Kolacinska et al., 2017; Mola et al., 2014; Rodriguez et al., 2012). Scintillation counting and ICP-MS have been used in the quantification of ^{90}Sr, whereas combination of ICP-OES and radioactivity counting has been used to determine total Sr and ^{90}Sr in the same samples. Samples have been as diverse as rainwater, nuclear reactor coolant, and water treatment sludge.

For high-throughput applications, especially in analytical laboratories that customarily count purified samples separately from the sample preparation, fraction collection is advantageous. Using column switching techniques so that each column need not be washed between samples, it is possible to process eight samples in just over an hour

(8 minutes per sample; Grate et al., 1999a). These samples can all be set up in advance and separated under computer control without further operator attention. Elimination of column cleanup steps and/or blank runs between sample runs minimizes the amount of time required to complete the separation of the sample set. Afterward, the columns can either be washed for reuse or replaced with fresh columns.

B. Technetium-99

Technetium-99 is a long-lived radioactive isotope that is present in defense-related nuclear wastes, stored spent nuclear fuel, and radioactive waste and process streams associated with spent fuel reprocessing. Due to the high abundance of ^{99}Tc in these wastes, its long radioactive half-life, and the high mobility of technetium in the environment, ^{99}Tc analysis is important throughout nuclear waste characterization and stabilization activities. The determination of ^{99}Tc in environmental samples has been reviewed (Shi et al., 2012a). ^{99}Tc is a pure beta emitter ($\beta_{max} = 294$ keV) with a half-life of 2.11×10^5 years and specific activity of ~630 Bq/μg, decaying to stable ^{99}Ru (Browne and Firestone, 1986). Analytical methods using radioactivity detection (beta counting) require separation of ^{99}Tc from inactive matrix constituents and various interfering radionuclides. Because of the low specific activity of ^{99}Tc, it can be measured by ICP-MS. However, separation is also desirable prior to ICP-MS analysis to avoid isobaric interferences (e.g., stable ^{99}Ru). In one of the earliest examples of automated radiochemical analysis using extraction chromatography, Hollenbach et al. (1994) used a TEVA resin column for online purification and preconcentration of ^{99}Tc prior to ICP-MS determination (Hollenbach et al., 1994). In work on standards and soil digestates, the online separation reduced detection limits tenfold and alleviated matrix and isobaric interferences.

Automated SI separation of ^{99}Tc from a nuclear waste sample is shown in Fig. 11.11 (Egorov et al., 1998b). The separation was carried out using TEVA resin (Eichrom Technologies, Inc.), a porous polymer impregnated with a quaternary amine-based liquid anion exchanger called Aliquat 336 (Horwitz et al., 1995). The sample was loaded on the column and washed with 0.1 M HNO_3, conditions under which Tc is strongly retained on the column and other potentially interfering species are largely unretained. (Inclusion of hydrofluoric acid in the wash solution assures that tetravalent Pu is not retained on the column.) The retained Tc was released from the column using strong nitric acid. The 6 M nitric acid concentration in Fig. 11.11 was selected as a trade-off between higher acid concentrations that provide narrower elution peaks at shorter retention times and lower nitric acid concentrations that cause less scintillation quenching than strong acid.

The Tc isotope is present at low activities in nuclear waste compared with other fission products such as ^{90}Sr, its daughter ^{90}Y, and ^{137}Cs (due to its comparatively lower specific activity). The ^{99}Tc peak is not evident in the full-scale detector trace, which is dominated by the abundant fission products. However, it can be easily seen in the vertically expanded inset. Technetium-99 activity can be quantified from the scintillation counts, and this is most effectively carried out in a stopped-flow mode (Egorov et al., 1998b). The principle of stopped-flow detection was described previously in Chapter 10, Volume 2 (see Eq. 10.38). It is illustrated here in Fig. 11.12 (and in Chapter 10, see Fig. 10.50, where continuous flow and 15 minute stopped-flow detection were compared using a high activity (2.502×10^4 dpm) ^{99}Tc(VII) standard). In stopped-flow

detection, this time position of the peak maximum in a continuous-flow run can be used to stop the flow; then, counting can be carried out for whatever time period is necessary to achieve the desired precision or minimum detectable activity. In the experiment shown in Fig. 11.12, 89% of the eluted technetium zone resided in the 2.5 mL detector flow cell during the stopped-flow interval. The duplicate detector traces for each type of experiment in Fig. 11.12 demonstrated reproducibility; the high precision of the fluidics and reproducibility of the separation process resulted in reliable capture of the eluted zone within the detector flow cell.

The stopped-flow approach facilitates much improved counting statistics, and its advantage is most apparent when counting low-activity standards or samples where the count rate is virtually indistinguishable from the background. For example, 268 dpm ^{99}Tc(VII) standard gave a continuous flow count rate that was statistically indistinguishable from the background. As shown in Fig. 11.13 (and Fig. 10.51 of Chapter 10, Volume 2), signal accumulation for a 15 minute stopped-flow interval allows reliable quantification of a 268 dpm ^{99}Tc(VII) standard, with 8% (3σ) counting error, which could not be detected in a continuous-flow mode.

Using a diverter valve to isolate the sample in the detector during stopped-flow counting allows the remainder of the SI separation system to be used to begin to process the next sample simultaneously. Thus, stopped flow does not necessarily lengthen the total analysis time (Egorov et al., 1998b).

An SI system was used to automate the extraction chromatographic purification of technetium from seawater after preconcentration in a precipitation step, as part of an analytical approach to determine ^{99}Tc by ICP-MS (Shi et al., 2012b). An LOV system using TEVA resin for separation of purified technetium for the determination of ^{99}Tc in water and soil samples using ICP-MS (Rodriguez et al., 2015b). An LOV approach was used to compare TEVA resin and Dowex-1 in the purification of Tc for analysis by ICP-MS. Samples were obtained from reactor coolant and the river surrounding a nuclear reactor (Kolacinska et al., 2017). Another automated system for ^{99}Tc determination in groundwater by ICP-MS was developed using modular components (Chung et al., 2013).

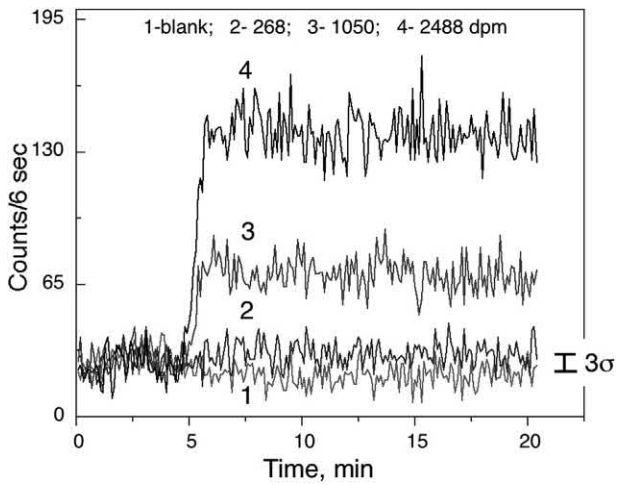

FIGURE 11.13 Selected detector traces from the analysis of ^{99}Tc(VII) standards using 15-minutes stopped-flow detection. The activities of the standards are listed. The error bar corresponds to three standard deviations of the background count rate. *Reproduced with permission from Egorov et al. (1998b). Copyright 1998 American Chemical Society.*

For urine samples from patients who had been dosed with ^{99m}Tc, an LOV system with TEVA resin separation was developed (Villar et al., 2013). This approach used liquid scintillation counting for determination of ^{99}Tc. In a subsequent study, an LOV system used weak base extraction chromatographic (WBEC) resin, and technetium was detected colorimetrically with diphenylcarbohydrazide and a long path-length liquid waveguide cell (Villar et al., 2017).

C. Actinides

Determination of actinides in a variety of sample matrixes is of great importance in the characterization and processing of nuclear wastes, the nuclear industry, safeguards, treaty monitoring for nuclear nonproliferation, and the remediation of radiologically contaminated sites. The analytical determination of plutonium in environmental samples has been reviewed (Qiao et al., 2009a), as have methods for other transuranium elements (Vajda and Kim, 2010, 2011). Both of the conventional detection methods for actinides, alpha spectroscopy and mass spectrometry, require separation of the actinides from the sample matrix and from one another, as discussed in Section II.A. Separation Requirements (Egorov et al., 2001; Grate and Egorov, 1998b; Grate et al., 1999b).

Anion exchange is a long-standing column separation method for actinides. Hirayama et al. (1985) described what may be the first fluidic system for automated analytical separations of the actinides using ion exchange processes. Solutions were delivered to the columns using either air-pressure-driven flow or gravity feed from elevated storage tanks of reagents. Flow control included sensors for drop rate, electric needle valves, and electrostatic capacity sensors to detect the liquid level above the resin bed. The system employed multiple columns for different separations, and the eluted solutions, captured in a fraction collector, could be evaporated and dried with a microwave oven. More recently, Grate et al. (2011) compared fluidic, robotic, and hybrid architectures for the automation of column-based separations. Methods to automate actinide ion exchange were described in detail. A system designed to process six samples using six anion exchange columns set up in parallel, called the PNX (Pacific Northwest

eXtraction) system, was described in detail (shown schematically in Fig. 11.5B). A custom fraction collector was designed to capture the eluents from the six columns.

A number of extraction chromatographic resins can be used to implement a variety of actinide separations. Selected automated radiochemical separations using TRU resin (Eichrom Technologies, Inc., Darien, Illinois), which is a solvent-impregnated resin loaded with the complexant carbamoylmethylenephosphine oxide (CMPO) in tributylphosphate (Horwitz et al., 1990, 1993), are illustrated in Fig. 11.14. The organic stationary phase in this resin strongly binds trivalent, tetravalent, and hexavalent actinides from nitric acid solutions, with retention increasing with aqueous phase acidity. Tetravalent actinides are more strongly retained than trivalent actinides, and trivalent actinides are not retained in hydrochloric acid solutions. This extraction chromatographic material can be used for simple separations of groups of actinides, or more complicated separations whereby individual actinides or small groups of actinides are sequentially eluted. In the latter case, several actinides are retained on the column during the sample load and wash steps. Then, a number of eluent solutions are delivered in sequence, each releasing a selected actinide or group of actinides. Actinides Am and Pu can be separated from each other and from other actinides if the speciation of Pu, i.e., its oxidation or valence state, is controlled throughout the multistep elution process.

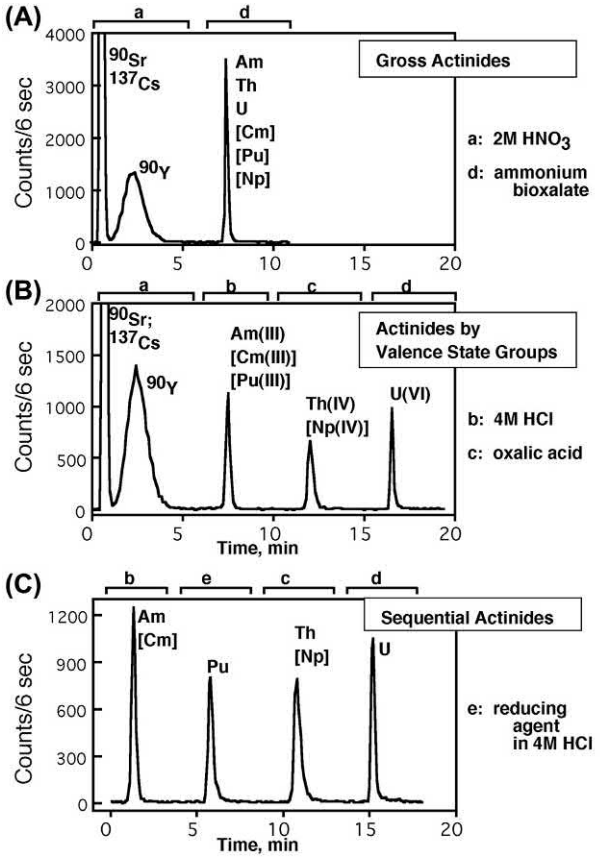

FIGURE 11.14 Three actinide separations performed using automated sequential injection separations with TRU resin extraction chromatographic material. (A) Separation of the actinides as a single group (gross actinides) from fission products and other species in the sample matrix. (B) Separation of the actinides from the fission products and other species in the sample matrix, with selective release from the column material in valence state groups. (C) Sequential elution of the actinides with separation of Pu from Am and the other trivalent f-element species using on-column redox chemistry. The separation of the actinides from the fission products and sample matrix is omitted from this plot. *Adapted with permission from Grate et al. (1999b). Copyright 1999 Royal Society of Chemistry. http://pubs.rsc.org/en/Content/ArticleLanding/1999/AN/a902579k.*

The plot in Fig. 11.14A shows the purification of the actinides as a group. Fission products are unretained (e.g., ^{90}Sr, ^{137}Cs) or slightly retained (e.g., ^{90}Y) and appear during the column wash with 2 M nitric acid (Grate and Egorov, 1998a; Grate et al., 1999b). Ammonium hydrogen oxalate (bioxalate) solution releases the actinides from the column.

The second plot, Fig. 11.14B, shows the release of captured actinides in groups of the same oxidation (or valence) state. First the trivalent actinides are selectively released with 4 M hydrochloric acid. Then, an oxalic acid solution is used to selectively release tetravalent actinides. Finally, an ammonium bioxalate solution releases the remaining hexavalent actinides (Grate and Egorov, 1998a; Grate et al., 1999b). This type of separation requires that the actinides be in well-defined valence states, so samples are pretreated off-line to adjust the redox states (e.g., Pu(IV) to Pu(III)).

The final plot, Fig. 11.14C, illustrates a sequential actinide separation. This separation is based on the valence state separation in the second figure, but it uses additional steps to separate Pu from Am and the other trivalent f-elements. This is achieved by converting Pu to the tetravalent state prior to eluting the trivalent species. Then, the tetravalent Pu that remains captured on the column is reduced to trivalent Pu and released. The remaining tetravalents and hexavalent species are then eluted as before (Grate and Egorov, 1998a; Grate et al., 1999b).

These actinide separations demonstrate that sequential injection separations can be extended from simple "load, wash, and elute" separations to multicomponent separations. In addition, the separation of Pu from Am demonstrates the use of on-column redox chemistries for selective elution of Pu, where the column serves as both a reactor and separator.

The detector traces in the figures were obtained by flow-through liquid scintillation counting. For trace detection applications, the eluted species from the automated radiochemical separations have been delivered to a fraction collector and quantified by off-line alpha spectrometry (Grate et al., 1999b). In addition, eluted actinides can be delivered to an ICP-MS instrument, either as fractions for analysis or as an online front end (Egorov et al., 2001).

Indeed, automated extraction chromatographic separations of actinides are largely directed to analysis by ICP-MS, and have been reviewed in detail elsewhere (Grate et al., 2010; Kim et al., 2007; Lariviere et al., 2006). As noted above, radiochemical separations are required for a number of reasons for ICP-MS detection, and this detection method provides separate detection traces for isotopes with different mass-to-charge ratios. The combination of automated separation with ICP-MS is shown schematically in Fig. 11.15. This diagram shows how the main fluid handling system can be maintained in a "cold" zone, whereas the sample injection valve, separation column, and ICP-MS instrument can be placed in a hot zone. Detector traces for the separation of several actinides are shown in Fig. 11.16 (Egorov et al., 2001). This separation procedure addresses a number of interferences (e.g., isobaric and molecular interferences) in the actinide analysis noted previously. This separation methodology was used to enable isotope specific determination of actinide species in dissolved vitrified waste sample matrixes.

The use of ICP-MS detection in conjunction with continuous-forward-flow FI to automate extraction chromatographic radionuclide separations was first described in papers by Hollenbach and Aldstadt. Hollenbach et al. (1994) described the automation of extraction chromatographic methods to separate and preconcentrate Tc, Th, and U from soil samples. Aldstadt et al. (1996) described the use of FI and extraction chromatography to analyze U in environmental samples. In both cases, the use of an online separation system resulted in improved ICP-MS detection limits relative to direct sample introduction.

TRU resin separations have since been automated for ICP-MS analyses by several authors and laboratories (Benkhedda et al., 2005a; Egorov et al., 2001; Epov et al., 2005a,b; Hang et al., 2004; Peterson et al., 2007; Truscott et al., 1999, 2001; Unsworth et al., 2001). In addition, two other extraction chromatographic resins have been used in automated actinide separations prior to ICP-MS measurement. UTEVA resin (Horwitz et al., 1992c), which is loaded with the extractant dipentyl pentylphosphonate (also known as diamyl amylphosphonate), has been used for uranium and plutonium determinations (Godoy et al., 2006; Hang et al., 2004; Kang et al., 2001; Kuwabara et al., 2002; Ohtsuka et al., 2005, 2006; Perna et al., 2001; Tolmachyov et al., 2004). TEVA resin, described above with reference to pertechnetate separations, is also used to isolate tetravalent actinides and has been used in automated systems for Pu determination by ICP-MS (Epov et al., 2007; Kim and Kim, 2002; Kim et al., 2000a, 2004; Lariviere et al., 2008a).

A number of automated actinide separations have been reviewed in more detail elsewhere, with tables providing comments on each paper's approaches (Grate et al., 2010). A fully automated flow system with three columns in sequence (TEVA, UTEVA, and DGA) and online ICP-MS detection was developed for determining long-lived actinides captured in air filters (Lariviere et al., 2010). In recent work, a protocol was developed for automated extraction chromatographic separations with Sr resin, TEVA resin, and TRU resin coupled to an online ICP-MS. This work was directed at actinide isotopes and strontium in solid samples, after a sample matrix breakdown using a fusion process (Habibi et al., 2017). Several recent papers have advanced the state of the art in applying SI methods to automate extraction chromatographic and anion exchange column separations for the determinations of plutonium and other actinides (Qiao and Hou, 2010; Qiao et al., 2009a,b, 2010, 2011a,b,c, 2013a,b,c,d).

D. Renewable separation column applications

The renewable separation column (RSC) approach offers a number of advantages in separation methods where the life of the separation column is limited or tedious regeneration steps are necessary prior to column reuse. These have been demonstrated for ^{90}Sr analysis using Sr resin, ^{99}Tc separation using TEVA resin, and Am separation using TRU resin (Egorov et al., 1999a).

For example, the recovery of the retained ^{90}Sr from the column upon release with water or dilute acid is typically 95%, with 3%–4% of the original sample eluting in a subsequent blank run if no additional column wash steps are used. This carryover is associated with the Sr resin extraction chromatographic material. Instead of washing the column after each analysis, the separation material can be automatically renewed. This eliminates the observed carryover, and it is then reasonable to analyze blanks or low-activity standards after high-activity samples (Egorov et al., 1999a).

When analyzing Am using TRU resin to separate it from fission products and other actinides, there are several actinides retained on the column after Am elution. If the column is to be reused, these must all be removed from the column (e.g., using a chelating agent such as ammonium bioxalate). However, using the renewable separation column technique, the column bed can simply be disposed of after Am elution and replaced with new column material for the next sample (Egorov et al., 1999a).

In the ^{99}Tc analysis, the renewable column technique offers an alternative analytical approach. After capturing Tc on TEVA resin and washing away interferences, one manual method for Tc analysis involves placement of the Tc-containing resin in a vial and adding cocktail for liquid scintillation counting. Thus, the Tc-loaded resin is counted directly. The SI-RSC method can perform the separation and deliver the resin material to a liquid scintillation vial automatically (Egorov et al., 1999a).

Since the early demonstrations of renewable separation column techniques for radiochemical analysis methods, the LOV technology has provided a platform for a variety of automated radionuclide separations, including ^{90}Sr, ^{99}Tc, ^{226}Ra, and actinides (Avivar et al., 2011, 2012; Beltran et al., 2013; Kolacinska et al., 2017; Mola et al., 2014; Qiao et al., 2013c; Rodriguez et al., 2012, 2015b, 2016b; Villar et al., 2013, 2017). Recently, a commercial off-the-shelf (COTS) system was developed for processing materials for the analysis of U and Pu isotopes in IAEA-related samples, so that carryover from sample to sample could not occur through repeated use of the same resin columns in an automated system (Metzger et al., 2018).

Finally, the SI-RSC technique enables a new type of automated radiochemical analysis instrument. It enables an "open architecture" where one instrument design can be used for various radiochemical separations simply by using the software to choose which separation material is loaded into the column and which solutions are selected for the washing and elution steps. A proof-of-principle demonstration for this approach has been described (Egorov et al., 1999a). Thus, this instrument could perform a series of separations of successive aliquots of one sample, or different analyses on each sample, as required.

V. Automation using robotics

Laboratory robotics represents an important aspect of automation in the analytical laboratory. Modern robotic instrumentation can be used to automate a range of routine analytical operations that may be encountered in wet radiochemical analyses, from sample preparation to separations. Some typical examples include sample labeling, bar-code reading, weighing, dissolution, liquid–liquid and solid-phase extraction, serial dilutions, filtration, and sample delivery to instrumentation (Hurst, 1995). Robotic operations are typically carried out using either a robotic arm, which represents an anthropomorphic approach, or an x–y–z Cartesian system such as a liquid handler. These systems move tools, apparatus, and liquids from place to place. Cartesian systems may include a fluidic subsystem to deliver liquids to a dispensing tip that can move to specific locations on the deck containing multiwell plates or solid phase extraction columns.

In the first edition of this Handbook, Beugelsdijk and Hollen (1998) described a fully automated system for dissolution of Pu metal based on the Zymate II (Zymark Corporation) laboratory robot. The robotic system was set up to perform dissolution of 2–5 g samples of Pu metal. The operational steps included verification of the sample identity through readout of the barcode label, weighing the sample on an analytical balance, transferring the sample to the dissolution vessel, and sample dissolution. After dissolution, the individual sample aliquots were prepared, weighed, labeled, and sorted for subsequent analysis.

Zahradnik and Swietly (1996) described a Zymark robotic system for preparation and chemical treatment of diluted spent nuclear fuel samples. The robotic system executed initial sample preparation steps, such as batching, weighing, aliquoting, and spiking with tracers. Following automated preparation of the sample batch, the robot executed separation steps designed to separate U and Pu from the highly radioactive spent nuclear fuel matrix. Initial chemical treatment steps included drying and redissolution of the sample to remove volatile fission products such as ^{106}Ru. Following Pu valence state adjustment, an extraction chromatographic separation using immobilized tri-n-octylphosphine oxide (TOPO) was carried out to separate fission products and to collect U and Pu fractions for subsequent

analysis using alpha spectroscopy and isotope dilution mass spectrometry.

Focusing on the separation of Pu from U, Ziegler and Mayer (1999) performed detailed investigations on the TOPO-based extraction chromatographic material, demonstrating that reduction with ascorbic acid in formic acid was an efficient method to rapidly strip Pu from the column. This separation was designed to be implemented by a Zymark XP robot in a glove box. The possibility of direct filament loading of the purified sample for thermal ionization mass spectrometry (TIMS) was discussed. UTEVA resin has also been described for robotic separations of actinides in a glove box without using corrosive reagents (Apostolidis et al., 1998; Morgenstern et al., 2002; Richer et al., 1998). The separation technique was developed to allow columns to run dry between steps, a condition that might occur in an unattended gravity-feed open-column process. Recovered fractions were suitable for TIMS source preparation without further purification or treatment.

Grate et al. (2011) described the adaptation of a robotic liquid handling system designed to perform column-based radiochemical separations. This system is shown in Fig. 11.17. A customized four-probe head was used to transfer samples from sample vials to the columns using disposable tips, deliver clean acid eluents to the columns, apply air pressure to the top of each column, and move the slider on the rack that positions columns over fraction collection vials. While proof of principle for programming and performing the steps of actinide anion exchange was demonstrated, the authors found that transporting liquid eluents from reservoirs on the deck to columns in racks on the deck, by aspirating them into a holding coil, translating the probe head, and delivering them to a column, was a slow process. The paper describing this system compared fluidic, robotic, and hybrid approaches (Grate et al., 2011).

Robotics represents a potentially attractive approach for the automation of sample preparation and separation steps in laboratory-based radiochemical analysis. Robotic methods have been routinely used by laboratories serving the analytical needs of the IAEA for many years (Brandalise et al., 1994; Deron et al., 1994; Midorikawa et al., 2007; Richer et al., 1998; Surugaya et al., 2007; Takahashi et al., 1994). However, the maintenance of robotic equipment that is isolated in radiological containment systems such as glove boxes can present ongoing challenges.

Finally, hybrid approaches combining fluidic columns separations and robotic fraction collection have been developed. Various approaches were critically compared, and the PNX system shown in this chapter in Fig. 11.5B was described. This system used the fluidic column switching approach with a mechanized fraction collector designed with two aims in mind. First, the collector was designed to effectively isolate the outputs of six parallel columns from one another so there could be no possibility of cross-contamination between purified samples. Second, it was designed to maximize performance reliability by restricting the possible motions to forward and back (to change the collection vial underneath each column), and up and down (to raise the collection vial around the tip of the column outlet). The PNX system shown in Fig. 11.5B, after proof of concept, was changed to a system with dedicated pumps for each of six columns as the reagent delivery system, to obtain more rapid parallel column separations. The overall diagram for this system is in Fig. 11.18.

VI. Automated monitors for industrial scale nuclear processes

The majority of work in automated radiochemical analysis has been directed to *laboratory-based* analyses, where the

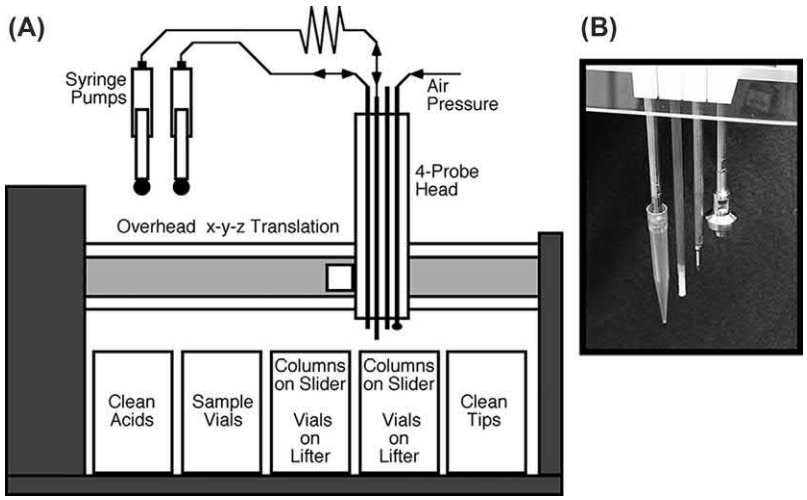

FIGURE 11.17 (A) Schematic diagram of the key components and layout of the Gilson liquid handling robot customized to perform anion exchange column separations. The diagram does not show the tip disposal chute, the air pressure cleaning probe station, or the liquid probe(s) cleaning station. Components are not to scale. FIGURE 11.18 (A) Schematic diagram of version II of the PNX system for automated column separations, combining fluidic column separation with a custom-designed mechanized fraction collector. (B) The custom fraction collector built for six parallel columns and up to five fractions per column. For the color version of the figure, the reader is referred to the online version of the book.

radiochemical separation is automated, and perhaps linked to an online detector. A more challenging objective is to perform rapid radiochemical measurements online/at-line. This task is especially challenging for the determination of non−gamma-emitting radionuclides that typically cannot be measured using remote nondestructive methods. The overall process of sampling and laboratory analysis is generally too time-consuming to provide adequate feedback for continuous process control (e.g., by off-line analysis of a liquid sample sent to a centralized laboratory for ICP-MS or classical wet radiochemical analysis). Moreover, process scale analytical applications present challenges due to the complexity of the process sample streams in industrial-scale nuclear facilities.

There are needs for process analysis at industrial-scale nuclear plants for the reprocessing or treatment of spent fuel and nuclear waste. In reprocessing, monitors could both improve operation of the plant by providing feedback and potentially support safeguards (O'Hara et al., 2008a,b, 2009). In nuclear waste processing, monitors are needed to determine specific radionuclides before and after a separation process that removes that radionuclide from the waste stream (Egorov et al., 2005a). Such analyzers can assess the effectiveness of the radionuclide separation column and can be used to indicate if the output stream will qualify for subsequent conversion to stable waste forms.

For example, in the United States, chemical processing of low activity waste (LAW) prior to vitrification at the Hanford site requires working with streams that are caustic brine matrixes with complex and varying chemical and radiological composition. The total base content, the concentration of organics, and the complexant concentrations all depend on the source of the feed, as do the aluminum, nitrate, nitrite, dichromate, and radionuclide contents.

Consider an online/at-line analytical method to detect ^{99}Tc in the effluent from a technetium removal separation column. In waste matrixes with high organic content, a substantial amount of the total ^{99}Tc is present in the reduced, nonpertechnetate form of unknown chemical composition. Thus, varying sources of feed material result in varying speciation of Tc. The commonly employed analytical separation chemistries for ^{99}Tc, such as those described above, are effective only for Tc in the pertechnetate form. Therefore, to enable total ^{99}Tc analysis via radiochemical measurement, oxidation chemistries and procedures are required to convert all Tc species to pertechnetate (TcO_4^-). Thus, radiochemical analysis of ^{99}Tc entails sample matrix modification (e.g., acidification), analyte oxidation, chemical separation (e.g., using ion exchange or solvent extraction), and radiometric analysis (e.g., scintillation or gas proportional counting).

A fluidic radiochemical analyzer system has been developed to perform all these functions in a fully automated fashion for the rapid analysis of total ^{99}Tc in aged LAW streams (Egorov and O'Hara, 2003; Egorov et al., 2004a,b, 2005a, 2012; Grate et al., 2004, 2010; O'Hara et al., 2008a,b, 2009c). The automated radiochemical analyzer executes fluid handling steps required to perform acidification of the caustic sample, microwave-assisted sample oxidation using peroxydisulfate (Egorov et al., 2004a), separation of ^{99}Tc(VII) from radioactive interferences using an anion exchange column, and delivery of the separated pertechnetate to a flow-through scintillation detector. A schematic diagram of the automated Tc measurement process is shown in Fig. 11.19. A photograph of the prototypical analyzer unit is shown in Fig. 11.20. A full schematic flow diagram is provided in Fig. 11.21. The instrument design incorporates advanced digital fluid handling techniques using several zero dead volume syringe pumps, multiple valves for sample and reagent delivery, a two-position valve for flow reversal through the column (see Fig. 11.4A), and a diverter valve immediately upstream of the detector.

The sample treatment protocol begins with the sample acidification followed by a first digestion (heating) step

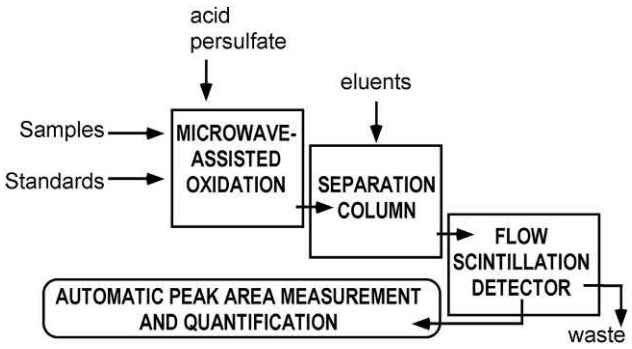

FIGURE 11.19 Schematic diagram illustrating sample processing, separation, and detection for an online analyzer for the continuous monitoring of the total Tc content of nuclear waste process streams.

within an open microwave vessel (Egorov et al., 2004a). This initial treatment ensures removal of the nitrites, which are expected to interfere with the subsequent oxidation. In addition, initial heating promotes rapid dissolution of the $Al(OH)_3$ precipitate that forms during acidification of the caustic LAW matrix. The nitric acid concentration and volume are selected to ensure complete dissolution of the $Al(OH)_3$ species upon heating, while maintaining relatively high pertechnetate uptake values on the anion exchange sorbent material during sample loading. The initial sample acidification procedure is followed by a second microwave-based digestion treatment using sodium peroxydisulfate oxidizing reagent. This oxidative treatment of the acidified sample ensures conversion of the reduced and organometallic Tc species to pertechnetate.

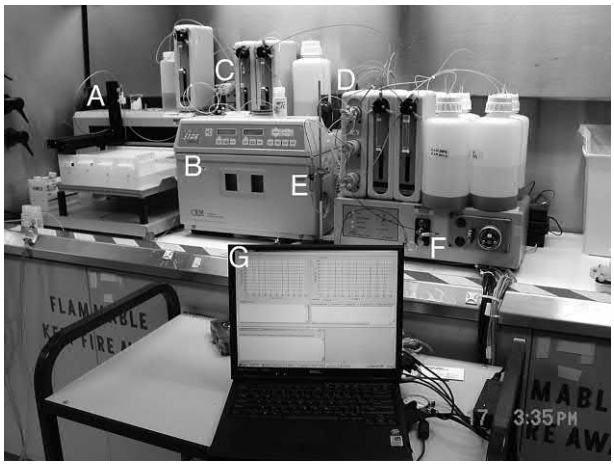

FIGURE 11.20 Photograph of the fully automated total ^{99}Tc analyzer instrument. (A) Robotic autosampler; (B) microwave digestion unit, (C) fluid handling components for sample injection, automated standard addition, sample acidification/analyte oxidation; (D) separation fluidics including syringe pumps, flow reversal, and diversion valves; (E) separation column; (F) flow scintillation detector; (G) computer with fluid control and data analysis software.

Pertechnetate separation is accomplished using a macroreticular strongly basic anion exchange resin (Egorov et al., 2005a, 2012). Compared with a similar extraction chromatographic chemistry using TEVA resin (described above), the solid-phase anion exchange material offers much longer column life. However, the pertechnetate elution kinetics of the extraction chromatographic material

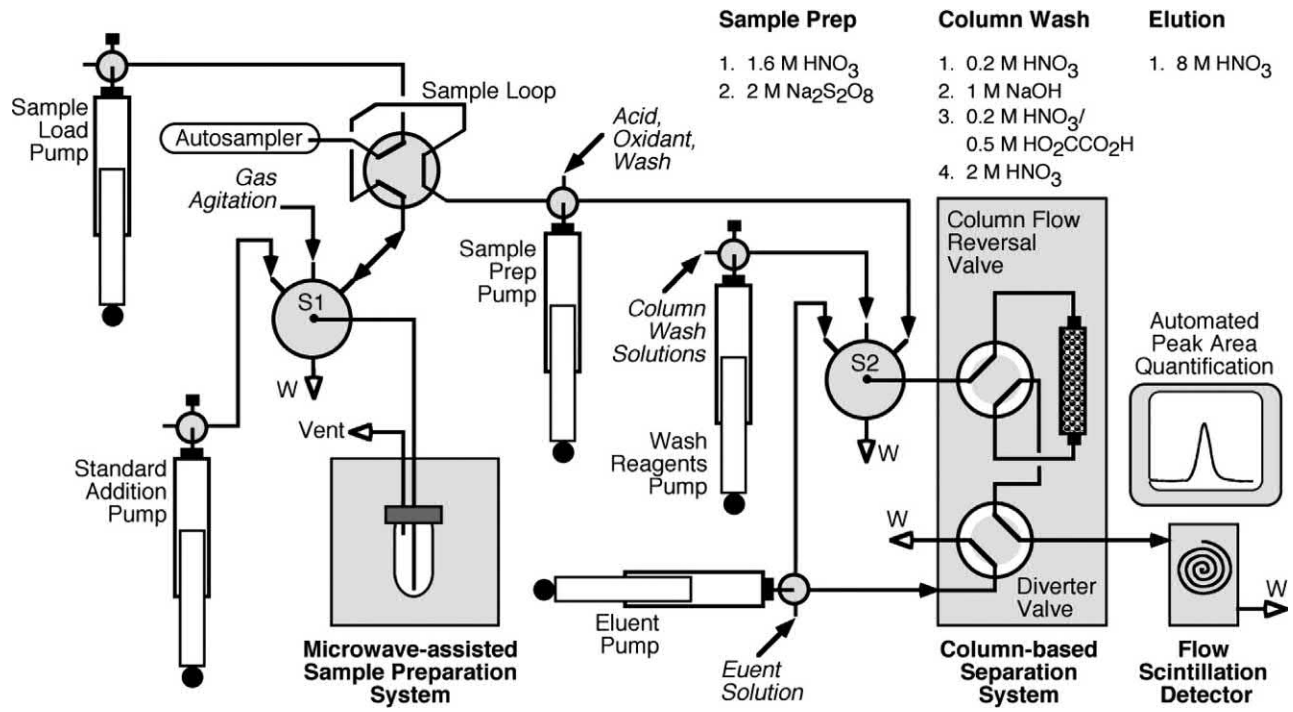

FIGURE 11.21 Schematic diagram of the fully automated total ^{99}Tc analyzer instrument. This system integrates several fluidic functions and approaches described in this chapter. *Adapted with permission from Egorov et al. (2012). Copyright 2012 American Chemical Society.*

are superior to those of the solid-phase anion exchange material. Nevertheless, rapid pertechnetate elution from the anion exchange material is possible when the eluent flow direction through the column is reversed (e.g., as shown in Fig. 11.4). The separation selectivity using anion exchange is adequate for the analysis of aged LAW sample matrixes and provides reliable separation of pertechnetate from the major radioactive constituents ($^{90}Sr/^{90}Y$, ^{137}Cs) and the minor constituents (e.g., radioisotopes of Sn, Sb, and Ru). However, a combination of column washes using dilute nitric acid, nitric−oxalic acid, sodium hydroxide, and moderately concentrated nitric acid is necessary for reliable isolation of pertechnetate from anionic species such as Sn, Sb, and Ru (Egorov et al., 2012).

The purified pertechnetate eluted from the column was detected and quantified with a flow-through scintillation detector packed with a lithium glass solid scintillator. This scintillator material exhibited excellent stability in strong nitric acid solutions used for final pertechnetate elution. The disadvantages of liquid scintillation detection (using scintillation cocktail) in this application would include increased waste generation associated with the cocktail and sporadic chemiluminescence signals in the presence of oxidants (e.g., Cr(VI)) and strong nitric acid. No chemiluminescence was evident when lithium glass solid scintillator cells were used for online quantification of ^{99}Tc in matrixes with high concentrations of Cr(VI) and nitric acid.

To obtain reliable ^{99}Tc quantification in varying sample matrixes, an automated standard addition technique was implemented as a part of the analytical protocol. The standard addition approach is based on the introduction of a ^{99}Tc standard solution during the sample acidification step in a duplicate analysis of a sample previously analyzed without standard addition. The ^{99}Tc standard is in a nitric acid solution with the same acid concentration used for sample acidification. The total effective efficiency (product of the ^{99}Tc recovery efficiency and the detection efficiency) is calculated based on the difference in analytical response obtained for the analysis of the spiked and unspiked samples. This approach provides a reliable method for matrix matched ^{99}Tc monitor instrument calibration.

The ^{99}Tc monitor instrument was fully automated for continuous operation with the control software performing asynchronous device control and detector data acquisition/processing, including peak search and integration as well as the instrument calibration via standard addition. Total analysis time was 12.5 minutes per sample, and the total analysis time for the standard addition measurement was 22 minutes (including analysis of both sample and spiked sample). In tests against various LAW samples from the US DOE Hanford site, including those with high organic content, the total Tc was accurately quantified as verified by independent sample analysis using ICP-MS. Fig. 11.22 compares results for total ^{99}Tc analysis of high organic content LAW samples using ICP-MS and the automated radiochemical ^{99}Tc analyzer.

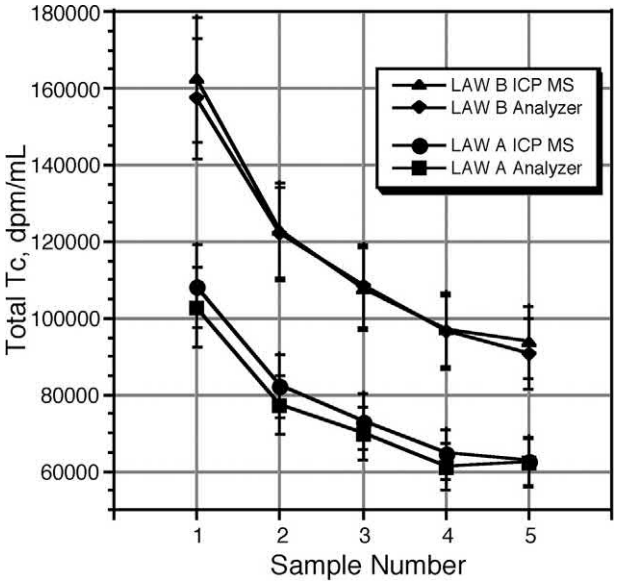

FIGURE 11.22 Total ^{99}Tc analysis in LAW matrixes with high organic content, comparing ICP-MS and automated radiochemical analyzer instrument results. Samples contain up to 60% of Tc in nonpertechnetate species. Error bars are ±10%. ICP-MS, inductively coupled plasma mass spectrometry.

VII. Radionuclide sensors and systems for water monitoring

A. Preconcentrating minicolumn sensors

The automated radiochemical separations described above entail detection of radionuclides after they have left the separation column. If the radionuclides captured on the column could be detected in place, the column would become a sensor. This approach has been successfully demonstrated using dual-functionality separation columns as preconcentrating minicolumn sensors (DeVol et al., 2000, 2001a,b; Egorov et al., 1999b, 2004b, 2005b, 2006; Grate et al., 2004; O'Hara et al., 2009a; Roane and DeVol, 2002). These columns perform both selective capture of radionuclides and transduction of the decay events of captured radionuclides into a measurable signal. The latter function is achieved by incorporating scintillating materials into the column. Light output is measured by PMTs placed around the transparent dual functionality column. The preconcentrating minicolumn sensor concept is shown in Fig. 11.23. Radionuclide sensors based on this concept were comprehensively reviewed by Grate et al. (2008).

Two approaches have been developed to achieve dual functionality in the columns. In one approach, the solid-

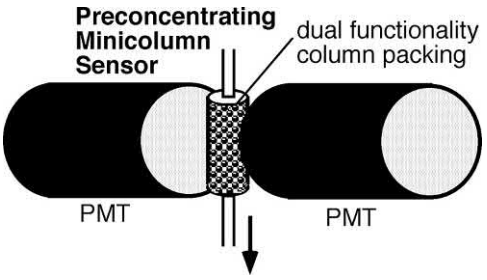

FIGURE 11.23 Schematic diagram of the preconcentrating minicolumn sensor concept, where the transparent column body is placed between two photomultiplier tubes (PMTs), counting in coincidence, for light collection. The packing material in the column body contains both selective separation media and scintillating materials to generate a luminescent output. The packing material may be delivered using renewable separation column methods.

phase extracting media are prepared to be scintillating by combining scintillating fluors with the separation chemistry in individual particles. These particles then represent "selective scintillating microspheres" (SSMs) (Egorov et al., 1999b). The alternative approach is to intimately mix scintillating particles with chemically selective particles to obtain both functionalities in the same column. If so desired, renewable separation column techniques can be used to deliver or renew the sensing material or mixture.

This sensing concept is designed to meet the challenging requirements for the direct measurement of alpha- and beta-emitting radionuclides in water. These radionuclides emit particles with short penetration ranges in condensed media and must be measureable within low analytical detection limits. The close proximity of selective chemistries and scintillating materials in particles (on the order of 10−250 microns in diameter) enables radiometric detection of alpha or beta emissions from the captured radionuclides. Because of the relatively long range of the beta particles, this approach appears to be particularly suitable for detection of beta emitters such as ^{99}Tc and ^{90}Sr. The maximum ranges in water for beta particles emitted by ^{90}Y ($E_{max} = 2282$ keV), ^{90}Sr ($E_{max} = 546$ keV), and ^{99}Tc ($E_{max} = 294$ keV) are 1.1 cm, 1.8 mm, and 750 μm, respectively. The average range of the beta particles from ^{99}Tc is ∼130 μm in water, which is comparable with the diameters of sorbent or scintillating beads used in the sensing columns.

In this sensing approach, the packed column format provides efficient fluidic processing of the sample for preconcentration. The selectivity is determined mainly by the separation chemistry used to preferentially capture and preconcentrate the analyte of interest, which localizes the radionuclides in the observed volume of a scintillating detection apparatus. For the analysis of important radionuclide contaminants such as ^{99}Tc, radiometric detection can offer much lower detection limits than those possible by chemical sensing approaches. Thus, this configuration meets all the functional requirements for effective radionuclide sensing.

B. Sensors for ^{99}Tc(VII) using quantitative capture

A radionuclide sensor for ^{99}Tc measurement in groundwater has been reported using SSMs as the column packing material (DeVol et al., 2001b; Egorov et al., 1999b). The SSMs were prepared by impregnating porous acrylic ester beads with a mixture of Aliquat 336 (a liquid anion exchanger based on long-chain quaternary ammonium ions) and scintillating fluors. The pertechnetate uptake characteristics of this material were characterized and found to be as expected for pertechnetate uptake by Aliquat 336 (i.e., high uptake at low-acid neutral pH range). The pulse height spectra of ^{99}Tc beta decay signal obtained using the SSM indicated a detection efficiency of 56%, which is sufficiently high for practical analytical applications. Similar uptake and luminosity (absolute detection efficiency, 30%−50%) characteristics were observed for Aliquat-336-based sensor materials prepared by diffusing scintillator fluors into the bead matrix or by incorporating scintillator fluors into the bead during the polymerization process.

Sensing properties were characterized with both ^{99}Tc(VII) standards (see Fig. 11.24A) and spiked Hanford site groundwater samples (Egorov et al., 1999b). Injection of an aliquot of ^{99}Tc standard in dilute acid results in analyte capture and measurable scintillation light output. In this example, the analyte capture was quantitative, and the signal persists as the sensor column is washed with dilute acid. The absolute detection efficiency for the ^{99}Tc was 45%. Integration of the light output provides a quantitative measure of the ^{99}Tc in the sample. Because the sensor material exhibits high binding affinity toward Tc(VII), large sample volumes can be concentrated using a small sensor column.

On the other hand, injection of a radioactive species that does not exhibit affinity to the sensor material results in only a transient peak signal, as shown for ^{137}Cs in Fig. 11.24A. Interfering species are promptly removed from the system using a small volume of wash solution. In this manner, the sensing method is selective toward the target analyte.

Analytes can be quantified from either the slope of the uptake signal or from the steady-state signal after washing to remove interferences. Detector traces for several standards are shown in Fig. 11.24B (Egorov et al., 1999b). This type of sensor has been successfully demonstrated using actual contaminated groundwater samples from the Hanford site and the standard addition method for quantification. Analytical results were in close agreement with the results of standard radiochemical measurements. Detection

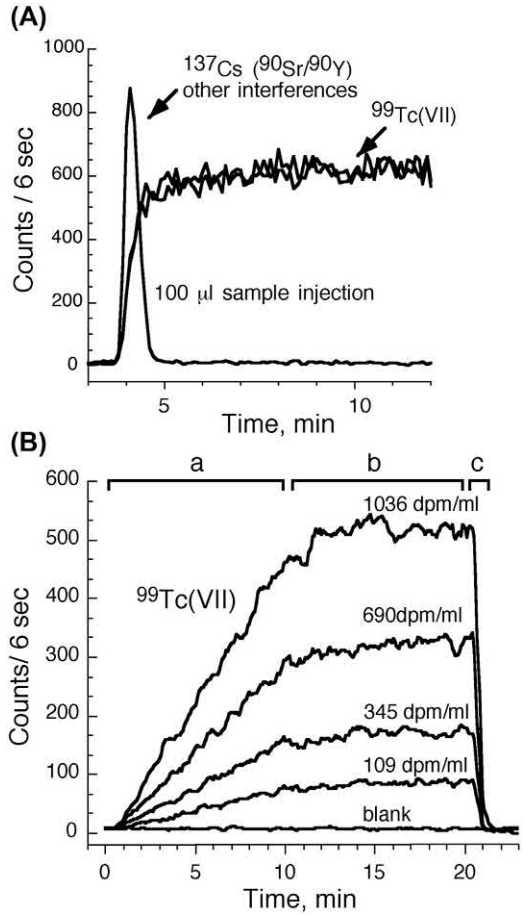

FIGURE 11.24 (A) Sensor response to injected aliquots of ^{99}Tc(VII) analyte and potentially interfering species (^{137}Cs) unretained by the sensor material. Following the analyte injection, the sensor bed is washed with 10 mL of 0.02 M nitric acid, and static counting ensues. (B) Detector traces for the capture and quantification of ^{99}Tc(VII) from 10 mL standard solution volumes, followed by column wash with 10 mL of 0.02 M nitric acid, and finally ejection of the column bed material. *Reproduced with permission from Egorov et al. (1999b). Copyright 1999 American Chemical Society.*

limits were well below the regulatory drinking water standard.

The preconcentrating minicolumn sensor concept has also been demonstrated using mixed beds to obtain the required dual functionality of preconcentration and beta decay signal transduction (Grate et al., 2004). Nonporous plastic scintillator beads (BC400, particle size 100−250 µm) were mixed with the strongly basic anion exchange material AGMP1 (particle size 20−50 µm) in a 20:1 weight ratio. The anion exchange beads provide selective pertechnetate uptake with a very high uptake affinity. As a result, the sensor could be prepared with a total bead volume of only 50 µL. The absolute detection efficiency of the composite sensor column was 34%, and analyte recovery (loading efficiency) was 97%. The ^{99}Tc(VII) selective composite bed sensor can be regenerated using a small volume of 2 M nitric acid solution, resulting in rapid elution of the retained analyte without the loss of the scintillation properties.

This ^{99}Tc(VII) sensing method was tested using unacidified Hanford groundwater samples. Approximately 60 mL of the groundwater sample can be preconcentrated without analyte breakthrough using this sensor, and these experiments showed that radionuclide sensing could be successful on chemically untreated groundwater samples.

Using a mixture of separate solid-phase extraction beads and nonporous plastic scintillator beads is advantageous in two ways. The nonporous scintillating beads were found to have much higher chemical stability in sensing and regeneration solutions than extraction chromatographic materials impregnated with scintillating fluors. In addition, this approach facilitates the use of solid-phase extraction materials for radionuclide uptake that are not readily impregnated with scintillating fluors.

Several recent papers have expanded on the development of stable dual-functionality materials and columns and introduced deliberate synthetic steps to covalently bind fluorophores into the polymer, or to chemically modify polymers with functionality for radionuclide uptake, or both (Bliznyuk et al., 2015, 2018; Duval et al., 2016a,b,c; Grogan and DeVol, 2011; Seliman et al., 2011, 2015, 2017). A sensing material for ^{99}Tc(VII) sensing was developed by diffusing 2-(1-naphthyl)-5-phenyloxazole (NPO) into (chloromethyl)polystyrene beads and then covalently grafting polymer chains onto the surface (Seliman et al., 2011). These grafted chains of poly[[2-(methacryloyloxy)ethyl]-trimethylammonium chloride] provided anion exchange sites for pertechnetate capture. The NPO dye has also been modified for covalent bonding into the polymer matrix to prevent leaching and create a more stable detection material (Duval et al., 2016a,b,c; Seliman et al., 2015). Responses to ^{99}Tc were demonstrated (Seliman et al., 2015).

Although the examples above focus on ^{99}Tc(VII) sensing, these analytical concepts have also been used to develop sensors for ^{90}Sr, radioiodine, and actinides (Bliznyuk et al., 2018; DeVol et al., 2000, 2001a,b; Duval et al., 2016a,c; Egorov et al., 1999b; Grogan and DeVol, 2011; Roane and DeVol, 2002; Seliman et al., 2017). In particularly elegant synthetic work, solid-phase extraction material SuperLig 620, which is selective for ^{90}Sr, has been covalently modified on the surface, sometimes in multiple steps, to add scintillation properties (Bliznyuk et al., 2018; Seliman et al., 2017). In one of the penultimate architectures to date, SuperLig particle surfaces, first modified to have pendant epoxy groups, are reacted with halloysite clay nanotubes that have been modified to have amine-terminated surface groups (Bliznyuk et al., 2018). These attach covalently, and then polyvinyltoluene brushes

containing covalently bound fluorophore are grown from the nanotube surfaces. This approach coats the selective SuperLig material with scintillating material in close proximity, and it does not impede access of the analyte to the selective SuperLig binding sites. "The two structural components of the system can be tailored independently" (Bliznyuk et al., 2018).

C. Equilibration-based radionuclide sensors

As originally conceived, these sensors were based on the concept of quantitative capture of the radionuclides of interest on the preconcentrating minicolumn, with either fluidic renewal via reagents or automated renewal of the solid-phase sensing material using renewable separation column techniques. However, a new approach has been developed based on the concept of equilibrating the preconcentrating minicolumn with ambient radionuclide concentrations (Egorov et al., 2002a,b, 2005b, 2006; O'Hara et al., 2009a). In this scenario, the sample is delivered to the sensor column until complete breakthrough has occurred and the entire column reaches dynamic equilibrium with the sample solution. Under these breakthrough conditions, no further analyte preconcentration occurs on the column and analyte concentration in the sample solution before and after the sensor column are equal. This principle of equilibration-based sensing is shown in Fig. 11.25, where the lower plot shows breakthrough from the column based on fraction collection after the sensor column, whereas the upper plot shows the capture and equilibration of the radionuclide on the column, as measured by the sensor's scintillation response. Chromatographic theory indicates that under these dynamic equilibrium conditions, analyte concentration on the sensor column is proportional to the analyte concentration in the sample used for equilibration. Fig. 11.26 illustrates sensor column equilibration to several samples of varying activity and a linear calibration curve of the steady-state signals from each sample (inset). Under these conditions, the sensor column does not require regeneration or renewal, since the signal will go down upon equilibration with a new sample of lower concentration or up in response to a sample of greater concentration (O'Hara et al., 2009a). The equilibration approach forms the basis for the reagentless radionuclide selective sensing that is particularly well suited for the development of sensor monitors or probes for at-site or in situ monitoring.

Analyte activity, A, on the sensor after equilibration can be calculated using the following formula:

$$A = DV_sC_l$$

where D is the volume/volume distribution coefficient of the sorbent material, V_s is volume of the stationary sorbent phase in the sensor column, and C_l is analyte activity in the sample used for sensor equilibration. In addition, the dynamic response of the sensor as it is equilibrating with the sample can be modeled using concepts and functions from frontal chromatography (Egorov et al., 2006). In Fig. 11.25, the solid black lines represent the model fits, whereas the gray traces or markers are the experimental data. The fits are very precise.

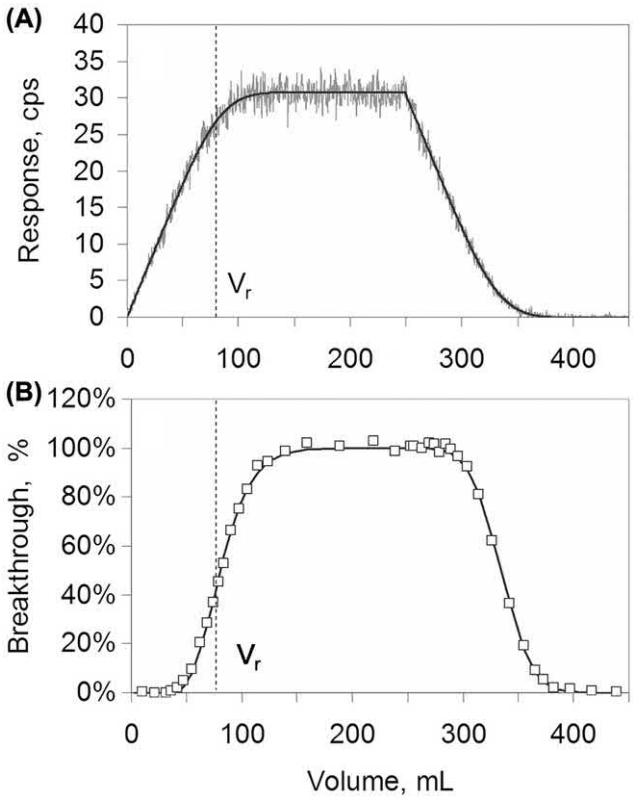

FIGURE 11.25 (A) Trace showing sensor equilibration with 1 Bq/mL ^{99}Tc solution followed by a reequilibration to a blank solution in a matrix of 0.01 M nitric acid. The sensor cell (dimensions 4 mm ID × 29 mm height) is composed of a 1:4 dry w/w ratio AG 4-X4:BC-400. (B) Fractions collected immediately downstream of the sensor cell show the breakthrough profile of ^{99}Tc from the sensor column. Both the Gaussian model (*black lines* in each plot) and low plate model (not shown) provide a good fit to the observed data. *Reproduced with permission from Egorov et al. (2006). Copyright 2006 American Chemical Society.*

This equilibration approach has been demonstrated successfully for sensing ^{99}Tc(VII), both in the laboratory and on groundwater samples from the Hanford site (Egorov et al., 2002a; Egorov et al., 2006; Egorov et al., 2005b; O'Hara et al., 2009a). The potential for other anions in groundwater to interfere was examined in detail, and a method for accurate quantification in complex groundwater matrixes containing cocontaminants, using automated standard addition, has been described (O'Hara et al., 2009a).

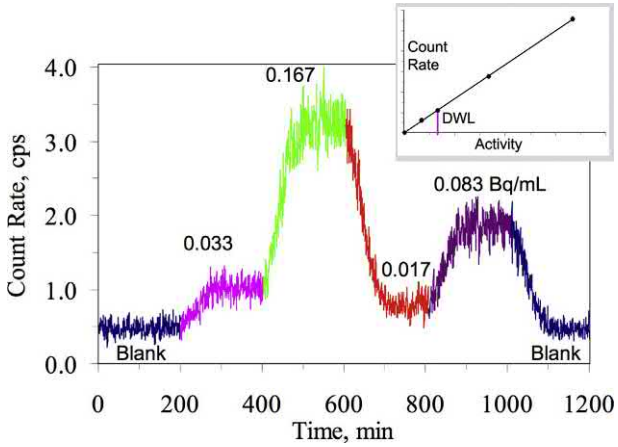

FIGURE 11.26 Response of a preconcentrating minicolumn sensor to four ^{99}Tc calibration standards in Hanford groundwater, delivered to the sensor in a random order with regard to activity concentration. Blank groundwater was delivered at the beginning and end of the series. The smaller plot illustrates the strict linearity of the calibration curve and quantification to below the drinking water limit (DWL). D. Sensor probes and systems for water monitoring

Radionuclide sensors are particularly important for monitoring contaminated ground and surface waters, although they may also be useful in monitoring nuclear processes. Monitoring groundwater is important for detecting migration of contaminant plumes and assessing in situ remediation approaches such as barriers. The most significant radionuclide analytes are alpha- and beta-emitting radionuclides that cannot be detected by gamma spectroscopy and which are mobile in the environment. In situ sensors or at-site monitors for these species must succeed in obtaining accurate analytical results for species that are normally analyzed by multistep laboratory sample preparation, separation, and detection processes, while minimizing or eliminating reagents.

The preconcentrating minicolumn sensor concept (Fig. 11.23) has been successfully engineered into a sensor probe in a configuration that fits into a 4-inch (10.2 cm) well casing for down-hole monitoring, using an anticoincidence shield around the sensing flow cell (observed by PMTs counting in coincidence) to reduce background counts (Egorov et al., 2005b). Images of the engineered sensor probe are shown in Fig. 11.27. The sensor flow cell with two PMTs is shown in **A**, whereas **B** shows the sensor embedded within the anticoincidence shield in the probe housing, and **C** shows the complete probe.

These sensor concepts have also been incorporated as the detector into engineered systems for at-site groundwater

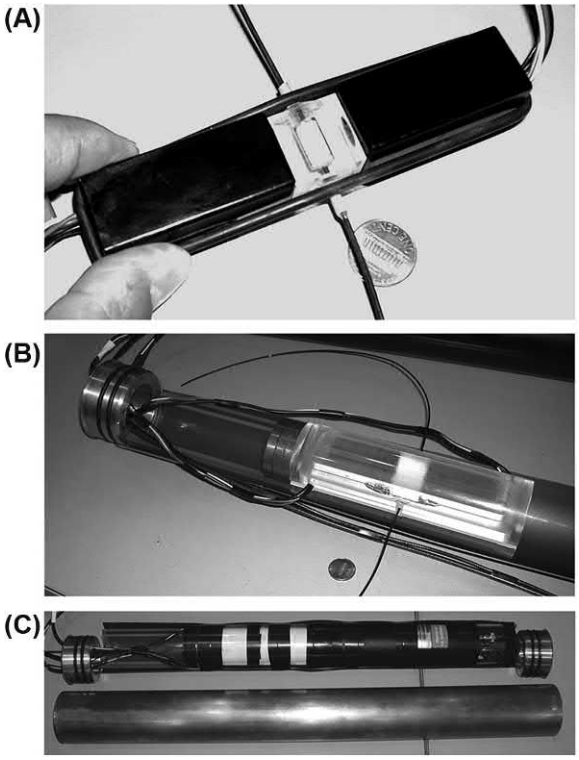

FIGURE 11.27 Images of the sensor probe for ^{99}Tc monitoring using the reagentless equilibrium sensing approach. (A) Sensor flow cell with two photomultiplier tubes (PMTs), (B) the sensor in an anticoincidence shield surrounding the probe housing, and (C) the complete probe prior to assembling the outer housing.

monitoring for quantifying ^{99}Tc in groundwater (O'Hara et al., 2009a). The PNNL worked with Burge Environmental to incorporate a minicolumn sensor operating in equilibration-based sensing mode into the Burge Universal Sensor Platform (Burge and May, 2005; Burge et al., 2005). These platforms are deployed above ground and obtain groundwater samples from sampling lines, while supporting a fluidic system and sensors with solar power, batteries, and remote command/data acquisition communications capabilities. The fluidic system and electronics are designed to acquire a precise volume of groundwater sample with which to equilibrate the sensor and determine the sensor response. Using an above ground system like this, additional services can be incorporated: a stock volume of standard solution is used to perform periodic programmed sensor calibrations by the method of standard addition to the groundwater sample, which compensates for any matrix effects on the sensor response, and enables accurate analyses over a wide range of groundwater compositions. In addition, a stripping solution can be periodically delivered to remove potentially fouling substances from the sensor column, such as soil organic matter. The fluidic architecture that supports the sensor in these engineered

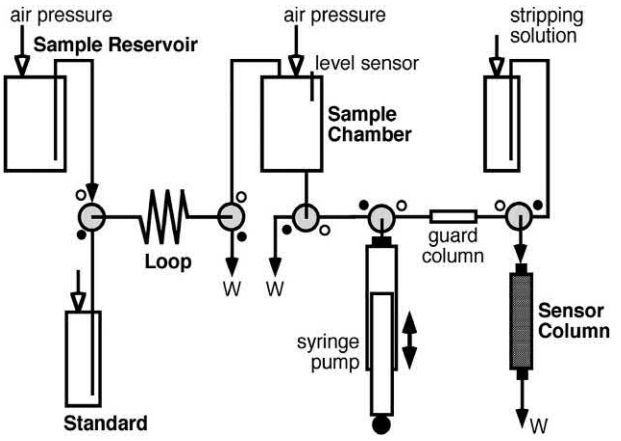

FIGURE 11.28 Automated fluidic system to support a preconcentrating minicolumn sensor in an at-site groundwater monitoring application, using the Burge Universal Sensor Platform. W = waste line. systems is shown in Fig. 11.28, using air pressure for some pumping operations and a syringe pump for others.

This monitoring approach has been deployed as a wall-mounted unit (shown in Fig. 11.29) inside the ZP-1 Pump and Treat Plant on the Hanford Site. This plant pulls water from multiple wells in the 200 Area of the site to remove carbon tetrachloride contaminants; some of the wells are also contaminated with ^{99}Tc. The monitoring system can sample from four lines connected to groundwater from specific wells of interest. Detector traces from 7 days of continuous operation, including blanks and a calibration matrix spike, are shown in Fig. 11.30. The four sample analyses determined concentrations of 0.17, 0.19, 0.16, and 0.14 Bq/mL, in good agreement with independent analysis.

The concept of an at-site monitor has also been applied to the development of sensing systems for ^{90}Sr in groundwater. The detection limits for ^{90}Sr are extremely challenging. O'Hara et al. (2009c) described an approach that automates the purification of ^{90}Sr from groundwater samples using a SuperLig 620 column, retention of the purified ^{90}Sr on the column to allow for ^{90}Y daughter ingrowth, and then transfer of the ingrown daughter nuclide to a Cherenkov detection flow cell. The principles of Cherenkov detection were described in detail in Chapter 6, Volume 2. Briefly, energetic beta particles, such as those from ^{90}Y, can produce light in aqueous solution without the need for a scintillator. The Cherenkov signal from the transferred ingrown ^{90}Y can be related back to the original ^{90}Sr activity in the sample given known ingrowth and counting times. These times are established in the automated separation, ingrowth, and detection method. It was

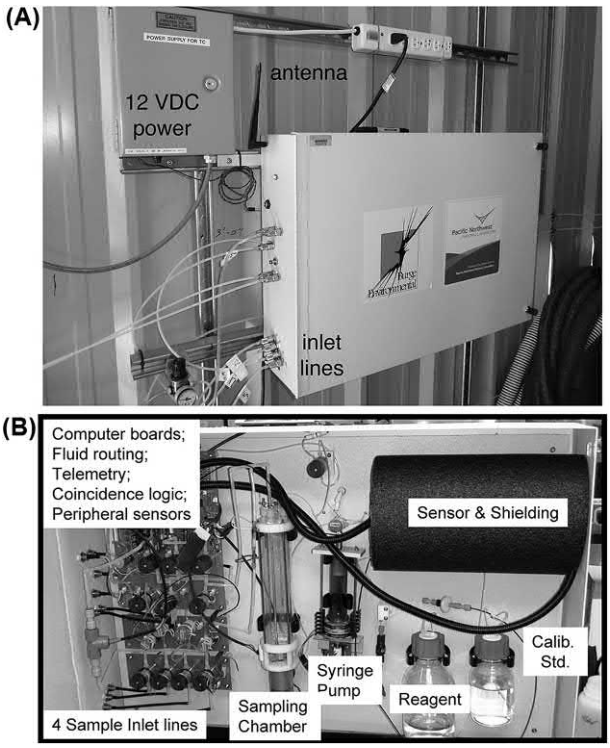

FIGURE 11.29 Images showing the ^{99}Tc groundwater monitoring system deployed as a wall-mounted box in the Hanford 200-ZP-1 groundwater pump and treatment plant. The primary purpose of this plant is to remove carbon tetrachloride; however, some source wells also contain ^{99}Tc as a contaminant, and ^{99}Tc must be monitored to assure that regulated ^{99}Tc levels are not exceeded. (A) External view of the monitor, showing the main box, the water sample inlet lines, the antenna, and the 12 VDC power unit that supplies the main box. (B) Interior of the main box highlighting key components. The system selects and analyzes water from one of four sample inlet lines corresponding to two groundwater wells, the pretreatment water consisting of combined inputs from multiple wells, and the posttreatment water.

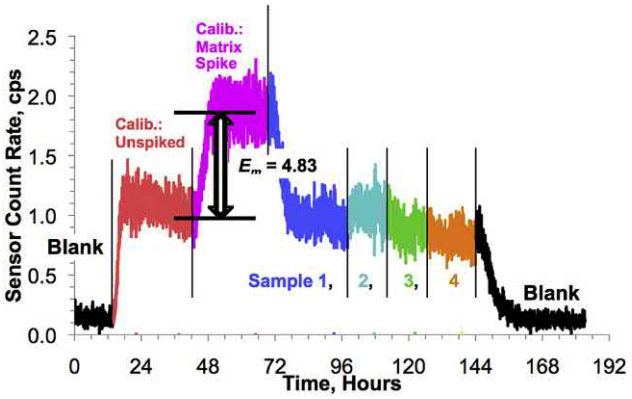

FIGURE 11.30 Sensor response traces from the ^{99}Tc groundwater monitoring system deployed in the Hanford ZP-1 pump and treatment plant. An unspiked sample and a calibration matrix spike into the groundwater matrix are shown, followed by four samples and a blank. The calibration spike provides a parameter, E_m, used in the calibration.

determined that optimum split of the total time between ^{90}Y ingrowth time and Cherenkov counting time was 2:1, i.e., where the count interval is one-third of total time. Under these conditions, a minimum detectable activity (MDA) that is equivalent to the drinking water limit (DWL) of 0.3 Bq/L can be obtained in 41.5 hours of total time, of which 27 hours (0.42 ^{90}Y half-lives) are spent on ^{90}Y ingrowth and 13.5 hours are spent counting. Beginning with a 0.35 L sample volume, these authors demonstrated a detection limit of 0.057 Bq/L using a 5 mL volume Cherenkov flow cell. This result is below the radioactivity detection limit requirement for drinking water of 0.3 Bq/L, which corresponds to a mass-based concentration equivalent for ^{90}Sr of only 5.8×10^{-11} ppm. The combination of a chemical separation, ingrowth process, and Cherenkov detection provides a number of advantages, including independence from concerns about disequilibrium between ^{90}Sr and ^{90}Y in the environment, removal of potential radioactive interferences, freedom from concerns of any radionuclide contaminants that have emissions with energies below the Cherenkov threshold, separation from matrix interferences that could absorb (or quench) Cherenkov photons, and preconcentration of a larger environmental sample into a small volume detection cell, which simplifies light collection. No scintillation materials are required.

VIII. Digital microfluidics for microscale single bead manipulations

While radiochemical separations are typically conducted on column bed volumes from 100 μl to 2 ml and entail milliliter volumes of solutions and eluents, sometimes separations are required on much smaller volume scales. In the sample preparation for TIMS, it is desirable to prepare a source of the highest possible purity. The presence of elements other than the actinides being analyzed, such as plutonium isotopes, can interfere with ionization and hence the measurement. Once the plutonium in a sample has been separated from the sample matrix and other elements, there are still traces of elements present as contaminants from the acid reagents. The only way to reduce those background contaminants is to repeat separations on smaller and smaller volume scales.

In some cases, these can entail performing separations on single anion exchange beads. Single bead anion exchange separations have been used as purification steps for actinides and other trace elements (Dai et al., 2001, 2002a,b; Kelley et al., 1999). Similarly, uptake on single resin beads is routinely used to prepare ion sources for TIMS (Beasley et al., 1998; Bischoff et al., 2005; Dai et al., 2001, 2002b; Fassett and Kelly, 1984; Kelley and Robertson, 1985; Manton, 1988; Stoffels et al., 1994; Walker et al., 1974). Single bead separations, and single bead uptake for TIMS source preparation, present two challenges. First, the diffusive uptake processes are slow, generally requiring many hours to come to equilibrium; second, these processes are difficult to automate. An acoustic streaming approach was developed to accelerate diffusive uptake (Paxton et al., 2008). While this approach accelerated uptake rate by five to six times, it did not address microscale fluid handling techniques to automate multistep single bead separations.

In a collaboration between Sandia National Laboratories, led by Michael Bartsch, and Pacific Northwest National Laboratory (PNNL), led by Jay W. Grate, the methodology of digital microfluidics (DMF) has been adapted to the automation of radiochemical analysis at the microscale. Conventional fluidics and microfluidics can refer to a range of scales from systems composed of extruded tubing and discrete valves and pumps, to systems microfabricated on chips. The intermediate scale between tubing-based systems and microchannel (meaning channels on the order of 50 micron by 100 microns) systems can be useful for microscale sample preparation processes.

DMF has emerged as a new technology to create programmable intermediate scale platforms that are simpler than tubing-based systems (Choi et al., 2012; Jebrail et al., 2011, 2014; Kim et al., 2011, 2013; Kirby and Wheeler, 2013; Shih et al., 2012; Thaitrong et al., 2012; Yang et al., 2009). In addition, it introduces an entirely new way to manipulate the fluids, over a range of fluid volume scales without tubing or microchannels. The DMF methodology has been critically reviewed (Jebrail et al., 2012). Fluid droplets are manipulated over an insulating hydrophobic surface that has an underlying pattern of electrodes. Electrowetting forces are created by activating particular electrodes. Different programmed sequences can move the droplet in different directions over the surface. This concept is suggested in Fig. 11.31. In this way, ***fluids can be automatically transported and routed over the surface, without pumps, valves, or tubing,*** according to preprogrammed protocols. In practice, DMF chip surfaces are interfaced with additional fluid handling components to deliver solutions and reagents to and from the device surface. Multiple droplets on the platform, containing sample, and various reagents, can be manipulated to carry out sample preparation, separation, and routing functions.

The teams at Sandia and PNNL developed a design and workflow that introduced a Pu-containing microcolumn eluent onto an open format DMF chip. Images of the design are shown in Fig. 11.32. Droplets of this solution were routed to a heating strip for evaporative volume reduction and transposition into another acid dispensed onto the chip. The transposed solution was routed over the chip to the tip of an off-chip tube containing a single anion exchange bead trapped between two tubing crimps. This bead-in-a-tube

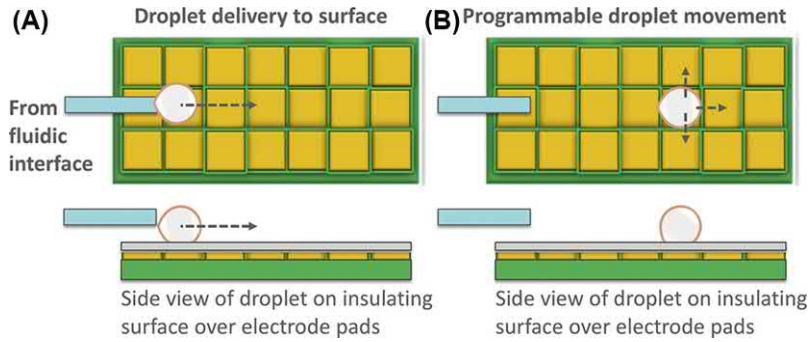

FIGURE 11.31 Schematic diagrams in top and side views of the digital microfluidic concept for programmable manipulation of droplet(s) on a hydrophobic insulating surface over a pattern of electrode pads, shown as gold (light gray in print version) on a green (gray in print version) substrate, with the insulating hydrophobic layer on top in the side views. (A) Droplet delivery via the tip of a tube or capillary from a pumped fluidic interface. (B) Droplet can be moved in any direction over the surface using electrowetting forces created by activation of the underlying electrodes. These images show open format digital microfluidics, meaning there is no top plate and the droplets are in an air medium, rather than closed format with a top plate over the bottom plate and an oil medium in between.

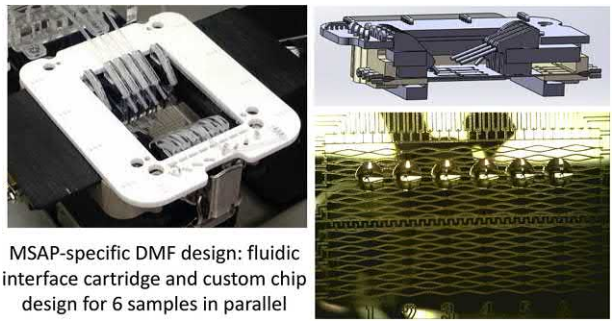

FIGURE 11.32 Various views of the Microscale Sample Automation Platform (MSAP)-digital microfluidic design for single bead separations (denoted as MSAP-specific DMF design). A fluidic interface cartridge (white) serves to deliver samples and reagent solutions and to provide the devices for bead-in-a-tube anion exchange separation. The electrode design on the DMF chip (lower right) can process six samples in parallel and perform evaporative volume reduction.

configuration on the fluidic interface is shown in Fig. 11.33. The solution was pulled by a pump up off the chip and into this bead-in-a-tube device, and pumped back and forth over the bead. Then this solution was pumped away from the bead, and a clean acid solution was pulled into the bead-in-a-tube to wash the bead. This clean acid had been separately delivered to the DMF surface and moved into position for the bead-in-a-tube manipulations. Again, the acid was pumped back and forth over the bead. These processes automated the fluidic handling and accelerated the diffusive processes that occur at the bead. Another clean acid was used to elute unwanted thorium ions off the bead. Finally, an eluent was used to release the Pu from the bead and deliver this solution back to the DMF surface. The overall design was set up to move six sample droplets in parallel and to process each sample through a sequence of sample processing steps to purify the Pu at the microscale, to minimize background contaminants for TIMS sources.

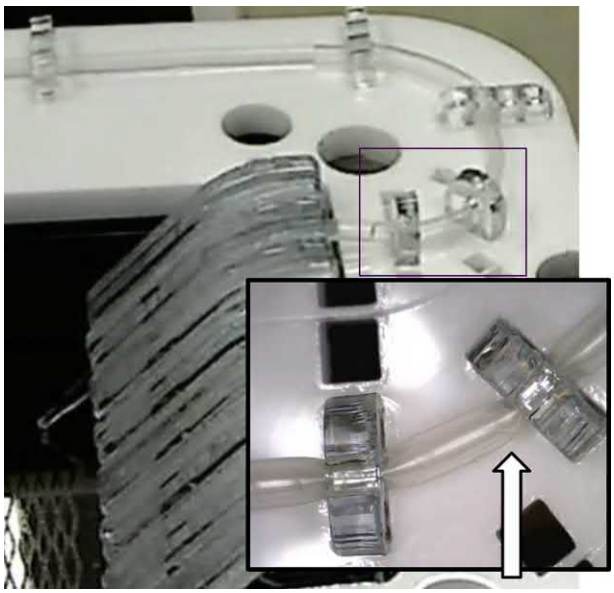

FIGURE 11.33 Detailed views of the bead-in-a-tube device for automating and accelerating single bead anion exchange. The bead location is indicated by the *arrow*. These details are part of the fluidic interface cartridge above the DMF chip surface.

IX. Radioisotopes in medicine

Automated methods for radiochemical separations and chemical reactions are also applied to the production of radionuclides used in medicine, including:

- medical isotope generation by separation of a desired daughter isotope from the parent isotope;
- isolation of a radionuclide produced through fission, neutron activation, or accelerator bombardment of a target material;
- attachment of radioisotopes to cancer targeting molecules; and

- the synthesis of organic chemicals containing a radionuclide in the structure (e.g., radiopharmaceuticals).

Such automated systems can be employed for generating patient doses at a remote production facility or to provide single-patient doses at or near the point of care. Automation is particularly useful if the radionuclide is short-lived and therefore must be produced and used quickly at the location where it is needed. In addition, automation enables more efficient execution of elaborate separation schemes that can be applied to parent/daughter radionuclide pairs of interest or to improve product purity and consistency. Autonomous, remote processing systems can be important to ensure that sterility is maintained, radiological dose to production staff and medical personnel is minimized, and human error is avoided (IAEA, 2004).

A radiopharmaceutical is a drug with radioactivity and known chemical form. The radioactive atom in the drug is either incorporated covalently by synthesis or conjugated to a targeting agent such as an antibody. Radiopharmaceuticals are generally classified by their primary intended purpose, which is diagnostic or therapeutic (Boros and Packard, 2018; Khalil, 2010; Zimmermann, 2006). Radionuclides used in medicine may have decay-induced emissions that fulfill both purposes. Alternatively, the same pharmaceutical may be labeled with different radionuclides to achieve a diagnostic/therapeutic pairing; this approach is known as theranostics (Yordanova et al., 2017). The field of nuclear oncology employs radionuclides in the diagnosis and/or treatment of cancer in patients; it represents one of the largest applications of radionuclides in medicine (Srivastava and Mausner, 2014; L'Annunziata, 2016).

A. Therapeutic radionuclides

Therapeutic radionuclides are typically bound to a targeting agent that seeks and accumulates in cancerous or diseased tissue; these targeted cells are subsequently damaged or destroyed when the proximate radionuclide decays and sends a high-energy particle(s) through the tissue (Cutler et al., 2013). Therapeutic particle emissions from radionuclide decay include Auger and conversion electrons, and alpha and beta particles. The range of these emissions through tissue is dependent on their energy and linear energy transfer (LET). Each of the above emission types except for beta particles is classified as high LET; their range in tissue is generally between 10's and 100's of microns. They are generally effective for treatment of diffuse and micrometastatic diseases. As such, they require highly specific targeting mechanisms. In contrast, low-LET beta particles can penetrate between 10's and 1000's of microns. These are more effective on larger tumor masses and macrometastatic disease (Marcu et al., 2018; Srivastava and Mausner, 2014). In this section, we will discuss the use of automated fluidic systems in the preparation of a few beta- and alpha-emitting radionuclides used in therapeutic applications.

1. Beta emitters

One class of therapeutic radionuclide employs the low-LET beta particle emissions to apply dose to tumors (Banerjee et al., 2015; Jeong and Chung, 2003; Juweid, 2002; Lambert and de Klerk, 2006; Novak-Hofer and Schubiger, 2002; Pauwels and Erba, 2007; Pohlman et al., 2006). Some common beta-emitting therapeutic radionuclides are listed in Table 11.1. As these radionuclides are generally long-lived ($t_{1/2} > 2.5$ d), they are commercially available in their purified form from off-site production facilities. The exception is the shorter-lived ^{188}Re, which is produced at-site via a ^{188}W/^{188}Re generator. Below, we discuss automated systems as they are applied to generator-produced ^{188}Re and ^{90}Y.

a. Rhenium-188

Rhenium-188 (^{188}Re) is used in therapeutic radiopharmaceuticals due to its energetic beta emissions (2.12 MeV max.) for abnormal tissue penetration and destruction, and gamma-ray emissions that can concurrently be used for imaging and dose estimation (Boschi et al., 2014). It is prepared with a ^{188}W/^{188}Re generator that is similar to the ^{99}Mo/^{99m}Tc generator in that the ^{188}W parent is bound onto an acidic alumina column. Further, as with ^{99m}Tc, the ^{188}Re (as perrhenate, $^{188}ReO_4^-$) is eluted with a saline solution. However, the radionuclide does not elute from the alumina column in a small volume as required for the preparation of the radiopharmaceutical, and so it is usually concentrated onto an in-line anion exchange column prior to its final elution and use.

The multistage isolation/concentration process and the high radiological dose imparted by this radionuclide have driven teams to apply laboratory automation in the

TABLE 11.1 Common beta-emitting therapeutic radionuclides.[a]

Nuclide	Approximately $t_{1/2}$, h	End-point emission energy, keV	Emission intensity, %
Cu-67	62	377/468/562	57/22/20
Y-90	64	2280	100
I-131	193	606	90

[a]*Decay data obtained from National Nuclear Data Center (2019).*

preparation of ^{188}Re. Teams at the Paul Scherrer Institute (Switzerland) and the Institute of Nuclear Energy Research (Taiwan) have recently demonstrated concentration and elution systems for preparation of ^{188}Re using fluidic systems. Each system employs a commercially available ^{188}W/^{188}Re generator column and utilizes computer-controlled fluidics to concentrate the ^{188}Re and elute it in a highly concentrated product solution. The Jäckel et al. (2005) system is semiautomated, using a syringe pump and Teflon switching valves for fluid delivery and routing, respectively. The Luo et al. (2007) system is fully automated, relying on a peristaltic pump for fluid delivery. Saline is used to elute ^{188}Re from the generator as the perrhenate ion ($^{188}ReO_4^-$). As the milking process requires over 30 mL to achieve good ^{188}Re yield, a secondary silver cation exchange column must be used to remove chloride ions from the primary column saline eluent, and a tertiary anion exchange column is used to concentrate the perrhenate. The $^{188}ReO_4^-$ is subsequently eluted from the anion exchange column using a small volume of saline. Luo et al. compared the behavior of three anion exchange cartridges and found that the Waters Accell QMA resin provided superior chromatographic performance.

Rhenium-188 is considered for the treatment of hepatocellular carcinoma. Lipiodol (ethiodized oil), when injected intraarterially, can deposit and emulsify into hepatoma cells. Thus, this oil can act as a ^{188}Re transporter to tumors of the liver (Boschi et al., 2014). Italian and French research teams have developed automated generator/synthesis systems to prepare this radiopharmaceutical (Lepareur et al., 2011, 2012; Uccelli et al., 2011).

b. Yttrium-90

Yttrium-90 (^{90}Y) is an important beta-emitting radionuclide that is coupled to antibodies used in peptide receptor radionuclide therapy (Sabet et al., 2016), radioimmunotherapy (Goffredo et al., 2011; Kawashima, 2014), and radioembolization (Khajornjiraphan et al., 2015; Tong et al., 2016). Because of its relatively long half-life, ^{90}Y is primarily purified at high activity levels in centralized production facilities, aliquoted, and shipped to the point of use.

An automated ^{90}Y purification process was developed to generate patient dose levels of ^{90}Y (O'Hara et al., 2009d). A radiolysis-resistant inorganic sorbent column was developed and demonstrated to strongly bind the ^{90}Sr parent while allowing periodic elution of ^{90}Y. The resulting ^{90}Sr/^{90}Y generator column was set up as part of a fully automated radionuclide generator system. Unbound ^{90}Y is separated from the parent isotope during a milking step. Due to the relatively broad elution profile of ^{90}Y from the generator column, a secondary "mini" ion exchange column is placed in-line to capture ^{90}Y quantitatively during the generator column milking process. Subsequent elution of ^{90}Y with a secondary stripping solution (applied in the reverse flow direction) yields the product in a small volume.

A ^{90}Sr/^{90}Y isolation process has also been demonstrated using a fully automated electrochemical purification system (Dash and Chakravarty, 2014). A two-step electrolysis is performed to separate ^{90}Y from a ^{90}Sr stock solution. An electrolyte solution containing $^{90}Sr(NO_3)_2$ first undergoes electrolysis at −2.5 V (100−200 mA current); ^{90}Y is collected on a Pt cathode. Next, the cathode is rinsed and transferred to a fresh cell containing dilute HNO_3 and another Pt electrode. The polarity of the electrodes is reversed, and ^{90}Y is collected on the fresh cathode. The process is claimed to be capable of producing a ^{90}Sr/^{90}Y activity ratio of $<10^{-5}$.

2. Alpha emitters

Alpha particles are highly energetic and ionizing, the combination of which is lethal to cells within a short range (Poty et al., 2018b). As such, the coupling of alpha emitters to diseased cell-targeting molecules (e.g., monoclonal antibodies, peptides, nanoparticles, nanobodies) can result in high toxicity to cancer cells (Makvandi et al., 2018; Poty et al., 2018a); this is referred to as targeted alpha therapy (TAT).

Alpha particle-producing radionuclides of current interest in TAT include ^{225}Ac, ^{213}Bi, ^{212}Bi, and ^{211}At (Allen, 2008; Allen et al., 2014; Couturier et al., 2005; Dahle et al., 2011; Kim and Brechbiel, 2012; Kitson et al., 2013; Li et al., 2004; Morgenstern et al., 2018; Wadas et al., 2014; Wilbur, 2011; Yong and Brechbiel, 2015; Zalutsky et al., 2007). These radionuclides have branched decay chains that produce multiple short-lived daughters that generate alpha or beta emissions on the path to a stable isotope (Table 11.2).

TABLE 11.2 Common alpha-emitting therapeutic radionuclides.[a]

Nuclide	Approx. $t_{1/2}$, h	Decay pathway # α′s	Decay pathway # β′s	Stable end product
Ac-225	240	4	2	Bi-209
Bi-213	0.8	1	2	Bi-209
Pb-212 (Bi-212)[b]	10.6 (1.0)	1 (1)	2 (1)	Pb-206
At-211	7.2	1	0	Pb-207[c]

[c] *Decay results in ~42% branching through Bi-207 ($t_{1/2} \approx 32$ a).*

Therapeutic alpha emitters are commercially available without preparation (^{225}Ac), as column-based generators (^{225}Ac/^{213}Bi; ^{224}Ra/^{212}Pb/^{212}Bi), and as cyclotron-bombarded metal targets (^{nat}Bi/^{211}At). Herein, we discuss some examples of fluidic automation applied to radionuclides used in TAT.

a. Bismuth-213

Although inorganic sorbents (as employed in the ^{90}Y generator system described above) may have advantages with regard to radiolytic stability over polymer-based sorbents (Marsh and Pillay, 1993; Pillay, 1986), organic extractants and resins often provide more versatility in their capacity and chemical selectivity for radioisotopes of interest. An automated, dual-column system to generate high-purity ^{213}Bi from a source of ^{225}Ac bound to a cation exchange polymer resin column has been demonstrated (Egorov and O'Hara, 2005). The ^{225}Ac was evenly distributed throughout two-thirds of a ~3 cm^3 cation exchange column. The lower one-third of the column was packed with cation exchange polymer resin that did not contain ^{225}Ac; this was to provide a "catch bed" to assure capture of any ^{225}Ac that might migrate from the upper resin bed during milking cycles. The ingrown ^{213}Bi daughter was periodically milked with strong HCl and captured on a small (0.12 cm^3) in-line anion exchange resin column. The purified ^{213}Bi was subsequently eluted with acetic acid. Ninety-two percent of the ^{213}Bi was recovered in the eluted fraction. Of this, 91% was successfully bound to CHX-A-HuM-195 monoclonal antibody to create the desired radiopharmaceutical. At the 3 mCi ^{225}Ac level, no radiolytic effects on the generator column were observed during a testing period of several days.

Polymer-based resins can also be used advantageously for on-demand separation of a daughter radionuclide of interest from a parent radionuclide stored in the liquid form, thus minimizing radiolytic degradation of the sorbent materials. Automation is particularly useful in this approach, where the high-activity parent is not kept stationary in a shielded column. Researchers at PNNL demonstrated an automated ^{225}Ac/^{213}Bi generator that utilized a polymeric anion exchange membrane disc to selectively capture ^{213}Bi, whereas ^{225}Ac was unretained and remained in solution (Bray et al., 2000; Egorov et al., 2000). The unbound ^{225}Ac parent was routed back to the storage vessel, whereas the ^{213}Bi product was subsequently stripped from the membrane disc using a sodium acetate solution that provided a chemical matrix that was directly suitable for subsequent labeling steps. This single-stage separation method with aqueous storage of the parent was performed at clinically relevant (~16 mCi) levels.

Dual-column separation processes using extraction chromatography resins have been demonstrated in the production of ^{213}Bi using a "multicolumn selectivity inversion generator" (Horwitz and Bond, 2003; McAlister and Horwitz, 2009). The generalized fluidic process scheme is shown in Fig. 11.34. The ^{225}Ac/^{213}Bi load solution is delivered using automated fluidics comprising two syringe pumps and three multiport valves (McAlister and Horwitz, 2009). The ^{225}Ac stock solution is passed through a primary column of UTEVA resin in HCl, where the ^{225}Ac is unretained while the ^{213}Bi is retained. The parent radionuclide is returned to a storage vessel, whereas the daughter is eluted from the primary column and passes unretained through a secondary column of cation exchange resin using a sodium chloride/sodium acetate buffer. The secondary column captures traces of the parent radionuclide and thus facilitates the required high decontamination factors between the parent/daughter radionuclides.

b. Lead/bismuth-212

The relatively simple ^{224}Ra/^{212}Pb (^{212}Bi) generator column system that was initially reported ~30 years ago is still in use today. The device employs a small column packed with macroporous cation exchange resin (BioRad MP-50). The ^{224}Ra is adsorbed in a distributed fashion throughout the resin bed, with a small non-^{224}Ra-bearing "catch bed" at the base of the column. Upon receipt of the generator at the point of use, the ^{212}Pb/^{212}Bi daughter products are periodically eluted with a small volume of 2 M HCl or 0.5 M HI. Alternatively, ^{212}Bi can be selectively eluted with 0.5 M HCl or 0.15 M HI (Atcher et al., 1988; Mirzadeh and Knapp, 1996).

Recently, Li et al. (2017) developed an automated cassette-based system that is capable of concentrating radio-Pb from the above-described generator column onto a concentrating column, then eluting it and subsequently labeling radio-Pb onto a DOTA-conjugated peptide. The system allows for purification of the labeled compound using HPLC. The process is adaptable to either ^{212}Pb (via the ^{224}Ra/^{212}Pb generator column) or a ^{203}Pb diagnostic source. When used sequentially or in combination, the $^{203/212}$Pb mixture can be used in theranostic applications.

Alternative ^{224}Ra/^{212}Pb (^{212}Bi) generator systems have been demonstrated on automated or semiautomated platforms. Bond et al. (2003) presented a prototype automated radionuclide separation system ("automated radionuclide separator") that was capable of isolating ^{212}Bi from ^{224}Ra. The fluidic system loaded a ^{224}Ra solution onto a Dipex resin column in 1 M HNO_3 and then washed the column with the same solution. The ^{212}Bi was retained on the column during load; ^{224}Ra had no retention and was recovered. Next, the isolated ^{212}Bi was eluted from the column using 2 M HCl.

More recently, Guseva (2007) described a tandem column generator process for delivery of purified ^{212}Pb from a ^{228}Ra source. While the process was not fully automated, the tandem columns were coupled inline, with reagents delivered via peristaltic pump. Therefore, the process could be easily adapted to automated fluid delivery by modern digital techniques. The primary generator column was packed with cation exchange resin (Dowex 50X8), and the secondary column was packed with anion exchange resin (Dowex 1X8). The ^{228}Ra parent stock was loaded onto the primary column with a small volume of dilute HNO_3 solution. Next, 0.5 M HBr or (0.5 M HBr/90% CH_3OH) was passed through both columns; ^{228}Ra remained bound, while ^{212}Pb/^{212}Bi was eluted and subsequently retained on the secondary column. After disconnecting the secondary column, the isolated ^{212}Pb/^{212}Bi could be eluted with a range of solutions that included water, NaCl, EDTA, or DTPA solutions. Chemical yields of ^{212}Pb ranged between 50% and ~98%, depending on the eluent solution employed.

c. Astatine-211

Astatine-211 (^{211}At) is a promising radionuclide for TAT (Guerard et al., 2013). Unlike the other commonly used TAT radionuclides that are prepared from generator columns, ^{211}At is produced by cyclotron. The primary production route is by accelerated α-beam bombardment of naturally monoisotopic ^{209}Bi metal (via the ^{209}Bi(α, 2n)^{211}At reaction) (Gagnon et al., 2012b; Zalutsky and Pruszynski, 2011). Two methods for the isolation of ^{211}At from Bi metal are predominantly in use. One method is dry distillation from molten Bi metal targets (Johnson et al., 1949; Lambrecht and Mirzadeh, 1985; Lindegren et al., 2001). The second method is chemical purification using wet chemistry, which involves dissolution of the Bi metal target followed by solvent extraction (Alliot et al., 2009; Balkin et al., 2013; Groppi et al., 2005; Neirinckx and Smit, 1973; Neumann, 1957; Sultana et al., 2000; Yordanov et al., 2004; Zona et al., 2008).

This radionuclide shows promise for the treatment of brain tumors (Zalutsky et al., 2008), breast cancer (Makvandi et al., 2016), synovial sarcoma (Keiko et al., 2018), lymphoma (Green et al., 2015), and ovarian cancer microtumors (Andersson et al., 2009; Bäck et al., 2016; Cederkrantz et al., 2015; Palm et al., 2016).

Recently, O'Hara et al. (2018b, 2019) developed an automated fluidic system to perform a complex method for ^{211}At isolation based on an approach used at the University of Washington (UW) Department of Radiation Oncology. The UW ^{211}At isolation process has been described in detail by Balkin et al. (2013). Once a cyclotron-bombarded Bi target is dissolved and chemically prepared for ^{211}At isolation, UW employs a solvent extraction process to separate ^{211}At from Bi ions. While the manual UW process is effective and robust, it is cumbersome (performed within a glovebox) and time-consuming and must be performed by a highly trained radiochemist. Conversion of the manual process to an inline automated platform would enable improved laboratory efficiency, assure consistent ^{211}At product characteristics between operators, and ultimately facilitate the wider use of this radionuclide at other hospitals in the United States.

Automated modules were engineered to perform each of five successive chemical processing steps:

(1) Bi target dissolution in HNO_3 solution;
(2) distillation of HNO_3 and subsequent dissolution of Bi salt residues in HCl solution;
(3) extraction of ^{211}At with diisopropyl ether (DIPE);
(4) repeated washings of the DIPE with HCl solution to remove residual Bi ions; and
(5) back-extraction of ^{211}At from the DIPE into ≤1 mL of NaOH solution.

The process is described subsequently in more detail.

First, the cyclotron-bombarded ^{nat}Bi target is sealed within a target dissolution block that facilitates inline dissolution of the Bi metal (Fig. 11.35) (O'Hara et al., 2017b). A target dissolving solution (10 M HNO_3) is pumped, via digital syringe pump, into a port at the base of the block; the dissolved ^{nat}Bi/^{211}At is then routed through an outlet port and into a distillation vessel. The reproducibility of the inline dissolution process on freshly bombarded Bi targets is shown in Fig. 11.36.

Next, the system remotely triggers a hot block and stir bar to distill the HNO_3 and leave a dry Bi nitrate salt

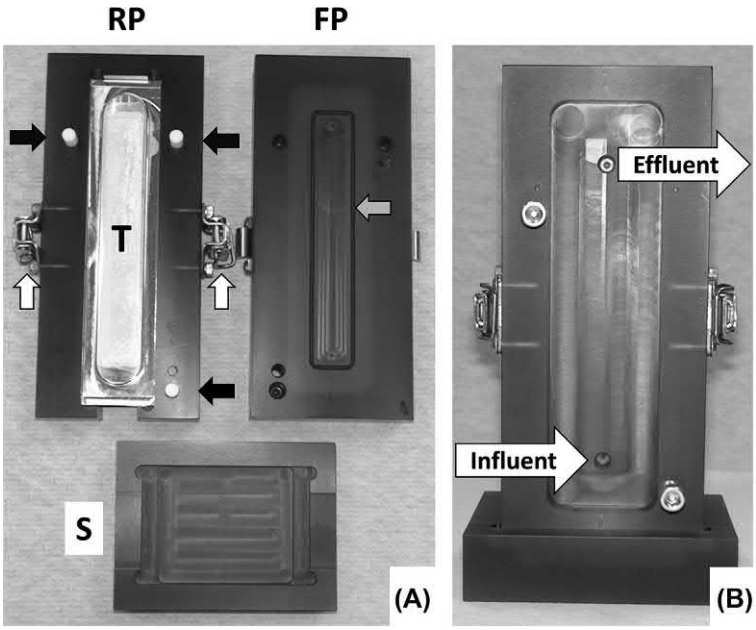

FIGURE 11.35 (A) Disassembled target dissolution block components comprising the rear panel (RP), into which a Bi target assembly (T) is inserted, the front panel (FP), and stand (S). *Black arrows* show Teflon guide rods, *gray arrow* shows the O-ring seal and HNO_3 flow channel within, and *white arrows* show fastening clamps. (B) Fully assembled dissolution block atop the stand showing reagent influent and effluent ports. *Reproduced with permission from O'Hara et al. (2017b). Copyright 2017 Elsevier.*

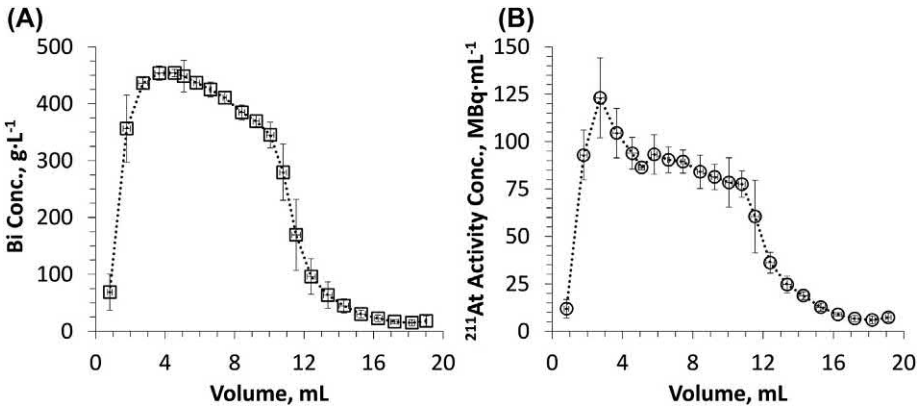

FIGURE 11.36 (A) Mean dissolution profile for quadruplicate cyclotron-bombarded ^{nat}Bi metal targets emerging from the target dissolution block. (B) Mean activity profiles for ^{211}At released from the same set of bombarded ^{nat}Bi targets. *Reproduced with permission from O'Hara et al. (2017b). Copyright 2017 Elsevier.*

residue. Once the salts are dry, the system turns off the hot block and toggles valves to allow chilled fluid to enter the hot block, thus quickly quenching heat from the block. Once the block is cooled, the salt cake is redissolved in 8 M HCl using repeated aspirate/dispense cycles from a syringe pump.

The acidic ^{nat}Bi/^{211}At solution is then processed through an automated solvent extraction system to obtain the isolated ^{211}At fraction. The system comprises three digital syringe pumps and two mixer/settler units. DIPE is used to extract ^{211}At into the organic phase; the non-extracted ^{nat}Bi in the aqueous phase is sent to waste. The DIPE solution is washed several times with fresh HCl to remove residual ^{nat}Bi, and the ^{211}At is finally back-extracted into 4 M NaOH. The automated solvent extraction process is accomplished using a mixing/settling approach, wherein aqueous/organic phases are simultaneously routed to a mixing tee and then through either a column packed with glass beads (acid/organic phase mixing) or a serpentine tubing reactor (organic/base phase mixing). The settler reservoirs, which collect the aqueous/organic phases after mixing, are fitted with sensors that enable the system to precisely determine the location of the liquid phase boundary so that each phase can be routed into its respective syringe pump at the conclusion of each cycle (Fig. 11.37) (O'Hara et al., 2017a, 2019).

To date, the automated fluidic system has demonstrated ^{211}At radiochemical yields and Bi decontamination factors that are indistinguishable from those obtained by the manual method. Additionally, the ^{211}At products possess the same distribution of chemical species and antibody labeling efficiency.

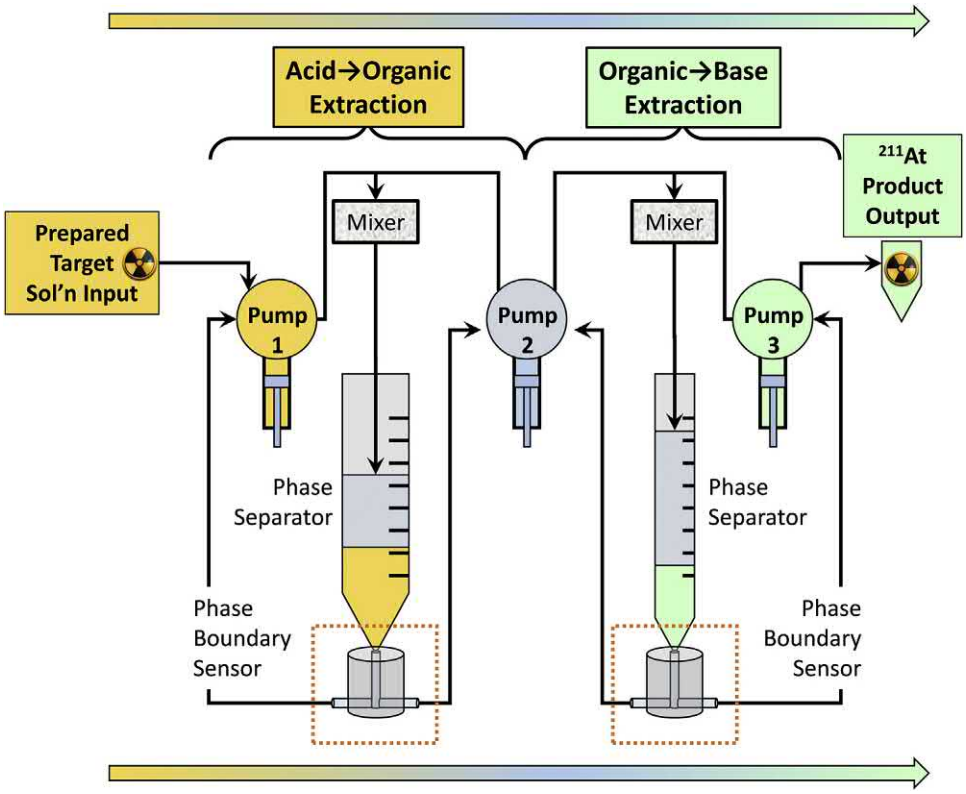

FIGURE 11.37 Fully automated solvent extraction system for isolation of ^{211}At from dissolved and chemically treated ^{nat}Bi targets. System performs ^{211}At load into DIPE from target solution, performs several washes of the DIPE in 8 M HCl to clean the DIPE, and finally performs a back-extraction to extract ^{211}At from the DIPE into 4 M NaOH. *Figure adapted from a conference poster presentation (O'Hara et al., 2017a).*

Recent work at Gothenburg University has been performed to automate the radiolabeling of ^{211}At onto antibodies (Aneheim et al., 2015a) via an electrophilic aromatic substitution reaction. Once the manual labeling method was adapted for use with a fluid handling system, a fully automated system for ^{211}At isolation and biomolecule labeling was devised (Aneheim et al., 2015b). The system employs a computer-controlled distillation and synthesis/purification component. The ^{211}At is dry distilled from the cyclotron-bombarded ^{nat}Bi metal target at ~ 700 °C, which is sufficient to melt the metal and volatilize ^{211}At; a carrier gas moves the ^{211}At vapor out of the furnace where it is condensed within a capillary tube within a cryotrap. A small volume of organic solvent (with oxidizer) elutes the ^{211}At from the capillary and transports it to a reaction vial. If the ^{211}At is eluted with a water-soluble solvent (methanol or ethanol), the labeling can proceed immediately. Otherwise, non−water-soluble solvents (chloroform) can be evaporated using an on-board heating element while under nitrogen flow, with subsequent resolubilization of the residue in an appropriate solvent. Next, labeling agents are added to the reaction vial, mixed with bubbling by nitrogen gas, and the reaction is quenched with the addition of sodium ascorbate. Finally, the astatinated compound is purified by injection onto a size exclusion column and sterilization filter. The system demonstrated astatinated immunoconjugate reactivities that were equivalent to those prepared via the manual method.

B. Diagnostic radionuclides

Radionuclides used in imaging applications are generally employed in either single photon emission computed tomography (SPECT) or positron emission tomography (PET), wherein the former category emits moderate-energy gamma radiation and the latter emits coincident 511 keV annihilation photons following positron emission (Pimlott and Sutherland, 2011; Rahmim and Zaidi, 2008; L'Annunziata, 2016). When tethered to molecular imaging agents, pathophysiological processes can be monitored noninvasively.

1. Gamma emitters

Certain gamma-emitting radionuclides are used in diagnostic and prognostic imaging via SPECT (Table 11.3). These radionuclides generally decay by electron capture or isomeric transition; their photon emissions range from 10's to 100's of keV (Pimlott and Sutherland, 2011). As ^{99m}Tc is available in generator formats, it has been the focus of automation applications; some examples will be discussed below.

TABLE 11.3 Common SPECT imaging radionuclides.[a]

Nuclide	Approx. $t_{1/2}$, h	Decay mode[b]	Principal photon emission, keV
Ga-67	78	ε	93/185/300
Tc-99m	6	IT	140

a. Technetium-99m

Technetium-99m has been used as an SPECT isotope for decades and is considered to be the most widely employed diagnostic radionuclide (Rösch and Knapp, 2011; Synowiecki et al., 2018). While several methods have been employed to generate ^{99m}Tc from high specific activity ^{99}Mo, the acidic alumina column approach found the most popularity; the SPECT radionuclide is simply milked from the column using sterile saline (Banerjee et al., 2001). In the past decade, there has been a shift from producing the ^{99}Mo parent radionuclide from fissioned high-enriched U (HEU) targets to fissioned low-enriched U (LEU) targets (National Research Council, 2009) and through other production methods, such as proton bombardment of natural or enriched Mo targets (Bénard et al., 2014; Das et al., 2016; Gagnon et al., 2012a; IAEA, 2013).

Accelerator-based production of ^{99m}Tc from $^{natural/100}$Mo targets necessitates its chemical isolation from masses of Mo that are far greater than those found in HEU-produced ^{99}Mo (Das et al., 2016; Gumiela, 2018). Several research teams have been developing automated ^{99m}Tc generators that are capable of handling these larger Mo mass quantities. Some teams have designed automated systems for ^{99m}Tc separation from proton bombarded ^{100}Mo and ^{nat}Mo metal targets that are first dissolved in 30% hydrogen peroxide. Two examples are provided.

Morley et al. (2012) evaluated ^{99m}Tc isolation processes with Dowex 1X8 anion exchange and aqueous biphasic extraction chromatography (ABEC) resin columns. The system delivered the dissolved target through the separation column in a potassium hydroxide solution. After washing the column of residual Mo, the ^{99m}Tc was eluted with either tetrabutylammonium bromide (TBAB) in chloroform (anion exchange column) or water (ABEC column). With the ABEC column, the researchers found that they could deliver the ^{99m}Tc eluent solution through two additional columns placed inline with the primary column to obtain high-purity product: the first being an acidic cation exchange cartridge (for influent solution pH neutralization) and the second being an alumina cartridge (for secondary ^{99m}Tc capture). Finally, the ^{99m}Tc could be eluted from the alumina cartridge with saline. The two separation processes resulted in ~70% and ~90% ^{99m}Tc product yields for the anion exchange and ABEC resin columns, respectively.

Das et al. (2016) developed an automated fluidic system named TCM-AUTODOWNA for ^{99m}Tc isolation. The dissolved Mo target solution is made basic with ammonium carbonate and is passed through a Dowex 1X8 column. After washing the column with carbonate solution, the retained ^{99m}Tc is eluted with 4 M HNO_3. The eluent solution is routed to an inline flask positioned within a heated bath; the nitric acid is evaporated to yield a dried ^{99m}Tc residue. Following the drying step, saline is injected into the flask to dissolve the ^{99m}Tc residue, and finally the saline solution is routed through an acidic alumina column and membrane filter to obtain a purified ^{99m}Tc product.

The team of Martini et al. (2016) developed an automated ^{99m}Tc isolation module that employs solvent extraction instead of the more traditional column-based methods. Methyl ethyl ketone (MEK) is used to extract ^{99m}Tc from proton-bombarded ^{100}Mo targets that are dissolved in hydrogen peroxide and then made basic in strong sodium hydroxide solution. The dissolved target solution and the organic solvent are coinjected into a tall glass tube, and He gas is bubbled into the tube to affect phase mixing. After several minutes of mixing, the gas delivery is stopped, and the phases are allowed to settle. At this point, the ^{99m}Tc resides in the lighter organic phase. After collection of the organic phase from the separation column, it is passed through a silica SepPak cartridge, onto which the ^{99m}Tc is adsorbed from the organic phase. Following a second ^{99m}Tc extraction of the dissolved target phase with MEK and delivery of the postcontacted MEK to the SepPak cartridge, the ^{99m}Tc is eluted with a pure MEK solution that has not been previously contacted with sodium hydroxide solution. The SepPak cartridge eluent is in turn routed through an acidic alumina column, wherein ^{99m}Tc is once again adsorbed. Finally, the alumina column is washed with water, and the ^{99m}Tc eluted as a final product fraction with saline solution. The overall process results in a radiochemical yield of ~93%.

Other technologies that employ automated modules in the separation of ^{99m}Tc from $^{100/natural}$Mo targets can be found in the recent review by Gumiela (2018).

2. Positron emitters

Diagnostic imaging was significantly improved with the emergence of PET. The coincident detection of 511 keV photons produced during positron annihilation enables better spatial and temporal resolution and greater sensitivity

TABLE 11.4 Common positron emission tomography imaging radionuclides.[a]

Nuclide	Approx. $t_{1/2}$, min.	Emission type[b]	Annihilation photon intensity, %
C-11	20	β^+	200
N-13	10	β^+	199
F-18	110	β^+	193
Cu-64	762	β^+/ε, β^-	35
Ga-68	68	β^+/ε	178
Br-76	972	β^+/ε	109
Ru-82	1.3	β^+/ε	191
Zr-89	4705	β^+/ε	46
I-124	6013	β^+/ε	45

than SPECT (Pimlott and Sutherland, 2011; L'Annunziata, 2016). Positron emitters are typically short-lived nuclides that must be produced via a nearby cyclotron (Olivier, 2004), separated from the target material, and then chemically incorporated into organic compounds (Conti and Eriksson, 2016; Miller, 2009). A few positron emitters, such as ^{89}Zr and ^{124}I, have half-lives measured in days (Table 11.4).

Alexoff (2005) and Krasikova (2007) have provided historical and current perspectives on the use of automation in the synthesis of PET radiopharmaceuticals. Systems for radiolabeling PET radiopharmaceuticals are needed to cope with the frequently very short-lived nuclides, in addition to dealing with radionuclides emitting high fluxes of 511 keV annihilation photons. Several papers describe the automated synthesis of specific PET radiopharmaceuticals (Krasikova, 2007; Marengo et al., 2008; Rahman et al., 2010; Scott and Shao, 2010; Tang et al., 2010). The most prevalent of these is 2-[^{18}F]fluoro-2-deoxy-D-glucose ([^{18}F]-FDG) (Yu, 2006), and platforms for this synthesis have been adapted to other radiopharmaceuticals.

a. Short-lived positron emitter gallium-68

Gallium-68 and ^{82}Rb are likewise used in PET, but these are unique in that they each have a moderately long-lived parent (Ballinger, 2009; Fani et al., 2008). They can be milked from a generator and therefore do not require a near- or on-site cyclotron.

McAlister and Horwitz (2009) have demonstrated an automated two-column generator system to elute ^{68}Ga from a ^{68}Ge liquid source using strong cation exchange and UTEVA columns in tandem (Fig. 11.34). The ^{68}Ge/^{68}Ga source is passed through a primary cation exchange column in 0.5 M HCl, where ^{68}Ge is unretained and ^{68}Ga is retained. After rinsing this column, the ^{68}Ga is eluted from the primary column using 4 M HCl; the primary column eluent solution is directed to the secondary column of UTEVA resin, where the ^{68}Ga is retained. Finally, the ^{68}Ga is eluted using 0.1 M HCl. Radiochemical yield was reported at 95%, with a 10^{-7}% ^{68}Ge impurity.

Gallium-68 is widely used to target/image somatostatin and other receptors by coupling it to peptides containing a 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) conjugate. It, along with the therapeutic beta-emitting radionuclides ^{90}Y and ^{177}Lu, is emerging as promising radionuclide combinations for theranostic applications (Rösch and Baum, 2011; Weineisen et al., 2015; Werner et al., 2015). A number of semiautomated and automated ^{68}Ga DOTA peptide radiolabeling systems are commercially available at the present time; these systems have been recently reviewed by Boschi et al. (2013).

In the same year as Boschi's review, Schultz et al. (2013) described an automated fluid handling system to synthesize ^{68}Ga DOTATOC, a DOTA-conjugated somatostatin-targeting peptide. Gallium-68 was first eluted from a commercially available generator with dilute HCl; the eluted ^{68}Ga was captured on a strong cation exchange (SCX) cartridge and eluted, via syringe pump, with an HCl/NaCl mixture. The purified ^{68}Ga was injected slowly into a temperature-controlled vessel that contained buffer solution containing sodium acetate, ascorbic acid, and DOTATOC. The mixture was heated to 90 °C within the vessel for 400 seconds and then diluted with an aliquot of water, and the prepared solution was pumped through a filter for sterilization. The system was capable of preparing the radiolabeled peptide in <15 minutes, with 97−100% labeling efficiency. The specific activity was reported to be > 40 MBq·nmole^{-1}.

b. Long-lived positron emitters: zirconium-89 and iodine-124

Long-lived positron-emitting radionuclides have resulted in a new PET imaging modality referred to as ImmunoPET; this combines the specificity of monoclonal antibodies (mAbs) with the high resolution of PET to provide in vivo diagnostic imaging (Bailly et al., 2017; McCabe and Wu, 2010; van Dongen et al., 2007; Verel et al., 2005; Wright and Lapi, 2013). Targeted delivery with mAbs can take as many as 2−4 days (2−6 days for mAb fragments) to distribute in the body and establish maximum tumor to nontumor contrast (Verel et al., 2005). The coupling of long-lived positron emitters such as ^{89}Zr ($t_{1/2} \approx 3.3$ d) and ^{124}I ($t_{1/2} \approx 4.2$ d) to monoclonal antibodies enables PET imaging after immunochemically targeted delivery (Belov et al., 2011; Cascini et al., 2014; Holland et al., 2009; Verel et al., 2003a,b).

Several automated ^{89}Zr purification systems have been reported recently. Most systems employ a single hydroxamate resin column to isolate ^{89}Zr from dissolved cyclotron-bombarded ^{nat}Y targets, a method that was defined by Meijs et al. (1994) over two decades ago. The method was more recently defined as a standardized method by Holland et al. (2009). The hydroxamate resin is not commercially available but can be synthesized in house, as described by Verel et al. (2003a). Briefly, a cyclotron-bombarded ^{nat}Y target is dissolved in HCl, and the resulting solution is passed through a hydroxamate resin column, where ^{89}Zr is adsorbed. The ^{nat}Y is washed from the column using HCl, and then the HCl is removed from the column with water. Finally, ^{89}Zr is eluted with 1 M oxalic acid (a nearly saturated solution). Automated or semi-automated fluidic systems that have employed this standard method have been reported by Wooten et al. (2013), Poniger et al. (2014), Siikanen et al. (2012), and Lin et al. (2016).

O'Hara et al. (2018c) described a simple automated fluidic system (Fig. 11.38A) that injected a hydrochloric acid dissolver solution into a vessel containing a cyclotron-bombarded ^{nat}Y target. After target dissolution was complete, the solution was pushed through an inline filter and then passed through a hydroxamate resin column; the column was washed, and ^{89}Zr was then eluted using 0.8 M oxalic acid. Batch distribution coefficient (K_d) studies demonstrated that this lower concentration of oxalic acid resulted in a Zr K_d of <2 mL/g, which is sufficient to enable efficient ^{89}Zr elution. The reduced oxalic acid eluent concentration had the benefit of being further from the saturation point and also required less buffering salts to be added to the purified ^{89}Zr product prior to radiolabeling. The fluidic system was configured with an online radiometric detector to monitor all column effluents. Evaluation of the ^{89}Zr elution peak across several production runs indicated that 90% of the retained ^{89}Zr could be eluted in 1.02 ± 0.09 mL. Titrations of the resulting ^{89}Zr products with deferoxamine solutions indicated that ^{89}Zr product chemical purity was as good as that observed using the standardized method.

To improve the ^{89}Zr chemical purity, the fluidic platform was modified by O'Hara et al. (2018b) to accomplish a tandem column purification. To accomplish this, the fluidic system was expanded to a three-pump, three-valve system with configurations that allowed a separation process to occur on two columns separately and a configuration that enabled ^{89}Zr transfer from the primary column to a secondary column (Fig. 11.38B). The primary column was packed with an anion exchange resin (~ 0.83 cm^3), and the secondary microliter-scale column was packed with hydroxamate resin (~ 0.03 cm^3). The process was capable of good decontamination of iron, which is a major contaminant in ^{nat}Y foil targets and competes for binding sites with ^{89}Zr on deferoxamine-conjugated mAbs (O'Hara et al., 2018a). The ^{89}Zr product elution profiles were monitored by online radiochromatography to reveal that 90% of the product was contained within 0.29 ± 0.06 mL (Fig. 11.39). This resulted in a product that was ≥ 3.4 times more concentrated relative to the standardized method. Additionally, evaluation of the ^{89}Zr product quality by titration with deferoxamine indicated that the ^{89}Zr product purity was greater than that obtainable by the single hydroxamate resin column method.

Iodine-124 is produced through the cyclotron bombardment of an isotopically enriched $^{124}TeO_2$ target. The ^{124}I can subsequently be isolated from the target material through dry distillation (Fonslet and Koziorowski,

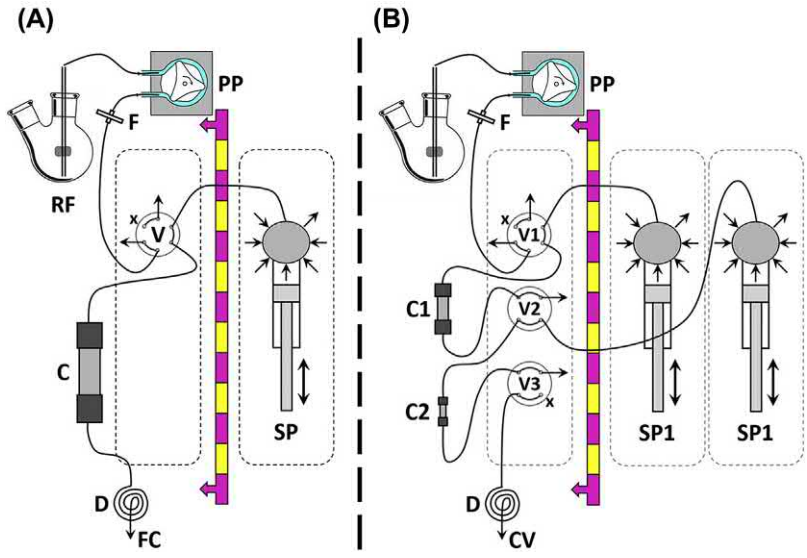

FIGURE 11.38 Fluidic systems for single-column isolation of ^{89}Zr from cyclotron-bombarded ^{nat}Y metal targets. (A) Two-pump, one-valve system that employs a single hydroxamate resin column. (B) Three-pump, three-valve fluidic system for tandem column-based isolation of ^{89}Zr from cyclotron-bombarded ^{nat}Y metal targets. System components include syringe pumps (SP), valves (V), columns (C), inline radiochromatography detector (D), product collection vial (CV), peristaltic pump (PP), and inline filter (F). *(A) Reproduced with permission from O'Hara et al. 2013; IAEA, 2016). Poniger et al. (2012) have described a simple distillation system adapted from a commercially available unit (IBA Terimo). In comparison, Nagatsu et al. (2011) developed a complex automated system that combined target handling, dry distillation, and column-based purification steps. The authors have speculated on applying this same platform in the production of the SPECT isotope ^{123}I, using an enriched $^{123}TeO_2$ target.

X. Discussion

The techniques and examples above demonstrate that modern robotic, fluidic, and sensing technology can be used to develop automated workstations for radiochemical separation and/or analyses. If desired, many of the fluidic components and solutions can be located remotely from the radioactive samples and other hot sample processing zones.

There are many issues to address in developing automated radiochemical separations that perform reliably, time after time, in unattended operation. These are associated primarily with the separation and analytical chemistry aspects of the process. The relevant issues include the selectivity of the separation, decontamination factors, matrix effects, and recoveries from the separation column. In addition, flow rate effects, column lifetimes, carryover from one sample to another, and sample throughput must be considered. Nevertheless, successful approaches for addressing these issues have been developed.

Radiochemical separations and analyses are becoming increasingly important for applications outside the conventional analytical laboratory. Applications exist where radionuclides must be measured or manipulated in at-site or in situ settings. Monitors for nuclear waste processing operations represent an at-site application where continuous unattended monitoring is required to assure effective process radiochemical separations that produce waste streams that qualify for conversion to stable waste forms. Radionuclide sensors for water monitoring and long-term stewardship represent an application where at-site or in situ measurements will be most effective. Demonstrated automated radiochemical separation systems, analyzers, and sensors have shown that applications beyond the analytical laboratory are both possible and practical.

Automation is also becoming more essential in the isolation and purification of medical radioisotopes and for coupling them into radiopharmaceuticals for medical therapies and diagnostics. Here, the dangers of radiation and the short-lived nature of the radiopharmaceuticals motivate the use of automation. Automation improves safety, whether performing processes to create patient doses at a central facility, or at the point of care in a clinical setting. Automated point-of-care processing becomes especially attractive for short-lived radioisotopes. The current trends in this field are the combination of radionuclide isolation, purification, and radiopharmaceutical preparation into sequences; the maximum degree of automation; and control of quality. The use of modern separation materials to manage process complexity, and the consistent and reproducible operation of automated systems, will facilitate development of new radiopharmaceuticals and advancements in the field of theranostics.

Acknowledgments

The Pacific Northwest National Laboratory (PNNL) is a multiprogram national laboratory operated for the US Department of Energy (DOE) by Battelle Memorial Institute under contract number DE-AC05-76RL01830. The authors would like to acknowledge our collaboration with Sandia National Laboratory in developing digital microfluidic technology to the needs of radiochemical analysis, and specifically Michael S. Bartsch and Harrison Edwards.

Jay W. Grate, PhD

Dr. Jay W. Grate is a Laboratory Fellow at the Pacific Northwest National Laboratory (PNNL) and an Affiliated Professor with the Chemistry Department of the University of Washington. He is a Fellow of the Electrochemical Society, a Battelle Distinguished Inventor, and a Wiley Research Fellow of the Environmental Molecular Sciences Laboratory at PNNL. He received a BA in Chemistry at Rollins College (summa cum laude) and received his PhD in Chemistry from the University of California, San Diego. After postdoctoral research at the University of California Irvine, he joined the Naval Research Laboratory in 1984, moving to the PNNL in 1992. Prior to joining PNNL, he spent a sabbatical at the Scripps Research Institute in a group developing catalytic antibodies. Dr. Grate has broad research experience in separation, sensing, and analysis as they apply to diverse national mission areas. In the course of his research, he has found the science in the applications and published in journals, reviews, and books; his work has appeared on the covers of *Analytical Chemistry*, *Langmuir*, *Chemical Communications*, *Analyst*, and *Chemical Reviews*. At the Naval Research Laboratory, he established his reputation in analytical chemistry in the development and understanding of polymer-coated acoustic wave vapor sensors. He continued this work at PNNL, winning ACS and R&D100 awards for development of polymeric materials for sensor applications; these materials developments were enabled by a more fundamental understanding of vapor−polymer chemical interactions. He has developed and sustained programs at PNNL in such areas as radiochemical separations and analysis, analytical microfluidics for biodetection, radionuclide sensors for water monitoring, and fluorescent techniques for oxygen sensing in microfluidic structures. He has also developed biocatalytic nanostructured materials and new sequence-defined biomimetic polymers.

Matthew J. O'Hara

Matthew J. O'Hara is a senior research scientist in the Nuclear Chemistry and Engineering technical group of the Pacific Northwest National Laboratory. He has more than 20 years of R&D experience, with extensive knowledge in the fields of radiochemistry and laboratory automation. A major focus of his research has been the selective online preconcentration/separation/purification/detection of radionuclides from various media using autonomous fluid handling and measurement systems. Instrumentation and chemistries developed during his career at PNNL have targeted specific radionuclides, with the objective of activity quantification ranging from trace levels in environmental matrices to high-level nuclear waste solutions. He has also developed sample processing platforms used to expedite the radiochemical processing of samples for national security applications. Additionally, he has developed a number of fluid processing systems for the isolation of medically relevant radionuclides from longer-lived parent isotopes and accelerator targets.

Oleg B. Egorov, PhD

Dr. Oleg B. Egorov is recognized for his research work in radiochemistry, radioanalytical chemistry, analytical chemistry, and instrumentation. His current professional interests include production of medical isotopes, development of new radiopharmaceuticals, and medical devices for brachytherapy, theranostics, nuclear medicine imaging software, and technology commercialization. Prior to becoming an independent consultant in 2009, Dr. Egorov had worked as a director of Research and Development for Isoray Medical Inc. Dr. Egorov had worked as a senior research scientist at the Pacific Northwest National Laboratory (PNNL) where he had led and contributed to world-class basic and applied R&D programs directed at new chemistries and instrumentation for automated production of short-lived medical isotopes for the treatment of cancer, automated process monitoring, radionuclide sensors for groundwater monitoring, and laboratory automation. He has authored/coauthored numerous peer-reviewed publications and holds nine US/international patents. Dr. Egorov holds a PhD in Analytical Chemistry from the University of Washington.

I. Introduction

Nuclear safeguards is the system of policies and technical measures developed to ensure that fissionable materials are being used for their intended peaceful purposes and are controlled through the implementation of technologies, procedures, and policies. Nuclear material of safeguards concern is most commonly plutonium or enriched uranium, but thorium and other isotopes of uranium are also under safeguards. All states have internal safeguards standards typically framed in legislative requirements. For nonnuclear weapon states, safeguards is also implemented

at the international level. The International Atomic Energy Agency (IAEA) is the world's safeguards organization. Other safeguards organizations exist at the regional level, for example, the Brazilian-Argentine Agency for Accounting and Control of Nuclear Materials (ABACC) and the European Atomic Energy Community (EURATOM). While ABACC is purely a safeguards verification organization, both EURATOM and the IAEA also play a role in fostering international cooperation on the use of nuclear technology. These international organizations' safeguards measures are generally applied in addition to national requirements. It is important to note that unlike most state-level safeguards organizations, international organizations are not enforcement organizations. The U.S. Nuclear Regulatory Commission regulates safeguards implementation as part of the licensing process and can therefore take action against a facility found to have inadequate safeguards measures in place. International organizations such as the IAEA do not exercise such authority over facilities in member states. International organizations are verification and reporting organizations. If a facility or state is found to have inadequate safeguards measures or cannot be shown to have complied with their safeguards obligations, the response focuses on attempting to improve cooperation on the part of the facility or state and on notifying the other member states of the issue to be resolved in a political forum. In the case of the IAEA, the United Nations Security Council is also informed in addition to member states.

For many years, the primary means of implementing safeguards was verification of information provided by the facility or state. Inspectors would be provided with a list of nuclear material in use at a facility, commonly referred to as a declaration. Inspection efforts focused exclusively on verifying the accuracy of that declaration by auditing records of material receipt, use, and transfer out of the facility. The measurement technology and methodology discussed in this chapter was and is used to independently verify characteristics of the nuclear material such as uranium enrichment or total plutonium mass.

After the first Gulf War in 1990–91, the international safeguards community realized that verifying the accuracy of a declaration was necessary, but not sufficient, to conclude that a state was in full compliance with its safeguards agreements. The Additional Protocol (IAEA, 1997) was drafted by the IAEA to clarify the authority necessary for Agency personnel to verify both the accuracy and completeness of a state's declaration. This involves new technology challenges, which are often directed at the detection of possible undisclosed facilities, more than the nuclear material itself. As such, technology used toward these ends is beyond the scope of this reference.

As part of the safeguards approach, nuclear material samples are obtained and sent to laboratories for destructive analysis (DA). Laboratory measurements can produce very precise, highly accurate results. These measurements, however, require opening containers (involving the potential risk of generating loose contamination), shipping radioactive materials, and waiting for results (typically on the order of weeks to months) and are expensive. In-field measurements, while less precise and accurate than laboratory measurements, do not require sample collection, generally give results in minutes, and are less expensive. The measurement techniques used for measurements of nuclear material are based on conventional detectors such as NaI(Tl) and germanium detectors for detection of gamma rays or ^{3}He tubes and fission chambers for detection of neutrons. The specific analysis techniques utilized are adapted to the particular characteristics of the nuclear material and measurement environments found in nuclear fuel cycle facilities. Also, in most cases, the information of greatest importance to safeguards personnel is the total nuclear mass of ^{235}U or plutonium, and this often cannot be obtained from a single instrument. For example, a plutonium mass value obtained by nondestructive assay (NDA) is calculated by multiplying the power (in watts) obtained from a calorimeter with the effective specific power (in watts/gram Pu) obtained by analysis of a spectrum taken from the item with a germanium detector. This chapter will focus on the NDA measurements most often used for nuclear material accounting.

II. Photon-based assay for safeguards

A. Introduction: characteristics of U/Pu and their spectra

Gamma ray spectroscopy plays an important role in NDA. With few exceptions, all measurement techniques require information about the enrichment of uranium or isotopic composition of plutonium of the item being assayed to produce a mass value. Gamma spectroscopy is the primary NDA tool that meets this need.

Uranium is found in nature with approximately 0.72% ^{235}U (this and the following values are in atom percent). Uranium-235 is usually the principal uranium isotope of safeguards concern. Uranium-238 is the most abundant isotope found in natural uranium, at 99.27%. Uranium-234 is a trace isotope with a natural value of 0.0006%. "Recycled" uranium that has been recovered from spent nuclear fuel will also contain ^{236}U. Some NDA techniques need to be adapted to take the ^{236}U signatures into account.

Plutonium is a mixture of five plutonium isotopes (^{238}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, ^{242}Pu), ^{241}Am, and to a small amount ^{237}U. The half-life of ^{242}Pu is an order of magnitude longer than any other plutonium isotope, and it does not produce detectable gamma rays in typical gamma ray measurement of plutonium items. The implication of this on safeguards measurements will be discussed further on in this chapter.

Plutonium 241 has a short half-life (14.35 years) and decays both by alpha decay and β^- decay so its daughter products (^{241}Am and ^{237}U) are present in all plutonium very soon after chemical separation. All plutonium items produce detectable americium and uranium radiations. In the case of americium (^{241}Am), the 60-keV gamma ray will dominate the spectrum if measures are not taken to attenuate it. This will be discussed in greater detail below. The uranium (^{237}U) is important because it contributes characteristic X-rays in the X-ray region of the spectrum and because it quickly achieves secular equilibrium with ^{241}Pu, enabling ^{237}U gamma rays to be used as if they originated directly from the decay of ^{241}Pu. The analyst can therefore use ^{237}U gamma rays to measure ^{241}Pu concentration.

The spectrum of plutonium, and to a lesser extent, uranium, is complicated. There are many gamma rays present, often coenergetic with gamma rays from other isotopes or elements. There are unresolved multiplets and complex regions including characteristic X-rays and gamma rays, and there may be cascade sums. However, measurements can often be taken under well-controlled conditions, on material that is free of gamma ray–producing impurities. This enables us to perform a surprising number of measurement tasks with low-resolution detectors, despite the complexity of the gamma ray spectrum.

1. Attribute tests

An attribute test is a test performed to prove or disprove the hypothesis that a given item contains the declared nuclear material. This is a quantitative test in the sense that mathematical criteria are used to determine if the hypothesis is proven or disproven. The qualitative test only provides an answer that is simply a "yes" or a "no." Attribute tests do not provide information such as the mass of uranium or the isotopic composition of plutonium but simply confirms the presence of the nuclear material.

Gamma ray-based attribute tests are typically performed by taking a background spectrum and comparing the background spectrum to a spectrum taken from the item being tested. A region of interest (ROI) is chosen around one or more gamma ray peaks that are used to indicate the presence of the isotope in question. The ROI should be selected to minimize the risk of a false positive result. This means selecting a region that contains a dominate gamma ray emitted from the material to be tested. For uranium, the 185.7-keV peak that comes from ^{235}U or the 1001-keV peak from ^{238}U is typically chosen. For plutonium, the 208 keV region or the 375–414 keV regions are typically chosen for attribute testing.

The location of the background spectrum is a critical choice in the proper performance of an attribute test. Usually, an item will have to be tested in the presence of other items containing the same nuclear material. Consequently, taking a background in a location that is too isolated from the nuclear inventory located and stored in the facility will produce a background count rate in the ROI that is unrealistically low. When this occurs, any spectrum taken under more realistic conditions—near the rest of the material—will indicate that the item passes the attribute test, regardless of whether the item being tested actually contains the material in question. The NDA practitioner should take a background in a configuration as close to the measurement configuration as possible. If possible, the best approach would be to bring the nuclear material to a location where the background was measured. If this is not possible, the background should be measured at a location that best represents the background at the measurement location.

The acceptance criterion used to determine if a given item passes or fails the attribute test is shown in Eq. (12.1).

$$A_i > Al, \quad \text{where } AL = T_i\left[BR + 3\sqrt{\left(\frac{S_B}{T_B}\right)^2 + \left(\frac{S_i}{T_i}\right)^2}\right] \tag{12.1}$$

where AL is the acceptance level, A_i is the item net area in the ROI, S_i is the uncertainty of A_i as calculated by the spectral analysis software, T_i is the count time for item verification, T_B is the count time for background measurements, BR is the background net area in the ROI divided by background count time T_B, and S_B is the uncertainty of the background net area in the ROI.

Conceptually, an item will pass the attribute test if the count rate in the ROI taken from the item is more than the background count rate plus three times the combined uncertainty of the two counts. If the items are being measured in a very-low-background area, Eq. 12.1 simplifies to three times the uncertainty in the ROI from the item spectrum itself.

For individual items, the detector can often be shielded well enough to virtually eliminate background and allow the user to employ the simplified acceptance limit calculation. For fresh fuel assemblies, which require a crane to move, the items must generally be evaluated in the storage racks where they are found, necessitating the use of the more rigorous acceptance level shown in Eq. (12.1).

Spent fuel attribute tests are significantly different from other attribute tests. Spent fuel contains the majority of the plutonium in the world and is consequently of great safeguards significance. However, the gamma signal from the plutonium is typically difficult or impossible to identify in the presence of the fission fragments and activation products in the spent fuel. Furthermore, spent fuel that has recently been removed from the core of a power reactor produces radiation levels that need to be shielded for the

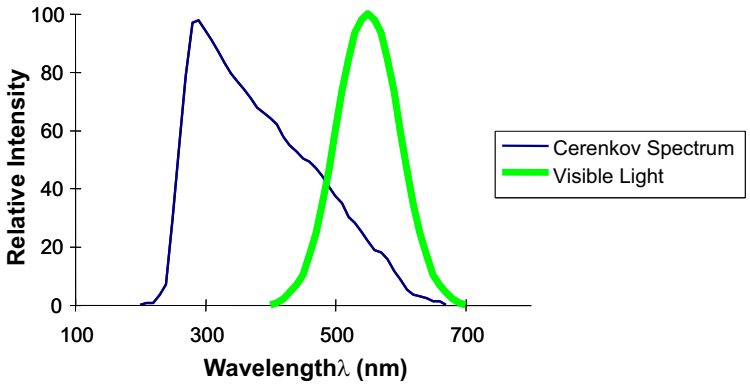

FIGURE 12.1 Spectrum of Cerenkov light compared with visible light. For the color version of the figure, the reader is referred to the online version of the book.

safety of the workers. This is commonly accomplished by storing the spent fuel in water. The attribute tests performed by safeguards personnel are indirect indications of the presence of plutonium. They assume that in a spent fuel assembly, the presence of fission products indicates that the assembly is undisturbed, and therefore, the plutonium is still present. Typically, the 662-keV gamma ray emitted from ^{137}Cs is used to indicate the presence of fission products and hence a spent fuel assembly. There are no credible techniques for removing the plutonium from a spent fuel assembly without significantly and obviously altering the physical appearance of the fuel and removing the fission products that produce the signals on which the attribute tests are based.

2. Cerenkov analysis of spent fuel

Two signals that are used for attribute testing of spent nuclear fuel are gamma rays and Cerenkov light. Cerenkov analysis is a widely used evaluation technique for spent fuel (IAEA, 2003). This technique has the advantage of allowing very rapid analysis of spent fuel assemblies. The drawbacks of this technique are that it is based on a qualitative analysis of the light produced by a spent fuel assembly. No quantitative data is produced by older systems. Newer, digital systems can produce quantitative data (Grape et al., 2010). Also, this technique can only be applied when the water in the spent fuel pond allows the clear transmission of light from the spent fuel assemblies to the surface of the pond. In some facilities, the pond water is not clear enough to permit Cerenkov analysis of the spent fuel attributes. In this case, an attribute test using gamma rays as discussed above must be used.

Cerenkov light is produced by radiation emitted from the spent fuel. Charged particles, primarily electrons, are produced by ionization of the water by gamma rays from the spent fuel. Some of these particles will be traveling at speeds greater than the speed of light in water. These particles produce a shock wave in the water, analogous to the shock wave produced by a body moving through air at greater than the speed of sound. This shock wave produces photons of visible light, as excited electrons revert to lower energy states. See Chapter 6, Volume 2 of this book for additional information on Cerenkov radiation, and a comprehensive treatment on Cerenkov radiation is provided by L'Annunziata (2007, 2016). The energy spectrum of the light produced is shown in Fig. 12.1.

Cerenkov light has a distinctive appearance when produced by spent fuel submerged in water. The long, thin fuel rods collimate the light, producing a glow profile that is maximized when the Cerenkov viewing device is directly above the assembly and drops off rapidly, as the device is moved off axis from the assembly. The intensity of the light produced by an assembly increases with burnup and decreases with cooling time, as the short-lived isotopes decay away.

The detectors used to evaluate Cerenkov glow are telephoto lenses with infrared filters and image intensifiers. The infrared filters reduce the interference from other visible light sources. The image intensifiers can be either photocathodes combined with phosphor screens, to bring the filtered light into the visible range and increase its intensity, or digital cameras (Chen et al., 2007). The images are evaluated by trained personnel, who look at the intensity of the light and the distinctive intensity profile arising from the collimation effects. Training is important, as the evaluation of the attribute test result is fundamentally a judgment call made by an investigator. This evaluation becomes more difficult as items age in the pond. The evaluation is also more difficult when a weak Cerenkov source or an item that is not a source of Cerenkov light is surrounded by many strong sources of Cerenkov light.

When Cerenkov evaluation is not possible, because of the poor transmission of light in the spent fuel pond or because the age of the items needs to be verified, safeguards personnel apply techniques based on the evaluation of ionizing radiation produced by the fuel assemblies. Gamma spectra are obtained either by positioning the detector in close proximity to the fuel (i.e., Fork detectors (Rinard and Bosler, 1998) or Irradiated Item Attribute Tester (Zendel,

2008)) or by introducing an air column into the pool to provide an unshielded path for the gamma rays to travel from the spent fuel assembly to the detector (i.e., the Spent Fuel Attribute Tester (Tikkinen and Tarvainen, 1990)). The acceptance level criteria for the Irradiated Item Attribute Tester and the Spent Fuel Attribute Tester are calculated as shown in Eq. (12.1). In addition to gamma spectroscopy data, the Fork detector also contains fission chambers for the collection of neutron rate data. The combination of the gross gamma ray count rate and the neutron signal is attributed to the spent fuel assembly.

3. Active length measurements

Operator declarations of fresh fuel rods or fuel assemblies typically give the total grams of ^{235}U, while the neutron collar (Menlove et al., 1990) used to verify fresh fuel assemblies produces results in grams of ^{235}U per unit length. To verify the total ^{235}U mass in this case, the length of the rod or assembly must be verified. This is referred to as the active length of the rod or assembly. The active length is less than the full length of the rod or assembly because of internal structures at the ends of the rod, such as the spring that is included in one end of most fuel rods or the end caps that provide structural support to the fuel assemblies.

Active length measurements are performed with gamma detection instruments such as thallium-doped sodium iodide [NaI(Tl)] detectors. To determine the active length, the count rate within the active area containing nuclear material and the count rate from the inactive portion without nuclear material is measured. The limits of the active length are the two locations where the measured count rate equals the average of the two measurements (one within and one outside the zones containing nuclear material). The limits are found by scanning the length of the item and identifying the two end locations, as they are found. The distance between these two points is then measured with a tape measure or other similar means. These measurements can be performed with almost any spectroscopic system. With a good detector and some simple software, measurement bias can be as low as 2- or 3-mm for a 4-m rod or assembly, but for realistic measurements in an operating facility, the uncertainties are usually 1 or 2 cm. If a slit collimator is being used, the point under the center of the slit should be marked when the end of the active zone is found. If a round collimator is used, any reference point can be used (left edge, center, or right edge) as long as the same point in the collimator area is used at both ends of the item.

4. Sample screening with X-ray fluorescence

X-ray fluorescence is a well-known technique that is used in safeguards to identify the presence of elements in items and to identify impurities in nuclear material. Characteristic X-rays of nuclear material are found in the 100-keV region of the spectrum. The intensity of the characteristic X-rays is determined by the activity of the irradiation source and the concentration of the material being evaluated. In large masses, self-irradiation can produce strong X-ray fluorescence signals. External irradiation sources are only necessary when the volume visible to the detector is very small. High intensity can be obtained by proper selection of setup parameters such as source–detector geometry, source strength, and sample size. Either isotopic or machine-generated radiation can be used to irradiate the sample. The general assay equation is

$$\rho = \{RR \times CF(RL) \times CF(AT)\}/K \tag{12.2}$$

where ρ is the concentration of the element, RR is the raw (uncorrected) rate of X-ray detection, $CF(RL)$ is the correction factor of rate-related losses, $CF(AT)$ is the correction factor for sample self-attenuation, and K is the calibration constant.

The calibration factor takes into account the effect of the intensity of the irradiation source. A change in calibration source (through decay or because of a replacement of the source) will necessitate the determination of a new calibration constant.

These techniques can be used to screen for the presence of nuclear material in samples, to screen nuclear material samples for selected impurities, to measure nuclear material concentrations, or to measure U/Pu ratios.

B. Uranium enrichment (infinite thickness)

1. General approach

One technique for the measurement of uranium enrichment by gamma ray spectroscopy involves correlating the count rate for a ^{235}U gamma ray to the enrichment of the item being analyzed. Enrichment is typically expressed in one of two ways. Enrichment can be expressed as weight percent, which is the mass of ^{235}U as a percentage of the total mass of the element uranium. Enrichment can also be expressed as an atom percent, which is the total number of ^{235}U atoms as a percentage of the total number of elemental uranium atoms. DA techniques typically report results in atom percent, whereas NDA techniques typically report results in weight percent. Many NDA software packages, however, have been programmed to display both the atom percent and weight percent values to facilitate comparison between the NDA result and the DA results. Consult the manufacturer's documentation for the software or NDA system to determine which type of enrichment value the system provides. The conversion equation is

$$E_{\mathrm{wt\%}} \approx (235E_{\mathrm{at\%}})/(238 - 0.03E_{\mathrm{at\%}}) \tag{12.3}$$

where $E_{at\%}$ is the enrichment in atom percent and $E_{wt\%}$ is the enrichment in weight percent.

The 185.7-keV gamma ray is the almost universal choice for uranium enrichment measurements using the infinite thickness technique. The efficiency of most detectors is good in this energy range, the gamma ray is penetrating enough to be detectable through most container walls found in the nuclear industry, and the gamma ray is sufficiently well resolved to produce results with acceptable accuracy and precision in gamma ray detectors of both low and high resolution.

The most commonly applied method of measuring uranium enrichment is referred to as the infinite thickness technique or the enrichment meter technique (ASTM-C1514-08, 2017). This method requires a very reproducible geometry typically obtained by enclosing the gamma spectroscopy detector in a collimator, which restricts the detector's field of view. This method assumes that the volume of material defined by the collimator is completely filled with nuclear material. Self-attenuation within the uranium provides a consistent depth of view within the material. This depth is defined as the infinite thickness.

For the infinite thickness criterion to be met, the item must be thick enough that the 185.7 keV gamma rays from the back edge of the item *cannot* penetrate through the uranium to reach the detector. Once the item is thick enough to meet this condition, it is said to be infinitely thick because the detector would produce the same count rate from the actual item being measured or from an item that was thicker. For practical purposes, this requires the item to be at least seven mean free paths thick. A mean free path is defined as the thickness of material that will reduce the gamma intensity at a given gamma ray energy to one half of its unattenuated intensity, as described in Chapter 1, Volume 1 of this book. The mean free path is the average distance the gamma ray travels through the material before it undergoes some sort of interaction, such as Compton scattering or the photoelectric effect. The criteria for infinite thickness for a variety of uranium compounds are shown in Table 12.1.

A simple *Gedankenexperiment* will explain this requirement. Imagine a single mean free path thickness of uranium, wider than the collimator on a spectroscopic detector. If we determine a count rate from the single mean free path thickness layer and then add a second mean free path thickness layer (doubling the thickness and hence the mass of material above the collimator opening), less than half of the gamma rays from that second layer will penetrate the first mean free path thickness layer to reach the detector. So the count rate will increase, but by much less than a factor of 2. Each additional layer added will produce a diminishing increase in the count rate, until so much material is already present that the gamma rays from an additional layer have a negligible probability of reaching the detector. Once this is true, the "infinite thickness" criterion for that material has been reached and adding additional layers will not change the count rate in the detector. Less than 0.1% of gamma rays emitted beyond seven mean free paths thickness will reach the detector. Given items with the same chemical form and container walls, the only source of variation in the 185.7 keV count rate will therefore be the number of ^{235}U atoms within the detectable volume. This enables us to correlate the count rate to the ^{235}U enrichment.

2. Correction factors

Unless calibration standards are available that are in identical containers and of the same chemical form as the items to be measured, obtaining accurate results requires corrections to be applied to account for differences in container attenuation and uranium chemical composition.

a. Wall thickness

Gamma rays that penetrate the uranium itself must also pass through the container wall to be detected. For example, if the calibration sources have a 1-mm-thick steel wall and the items to be measured/verified have a 2-mm-thick steel wall, uncorrected measurements will be biased toward results

TABLE 12.1 Mean free path and infinite thickness values for common uranium compounds.

Material	Density ρ (g/cm^2)	Mean free path λ (cm)	Infinite thickness (cm)
Metal	18.70	0.04	0.26
UF_6 (solid)	4.70	0.2	1.43
UO_2 (powder)	10.90	0.07	0.49
UF_6 (sintered)	2.00	0.39	2.75
U_3O_8 (powder)	7.30	0.11	0.74
Uranyl nitrate	2.80	0.43	3.01

TABLE 12.2 Chemical composition correction factors.

	Measured item					
Calibration Standard	U	UC	UO2	U3O8	UF6	Uranyl nitrate
U (100% U)	1.000	1.004	1.011	1.014	1.038	1.090
UC (95% U)	0.996	1.000	1.007	1.010	1.033	1.086
UO_2 (88% U)	0.989	0.993	1.000	1.003	1.026	1.078
U_3O_s (85% U)	0.986	0.990	0.997	1.000	1.023	1.075
UF_6 (68% U)	0.964	0.968	0.975	0.978	1.000	1.051
Uranyl nitrate (47% U)	0.917	0.921	0.927	0.930	0.952	1.000

that are below the true enrichment values. This is because the 2-mm-thick steel wall will absorb more of the 185.7 keV gamma rays than with the calibration standard containers. The attenuation properties of the most common container materials are well known and can be calculated using the standard attenuation formula:

$$I = I_0 e^{-\mu_m \rho x} \tag{12.4}$$

where I is the intensity of the gamma radiation transmitted through an absorber, I_0 is the initial gamma ray intensity, μ_m is the mass attenuation coefficient with units of cm^2/g, ρ is the density of the absorber in units of g/cm^3, and x is the absorber thickness in cm.

(See Chapter 1, Volume 1 of this book for a detailed treatment of gamma ray attenuation calculations). This formula is a sensitive function of wall thickness necessitating precise knowledge of the wall thickness. This can be done with reference to institutional knowledge of the container design in some cases. In other cases, the containers may not be sufficiently well characterized, and measurements may be necessary. These measurements can be performed with an ultrasonic thickness gauge. For containers such as 30B containers used for UF_6 storage and transportation, the thicknesses can vary significantly between different locations on the same container. For these containers, the thickness should be determined at the exact point where the calibration measurements or assay measurements are going to be performed.

Many of the software tools in use for infinite thickness uranium measurements automate the wall thickness correction process if provided with calibration standard wall parameters and measurement item wall parameters.

b. Sample composition

As shown in Table 12.1, the density of the commonly encountered chemical forms of uranium varies by almost an order of magnitude. Consequently, the volume of loose UO_2 powder visible to a detector is significantly greater than the volume of uranium metal that would be visible to the same detector. This will significantly bias uncorrected measurements made with a system calibrated using a different form of uranium from the items to be measured. Again, however, the correction factors can be easily calculated. Values for a variety of common forms of uranium are shown in Table 12.2. These correction factors are often applied automatically by the commonly used software packages.

3. Low-resolution measurements

The infinite thickness technique is widely employed using low-resolution detectors such as NaI(Tl) scintillators. The resolution of a NaI(Tl) detector is not sufficient to isolate the 185.7 keV gamma ray. The primary consequence of the low resolution is the inability to position a background ROI below the 185.7-keV gamma ray, because the X-ray region and the 143.8 keV gamma ray (also from ^{235}U) provide too much interference. The only location available for the background ROI is at an energy region above 185.7 keV. The usual practice is to position an approximately 50-keV-wide ROI around the 185.7-keV-peak and an approximately 60-keV-wide background ROI above the peak ROI. This background ROI is usually separated from the peak ROI by about 10 keV. The enrichment calculation equation for this method is

$$E\% = \{A(\mathrm{ROI}_{\mathrm{peak}}) + B(\mathrm{ROI}_{\mathrm{background}})\}K_1K_2 \tag{12.5}$$

where $E\%$ is the enrichment of the item, A is a calibration constant, $\mathrm{ROI}_{\mathrm{peak}}$ is the count rate in the ROI positioned on the 185.7-keV peak, B is a calibration constant possessing a negative value, $\mathrm{ROI}_{\mathrm{background}}$ is the count rate in the background ROI, K_1 is the container wall correction discussed above, and K_2 is the item composition correction discussed above.

Low-resolution enrichment measurements require two or more calibration standards to determine the calibration constants because there are two calibration constants. The

background count rate is inversely proportional to enrichment because the primary source of counts in the background ROI is Compton scattered high-energy gamma rays dominated by the 1001-keV gamma ray from the decay of ^{234m}Pa, a daughter product of ^{238}U. For lower enriched items, the high-energy gamma rays from ^{238}U decay will be abundant, leading to a higher level of background counts than will be found in highly enriched items. In highly enriched items, little ^{238}U is present, leading to less count rate in the background ROI.

Despite the low resolution of detectors such a NaI(Tl), the high efficiency of these detectors results in good measurement statistics in a short measurement time, producing low bias results with random uncertainties on the order of 3%−5% for typical measurements on low enriched uranium with typical measurement times of 60−120 s.

The wall thickness corrections, as typically employed, are based on the standard thin beam attenuation function (see Eq. 12.4). This limits their applicability to wall thicknesses that are comparable with those used for the calibration measurements. If the calibration sources are contained within 2-mm steel walls, the correction factor will work well for 1−4 or 5 mm of steel. The correction factor will not produce good results for 15-mm steel walls, as this no longer approximates the thin beam geometry that is assumed by the formula and does not correct for scattering and buildup effects. When calibrating a system for use on thick-walled containers, such as a UF_6 cylinder, one must calibrate using a thick-walled container for the correction factor to work well or use the response function fitting method described below.

The response fitting method is an alternate technique for the analysis of uranium enrichment using low-resolution detectors, which has been developed by Dr. Ray Gunnink (Gunnink and Arlt, 2001; Mortreau and Berndt, 2004). This technique takes advantage of the fact that the shape of the background under the 185.7-keV gamma ray can be modeled based on the well-known physics of Compton interactions. The 185.7-keV and surrounding gamma rays can also be fitted with response functions, as their energies and branching ratios are well known, and the resolution and tailing parameters of the detector can be determined from any uranium item measurement. Knowing all of this physics, the 185.7-keV peak can be accurately fit. This fit contains three components: a background component that is predominately resulting from Compton scattering of the 1001-keV gamma ray from ^{238}U, small angle Compton scattering of the 185.7-keV gamma rays, and full energy 185.7-keV gamma ray peak. By fitting the response of the detector to these three components, an accurate net peak area for the 185.7-keV gamma rays can be determined. This simplifies the enrichment measurement equation to

$$E\% = AC_{peak}K_1K_2 \tag{12.6}$$

where $E\%$ is the enrichment of the item, A is a calibration constant, C_{peak} is the count rate determined from the response function fit to the full-energy 185.7-keV ^{235}U peak, K_1 is the container wall correction discussed above, and K_2 is the sample composition correction discussed previously.

This is an infinite thickness technique, so the corrections and geometry requirements discussed above still apply. The technique also requires that the user enters geometric information about the collimator and data on container wall thickness and composition. The more accurate physics in the software makes the container wall thickness correction more flexible and robust than the standard correction factors applied to the two ROI method of infinite thickness and eliminates bias caused by calibrating and assaying items with substantially different wall thicknesses.

4. High-resolution measurements

High-resolution detectors, such as germanium detectors, are typically used in situations where the uranium enrichment must be measured in the presence of other radioactive materials that emit interfering gamma ray lines. Other radioactive materials can produce gamma rays that would interfere with the wide ROIs necessary for low-resolution systems. The best example of interference effects is enrichment measurements of UF_6 cylinders. These cylinders often contain residue daughter products that remain after the UF_6 has been removed. When new uranium is added to the cylinder, the daughter products can produce gamma rays that interfere with the usual ROIs described above for low-resolution systems, producing biases in the enrichment measurements. With the significantly better resolution of germanium detectors, such interferences can easily be avoided. Background ROIs can easily be chosen above and below the 185.7 keV peak, enabling simple calculation of an accurate net peak area. This enables us to use Eq. (12.6) for the calibration of the system. The wall thickness correction factor, K_1, is critically important, as the UF_6 cylinder thickness varies from location to location on one cylinder, much less from cylinder to cylinder. Typical wall thickness is around 1.5 cm of steel, which results in correction factors on the order of 8. Wall thickness variations of 5% will result in correction factor changes of around 10%. To minimize this uncertainty, the wall thickness correction is best calculated based on a measurement of the wall thickness at the position where the germanium detector will be located. An ultrasonic gauge is commonly used for determining wall thickness.

Planar or coaxial germanium detectors can be used for UF_6 cylinder enrichment measurements. The IAEA typically uses planar detectors, with 1000 mm^2 surface area for good efficiency at 185.7 keV. Good collimation and side

shielding is essential. This is always true with infinite thickness measurements, but particularly so with UF_6 measurements, as they are typically performed in crowded conditions, with one cylinder located centimeters away from another, if there is any separation at all.

5. Specialized geometries (fuel pellets and rods)

The infinite thickness technique requires two conditions to be true that the item is infinitely thick and that the entire field of view, as defined by the collimator, is completely filled with nuclear material. However, if other methods are available to ensure very consistent geometry without meeting all the conditions typically required for the infinite thickness method, the technique can still be applied. This is commonly referred to as the infinite thickness technique with fixed geometry. In the nuclear industry, fuel pellets and fuel rods are made to specified dimensions with strict quality control standards. As such, the enrichment of these items can be measured with the infinite thickness technique with the fixed-geometry method.

Several measurement conditions must be fulfilled for the infinite thickness with fixed-geometry method to yield accurate results. The geometry of the item must be identical to the calibration standard, and the item-to-detector distance must be fixed. In the case of fuel pellets and fuel rods, the dimensions of the nuclear material are essentially identical as required by production standards. Maintaining a fixed distance between the item and detector is easily obtainable by positioning the pellets or rods into a specially made holder. For rods, the holder is typically made with a semicircular groove that allows the rods to be reproducibly placed at the same position within the field of view of the detector. For pellets, a holder with five circular holes is typically used, and the measurement is made with five fuel pellets of the same enrichment standing on end. In theory, any number of pellets could be used, but five was chosen as a good number to get reasonable uncertainty for count time on the order of minutes.

Under these conditions, the count rate will vary proportionally to the enrichment. Typically, the responsive fitting method is used to determine the count rate from the 185.7-keV gamma rays, and this method allows for calibration with one standard. In theory, every pellet or fuel rod with different dimensions would require a separate calibration. In practice, this would be impracticable because of the many different dimensions of fuel pellets used in the nuclear industry. To account for varying dimensions, a correction factor is applied that accounts for different detector response to varying dimensions of fuel pellets. The correction factor essentially adjusts the detector response from the geometry of the fuel pellets or rods used to calibration that the system to the geometry being assayed.

Since fuel pellets are assayed in a bare state, no other correction factors are required besides the detector response adjustment for varying geometry. Fuel rods come in a variety of diameters and cladding wall thicknesses, so both a geometric correction factor and an attenuation correction factor must be applied.

These measurements yield results with accuracies on the order of a couple of percent with a several-minute count time. Care must be taken to ensure that the correct dimensions are used, which are provided by the facility operator. Background from the material contained within the facility can potentially bias the measurement results if not corrected for.

C. Isotopic measurements of uranium and plutonium

1. Characteristics of the uranium and plutonium spectra

The uranium spectrum contains characteristic X-rays in the 90−120 keV region, and many gamma rays spread over the energy range from 90 to 1001 keV. The spectrum from a 20% enriched item is shown in Fig. 12.2.

The X-ray region from ~90 to 120 keV is so named, because the gamma rays in this portion of the spectrum are collocated with the characteristic X-rays of uranium. This region contains gamma rays associated with ^{234}U, ^{235}U, and ^{238}U. Careful peak deconvolution methods must be applied to analyze this region of the spectrum, but faster and more precise results are generally obtainable in this region of the spectrum than any other because of the large intensity of the gamma rays and the high intrinsic detector efficiency in this region. Poor detector resolution or thick-walled containers can prevent the successful analysis of this region.

Above the X-ray region, we find four strong gamma rays from ^{235}U, including the peak that is usually the most intense in most uranium spectra; the 185.7 keV peak. These peaks are each separated by approximately 20 keV and form a distinct quartet that make the high-resolution uranium spectrum immediately recognizable as such. These four peaks are 143.7, 163.4, 185.7, and 205.3 keV.

The qualitative appearance of the spectrum above the 205.3 keV can provide a quick indication if the item is low or highly enriched. For items of enrichment below approximately 10%, the spectrum appears essentially featureless for energies above 205.3 keV. As the enrichment exceeds 20% by a larger and larger margin, the region immediately above 205.3 keV exhibits more and more gamma rays. These gamma rays never match the intensity of the 205.3 keV gamma ray but become more and more clearly visible on a logarithmic scale. Experienced spectrometrists can give a very rough estimate of the enrichment

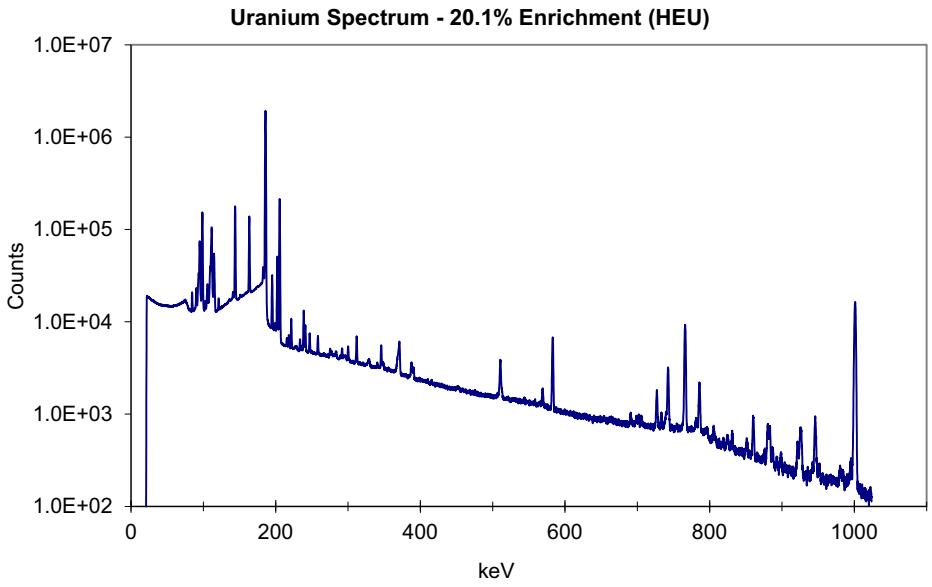

FIGURE 12.2 High-resolution spectrum of uranium. For the color version of the figure, the reader is referred to the online version of the book.

by simply observing the spectrum, but care must be taken as shielding can easily distort the spectrum.

Above approximately 500 keV, virtually all of the significant gamma rays are from ^{234m}Pa, which can be used to determine ^{238}U content in aged items. The most intense peak in the higher energy portion of the spectrum is the 1001.0 keV. One should not attempt to estimate uranium enrichment, even approximately, by comparing the intensity of the 185.7 keV gamma ray with that of the 1001.0 keV gamma ray. Item shielding and detector efficiency can have very strong effects on the detection efficiency over this large energy range.

The plutonium spectrum, shown in Fig. 12.3, is considerably more complex than the uranium spectrum.

The major gamma rays from the principal plutonium isotopes and ^{241}Am are shown in Table 12.3.

As can be seen in Table 12.3, there are many options for analyzing the plutonium spectrum. Complete isotopic information can be found in the X-ray region, the 125−300 keV region, and at energies above 300 keV. This gives the spectroscopist a variety of choices for how to analyze a plutonium spectrum.

The first visible peak in Fig. 12.3 is the 59.6 keV gamma ray from ^{241}Am. This is by far the most intense gamma ray in the plutonium spectrum. For bare plutonium or plutonium in thin-walled containers, this gamma ray will dominate the spectrum to such an extent that the intensity reaching the detector must be reduced to make measurements of plutonium isotopics practical. In the spectrum shown in Fig. 12.3, the 59.6-keV gamma ray has been filtered with approximately 2 mm of cadmium metal. Cadmium is an excellent choice for this filter, as the

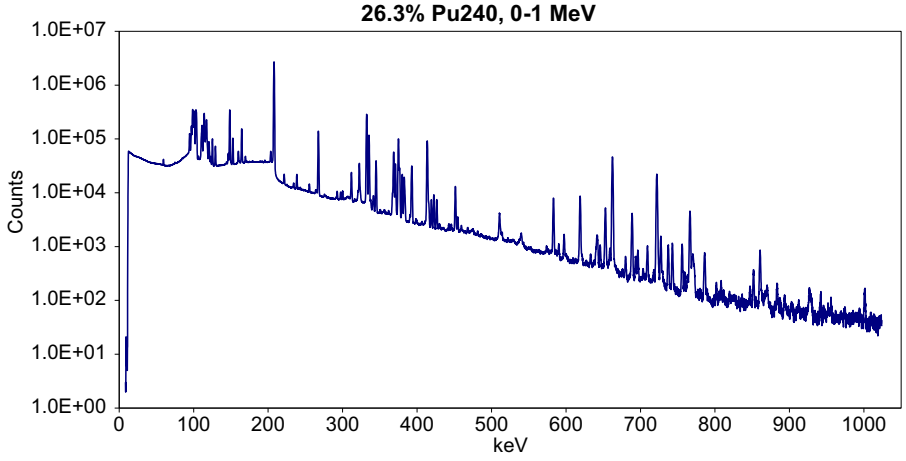

FIGURE 12.3 High-resolution spectrum of plutonium. For the color version of the figure, the reader is referred to the online version of the book.

TABLE 12.3 Major gamma rays from plutonium and ^{241}Am.

	Low energy		X-ray		125–300 keV		300–500 keV		High energy	
	E	BR (%)	E	BR (%)	E	BR (%)	E	BR (%)	E	BR (%)
238Pu	43.5	0.395	99.9	7.35E−03	152.7	9.37E−04			766.4	2.20E−05
239Pu	51.6	0.0271	98.8	1.22E−03	129.3	0.00631	345.0	5.56E−04	645.9	1.52E−05

							413.7	1.47E−03		
240Pu	45.2	0.045	104.2	7.08E−03	160.308	4.02E−04			642.4	1.3E−5
241Pu			103.7	1.02E−04	148.6	1.86E−04	332.4	*		
					164.6	6.67E−05				
					208.0	*	370.9	*		
241Am	59.5	35.9	99.0	0.0203	125.3	4.08E−03	335.4	4.96E−04	662.4	3.64E−04
	26.3	2.4	103.0	0.0195	208.0	7.91E−04			722.0	1.96E−04

The gamma ray energies are given in keV, and the branching ratios (BRs) are in percent, as discussed in Section II.C.2

transmission curve of cadmium is very steep at 60 keV but levels out significantly at 100 keV. This enables a significant reduction in the 59.6 keV intensity without losing too much data in the X-ray region of the spectrum. For freshly separated plutonium, the 59.6-keV gamma ray will not be intense enough to require cadmium filtration. After 2–4 weeks, however, the decay of ^{241}Pu will have produced enough ^{241}Am that the 59.6-keV gamma ray will typically require filtration.

As in uranium, the X-ray region of the plutonium spectrum contains gamma rays from all the detectable isotopes of plutonium (^{238}Pu, ^{239}Pu, ^{240}Pu, and ^{241}Pu). This region is an excellent choice for analyzing plutonium isotopic composition because intense peaks are available to analyze from ^{238}Pu, ^{239}Pu, and ^{240}Pu. This region also contains gamma rays from ^{241}Am and characteristic X-rays of uranium and plutonium. The americium and uranium are present in all plutonium items because of the decay of ^{241}Pu. Alpha decay of ^{241}Pu produces ^{237}U. Beta decay of ^{241}Pu produces ^{241}Am. While very complete isotopic information is available in the X-ray region, this region is the most complex region of the spectrum, as illustrated in Fig. 12.4.

The precise, low-bias analysis of the X-ray region requires excellent detector resolution and abundant data to provide good counting statistics. Planar germanium detectors are preferred, although X-ray region analysis has been successfully performed using coaxial germanium detectors.

The X-ray region is generally viewed as ending with the 125.3 keV gamma ray from ^{241}Am or the 129.3 keV gamma ray from ^{239}Pu. The spectrum is not densely populated between the X-ray region and the 300–400 keV region, but gamma rays can be found here from every isotope except ^{242}Pu. Detector efficiency in this region is good for most detectors, and detector resolution in this and higher energy regions is less critical than in the X-ray region, so coaxial detectors are more commonly employed for their superior high-energy efficiency. The 125–300 keV region also contains the 203/208-keV peak pair. This pair can give a quick, qualitative visual indication of the composition of the plutonium being measured. The 203.5-keV gamma rays are from ^{239}Pu. The 208.0-keV gamma ray is from ^{237}U, which is in secular equilibrium with ^{241}Pu, but also has a contribution from ^{241}Am. For qualitative visual analysis of the plutonium composition, these two peaks should be compared with a linear vertical scale. For high burnup plutonium, such as that produced by normal operation of a light water reactor for the production of electricity, the 208.0-keV gamma ray will be significantly more intense than the 203.5-keV gamma ray. The 208.0-keV gamma ray can exceed the 203.5-keV gamma ray in height by a factor of more than 100. For low burnup plutonium, the peak heights are often comparable, and for very pure ^{239}Pu, the 203.5-keV gamma ray may even slightly exceed the height of the 208.0-keV peak.

The 300–500 keV region is another complicated region of the spectrum, containing many partially resolved peaks. Normal peak analysis routines and peak deconvolution techniques should suffice to analyze this region. Only ^{238}Pu and ^{240}Pu are not represented in this region. They do have gamma rays at higher energy, so as long as the detector efficiency is sufficient at high energy, complete isotopic analysis is possible. If the low–300 keV region is too

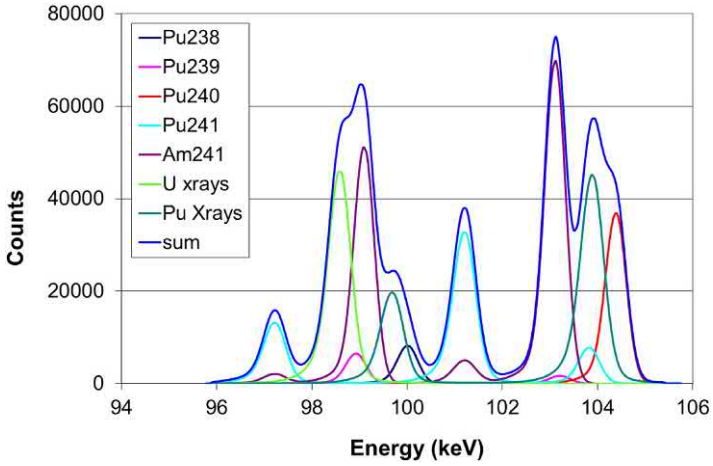

FIGURE 12.4 The components contributing to a plutonium spectrum in the X-ray region. For the color version of the figure, the reader is referred to the online version of the book.

strongly attenuated, complete isotopics cannot be determined. However, this requires significant amounts of shielding. Successful analysis in the low-300 keV region has been demonstrated through as much as 33 mm of lead. The measurement time may be long, depending on the choice of detector, but isotopic fraction values for all isotopes can be obtained, even when the material is in a thick-walled, heavily shielded shipping container. Use of detectors with high efficiency is preferred.

The highest energy region of importance to plutonium isotopic analysis is the 600−800 keV region. This region is similar to the 300−400 keV region in complexity. There are no ^{241}Pu data in this region, which is why the 300−400 keV region is the cutoff region for complete isotopic analysis. At these energies, large detector volumes or large plutonium surface areas (not necessarily high mass, because of the strong self-attenuation of plutonium) are helpful in keeping measurement times down to reasonable values.

2. Ratio-based measurements of isotopic composition

Direct measurements of absolute gamma ray intensities in a uranium or plutonium item would be very difficult, as they would require precise, detailed knowledge of the absolute detector efficiency, container wall composition and thickness, and source/detector geometry. However, it is possible to measure isotopic composition using the *ratios* between uranium or plutonium isotopes with greatly relaxed measurement requirements (ASTM C1030, 2018).

The general equation for the count rate in a particular gamma ray is

$$C = N \cdot \lambda \cdot E \cdot BR \tag{12.7}$$

where C is the net count rate for a gamma ray produced by the isotope, N is the number of atoms of that isotope, λ is the decay rate of that isotope, E is the detection efficiency at the gamma energy in question, and BR is the branching ratio or intensity (in absolute terms) of the gamma ray in question.

The activity ratio between two isotopes from the same item can therefore be expressed as

$$\frac{C_1}{C_2} = \frac{N_1}{N_2} \cdot \frac{\lambda_1}{\lambda_2} \cdot \frac{RE_1}{RE_2} \cdot \frac{BR_1}{BR_2} \tag{12.8}$$

where C_i is the net count rate for a gamma ray produced by isotope i, N_i is the number of atoms isotope i, λ_i is the decay rate of isotope i, or $\ln(2)/T_{1/2}$ for that isotope, RE_i is the *relative* (not absolute) efficiency at the gamma energy in question, and BR_i is the branching ratio or intensity (in absolute terms) of the gamma ray in question.

Eq. (12.8) can be rearranged to produce

$$\frac{N_1}{N_2} = \frac{C_1}{C_2} \cdot \frac{\lambda_2}{\lambda_1} \cdot \frac{RE_2}{RE_1} \cdot \frac{BR_2}{BR_1} \tag{12.9}$$

For any given pair of isotopes/gamma rays, the branching ratio and decay constants can be found in nuclear references. The count rates can be obtained from the spectrum using standard spectrographic analysis techniques. To determine the activity ratio, therefore, we need only to determine relative efficiency values for the gamma rays in question. Note that *relative* efficiency values are all that are required, because all that matters for Eqs. (12.8) or (12.9) are the ratio of the efficiency at the two gamma energies.

The relative efficiency curve for a specific measurement (source, package, and detector combination) can be determined by selecting a variety of gamma rays from a single isotope. These gamma rays should be as evenly distributed over as much of the relevant energy range as possible. Given such a selection of gamma rays, we can look up branching ratios in nuclear references and determine count rates from the spectrum itself. For each gamma ray, we can

calculate the ratio of the count rate to the branching ratio. Each of these ratios becomes a data point that can be plotted and fit to create a relative efficiency curve for the spectrum. Empirical or physics-based models can be used to fit the data to determine the relative efficiency curve. If the item being analyzed is isotopically homogenous, data from multiple isotopes can be used to determine the relative efficiency curve. In a homogenous item, each isotope's gamma rays will be subjected to the same shielding effects and absolute detector efficiency characteristics, so the shape of the relative efficiency curve will be the same. Normalization of the data from one isotope to the other will be necessary because of the different decay rates and concentrations of the different isotopes, but using data from multiple isotopes may enable gaps in the relative efficiency curve data to be filled in.

Once the relative efficiency curve has been determined, the relative efficiency value for any gamma energy can be obtained from the curve. Therefore, all of the inputs needed to calculate the isotopic ratios using Eq. (12.9) can be determined from nuclear references or from the spectrum itself. This enables us to determine isotopic ratios without prior calibration of the analysis system.

Logic dictates that if the isotopic fractions in an item, e.g., a plutonium item, were added up, the fractions must sum to unity, as shown below:

$$F_{238} + F_{239} + F_{240} + F_{241} + F_{242} = 1 \qquad (12.10)$$

where F_i is the fraction of the plutonium isotopes with atomic mass of i.

If we divide both sides of the equation by the ^{239}Pu fraction, we have

$$\frac{F_{238}}{F_{239}} + \frac{F_{239}}{F_{239}} + \frac{F_{240}}{F_{239}} + \frac{F_{241}}{F_{239}} + \frac{F_{242}}{F_{239}} = \frac{1}{F_{239}} \qquad (12.11)$$

Rearranging Eq. (12.11) shows us that the ^{239}Pu fraction is therefore

$$F_{239} = \left(\frac{F_{238}}{F_{239}} + 1 + \frac{F_{240}}{F_{239}} + \frac{F_{241}}{F_{239}} + \frac{F_{242}}{F_{239}}\right)^{-1} \qquad (12.12)$$

Having obtained a value for the ^{239}Pu fraction in the item being analyzed, we can then use the individual isotopic ratios to determine the fractions of the other isotopes. Note, again, that all of this is accomplished without calibration of the analysis system. The same logic can be applied to isotopic analysis of uranium items.

For plutonium analysis, there are two complications to the logic explained above. First, all plutonium items contain measurable quantities of ^{241}Am because of beta decay of ^{241}Pu. This presents no real difficulties for the analysis procedure; we simply add another ratio for americium to ^{239}Pu to Eq. (12.12). ^{241}Am produces an abundance of gamma rays (many of them are coenergetic with ^{241}Pu gamma rays), so analyzing the ^{241}Am content using this method is not difficult. In fact, ^{241}Am gamma rays can be used to determine a relative efficiency curve on their own, as is done for certain plutonium waste materials.

The second complication is caused by the fact that ^{242}Pu does not produce any gamma rays that can be detected in the presence of the other plutonium isotopes. In practice, the ^{242}Pu term has to be left out of Eq. (12.12). Once fractions have been determined for the other isotopes, those fractions can be used in empirical equations to estimate the ^{242}Pu content. At this stage, the total of all the plutonium fractions will exceed unity by the amount estimated for the ^{242}Pu content. The other isotope fractions must be proportionally reduced to ensure that all plutonium fractions sum to 100% and therefore avoid introducing bias by including the ^{242}Pu content. For uranium analysis, ^{236}U content must be determined through similar means, as it does not produce measurable gamma rays.

Another difference between uranium measurements and plutonium measurements is caused by the fact that, with few exceptions, the gamma rays used to measure ^{238}U content actually come from the decay of ^{234m}Pa, as discussed previously. If measurements must be performed on material in which the uranium and protactinium have not yet reached secular equilibrium, a correction factor must be applied to the measurement results to remove bias. This correction factor is automatically applied in the FRAM software (Sampson et al., 2003). The date of chemical separation must be known for the proper correction factor to be determined. After 6 months, equilibrium will be reached, and no measurement biases will be present. In most facilities in the fuel cycle where freshly separated material can be found, the enrichment measurements are usually made with an infinite thickness technique as discussed previously.

3. Typical results from fielded software (Sampson et al., 2003)

a. X-ray region analysis

For a detector with a surface area of 500 mm^2, even small (2−10 g) items produce enough signals to give good statistics in 300−600 s. For X-ray region analysis, the cadmium filter thickness is usually adjusted to produce a 59.6-keV peak comparable (50%−150%) in height to the tallest peaks in the X-ray region. The source to detector distance is adjusted to produce 40%−50% dead time. Under these conditions, the ^{239}Pu precision is typically less than 0.5% relative standard deviation (RSD). The ^{240}Pu precision is typically less than 1% RSD. Systematic biases are usually less than the quoted precision values.

b. Higher-energy analysis

The quality of the results from higher-energy analysis depends strongly on the amount of data available—the statistics of the spectrum and the peaks that are crucial to the analysis. The ^{239}Pu precision is typically less than 1% RSD. The ^{240}Pu precision is typically less than 3% RSD. Systematic biases are usually less than the quoted precision values.

D. Mass measurements

Gamma ray measurements are rarely used to determine mass values for uranium or plutonium because the gamma rays are easily self-shielded and thus not sensitive to thick materials. As shown in Table 12.1, uranium is a very dense material, with a much higher atomic mass than lead. This makes uranium (and for the same reasons, plutonium) a very effective gamma ray shield. Depleted uranium is often used as a shield for industrial radiation sources where the volume of a lead or even tungsten shield would present design problems.

However, there are materials containing uranium or plutonium in geometries and densities that make mass measurements by gamma ray analysis possible. These materials incorporate thin layers of uranium or plutonium that enable at least a fraction of the gamma radiation produced to reach the detector.

1. Material test reactor fuel

Material test reactor fuel is often manufactured in the form of thin plates of uranium (often highly enriched) clad in a layer of aluminum. Possible uranium forms include metal (as a uranium–aluminum alloy), uranium oxide, or uranium silicate. The fuel assemblies can be arrays of flat or slightly curved plates, or concentric square, hexagonal, or cylindrical cross-sectional tubes.

Calculations or measurements specific to the geometry of the assemblies being measured should be performed to verify that the assemblies are not infinitely thick. Many assemblies can be loaded and unloaded by the operators, enabling the *Gedankenexperiment* described in the infinite-thickness discussion to be performed almost exactly as described. If the assembly is infinitely thick, gamma measurements will be unable to detect diversion of material.

For assemblies that are not infinitely thick, predicted count rates at 185.7 keV can be obtained by calculation or by Monte Carlo methods. The prediction should be verified by measuring a known assembly. Once this has been done, fuel assembly mass can be verified, if the measured count rate is within good statistical agreement with the predicted and verified value.

For the calculations and the actual measurements, the setup is simple. The detector is positioned at the centerline of the fuel assembly, with the long axis of the fuel assembly perpendicular to the centerline of the detector. Low-resolution NaI(Tl) detectors are typically used because of their good efficiency and ease of operation. The ROIs used are similar to those used for infinite-thickness enrichment measurements.

This measurement technique is very dependent on consistent geometry. The plates furthest from the detector in an assembly contribute a very small percentage of the total signal. Source–detector distance changes or movement of the detector off of the centerline of the fuel will cause count rate changes that can easily overwhelm the difference in count rate between a 9-plate assembly and a 10-plate assembly.

2. Customized geometry efficiency modeling

Gamma ray–based mass measurements are being made for holdup and discrete items such as waste drums or boxes using a Monte Carlo modeling technique to calculate the absolute detection efficiency of the item being assayed. The technique requires that the item being assayed has a relatively well-defined geometry. Both the special distribution of nuclear material and all the interviewing attenuating material must be modeled. The germanium detector characteristics must also be known. Monte Carlo techniques are then used to sample the distribution of nuclear material to determine an absolute detection efficiency as a function of the gamma ray energy. From the absolute detection efficiency, it is straightforward to calculate the activity or mass of the radionuclides present in the item. Depending on the measurement situation, an iterative approach can be taken to match the geometry to the measured spectrum. Commercial software is available to perform this type of analysis (Canberra, 2008; ORTEC). This technique is gaining acceptance, having been approved as a measurement technique for generating data for Waste Isolation Pilot Plant (WIPP) compliance documentation (Wachter et al., 2014).

3. Holdup measurements

Bulk handling facilities such as uranium conversion plants, enrichment plants, and spent fuel reprocessing plants move large volumes of loose material through very complex networks of lines, ducts, and pipes. Some of this material will accumulate in joints, bends, valves, process equipment, and other areas where flow rates change and equipment geometry gives material a place to build up. Material can also accumulate in safety equipment such as air-handling ducts and air filters. Even dedicated cleanout campaigns cannot remove all material from a complex facility. This material is called holdup, and it has to be accounted for not only safeguards purposes but also health and safety reasons, including criticality safety.

a. Generalized geometry

A wide variety of actual deposit geometries will be encountered in facilities. Accurately modeling the holdup in a v-blender or ball valve, for example, would be very time-consuming and difficult. But most deposits can be treated as one of three basic geometries: point, line, or area source. Careful selection of detector distance and orientation can make most items meet the criteria for one of these geometries. Good training, experience, and professional judgment are necessary in selecting the measurement approach for all but very obvious choices of geometry.

Holdup measurements are far less precise than other gamma ray measurements discussed in this chapter. The uncertainties on an individual measurement may approach 50% RSD or higher in some cases when significant correction factors must be applied. There is often no practical way to precisely determine the uncertainty in a holdup result. The best approach would be to have a team measure a variety of holdup deposits of precisely known mass, but this is seldom practical. This may be possible when equipment, rooms, or an entire facility undergoes decontamination and decommissioning operations. In these cases, holdup can be measured in place before a piece of equipment is disassembled. When the equipment is removed, it can be disassembled and the components measured using more precise NDA or other techniques. The holdup measurements' accuracy and precision can then be quantified by very direct means. Another approach to uncertainty quantification would be to have multiple individuals or teams measure the same holdup deposit. The variation in the results will give a good estimate of the uncertainty in an individual result.

However, while the uncertainty (and bias) of an individual measurement is difficult to estimate, in large facilities a holdup measurement campaign will involve hundreds or perhaps thousands of measurements. With a measurement campaign on this scale, the biases should be random, so the total holdup estimate should have relatively low bias. This has been demonstrated in many holdup measurement training courses held at Los Alamos National Laboratory. In these courses, several teams participate in exercises in which a variety of simulated holdup deposits are measured. When the total holdup mass values determined by each team are summed and the sums are compared with the well-known sum of the material in the simulated deposits, the observed bias is typically on the order of 10%. Even lower biases are obtained, if the total holdup values from each team are averaged. This is similar to what occurs when repeat measurement campaigns of the same facility are performed over a long period of time; the knowledge of the total holdup in the facility will improve with each successive campaign.

The Rocky Flats plant was a plutonium processing facility that was decommissioned and decontaminated over the course of several years spanning the turn of the millennium. A large holdup measurement campaign was conducted, followed by dismantling of the equipment and the recovered material measured. Table 12.4 shows the agreement between holdup measurements and recovery values for several of the buildings on site.

The detector used for holdup measurements should have good efficiency, enough resolution to prevent interference from other radioisotopes/gamma rays in the area, and be rugged enough to withstand the environment of the facility, as well as the rough handling that may occur while attempting to reach every deposit location in a complex industrial facility. The detector needs to be collimated, so smaller diameter crystals will save significant weight. A circular collimator gives the detector rotational symmetry, which greatly simplifies detector positioning during calibration and measurements. The collimator needs to include a back shield, as background gamma rays may come from the opposite direction from the collimator opening in a complicated facility. The most common detector choice is a lead-collimated NaI(Tl) detector. The detector can be handheld, and the fabrication of holders that significantly reduce the effort and strain required to manipulate a lead-collimated NaI(Tl) detector throughout the day is easy to design. Painter's extension poles can be modified with detector clamps for this purpose. Germanium detectors are sometimes used when high resolution is required because of interference effects. For germanium detectors, a wheeled cart is usually used to position and hold the detector because they are not very portable.

Detector calibration is best performed with a single, small-diameter source of the same isotopic composition as

TABLE 12.4 Holdup measurement accuracy at selected Rocky Flats buildings.[a]

Building	Measured/recovered Pu
B-371 Glove boxes	1.09

the deposits to be measured. Bare or thin-walled sources are best to minimize the correction of attenuation from the wall thickness on the calibration. The source is measured at a defined distance to perform the point source calibration. The point source calibration constant is

$$K_P = \frac{M}{C \cdot r} \tag{12.13}$$

where M is the mass of the calibration item, C is the net count rate in the ROI being used for the isotope of interest, and r is the source-to-detector distance.

The net count rate is the difference between the integral (gross counts) in the ROI with the source present and the integral in the ROI without the source present. This eliminates the effect of any room background signal from the isotope of interest.

The source is then moved across a line perpendicular to the long axis of the detector, and a series of measurements are made. An example of such data can be seen in Fig. 12.5. Note that in this example, both sides of the curve have actually been measured; if time is short, the assumption of symmetry can be made and only half of the distribution measured.

The series of data points thus obtained approximates a line source and serves as the basis for the line geometry calibration. The calibration factor for line sources is

$$K_L = \frac{M}{L \cdot C \cdot r} \tag{12.14}$$

where M, C, and r are as defined previously in Eq. (12.13), and L is a term quantifying the effective source length visible to the detector.

L can be calculated using the following formula:

$$L = \sum_{-n}^{n} \left(s \cdot \frac{C_i}{C} \right) \tag{12.15}$$

where n is the number of radial measurements made on each side of the center point, s is the spacing of the radial measurements (5 cm in the example in Fig. 12.5), C_i is the count rate in the ROI determined at the ith radial measurement position, and C is the count rate at the central measurement position.

The plot of the radial response data (Fig. 12.5) also informs the user of the detectable arc formed by the collimator. This arc will be different for uranium and plutonium, as different gamma energies are used. Uranium holdup is almost always measured using the 185.7-keV gamma ray. Plutonium holdup can be measured using the 208-keV gamma ray or the 375/414-keV complex.

The area source calibration constant is

$$K_A = \frac{M}{A \cdot C} \tag{12.16}$$

where M and C are defined as in Eq. (12.13), and A is a term quantifying the effective source area visible to the detector.

The value of A can be calculated using the following formula:

$$A = \pi s^2 \left\{ 2 \sum_{1}^{n} i \frac{C_i}{C} + \frac{1}{4} \right\} \tag{12.17}$$

where s, n, C_i, and C are as previously defined.

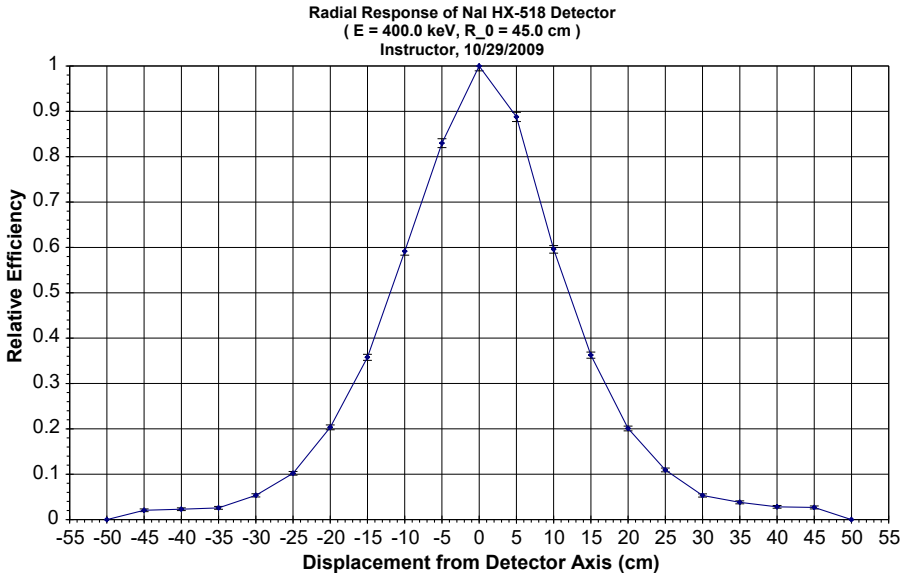

FIGURE 12.5 Plutonium calibration data for a holdup detector system.

10–12 measurement locations of the point calibration source can therefore produce calibration factors for point, line, and area sources.

The point source calibration will give results directly in mass. The line source calibration will give results in mass per unit length (i.e., g/cm). This calibration assumes that the line source extends beyond the visible view of the detector defined by the collimator. The user must determine the total line length and multiply the measured mass per unit length value by the length of the deposit. If a scan of the deposit indicates that it is not of uniform linear density, multiple measurements should be made of the different linear density zones. This may happen where a manifold steps down from a wider pipe to a narrower pipe, where the diameter and flow rates may change. Similarly, the area calibration produces results in mass per unit area. The detector should be positioned so that the source appears as an infinite plane—extends beyond the edge of the visible solid angle.

One method to assess if the deposits meet the criteria for each geometry can be judged by the change in count rate as a function of distance between the detector and the holdup deposit. For point sources, the count rate should vary according to the inverse square law. For line sources, the count rate should be inversely proportional to distance. For area sources, the count rate will be independent of distance. Detector positions can be chosen, so these criteria are met, and then the total source length or area used to calculate the total mass from the g/cm result or g/cm^2 result.

The deposit measurements must be corrected for the attenuation imposed by the equipment or piping in which the deposit is found. In some cases, a simple attenuation calculation using the classic attenuation equation will suffice. This is possible for well-defined thicknesses such as flat duct walls. The thickness can be either operator knowledge taken from reliable facility drawings or measured using an ultrasonic thickness gauge. For complicated geometries or when drawings/ultrasonic measurements are impractical, a transmission measurement using a radioactive source can be performed. The collimated transmission source is measured at a defined detector-to-source distance. The source is then moved behind the deposit, maintaining the same detector-to-source distance. The ratio between the two measurements is the transmission through both walls of the equipment or pipe. The correction factor applied to the holdup deposit measurement is one over the square root of the transmission, as the deposit radiation will only have to penetrate one of the two walls the transmission source beam had to penetrate. The transmission source will likely have a different gamma energy than the holdup isotope, so another correction factor must applied to take into account the different detector efficiency and absorption coefficients at the energies in question. Sometimes the attenuation correction factor must be based on an educated guess by the measurement technician.

Actual point and line holdup deposits will have physical dimensions, not the assumed infinitely small point and infinitely thin line geometries. The finite geometries of the point and line deposits require a correction factor to be applied to the measurements to minimize measurement bias. To determine the correction factor, the radial response curve determined during calibration is fitted to a Gaussian model and normalized to the central point. The deposit dimensions are determined, either from assumptions based on the equipment geometry or by measurement using a Geiger counter or the holdup measurement system with a slit collimator. The detector response at the edge of the deposit is averaged with the central response (defined as 1.0 because of the detector response normalization). The inverse of this value is the correction factor for the finite deposit dimensions (Reilly, 2007). Neglecting this correction factor will result in an overall mass defect bias, as this correction factor will always increase the measured mass values.

Uranium and plutonium exhibit significant self-attenuation necessitating the need for a correction factor. This correction factor increases as the deposit thickness increases. At some thickness, the deposit will become infinitely thick and, in this situation, this correction factor cannot be applied. The correction factor is based on the transmission correction factors (CF) for slab, cylindrical, and point sources as shown in the following Eqs. (12.18), (12.19) and (12.20), respectively:

$$\mathrm{CF}_{\text{slab atten.}} = \frac{-\ln T}{(1-T)} \tag{12.18}$$

$$\mathrm{CF}_{\text{cyl. atten.}} = \frac{-\ln T^K}{(1-T^K)} \quad \text{where } K = \pi/4 \tag{12.19}$$

$$\mathrm{CF}_{\text{sph. atten.}} = \left\{\frac{3}{2Z}\left[1 - \frac{2}{Z^2} + e^{-Z}\left(\frac{2}{Z} + \frac{2}{Z^2}\right)\right]\right\}^{-1} \tag{12.20}$$

where $Z = \mu\rho D$ and D is the sphere diameter.

Correction factors from self-attenuation can also be determined if the areal density of the deposit is known, as explained in (Reilly, 2007).

In some facilities with process equipment located within close vicinity, measurement must be performed in close proximity to one another, leading to unusually high backgrounds. In this case, a background subtraction procedure can improve the accuracy of the results. When the background is coming through the sides of the detector, the use of a tungsten plug is an effective way to determine the background. The plug fits into the collimator and totally attenuates the gamma rays from the holdup deposit being measured. For background coming from behind the holdup

deposit being measured, the detector can be moved to the side to estimate the background contribution. The use of portable shielding to either block the background or block the holdup deposit to determine the background can be used. Subtracting the background spectrum or ROI count rate(s) from the holdup deposit spectrum will produce more accurate results, specific to the visible cone of the detector.

Neutron holdup measurements are another technique useful for determining the holdup deposit especially in very dense machinery. In dense machinery, the thickness of the metal may attenuate the signal enough to make gamma ray measurements impractical. Another application for the use of neutron measurements is high-mass deposits, which suffer significant self-attenuation. If a deposit is infinitely thick (see the uranium enrichment section of this chapter for a discussion of infinite-thickness criteria), gamma ray measurements essentially become geometric estimates; the results are only as good as your knowledge of the dimensions and elemental composition of the deposit. Neutron measurements solve this problem, as neutrons are much more penetrating than gamma rays.

Neutron measurements require larger detectors that are not easily portable like the NaI(Tl) holdup instruments. They are also far less directional than gamma detectors. While plutonium deposits generally produce useable passive signals, uranium deposits may require active techniques—fission must be induced using an americium–lithium source or similar neutron source. The exception is uranium compounds containing fluoride, which produce neutrons through (α,n) reactions. For these materials, neutron totals counting is used. For passive plutonium measurements or active uranium measurements, neutron coincidence counting methods are often used.

Neutron detectors for holdup are usually calibrated by measuring known masses of plutonium or uranium with point neutron sources in a manner analogous to that used for gamma detector calibration. They can also be calibrated using Monte Carlo techniques.

Neutron detectors designed for holdup measurements are often simple slab detectors; flat polyethylene slabs with He^3 tubes are inserted in holes in the slab. The larger the slab/greater volume of He^3, the more efficient the detector will be. In some cases, customized neutron detectors have been designed and built to measure holdup in particular pieces of equipment, such as glove boxes (Shimizu et al., 2006).

b. Operational considerations

Holdup measurements are usually performed in more challenging environments than other NDA measurements. Facilities that have holdup are usually large industrial chemistry plants, where operating temperatures, humidity levels, noise levels, and physical hazards (heights, trip/slip/fall hazards, etc.) are present to a degree that can dominate the attention of the measurement team. Often, simply specifying the measurement point and determining the deposit-to-detector distance can be a challenge. Measurement teams need to be familiar enough with the facility to operate efficiently and safely in the measurement environment even while carrying lead collimated detectors and associated equipment for long periods of time. The measurement environment can also affect the measurement equipment. If the temperature changes significantly over time, or from one region of the facility to another, peak drifts can occur in NaI(Tl) detectors. Peak position should be closely monitored by the measurement team. High temperatures will reduce the service time provided by germanium detector liquid nitrogen tanks.

The term "measurement team" has been used extensively throughout this discussion. Working in teams of two or three is usually far more effective and time efficient. The amount of equipment that has to be manipulated, the need to maintain detector position during the measurement, and the record-keeping tasks to be performed make holdup measurements difficult for a single individual in most cases. Given the amount of professional judgment that may have to be exercised and the difficulty of accurately pointing a detector at a deposit, with the detector often located at the end of a 2-m-long pole, a second set of trained eyes can often be very helpful.

For simple facilities or infrequent holdup campaigns, simple pencil-and-paper or spreadsheet record keeping may suffice. Careful designation of the deposit location is important, as well as all the typical measurement characteristics such as equipment serial numbers, calibration data, count times, etc. Photographs can help to make deposit locations more clear in the records and link them more clearly to the corresponding measurement results.

For more complicated facilities or in facilities where holdup campaigns will be performed on a regular basis, computerized record-keeping systems may be a more appropriate choice. The same locations will likely need to be measured each time, and choices of detector orientation, distance, and generalized geometry choice (point, line, or area) can be standardized for each deposit. Bar codes can be used to mark each deposit, and the measurements thereby automatically linked in a database to each location (Rowe et al., 2016).

Some deposits can be difficult to categorize as point, line, or area sources. Two pipes or ducts located close together could be treated as separate lines if the detector is located close to each pipe. This approach may require a significant correction for the actual finite width of the pipe deposit. If measured from a greater distance, the pair of pipes could be treated as an area source. If time permits, both approaches can be attempted and the results compared for consistency. As a measurement team gains experience,

such judgments will come more quickly and accurately for unusual geometries.

The statistical uncertainties in holdup measurement results can be calculated from the usual counting statistics methods. The statistical uncertainty will always underestimate the actual uncertainty in holdup measurements because of the large number of other systematic and random uncertainties that contribute to the total measurement uncertainty. How accurately and consistently was the desired deposit-to-detector distance maintained? Did the detector wobble during the measurement or was it solidly, consistently pointed directly at the valve 3.5 m overhead? How accurately did the measurement team judge the distribution of the deposit in the valve, and therefore how accurate was the source dimension correction? These operational considerations typically contribute significantly more to the uncertainty than the contribution from the counting statistics. Uncertainties are therefore often assigned by the team based on their training, experience, and operational judgment. Typical uncertainties assigned to holdup measurements often range from 10% to 50% depending on the complexity of the measurement.

III. Neutron-based assay for safeguards

A. Radiation signatures from plutonium and uranium

The neutron signature measured for safeguards applications from uranium and plutonium is dominated by spontaneous fission neutrons, induced fission neutrons, and (α,n) neutrons, as discussed in Chapter 1, Volume 1 of this book. The relative importance of these three processes depends on the specific isotopes found in the assay item. Plutonium emits spontaneous fission neutrons at a high enough rate to make passive measurements practical. For uranium, an external neutron source must be used to induce fissions because uranium does not emit spontaneous fission neutrons at a high enough rate for an accurate quantitative measurement. Both Pu and U also emit neutrons by the (α,n) process. Depending on the application, this can be either detrimental or beneficial. A summary of the neutron emission rates for the different production processes is shown in Table 12. 5 (Ensslin et al., 1998a).

Table 12.5 contains some important information pertinent to quantitative safeguards measurements. The three even-numbered isotopes of plutonium have a spontaneous fission rate over four orders of magnitude greater than the odd-numbered isotopes. Therefore, the passive measurement of plutonium will only be sensitive to the combination of these three even isotopes. Since the neutrons emitted from different isotopes cannot be distinguished from one another, a term called the ^{240}Pu effective mass is defined. The ^{240}Pu effective mass is the ^{240}Pu mass that would be required to produce the same neutron emission rate as the combination of the ^{238}Pu, ^{240}Pu, and ^{242}Pu isotopes and is defined as:

$$^{240}\mathrm{Pu}_{\mathrm{eff}} = 2.52(^{238}\mathrm{Pu}) + {}^{240}\mathrm{Pu} + 1.68(^{242}\mathrm{Pu}) \qquad (12.21)$$

The percent ^{240}Pu$_{\mathrm{eff}}$ from the plutonium isotopic values is required to convert from the ^{240}Pu$_{\mathrm{eff}}$ mass to the total Pu mass, a value of importance for safeguards.

Another very important property of fission is that this process results in the production of two fission fragments plus several neutrons produced at the same time. The number of neutrons produced in a fission event can range from 0 to 8 or more with an average number emitted of 2.2 for plutonium (Ensslin et al., 1998a). Induced fission will also emit several neutrons produced at the same time but with a higher average number of neutrons emitted. For induced fission on ^{239}Pu, around three neutrons are emitted with the exact average number dependent on the energy of the inducing neutron. The distribution of emitted neutrons

TABLE 12.5 Neutron emission rates for different compounds of uranium and plutonium.

Isotope	Spontaneous fission yield (n/s-g)	(α,n) yield in oxide (n/s-g)	(α,n) yield in UF_6 or PuF_4 (n/s-g)
^{234}U	5.02×10^{-3}	3.0	5.8×10^{2}
^{235}U	2.99×10^{-4}	7.1×10^{-4}	0.08
^{238}U	1.36×10^{-2}	8.3×10^{-5}	0.028
^{238}Pu	2.59×10^{3}	1.34×10^{4}	2.2×10^{6}
^{239}Pu	2.18×10^{-2}	3.81×10^{1}	5.6×10^{3}
^{240}Pu	1.03×10^{3}	1.41×10^{2}	2.1×10^{4}
^{241}Pu	$\sim 5 \times 10^{-2}$	1.3	1.7×10^{2}
^{242}Pu	1.72×10^{3}	2.0	2.7×10^{2}
^{241}Am	1.18	2.69×10^{3}	

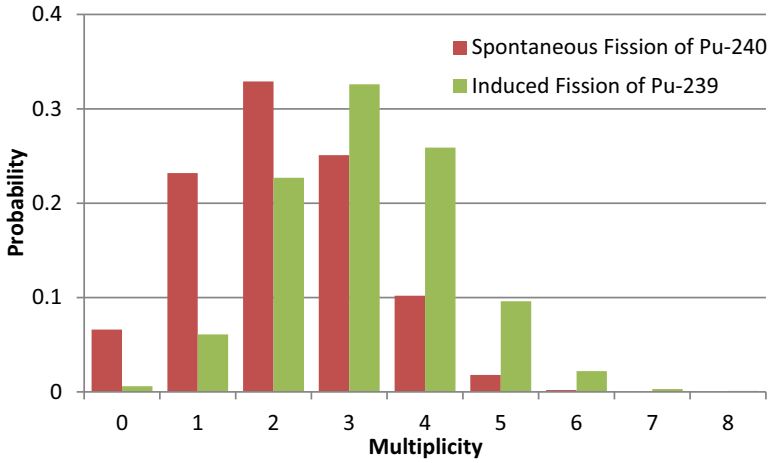

FIGURE 12.6 Spontaneous and induced multiplicity distribution for plutonium. Shown in the graph is the 2-MeV-neutron-induced fission multiplicity distribution. For the color version of the figure, the reader is referred to the online version of the book.

for spontaneous fission of ^{240}Pu and induced fission of ^{239}Pu with a 2 MeV neutron is shown in Fig. 12.6. The neutrons emitted from a fission, either spontaneous or induced, are correlated in time, and this property is used to differentiate between neutrons produced by fission from other production processes. Two neutrons detected close in time create a coincident event. Since fission neutrons are released at the same time, they will result in real coincident events. Two random neutrons can also be detected close in time, creating an accidental coincident event. Using sophisticated data processing electronics based on a sampling of a large number of events, the real coincidence events can be distinguished from accidentals events (Halbig et al., 1991). For safeguards measurements, the twofold and threefold coincident events, called doubles and triples, respectively, can be measured and used to quantify the mass of the item of interest.

The (α,n) neutron production rate can be a significant portion of the neutrons emitted from a plutonium or uranium item. From Table 12.5, one can note that ^{238}Pu, ^{241}Am, and ^{234}U are the dominant isotopes in the production of (α,n) neutrons when these isotopes are in proximity to a light element. For plutonium oxide items, the number of (α,n) neutrons is typically on the same order of magnitude as the number of spontaneous fission neutrons. For items that have small amounts of light element impurities mixed within the matrix, the (α,n) production rates can easily become much greater than the spontaneous fission neutron production rates. This can have a serious impact on the assay of plutonium items in instances where the plutonium mass is assumed to be proportional to the neutron count rate. For uranium items, the (α,n) count rate is insignificant with the exception for UF_6. The alpha value (α) of an item is defined as the number of (α,n) neutrons divided by the number of spontaneous fission neutrons emitted from the item. A pure plutonium metal item with no light element impurities will have an $\alpha = 0$, and a plutonium oxide item will typically have an α value in the range of 0.7−1.1 with the exact value depending on the isotopic composition of plutonium and the amount of ^{241}Am (Ensslin, 1991).

Another property seen in Table 12.5 is that the spontaneous fission rates of all the isotopes of uranium are very small. The passive assay of uranium is only practicable for items that contain large amounts of ^{238}U or is in a chemical form containing fluorine; otherwise, the neutron count rates will be comparable or less than typical background count rates. The technique of active neutron interrogation is used to assay uranium items. This technique induces fissions in the uranium from an external neutron source. The rate of induced fission will be dependent on the multiplication of the item, the intensity and energy spectrum of the interrogation source, and the properties of the surrounding medium, including the containment can and detector.

Multiplication is a property of both plutonium and uranium that must be accounted for to correctly assay these materials. The total multiplication of an item is defined as the total number of neutrons that exist in the item divided by the number of initial starting neutrons. For example, if 100 neutrons started in an item and 49 neutrons were created though induced fission events, then the total multiplication of the item would be 1.49. The 49 neutrons were created by multiplication through several generations. In the first generation, only a fraction of the original 100 will create additional neutrons. The same fraction of first-generation neutrons will create a smaller number of second-generation neutrons. This will continue for several generations until the no additional neutrons are created. The leakage multiplication reflects the number of neutrons that will leak out of the item, and this value will always be less than the total multiplication, because not all of the neutrons

will escape the items; some will be captured within the item, including those lost from induced fission events. The leakage multiplication is the property that is measureable.

The leakage multiplication will vary from item to item and is sensitive to the item characteristics and the detector design. The density, material form, and geometry of the item will have a significant impact on the multiplication. Denser and more compact items will generally have high leakage multiplication. Neutron coincidence counter designs can have a significant impact on the leakage multiplication.

B. General neutron counters for safeguards measurements

The most common neutron detector for safeguards applications is the ^{3}He tube (see Chapter 2, Volume 1 for a description of ^{3}He tubes.). Although many different detector types have been used for safeguards applications (Crane and Baker, 1991; Belian et al., 2003; Frame et al., 2004; McElroy et al., 2011a; Eccleston and Menlove, 2011; Henzlova et al., 2013), the ^{3}He tube has remained the detector of choice because it is robust, easily discriminates neutrons from other signals, is highly reliable, and has benign material characteristics that do not present safety issues in a nuclear facility. In the mid-2010s, the demand for ^{3}He gas exceeds the supply, necessitating the need to develop alternate technology for neutron detectors (Menlove et al., 2011). After many years, the ^{3}He technology is still preferred. Currently, ^{3}He gas is regulated, and the allocation supplied for Safeguards applications is currently meeting the demand.

A typical neutron detection system designed for Safeguards applications consists of many ^{3}He tubes embedded in polyethylene and arranged in either a linear or circular configuration. The former is called a slab detector and latter a well counter. Shown in Fig. 12.7 are two examples of typical neutron well counters. The nuclear material to be assayed is placed within the well counter. Neutrons from fission are emitted from the nuclear material with an average energy of around 2 MeV and enter the polyethylene matrix surrounding the ^{3}He tubes. The polyethylene serves to moderate the neutrons to thermal energy where the capture cross section of ^{3}He is greatest. Graphite or water would also be a good moderator medium but is often not chosen because of economical or operational disadvantages. Once the neutrons are thermalized, they then diffuse throughout the counter until they are either captured in the ^{3}He tubes, captured by other material within the counter, or escape the counter. For neutrons that are captured in the ^{3}He tubes, a pulse is produced in the tube and sent to electronics for processing.

FIGURE 12.7 Photo of a high-level neutron coincidence counter (left) used for the measurement of plutonium items and an active well coincidence counter (right) used for the measurement of uranium items. For the color version of the figure, the reader is referred to the online version of the book.

C. Neutron well counter properties

There are several properties of a neutron counter that directly affect the measurement performance of the instrument. These properties are the efficiency, die-away time, and gate fractions.

1. Efficiency

The efficiency of a neutron counter is defined as the number of neutrons detected divided by the number of neutrons emitted. Standard neutron well counters have a wide range of efficiency (ε) depending on the application; and the efficiency will directly impact the performance. For counting of doubles and triples coincidence events produced from spontaneous fission, a high efficiency is required because the count rate is proportional to the ε for singles, ε^2 for doubles, and ε^3 for triples. The greater the efficiency of a counter, the more neutrons will be detected, resulting in a reduction of the statistical uncertainty.

2. Die-away time

Another important property of a neutron well counter is the die-away time. The die-away time is related to the lifetime of a neutron in the detector. The die-away time is defined by the equation:

$$N(t) = N_o e^{-t/\tau} \tag{12.22}$$

where $N(t)$ is the number of neutrons at time t, N_o is the initial number of neutrons, and τ is the die-away time. The die-away time is an important characteristic for the detection of real coincidence neutron events produced

from the fission process because it determines the time window necessary to measure coincident events. For shorter die-away times, a smaller time window is needed to measure real coincident events, and correspondingly, there will be less accidental or false coincidence events. The well of a neutron counter is usually lined with cadmium to prevent neutrons that have been thermalized in the polyethylene surrounding the well from returning to the item and inducing additional fissions. Counters without a cadmium liner will have a much longer die-away time because of induced fissions from the thermalized neutrons.

3. Gate fractions

The doubles and triples gate fractions are also important properties for neutron multiplicity measurements. These parameters represent the fraction of double and triples coincident events that are detected within the time window, respectively. The doubles (f_d) and triples (f_t) gate fractions are related to the die-away time by the following formulas:

$$\begin{aligned} f_d &= e^{-PD/\tau}\left(1 - e^{-GW/\tau}\right) \\ f_t &= (f_d)^2 \end{aligned} \tag{12.23}$$

where PD is the predelay and GW is the gate width. The predelay and gate width are adjustable settings of the electronics and are described later in this chapter.

For safeguards applications, the design of a neutron-based detector system is dependent on the measurement requirements and the characteristics of the nuclear material. In some situations, the measurement requirements may be a simple attribute test, whereas other situations may require a quantitative assay with clearly defined accuracy and precision requirements.

In general, neutron measurement analysis can be divided into three types: singles counting, coincidence counting, and multiplicity counting. Singles counting measures only the total count rate and requires the simplest of detector design. In coincidence counting, the singles and doubles count rates are measured, and this type of analysis requires more complex detectors with better operational performance. For multiplicity counting, the singles, doubles, and triples count rates are used in the analysis. Multiplicity counting is a very sophisticated measurement technique and requires advanced detector designs with high neutron detection efficiency and small die-away times.

The design of a neutron counter requires a trade-off between detector efficiency, die-away time, cost, and operational constraints. To make a detector very efficient requires using many ^{3}He tubes, which increases the cost and die-away time. Considerable design analysis goes into selecting the proper number and placement of ^{3}He tubes so as to optimize the efficiency and die-away time to meet the measurement requirements for the system. The cost and operational constraints place additional restriction on the amount and types of materials that can be used in the design of the neutron counter. Monte Carlo techniques (Rising, 2016, Werner et al., 2018) are typically used to optimize the design before fabrication.

D. Singles neutron counting

Singles neutron counting can be an effective method for the quantification of nuclear materials (Sprinkle, 1991) but generally is used only in certain situations where the characteristics of the nuclear material are well known. The singles count rate (S) can be described by the simple formula:

$$S = \varepsilon M_L I_p \tag{12.24}$$

where ε is the efficiency, M_L is the leakage multiplication, and I_p is the passive neutron source intensity (n/s). The passive intensity is defined as the number of neutrons born in the item and includes neutrons from spontaneous fission and (α,n) reactions. The leakage multiplication is the number of neutrons emitted from the item per neutron born in the item.

For quantitative assay of plutonium and uranium, singles counting requires knowledge of the chemical form and isotopic composition of the item. Shown in Fig. 12.8 is the neutron production rate from three chemical forms of plutonium as a function of burnup. In metal items, there is no contribution to the singles rate from (α,n) neutrons. The neutrons are produced from the even isotopes of plutonium with the majority from ^{240}Pu. The singles neutron intensity from plutonium is a signature of the ^{240}Pu$_{\text{eff}}$ mass defined as:

$$^{240}\text{Pu}_{\text{eff}}(\text{for singles}) = 2.43(^{238}\text{Pu}) + {}^{240}\text{Pu} + 1.69(^{242}\text{Pu}) \tag{12.25}$$

The factors in front of ^{238}Pu and ^{242}Pu are the ratios of the neutron productions rate per ^{240}Pu production and are greater than unity reflecting the fact that both of these isotopes have a greater neutron production rate than ^{240}Pu. The ^{240}Pu$_{\text{eff}}$ mass can be related to the singles rate though a calibration

$$S = \text{k}^{240}\text{Pu}_{\text{eff}} \tag{12.26}$$

where k is an empirical calibration constant. If the isotopic composition is known, then the total mass can be calculated from the ^{240}Pu$_{\text{eff}}$. These equations assume that the item is metallic and nonmultiplying. This will only be true in the case where the mass is very small, for example, items containing waste.

For items that have an (α,n) contribution to the singles rate, the source term will contain contributions both from the isotopes contributing to spontaneous fission production

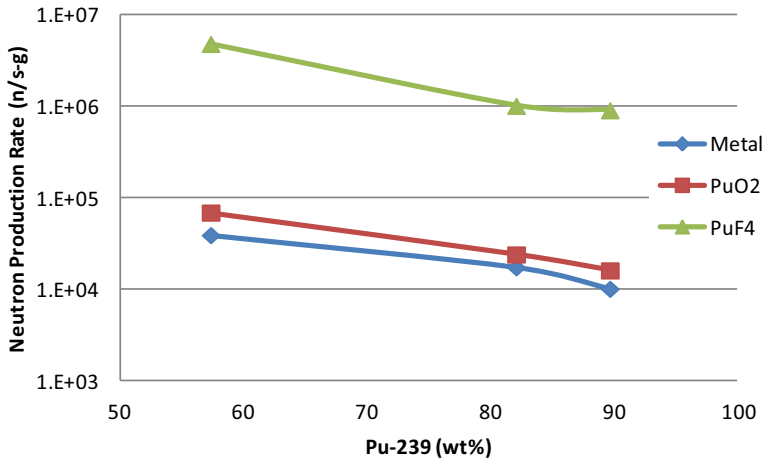

FIGURE 12.8 Neutron production rates for different forms of plutonium as a function of the burnup. For the color version of the figure, the reader is referred to the online version of the book.

and from (α,n) production. For PuO_2, ^{238}Pu, ^{239}Pu, ^{240}Pu, and ^{241}Am contribute to the (α,n) production and will be a term in the $^{240}Pu_{eff}$ mass equation with the multipliers containing a contribution from both spontaneous fission and (α,n) neutron production. Again, for a nonmultiplying item with known isotopic composition, the total plutonium mass can be calculated. For PuF_4, almost all the neutrons come from (α,n) production from four isotopes, ^{238}Pu, ^{239}Pu, ^{240}Pu, and ^{241}Am, and the multipliers will only contain a small component from spontaneous fission.

The assay of uranium compounds can be treated similarly to the plutonium case discussed above. The neutron production rates for 10 kg of several different forms of uranium typically found in the nuclear fuel cycle varying from low to highly enriched uranium (HEU) are shown in Fig. 12.9. Similar to plutonium compounds, assay personnel must have knowledge of the chemical form and isotopic composition for quantitative analysis using singles counting.

The dominant source of neutrons from uranium metal is the spontaneous fission of ^{238}U. This results in the count rate decreasing significantly as the enrichment increases. The contribution to the neutron production rate from the individual isotopes of uranium is shown in Fig. 12.10. An assay of the ^{238}U mass is possible using singles counting for large metal items that have enrichment below approximately 70%. As the enrichment increases, longer count times and larger masses are required to get acceptable measurement precision. A linear calibration along with known isotopic composition allows for the measurements of the ^{235}U mass.

For UO_2, the neutron production rate is nearly constant up to enrichments of around 60%. As the enrichment increases, the contribution to the neutron production rate from spontaneous fission of ^{238}U decreases, whereas the (α,n) contribution from ^{234}U increases. Typically, uranium items contain a very small amount of ^{234}U, less than 1%, but this isotope has a very large alpha decay rate and, as a

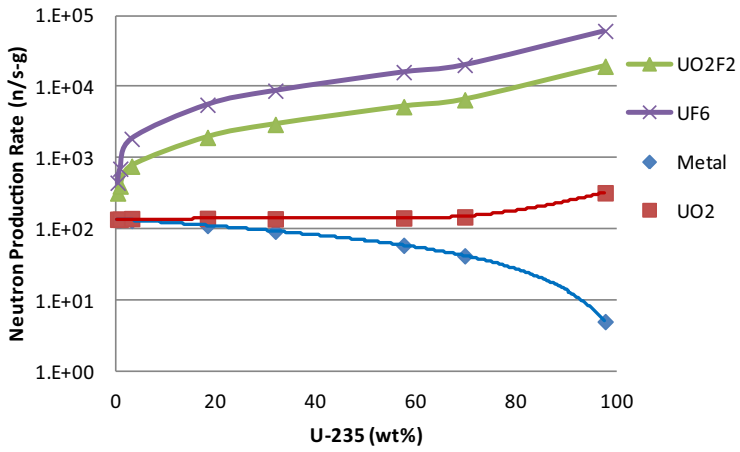

FIGURE 12.9 Neutron production rate for different forms of uranium as a function of enrichment. For the color version of the figure, the reader is referred to the online version of the book.

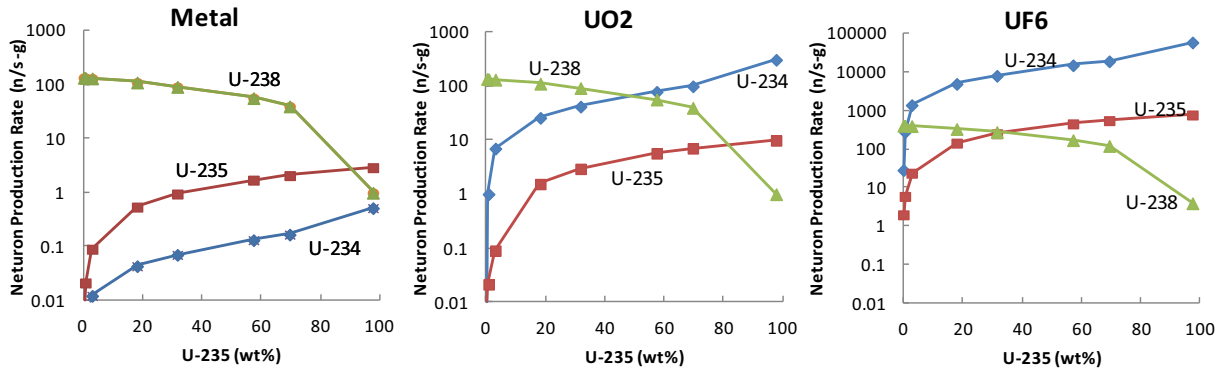

FIGURE 12.10 Neutron production rates for individual isotopes of uranium as a function of enrichment. For the color version of the figure, the reader is referred to the online version of the book.

result, is the main contributor to (α,n) neutrons in uranium. When uranium is processed in an enrichment plant, the ^{234}U is enriched at a faster rate than the ^{235}U, resulting in a larger increase in the (α,n) production than ^{235}U spontaneous fission production as the enrichment increases. When calibrating a detector for singles measurements of UO_2, all three isotopes of uranium need to be accounted for.

UO_2 is found in many places in the nuclear fuel cycle, for example, as bulk material in cans at a fuel fabrication facility or in finished assemblies at a nuclear power plant. These items are usually assayed using active techniques because of the low count rates, which are often comparable to room background. Active techniques measure the ^{235}U-induced fission neutrons and will be discussed later in this section. Very large UO_2 items can be assayed by passive counting depending on the material characteristics and the measurement goals.

For uranium compounds that contain fluorine, the neutron production is dominated by the (α,n) process from the ^{234}U alpha decay and subsequent ^{19}F(α,n)^{22}Na reaction. UF_6, the standard material type used in the enrichment process, and UO_2F_2, a reaction product of UF_6 and water (Mayer et al., 2008), are two fluorine-containing uranium compounds typically found in the nuclear fuel cycle. Calibration of instruments for singles counting of UF_6 or UO_2F_2 needs to account for the neutron production from ^{234}U, ^{235}U, and ^{238}U, although at high enrichments, only the contribution from ^{234}U is often considered. This simplification typically does not produce any significant biases.

As a result of the large singles neutron production rates in forms of uranium containing fluorine, passive counting is often used to quantify the uranium mass. Passive counting has been successfully used to quantity the UO_2F_2 deposits inside process equipment at enrichment plants (Auguston et al., 1983; Cooley et al., 1989). The verification of UF_6 cylinders (McElroy et al., 2011b), verification of uranyl nitrate in a conversion facility (Rauch et al., 2010), and the measurement of holdup inside a cascade hall (Beddingfield and Menlove, 2002) are additional examples of singles counting applications in the nuclear fuel cycle.

A shuffler measurement (Rinard, 2001) is one technique that is often used to measure uranium metal or oxides using singles neutron counting. The shuffler uses a ^{252}Cf source to induce fissions in the uranium, and the singles rate produced by delayed neutrons from the fission fragments is measured to quantify the ^{235}U mass. In this type of measurement, the Cf source is placed next to the item for several seconds and then moved away for several seconds at which time the singles neutron rate is measured. The source is "shuffled" many times during one measurement to obtain acceptable counting statistics.

A calibration for the shuffler is made with representative standards by determining the relationship between the ^{235}U mass and the delayed singles count rate. This calibration will be sensitive to material characteristics, such as density, enrichment, geometry, material type, and presence of moderators. Biases will occur when these characteristics of the assay items differ significantly from the calibration items, although with some knowledge of the items, reasonable correction factors can be determined with Monte Carlo calculations. Shufflers have been used successfully in many areas of the nuclear fuel cycle for quantifying uranium mass (Rinard et al.,1992; Mount et al., 2002).

E. Neutron coincidence counting

1. Introduction to coincidence counting

Uranium and plutonium found in bulk (cans, drums, holdup deposits, etc.) and item types (fuel pellets, assemblies, etc.) throughout the nuclear fuel cycle are often assayed nondestructively by neutron coincidence counting (Ensslin, 1991). This technique takes advantage of the fact that

multiple neutrons produced in spontaneous and induced fission events are emitted at the same time. This is a unique signature of the fission process; uranium and plutonium are among the few elements to decay by this process. A neutron detection system, which is sensitive to time-correlated neutrons, will be able to assay fission events independent of other neutron production processes. In this case, measurements will be insensitive to the presence of natural background or (α,n) sources because these production processes produce only random neutrons in time. Unlike singles counting, where the item characteristics must be known for accurate assay, some coincidence counting techniques are not nearly as sensitive to changes in these characteristics.

As discussed previously, the isotopes of plutonium that have significant spontaneous fission yields are ^{238}Pu, ^{240}Pu, and ^{242}Pu. With respect to uranium, there are no isotopes that have a measurable yield, with the exception of very large quantities of ^{238}U. Hence, a neutron detector that is sensitive to time-correlated neutrons will only be sensitive to these isotopes. Unlike gamma ray measurements that have unique signatures for the different isotopes, in neutron counting, there is no way to differentiate between neutrons produced from the different isotopes. For this reason, a quantity called the ^{240}Pu effective mass is defined as:

$$^{240}\mathrm{Pu}_{\mathrm{eff}} = 2.52(^{238}\mathrm{Pu}) + {}^{240}\mathrm{Pu} + 1.68(^{242}\mathrm{Pu}) \qquad (12.27)$$

The ^{240}Pu$_{\mathrm{eff}}$ mass value is the mass of ^{240}Pu that would give the same coincidence count rate as that obtained from the combination of all the even isotopes of plutonium. The effective mass is defined in terms of ^{240}Pu as opposed to ^{238}Pu or ^{242}Pu because ^{240}Pu is typically present in the largest quantity in both low- and high-burnup reactor grade plutonium and contributes the most to the coincident count rate. The coefficients of 2.52 and 1.68 give the relative coincidence emission rate of ^{238}Pu and ^{242}Pu, respectively, to ^{240}Pu. These coefficients account for the different spontaneous fission emission rates and the neutron multiplicity distribution of each isotope.

Passive coincidence counting is the most common application of coincidence counting for plutonium items. In cases where the spontaneous fission rate is weak and there are fissile isotopes present, such as ^{235}U or ^{239}Pu, active coincidence counting can be utilized. With the choice of an (α,n) interrogation source, the coincident counter can differentiate between the induced fission and the (α,n) interrogation neutrons. Both passive and active coincidence counting techniques have many applications for safeguarding the fuel cycle. Generally, coincidence counting is more accurate than singles counting because this technique measures a unique signature of the nuclear material independent of natural background or (α,n) sources.

2. Shift register electronics

A coincident event or doubles count is defined as the detection of two neutrons from the same fission event within a defined time interval, called the gate width (*GW*). Unfortunately, on an event-by-event basis, one cannot differentiate between coincident events resulting from two neutrons from the same fission or two random neutrons, for example, two neutrons from independent (α,n) events being detected within the gate width. The former is called a real coincidence event, and the latter is called an accidental coincidence event. The optimum gate length is related to the die-away time of the neutron detector. The optimum setting of 1.257τ minimizes the error on the doubles rate (Ensslin, 1991). Any neutron that is detected within a gate length of time of a previously detected neutron will define a coincident event or doubles count. Counting coincidence events using standard analog gating electronics would be very cumbersome; rather, this is accomplished using sophisticated and clever electronics. The measurement of coincidence events is accomplished with an instrument called a shift register (Halbig et al., 1991; Swansen et al., 1980).

The shift register is an integrated circuit that consists of a series of clock-driven flip flops linked together in stages. The incoming pulses "shift" through the register in stages at a frequency, such that it takes a gate length of time to move completely through the shift register. To differentiate between real and accidental coincidences, the shift register is triggered at two times: first to sample the real plus accidentals (R + A) and second to sample the accidental (A) coincidences. A block diagram of the shift register coincidence circuit is shown in Fig. 12.11.

A prompt trigger samples the shift register and measures the R + A coincidences. A delayed trigger samples the shift register at a much later time and measures the A coincidences. The delayed trigger is separated from the

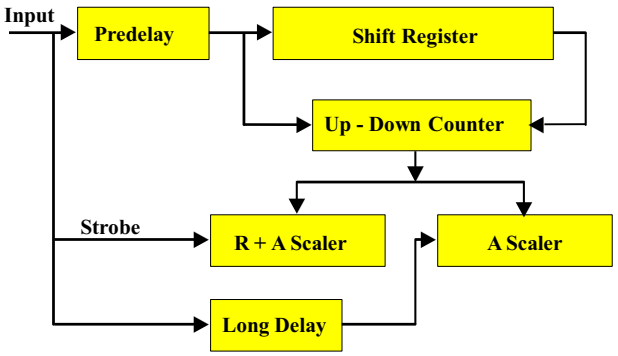

FIGURE 12.11 Block diagram of a neutron shift register coincidence circuit. For the color version of the figure, the reader is referred to the electronic version of the book.

prompt trigger by a time of many die-away times to ensure that the accidental coincidences will not include any real coincidences from fission events. The neutron is delayed from entering the shift register by a small time, called the predelay, to eliminate biases caused by dead time effects. When a neutron enters the shift register, it will increment the up-down counter; when it exits, it will decrement the up-down counter. The up-down counter will count the total number of neutrons being "shifted" through the shift register. A neutron signal entering the electronics will first trigger the contents of the up-down counter to be added to the R + A scaler and then will pass through the predelay entering the shift register. At the same time, a delay trigger will be generated to add the contents of the up-down register to the A scaler at the delayed time in the future. The number in the up-down register represents the number of coincidence events formed with a newly detected neutron.

Coincidences from fissions will only be counted in the R + A scaler since they are born at the same time and have an average lifetime in the counter described by the die-away time. The long delay is purposely set to many die-away times to ensure that there will be no real coincidence events between neutrons from the same fission event in the A gate. Coincidences from two random uncorrelated neutrons have an equal probability of occurring in the R + A or A gates. For example, two random neutrons have an equal probability of being separated by a short time as they would a long time. While two neutrons from the same fission event would have a high probability of being separated by a small time, they would have no probability of being separated by the long delay time because they only have a finite lifetime before they are either detected or lost. The number of real coincidences is the difference between the R + A scaler and the A scaler. The determination of the real coincident rate is only possible by sampling a large number of events. On a single event basis, one cannot determine if an R + A count is a real or accidental coincidence. With this understanding of how to measure the real coincidences or doubles, we can investigate how this quantity is converted into a plutonium or uranium mass.

3. Passive coincidence counting

Once the real coincidences or doubles are measured, the next step is relating this count rate to the $^{240}Pu_{eff}$ mass. The doubles rate can be defined as

$$D = R = \frac{F\varepsilon^2 f_d M^2 \nu_{s2}}{2} f(M,\alpha) \qquad (12.28)$$

where F is the spontaneous fission rate, ε is the neutron detection efficiency, f_d is the doubles gate fraction, M is the leakage multiplication, and ν_{s2} is the second reduced moment of the spontaneous fission neutron distribution and represents the average number of doubles emitted per fission. The function $f(M,\alpha)$ represents the effect on the doubles rate from induced fission from both the spontaneous fission neutrons and the (α,n) neutrons and will be dependent on the multiplication and alpha value of the item. In theory, the above equation can be solved to determine the mass, but this cannot be done in coincidence counting because there are too many unknown quantities in the equation. In general, the mass, multiplication, and alpha value are not known for the item to be assayed. If we are only measuring one quantity, the doubles rate, there are too many variables to solve this equation independently. The efficiency and gate fractions are detector parameters and can be accurately determined.

For standard coincidence counting an empirical calibration curve is generated to relate the measured count rate to a mass value. This curve is made by measuring a set of representative calibration standards with known mass values. The resulting data, $^{240}Pu_{eff}$ mass versus doubles rate, is then fit with a quadratic curve. An example of a typical empirical calibration curve for pure plutonium oxide items is shown in Fig. 12.12. The quadratic curve mentioned above is fitted to the black circles shown in the figure; the rate of increase in the doubles rate is greater than a linear increase. This is a result of the multiplication of the item, and in general, as the mass increases, the multiplication will also increase, resulting in a nonlinear increase in doubles.

Since the assay items have three unknown quantities (m, M, and α) and only one observable is being measured, an empirical calibration curve requires many constraints on the material characteristics to obtain accurate results. Both the

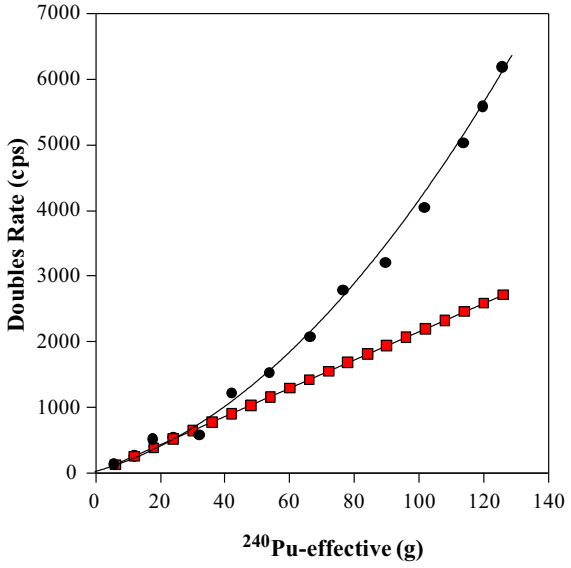

FIGURE 12.12 Typical calibration curves for the passive calibration technique (circles) and known-alpha technique (squares) for the measurement of plutonium. For the color version of the figure, the reader is referred to the electronic version of the book.

multiplication and alpha value affect the shape of the empirical calibration curve. The standards used to create the calibration curve need to be representative of the items to be measured. Important characteristics that will affect the shape of the calibration curve include material type, density, geometry, moisture content, and impurities. In general, the passive calibration curve works best in situations where the material characteristics are in a known and reproducible form, such as the output of a plutonium reprocessing plant.

Another more advanced coincidence counting technique that is often used for assaying pure plutonium items is called the known-alpha method. This method uses both the measured singles and doubles rates. The singles rate can be defined as

$$S = F\varepsilon M\nu_{s1}(1+\alpha) \tag{12.29}$$

where the parameters are defined as the same as in the doubles equation above. If the alpha value of the item is known, then the equations for the singles and doubles rates can be solved to determine the multiplication of the item. The multiplication describes the induced fissions in the item, so if the multiplication is known, then the subset of the doubles resulting from induced fission can be removed from the measured doubles rate. In the known-alpha technique, a quantity called the multiplication-corrected doubles rate is calculated. The multiplication-corrected doubles rate represents only the spontaneous fission component and will result in a linear calibration. An example of a known-alpha calibration, which is created in a similar way to the passive calibration approach, is shown by the red data points (square points) in Fig. 12.12.

The known alpha method has a big advantage over the passive calibration curve because changes in the item, such as geometry, density, and material form that change the multiplication, will not affect the assay accuracy of the method. The one drawback of the known alpha technique is that the alpha value of the item must be known, as this is used to solve the singles and doubles equations for the multiplication. For pure items, such as metals or oxides, the calculation of the alpha value is straightforward and is only dependent on the isotopic composition of the item (Ensslin, 1991). Any impurities (light elements) remaining in the item will create large amounts of (α,n) neutrons making the determination of the alpha value very difficult.

Coincidence counting techniques are used in many facilities throughout the nuclear fuel cycle. A typical instrument used for both the passive calibration and known-alpha analysis methods is the high-level neutron coincidence counter (HLNC) (Krick and Menlove, 1979), shown in Fig. 12.7. The HLNC consists of 18 ^{3}He detectors embedded in polyethylene and arranged in a ring to create a well. The plutonium item to be measured is placed within this well, and the emitted neutrons are detected by the surrounding ^{3}He tubes. This system has an efficiency of approximately 18% and works very well for the assay of pure plutonium oxides. Many other coincidence counters exist and are based on the same design principles of the HLNC (Baker et al., 1990; Tagziria et al., 2007).

4. Active coincidence counting

Active coincidence counting is a technique used to measure uranium. As discussed previously, the isotopes of uranium have a spontaneous fission rate that is too small to make passive assay practicable. The instrumentation and analysis techniques of active assay are very similar to the passive calibration curve analysis technique for plutonium. In active assay, an interrogation source is used to induce fission on the ^{235}U isotope in the item. The induced fission neutrons are then detected and processed with a shift register. An AmLi source is a good choice for the interrogation source for two reasons. First, the neutrons produced from an AmLi source are random in time and will not contribute to the coincidence signal. Also, the energy spectrum of an AmLi source is a low-energy distribution (Owen et al., 1981; Geiger and Van der Zwan, 1971) such that almost no neutrons are emitted above an energy of 2 MeV and thus will induce fission on the ^{235}U and not induce fission in the ^{238}U. Unfortunately, AmLi sources are no longer produced, requiring the use of alternate interrogation sources. Although a ^{252}Cf source is a fission source, it has been successfully used as an interrogation source for the active-well coincidence counter (AWCC) (Menlove, 2015).

An AWCC (Menlove, 1979) is a portable instrument specially designed for the assay of the ^{235}U mass content in uranium items. The counter has two rings of ^{3}He tubes surrounding a well yielding an efficiency of approximately 33%. The counter is designed to hold two AmLi sources, one in the top and one in the bottom end plug. The random neutrons from the AmLi sources induce fission in the uranium item, and the detected doubles rate is related to a ^{235}U mass through an empirical calibration curve. The instrument is calibrated using the same methods as passive coincidence counting of plutonium. Active coincidence counting techniques are used throughout the world for safeguards applications (Ferrari and Peerani, 2010). An active coincidence counting technique typically yields results with accuracy in the range of 1%−5% when calibrated with representative standards.

F. Neutron multiplicity counting

1. Introduction to multiplicity counting

Multiplicity counting is an extension to neutron coincidence counting that incorporates the multiplicity of detected neutrons in the analysis (Ensslin et al., 1998a). From the multiplicity distribution, the factorial moments are determined. The first factorial moment is related to the singles,

the second is the doubles, and the third is the triples. Standard coincidence counting uses the first two moments, and multiplicity counting uses all three factorial moments.

The general theory behind multiplicity counting is that by adding a third measured quantity to the analysis, one can solve explicitly for the three unknown item properties, which are typically chosen as the $^{240}Pu_{eff}$ mass, the (α,n) production rate, and the multiplication. The solution of these three quantities is exact and complete and will yield excellent results as long as the item meets the assumptions of the point model (discussed below) used to derive the equations for the singles, doubles, and triples. Biases will be observed, if the assumptions are not fulfilled and will become larger, the more in violation they are. In general, no calibration standards are required for multiplicity counting, but in practice, they are used to confirm the technique and to determine bias correction factors when the assumptions in the equations are violated.

2. Multiplicity shift register electronics

The measurement of the triples count rate for multiplicity counting requires some changes to the shift register and the neutron counter design. The standard coincidence shift register needs to be slightly modified to be used in multiplicity counting as shown in the simplified block diagram of Fig. 12.13 (Halbig et al., 1991; Stewart et al., 1999). The same shift register principle is still used, but instead of adding the contents of the up-down counter to the R + A and A scalers, the contents are histogramed by the number present in the scalers. This histogram defines the multiplicity distribution and describes the probability of having a specified number of neutrons in the shift register when triggered by a newly detected neutron.

Separate multiplicity distributions are measured for the R + A and A gates. An example of a multiplicity distribution for a plutonium item is shown in Table 12.6. This table lists the number of times multiplicities of from zero to nine were measured in the R + A and A gates. For example, 183 times and 42 times, 7 neutrons were in the R + A and A gates, respectively, when the gate was triggered. The singles, doubles, and triples count rates are calculated from these distributions and are related to the first, second, and third reduced factorial moments as shown by the following formulas:

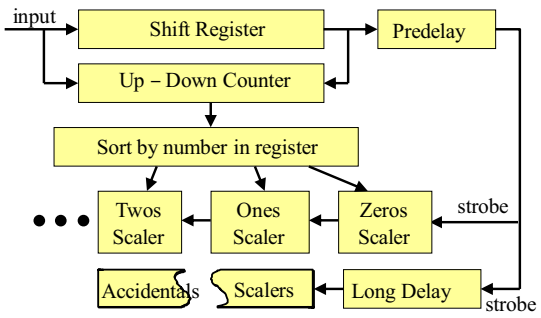

FIGURE 12.13 Block diagram of a multiplicity shift register electronics circuit. For the color version of the figure, the reader is referred to the electronic version of the book.

TABLE 12.6 The R + A and A multiplicity distribution of a 60-gram plutonium item measured in a multiplicity counter.

n	$(R + A)_n$	$(A)_n$
0	26,804,360	29,731,130
1	8,187,530	6,222,207
2	1,772,831	1,016,603
3	32,570	157,224
4	53,449	22,387
5	8231	3093
6	1237	402
7	183	42
8	30	8
9	2	1
10	0	0

$$S = \sum_{n=0} A_n$$

$$D = \sum_{n=1} n(R+A)_n - \sum_{n=1} nA_n$$

$$T = \sum_{n=2} \frac{n(n-1)}{2}(R+A)_n - \sum_{n=2} \frac{n(n-1)}{2}A_n - \left[\frac{\sum_{n=1} nA_n}{\sum_{n=0} A_n}\right]\left(\sum_{n=1} n(R+A)_n - \sum_{n=1} nA_n\right) \quad (12.30)$$

Every time a neutron is detected, the contents of the up-down counter is sampled and histogramed, so the singles is simply the sum of counts in the A distribution. The doubles rate is the difference of the means of the R + A and A distributions and is identical to the value measured with the standard shift register described earlier. Understanding the triples rate is not easy, as it is the difference in the third moments of the distribution with an additional term to account for correlations between the moments.

The equations that relate the measured count rates to the item properties are based on the point model (Boehnel, 1985; Cifarelli and Hage, 1986). The point model includes some fundamental assumptions about the fission process, the neutron emission process, and the detection process. The degree to which this model agrees with reality will

limit the accuracy of multiplicity counting and determine the range of material that this technique will apply to for quantitative assay. The point models equations are derived using the following assumptions:

1. The detector efficiency and fission probability are uniform over the entire item volume. This assumption is called the point model because it is equivalent to assuming that all the neutrons are emitted from a point.
2. All the induced fission neutrons are produced and emitted at the same time as the original spontaneous fission or (α,n) neutrons that created the induced fission. This idea is called the superfission concept (Boehnel, 1985).
3. The (α,n) and spontaneous fission energy distributions are the same. This assumption is not valid for many (α,n) reactions, although, for (α,n) neutrons produced in oxides, it is a good assumption.
4. The die-away time of the detector can be described by a single exponential time constant. Appropriate detector design can satisfy this assumption, although items containing moderating medium and item packaging can result in multicomponent die-away times.

The equations for the count rates, which are based on the point model and other assumptions described above, were derived by Boehnel (1985) and Cifarelli and Hage (1986) and are given by

$$S = F_o m \varepsilon M \nu_{s1}(1+\alpha)$$

$$D = \frac{F_o m \varepsilon^2 f_d M^2}{2}\left[\nu_{s2} + \left(\frac{M-1}{\nu_{i1}-1}\right)\nu_{s1}(1+\alpha)\nu_{i2}\right]$$

$$T = \frac{F_o m \varepsilon^3 f_t M^3}{6}\left\{\nu_{s3} + \left(\frac{M-1}{\nu_{i1}-1}\right)\right.$$

$$\left.\times\left[3\nu_{s2}\nu_{is} + \nu_{si}(1+\alpha)\nu_{i3}\right] + 3\left(\frac{M-1}{\nu_{i1}-1}\right)^2 \nu_{s1}(1+\alpha)\nu_{i2}^2\right\} \tag{12.31}$$

where F_o is the spontaneous fission rate, 473 fission/s-g, m is the $^{240}Pu_{eff}$ mass in grams, ε is the neutron detection efficiency, M is the neutron leakage multiplication, α is the (α,n) to spontaneous fission neutron ratio, f_d is the doubles gate fraction, f_t is the triples gate fraction, ν_{s1}, ν_{s2}, ν_{s3} are the factorial moments of the spontaneous fission distribution, and ν_{i1}, ν_{i2}, ν_{i3} are the factorial moments of the induced fission distribution.

The parameters in the point model equations can be grouped into four categories. The mass, multiplication, and alpha are the unknown quantities, with the mass being the quantity of interest to safeguards. The singles, doubles, and triples are the measured quantities. The efficiency and gate fractions are detector parameters, which are determined when the neutron counter is characterized. The factorial moments of the spontaneous and induced fission distribution are fundamental nuclear physics values and are fixed quantities.

The point model equations can be solved to get the $^{240}Pu_{eff}$ mass, multiplication, and alpha value. These equations are solved stepwise by first isolating the multiplication. This results in a cubic equation where only one of the roots yields a value for the multiplication that is physical and reasonable. Once the multiplication is determined, it is straightforward to find solutions for the mass and alpha value.

3. Multiplicity measurements

In the case of waste measurements where the plutonium mass is often very small and distributed over a large volume, the multiplication can be assumed to be unity. One of the complications in the assay of waste is that the waste matrix can cause changes in the detection efficiency. In this case, the multiplication can be assumed to be a known parameter, and the point-model equations can be solved for the mass, multiplication, and efficiency.

The accuracy of multiplicity counting is very good for items that meet the assumptions used to derive the point-model equations, but when these assumptions are violated, very large biases have been observed (Krick et al., 2005). One example is for the assay of large plutonium metal items (Geist, 2006). For these items, the assumption that the multiplication is constant throughout the item is not valid, as the multiplication on the edges is much smaller than in the center. In cases where biases are observed, working reference standards are used to determine a bias correction factor. For metal items, a multiplication-dependent correction factor of the form

$$CF = 1 + a(M-1) + b(M-1)^2 \tag{12.32}$$

has been found to correct the data. The coefficients a and b are determined empirically from measurements of working reference standards or calculated using Monte Carlo methods. The precision of multiplicity counting is influenced primarily by the statistical uncertainty in the triples count rate. Factors that determine the magnitude of the uncertainty include the detector efficiency, die-away time, count time, count rates, the multiplication, and the alpha value. Typically, the uncertainty is estimated by measuring the statistical scatter of multiple runs that make up a single assay, but theoretical models also exist (Dytlewski et al., 1993).

Multiplicity counting yields good accuracy over a wide range of material types as shown in Table 12.7 (Ensslin et al., 1998a). The metal data have been corrected with a multiplication-dependent correction factor. Plutonium oxide and slightly impure items assay extremely well with

TABLE 12.7 Typical passive multiplicity measurements results for several types of plutonium.

Material type	Mass range (g)	Alpha value	Count time	Relative standard deviation	Bias
Pu metal	200–5000	0–1	1000–1800	0.5%–4.6%	−0.8%–2.0%
Pu oxide	500–5000	1	1800	2.2%	0.0%
Impure oxide	20–900	0.7–4.3	1000	2%–3%	0.8%
Pu scrap	80–1175	1–6	3600	5.7%	−1.6%
Pu residues	0–10	1–82	1000	24%	−2.3%
	10–40	4–29	1000	22%	1.8%
	40–400	0.4–13	1000	17%	−1.4%
	160–340	7–34	3600	18.8%	−9.2%
Pu waste	~1	5	1000	1%–2%	1%–3%

multiplicity counting, although for pure items, standard coincidence counting will result in better precision. Plutonium scrap items generally have larger alpha values than found in the typical impure items, and this results in a loss of accuracy and precision. Plutonium residues often contain very large amounts of impurities, which can cause the item characteristics to severely violate the point-model equations. Various ranges of accuracy and precision are seen with these types of materials depending on the item multiplication and types of impurities. Neutron multiplicity measurements have been used successfully to fulfill the U.S. Department of Energy safeguards requirements (Dearborn and Mount, 2003; Geist et al., 2003; Dewberry et al., 2010; Stewart et al., 1998; Ensslin et al., 1998b).

Neutron multiplicity counting has advantages and disadvantages for assaying plutonium items. There are many properties of multiplicity counting, which makes its use advantageous. Calibration of multiplicity counting does not require representative standards, which in many cases can be very costly to fabricate or cannot be reasonably produced at all. For the assay of impure plutonium items, multiplicity counting will result in much better measurement accuracy than standard coincidence counting. For many item types, the required count times are much shorter than calorimetry, allowing for a greater throughput. Although multiplicity counting has many benefits, there are also several disadvantages. One of the biggest disadvantages to multiplicity counting is the cost of the counter, which is often several times the cost of a conventional coincidence counter. To obtain good measurement precision on the triples rate, the count times can be two to three times longer than standard coincidence counting. Multiplicity counting does not guarantee an unbiased result especially in cases where the characteristics of the items do not meet the assumptions of the point model. To correct for these biases, special correction factors need to be developed, or a measurement is required with an alternative technique such as calorimetry.

IV. Calorimetric assay

A. Introduction

Calorimetry is used as an NDA technique for determining the power output of heat-producing nuclear materials. The heat is generated by the decay of radioactive isotopes within the item. Because the heat measurement result is completely independent of material and matrix type, it can be used on any material form or item matrix. For items that contain only one radioactive isotope, such as tritium-bearing items, the thermal power that is measured from the item can be directly converted into the amount of tritium within the item without any additional information. For items that contain more than one radioactive isotope, such as Pu-bearing items, additional information concerning the isotopic composition of an item is needed to convert the measured thermal power of the item into the total mass of nuclear materials that is contained within the item. The combination of a calorimetry measurement with an isotopic composition measurement, which is performed with either gamma ray spectrometry or mass spectrometry, is referred to as calorimetric assay. Calorimetric assay of tritium- and plutonium-bearing items routinely achieves the highest precision and accuracy in terms of the mass of the item of any NDA technique because of the precision and accuracy with which the thermal power of an item can be determined.

The principle decay mode for most of the actinides of interest to nuclear safeguards and nuclear nonproliferation (except for ^{241}Pu and tritium) is alpha decay, in which the nucleus spontaneously emits an alpha particle into the medium within which the nucleus is located. Each

radionuclide has a specific disintegration energy associated with its decay; for example, ^{240}Pu decays to ^{236}U with the emission of an alpha particle and a release of 5.15 MeV. The total reaction energy for alpha decay is the sum of the alpha particle kinetic energy and the recoil energy of the daughter nucleus, as described in detail in Chapter 1,Volume 1 of this book. The alpha particle and daughter nucleus have very short ranges in matter. Thus, virtually all of the energy released by alpha decay will remain within the item as heat. If the daughter product is not in the ground state as a result of the decay, an additional small amount of energy is released in the form of gamma ray and internal conversion electron energy. The electron and low-energy gamma ray are absorbed in either the item or the item container. Higher-energy gamma rays that are emitted by the daughter nuclei from alpha decay are typically measured in gamma ray spectroscopy for these materials. The escape of these higher-energy gamma rays does not affect the calorimetric assay result because the portion of the total decay energy released as higher-energy gamma rays does not vary for a given isotope, so the decay heat generated per unit mass does not vary.

The determination of energy losses in matter is more complicated for beta emitters, such as ^{241}Pu and tritium, than for alpha emitters. With beta decay, the total reaction energy is in the form of a beta particle, neutrino, and the excitation and recoil energy of the daughter. The energy loss due to bremsstrahlung radiation, emitted as a result of deceleration of the beta particle, is negligible for ^{241}Pu and tritium; therefore, nearly all of the kinetic energy of the beta particle is absorbed by the item as heat. The neutrino is not absorbed by the item or calorimeter; therefore, its energy is not measured as heat. The thermal power measured by a calorimeter from beta decaying radionuclides is the product of the activity and the average beta particle energy, which is on average approximately one-third of the maximum disintegration energy.

The rate of energy emission for a given radionuclide is equal to the product of the total decay energy and the activity. This product for a single radionuclide is called the specific power, P, which can be calculated as (ASTM-C1458, 2011)

$$P = \frac{2119.3}{T_{1/2} \cdot A} \cdot Q \ (\mathrm{W/g}) \tag{12.33}$$

where $T_{1/2}$ is the half-life of the radionuclide in years, A is the atomic weight of the isotope in grams, and Q is the total disintegration energy (MeV) for alpha emitters or average energy (MeV) for beta particle emitters.

The specific power can also be determined empirically based on a total heat measurement in Watts (W) of a single isotope of known mass, m

$$P = \frac{W}{m} \ (\mathrm{W/g}) \tag{12.34}$$

The principal decay modes, specific heats, half-lives, and the associated uncertainties are listed in Table 12.8 for most of the common assayed radionuclides, all commonly encountered plutonium isotopes, ^{241}Am, and tritium (Bracken and Rudy, 2007). For most of the plutonium isotopes and ^{241}Am, the specific powers were determined empirically. The specific powers for the U isotopes were calculated using Eq. (12.33). The specific powers listed in Table 12.8 span a large range of values from over 0.5 Watts/gram for ^{238}Pu to less than 10 nW/g for ^{238}U. The magnitude of the specific power is inversely proportional to the half-life of the radionuclide.

All of the uranium and plutonium isotopes listed in Table 12.8 have very small spontaneous fission branching ratios. When fission does occur, the fission daughter products will deposit all of their kinetic energy within the item as heat. After fission, the daughter products can initially be in an excited energy state; this small amount of energy is released in the form of gamma ray and internal conversion electron energy. The low-energy electromagnetic emissions will be highly attenuated in the item, container, and walls of the calorimeter, depositing their energy with a resultant rise in the temperature of the calorimeter measurement well. The higher-energy gamma ray emissions can escape the calorimeter with minimal attenuation; thus, the energy is not measured. Another product of fission is neutrons. Because neutrons are very penetrating, a portion of the neutrons will escape the calorimeter without depositing their kinetic energy. The upper limits on lost energy, due either to escaping gamma rays from plutonium and uranium isotopes and ^{241}Am or from spontaneous fission, were quantified in Bracken et al. (2002) and are presented in Table 12.9.

The maximum energy loss listed in the last column in Table 12.9 was calculated using the assumption that 20% of the spontaneous fission energy is completely lost from the calorimeter due to the escape of all neutrons and photons. This assumption is a large overestimate of the photon energy loss, since all low-energy photons are attenuated in the item and the calorimeter, with the attenuation increasing with increasing item size.

B. Heat flow calorimetry

All calorimeters have four elements in common as shown in Fig. 12.14 (Bracken et al., 2002). Those elements are a sample chamber, well-defined thermal resistance (noted as R_{th} in the figure), temperature sensor, and environment. The interrelationship of these four components and the

hardware that are used for each component of the calorimeter determine the type of calorimeter.

Radioactive material with a long half-life continuously produces heat at nearly a constant rate. There is some change due to decay and ingrowth of daughter products, but the time scale for a measurable change is generally weeks to months. The most appropriate calorimeter design for radioactive material is an isothermally jacketed heat-flow calorimeter because heat is continuously produced by the item of interest. The design of the calorimeter is determined by the size and heat output of the items to be measured and the required accuracy in the heat measurement.

A heat-flow calorimeter consists of a sample chamber insulated from a constant temperature environment by a thermal resistance and a means to measure the temperature difference across the thermal gradient produced by the thermal resistance. When an item is placed in the calorimeter, the temperature gradient across the thermal resistance is disturbed and the gradient changes with time until it converges to a constant value and equilibrium is achieved. The heat produced in the sample chamber raises its temperature and causes heat to flow across the thermal resistance into the environment according to

$$\frac{dQ}{dt} = \frac{(T_{cal} - T_{env})}{R_{th}} = \frac{\Delta T}{R_{th}} \tag{12.35}$$

where Q is the heat energy, R_{Th} is the thermal resistance, T_{cal} is the internal calorimeter temperature, and T_{env} is the external environment temperature. At equilibrium, dQ/dt is constant and ΔT is proportional to the power of the item. The magnitude of the change in the measured temperature (passive mode) or in the change in power required to maintain a constant measurement chamber temperature (power-replacement mode) is used to determine the thermal power of the item in the calorimeter.

The curve describing the approach of the temperature difference to equilibrium is a function of several exponentials with different time constants. The time constants are related to the specific heats and thermal conductivities of the item matrix material, packaging, and, in some instances, the calorimeter. An example of a typical calorimeter approach to equilibrium is presented in Fig. 12.15 (Bracken et al., 2002). Equilibrium may be detected by visual inspection of the measurement data versus time or through statistical tests (Smith et al., 2003; Burr et al. 2001) performed on a set of the latest data points in the time series. Statistical prediction algorithms (Perry and Fiarman, 1988; Fellers and Seabaugh, 1979; Mayer, 1987; Wetzel et al., 1997; Smith and Bracken, 2000, 2002) may be used earlier during transient temperature conditions to predict equilibrium and reduce measurement time. Typical prediction algorithms that are currently in use consist of exponential functions that are used to fit the measurement data. The fitted parameters are then used to predict the final equilibrium power. The temperature of the item to be measured may be adjusted using preconditioning baths to shorten the time required to reach equilibrium.

The type and placement of the temperature sensors, the heat-flow path, and the type of heat sink are what differentiates between types of heat-flow calorimeters used for measuring radionuclides. The heat flow is directed to areas where the sensors are located by the use of conductive and insulating material or controlling temperatures.

1. Operating modes for heat-flow calorimeters

a. Passive mode

The most basic mode of heat-flow calorimeter operations is to measure the amount of change in the temperature gradient across the thermal resistance when a heat-producing item is placed in the measurement chamber, relative to the measured temperature gradient that was measured when the measurement chamber was empty, which is referred to as the baseline reading of the calorimeter. The difference between the temperature sensor readings, which are typically measured as a voltage, with and without an item in the chamber, is then equal to the heat flow that is produced by the item itself. This mode of operation is known as passive mode since the calorimeter is allowed to come to equilibrium without any external heaters or power supplies. Fig. 12.15 illustrates a measurement that was made in passive mode, with the difference between the sensor values at thermal equilibrium with the item in the chamber and the baseline sensor values being proportional to the power of the item that was measured:

$$V_{item} - V_{base} = \Delta V \propto W \tag{12.36}$$

where V_{item} and V_{base} represent the sensor output values with the item present and the baseline, respectively, and W is the thermal power of the item being measured. To correct for any drifts that may occur in the zero power response in the calorimeter during the assay of the item, and achieve the highest precision measurement possible,

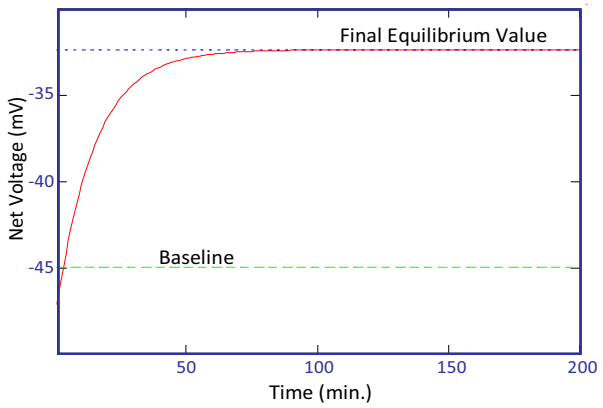

FIGURE 12.15 Example of approach to thermal equilibrium in calorimeter after insertion of heat-producing item. For the color version of the figure, the reader is referred to the electronic version of the book.

baseline measurements can be performed before and after an item measurement. An average baseline value $V_{base,avg}$ determined from those two measurements will be used to determine the net change in the sensor output due to the power of the item being assayed.

Calibration of a passive-mode calorimeter consists of determining the calorimeter sensitivity, S, which is the conversion factor between the differential sensor readings or resistance output and the thermal power of the item being measured. A series of calibration points within and bracketing the expected calorimeter operating range are needed to properly relate the sensor readings to the thermal power of the item. These calibration points can be made using either radioactive or electrical heat standards. The number of points will depend on the magnitude of the calorimeter differential sensitivity and the calibration accuracy required. A minimum of three different standard powers should be used. The form of the calibration curve varies according to the calorimeter design. Depending on the sensors that are used to measure heat flow, the sensitivity of a calorimeter can vary slightly with the amount of thermal power that is being measured by the calorimeter. The dependence in the sensitivity of a calorimeter on the thermal power being measured is given by:

$$S = S_0 + k \cdot W \tag{12.37}$$

where S_0 is the sensitivity of the calorimeter at zero thermal power and k is the slope of the varying sensitivity with the measured power. For most calorimeters, the magnitude of k is less than 1% of the zero power sensitivity over the operating power range. The sensitivity usually decreases with increasing power, which is qualitatively consistent with increased thermal conductivity of the material forming the primary thermal resistance. For example, the conductivity of dry air, a common thermal gap material, increases at the rate of 0.3% per °C. The intrinsic high-order nonlinearity of thermopile sensors can lead to differential sensitivities that are negative or positive but still relatively small compared with the base sensitivity.

Because of the dependence of the sensitivity of the calorimeter on the thermal power that is being measured, the calibration curve of a calorimeter operated in passive mode is usually well represented by a quadratic function:

$$\begin{aligned} \Delta V &= S \cdot W \Rightarrow \\ \Delta V &= (S_0 + k \cdot W) \cdot W \Rightarrow \\ \Delta V &= S_0 \cdot W + k \cdot W^2 \end{aligned} \tag{12.38}$$

The fit parameters S_0 and k are determined by a least-squares fit to a plot of net sensor output as a function of the thermal power of the heat standards that are used to calibrate the calorimeter. Since calorimeter noise is a function of the power of the item being measured, increasing variability with increasing power, the residuals of the least-squares fit will not be normally distributed. However, the parameter estimates are not affected by this abnormal distribution.

An example of actual calibration data used to determine the fit parameters in Eq. (12.38) are presented in Fig. 12.16 (Bracken and Rudy, 2007). The data presented in Fig. 12.16 were obtained using a dual-sensor water-bath calorimeter. Three to five measurements were made at each standard power. The linearity of the calorimeter response to power is typical of water-bath calorimeters.

A plot of the first derivative of calorimeter calibration data is normally designated a differential sensitivity plot as presented in the bottom of Fig. 12.16. It is easier to visually quantify the differential sensitivity of the calorimeter and the relative precision of the measurements at the different powers on a differential sensitivity plot than it would be from the top plot in Fig. 12.16. It is apparent in the bottom plot in Fig. 12.16 that multiple measurements were made using the three lowest-power heat standards; this observation is not possible in the top plot. The precision of this calorimeter is good enough that the multiple measurements, three each, at the largest two powers are not resolved on this scale.

b. Power-replacement mode

In power-replacement mode, the calorimeter sample chamber is maintained at a constant temperature differential via an internal heater and an external power supply, which is controlled and monitored by the data acquisition system using the temperature sensors within the calorimeter as a feedback signal. When a heat-generating item is placed inside the measurement chamber, the additional heat that is generated by the item causes the temperature sensors to initially rise triggering the controller on the power supply to adjust the power supply's output and subsequently reduce the heat that is generated by the internal heaters to maintain

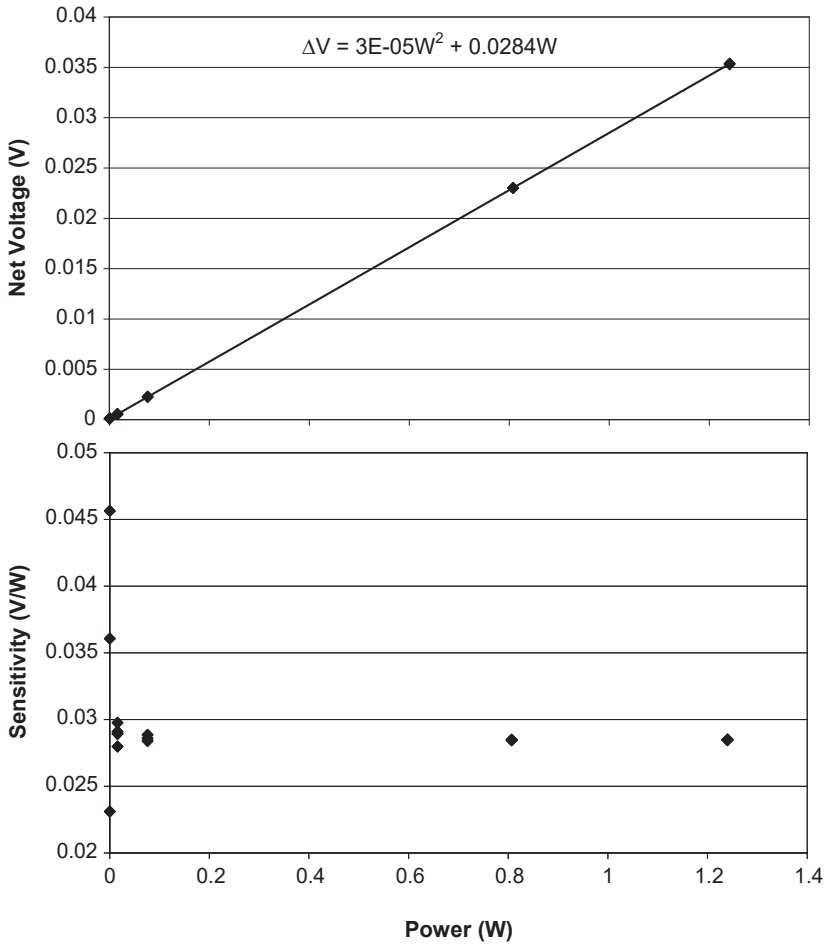

FIGURE 12.16 (Top panel) Example of sensor output as a function of thermal power of the heat standards used to calibrate a dual-cell water-bath calorimeter. The solid line is a least-squares fit to the measured data. (Bottom panel) Calorimeter sensitivity as a function item power derived from the data shown in the top panel.

a constant sensor output (and therefore a constant measurement temperature differential within the chamber). When the item reaches thermal equilibrium within the calorimeter, the difference in the measured output of the external power supply, from when the chamber was empty to when the item was placed inside the chamber, is equal to the thermal power output of the item. The reason the output of the external power supply changes is due to the fact that the item that is placed inside the measurement chamber supplies a portion of the thermal power, which was being supplied by the external power supply (through the internal heater) when the chamber was empty. Hence, the calculation of item power, W_i, in power-replacement mode is

$$W_i = W_0 - W_H \tag{12.39}$$

where W_0 is the power supplied to the calorimeter with no item in the calorimeter (known as the base power) and W_H is the power supplied to the calorimeter with the item in the calorimeter. Fig. 12.17 presents a graphical illustration of a calorimetry measurement performed in power-replacement mode (Bracken et al., 2002). The measurement time for the power-replacement mode of operation can be shorter than for the passive mode because the calorimeter components are at the equilibrium temperature and the servo-controlled internal heater can supply heat to actively bring the item to equilibrium.

Calibration of a power-replacement mode calorimeter consists of setting the sensor output set point voltage corresponding to a specific base power and determining the stability of the heater power. A single sensitivity point, S, must be determined by making a measurement of a heat standard. Any power within the operating range of the calorimeter is satisfactory. The sensor output set point (V_{sp}) is calculated using

$$V_{sp} = V_{base} + S \cdot W \tag{12.40}$$

where V_{base} is the baseline of the calorimeter. The heater power is controlled to maintain a constant sensor output equal to V_{sp}. The actual supplied heater power (W_0) used to maintain V_{sp} may be slightly different from the target value, W, because of the uncertainty in S used to calculate the set point. Measuring a standard power, which is as close

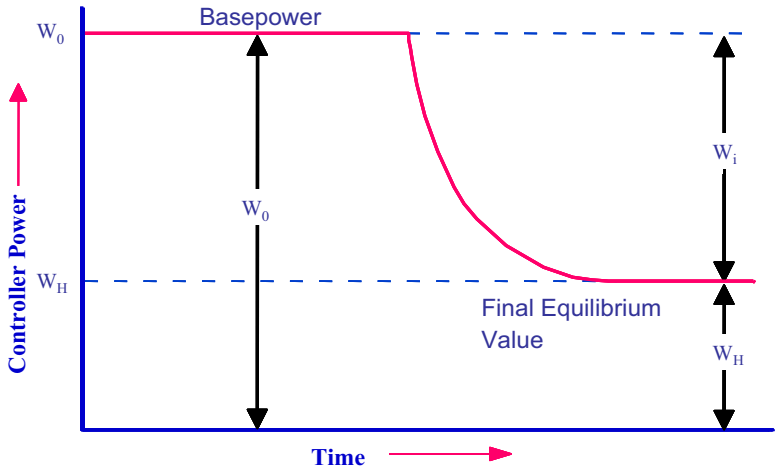

FIGURE 12.17 Graphical illustration of a calorimeter measurement performed in power-replacement mode. For the color version of the figure, the reader is referred to the electronic version of the book.

as possible to the value of W, will minimize the difference between W and W_0. Because the item power is the difference between W_0 and W_H, at equilibrium with item present, carefully matching W and W_0 will not increase the performance of the calorimeter in any way as both W_0 and W_H are measured to determine the item power. Matching W and W_0 will only minimize the difference between the requested base power and the actual base power.

For a calorimetry measurement to be made in power-replacement mode, it is critical that control of the measurement chamber temperature be maintained during a measurement. If the thermal power of an item being measured in power-replacement mode exceeds the base power of the calorimeter, the external power supply will end up being set to zero by the controller, and the heat flow sensors on the measurement chamber will end up raising in response solely to the thermal power that is produced by the item. To avoid this measurement scenario from occurring, the base power, W_0, of a calorimeter operated in power-replacement mode is typically set 10%–20% higher than the highest-power item expected to be measured. For some calorimeter designs, a calorimeter that is designed to operate in power-replacement mode can be used in passive mode, if it has been calibrated as described in the previous section.

The base power, W_0, is determined the same way as a baseline is determined in passive mode. The calorimeter can is filled with a conductive material and no heat-generating items. The heater power measurement at equilibrium is the base power, W_0, corresponding to V_{sp}. Replicate measurements should be made of the base power to determine the standard deviation of the value. To best characterize the stability of the calorimeter in performing measurements of heat-producing items, the calorimeter is opened and closed between repeat measurements of base power.

2. Calibrating a heat-flow calorimeter

Two types of heat standards are commonly used to calibrate calorimeters. The most reliable type of heat standard used in US facilities is a radioactive source of known power whose calibration is traceable to the National Institute of Standards and Technology (NIST). These standards are normally made from ^{238}Pu oxide, which is well characterized both chemically and physically. As these standards can be measured in the exact same manner as assay measurements of unknown nuclear material–bearing items, repeated measurements of these heat standards will provide a more accurate representation of the performance of the calorimeter than electrical standards can.

Electrical heat standards contain an electrical circuit consisting of standard resistors and standard voltage cells. Such standards are also traceable to the NIST or other national measurement systems. The resistor is used in place of a radioactive source, and the power dissipated in an electrical heater is measured using calibrated meters and calibrated resistors. The specifics of the calorimeter calibration depend on whether the calorimeter is operated in the passive mode or power-replacement mode. During all calibration measurements, the calorimeter should be operated in the same manner used to make assay measurements on items. The magnitude of heat distribution error (HDE) and convection noise should be quantified during initial calibration, if the calorimeter will be operated under nonideal conditions.

3. Types of heat-flow calorimeters

A variety of heat-flow calorimeter designs have been used to measure nuclear material. Most of the variations in the designs are related to the controlled environment that the calorimeter is placed in (water-bath or isothermal "air-bath" environments), the way in which the thermal power is

measured (e.g., Wheatstone bridge sensor or solid-state sensors), and the use of a reference set of sensors to reduce noise due to changes in the external environment.

A water-bath environment can provide the most stable and precisely controlled external environment temperature for calorimeters. Providing a stable and well-controlled external environment allows for higher precision measurements to be made, as the systematic variations in the external environment are reduced, as well as lower power measurements to be made within a given calorimeter as the variations in the baseline response of the calorimeter are reduced. In addition to placing a calorimeter into a large water bath, other methods for providing a consistent thermal environment using water include the use of a water jacket, which continuously circulates water through an external jacket that is in contact with the calorimeter. As water jacketed systems typically require a significantly smaller volume of water than a water-bath system does, the noise in the reference temperature of a calorimeter system that utilizes a water jacket is usually larger than the noise observed in a similarly sized water bath system due to ambient room-temperature fluctuations.

The isothermal "air-bath" calorimeter operates with three concentric cylinders at successively lower temperature from the inner cylinder (measurement chamber) to the outer cylinder. This creates a temperature gradient and heat flow from the inner cylinder to the outer cylinder. The calorimeter operates in power-replacement mode with the measurement chamber kept at a constant operating temperature. The system controller works to maintain a constant total thermal power in the measurement chamber. The total thermal power present in the measurement chamber is the power due to the internal heaters and the power due to the item being measured. Isolation from the thermal environment is achieved by circulating air through an exterior chamber either by forced air cooling using room temperature air or by a closed-loop air circuit employing a thermoelectric cooling unit to provide a sufficiently low heat sink temperature (ASTM-C1458, 2011).

To measure the thermal power that is emitted from an item of interest, a number of different types of heat-flow sensors have been utilized in calorimeters for assaying nuclear materials. Historically, one of the most common types of sensors that are encountered within heat-flow calorimeters are nickel wire temperature sensors connected in a Wheatstone bridge configuration. In a Wheatstone bridge calorimeter, two lengths of high-purity nickel wire are wound concentrically about a sample chamber and a reference chamber and serve as two-sensor arms of the Wheatstone bridge circuit, shown in Fig. 12.18. The thermal resistance between the sample sensor windings and the water bath is identical to the thermal resistance between the reference sensor windings and the water bath. This thermal resistance matching is done to maximize cancellation of

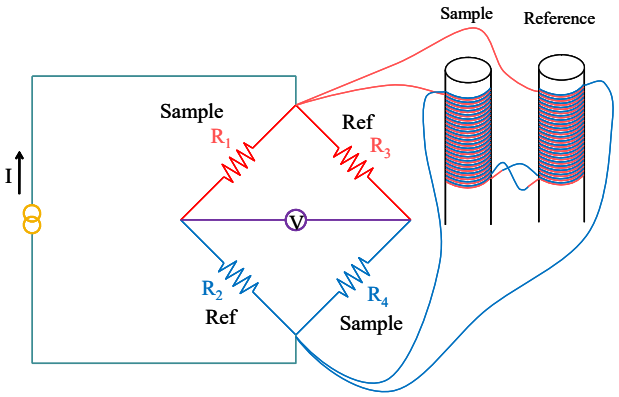

FIGURE 12.18 Schematic drawing of wiring of Wheatstone bridge calorimeter. For the color version of the figure, the reader is referred to the electronic version of the book.

temperature fluctuations in the external environment in the Wheatstone bridge signal. The sensitivity of the calorimeter is directly proportional to the thermal resistance of the thermal gap. The wider the thermal gap, the larger the internal temperature rise of the sample chamber for a given thermal power.

The change in resistance of the high-purity nickel wire with temperature is linear with a sensitivity of about +0.6% per °C. The temperature rise in the sample side due to the presence of radioactive material causes the resistance of the sample arms of the Wheatstone bridge to increase, whereas the resistances of the reference arms remain constant. When a constant electrical current is applied across the Wheatstone bridge, the resistance change between the sample and reference sides of the bridge causes an imbalance in the bridge, and the voltage across the bridge (the bridge potential) changes in proportion to the size of the temperature change. The reference sensor wire arms and sample sensor wire arms of the Wheatstone bridge are each helically wound interleaved (bifilar winding) and concentrically around a cylindrical chamber. While Wheatstone bridge calorimeters are able to perform high-precision thermal power measurements, the calorimeters are sensitive to environmental factors, which could change the resistance of the nickel wire such as physical stress or strain on the wire itself.

Other common type of sensors that are used in heat-flow calorimeters are solid-state sensors, which use thermopile components as heat-flow sensors (Bracken and Hypes, 2000; Bracken et al., 1997, 1998). A thermopile consists of numerous thermocouple pairs electrically connected in series. Thermocouples are formed by electrically joining one set of ends of two dissimilar conductors or semiconductors. A temperature difference between two thermocouple junctions causes the development of an electromotive force, known as the relative Seebeck effect that is proportional to the temperature difference. The greater the temperature

difference, the larger the voltage measured from the sensor. The thermopile hot junctions are placed facing the sample chamber, whereas the cold junctions are held at the reference temperature. Because the solid-state sensors are insensitive to physical stress or vibrations that may be encountered by the calorimeter, solid-state calorimeters tend to be more stable in terms of their baseline response than Wheatstone bridge calorimeters.

Calorimeters that typically achieve the highest precision and sensitivity in measuring nuclear materials utilize a twin-cell design, which uses two identical chambers with one chamber used as a reference for the chamber that is used to measure the nuclear material–bearing items. The fact that the reference and sample chambers will have identical responses to changes in the controlled external environment allows for the calorimetry system to compensate for changes in the sensor readings due to the changes in the external environment. This reduces the effects of thermal noise in the system on the measurement results, which improves the precision of the measurements as well as increases the sensitivity of the calorimeter to lower amounts of heat being produced by an item of interest. A twin-cell calorimeter can be made with either a Wheatstone bridge sensor system or solid-state sensors. Other calorimeter designs, which utilize a reference set of sensors for noise reduction, include a gradient design where the sample sensors and reference sensors are placed in concentric circles about a single measurement chamber, and an over-under design where the reference chamber is located underneath and along the same axis as the sample chamber. In these designs, because the reference set of sensors will have slightly different responses to the thermal changes as the sample sensors, the noise reduction is not as effective as is observed in the twin-cell calorimeters.

C. Calorimetric assay

Calorimetric assay has been routinely used at US and European facilities for plutonium process measurements and nuclear material accountability for the past 60 years (Eichelberger et al., 1954; Gunn, 1964, 1970; ANSI, 1987; ASTM-C1458, 2011; Mason, 1982; IAEA, 1987). Calorimetric assay is routinely used as a reliable NDA technique for the quantification of plutonium and tritium content within items. Calorimetric assay of tritium- and plutonium-bearing items routinely obtains the highest precision and accuracy of all NDA techniques. Plutonium items usually contain varying amounts of ^{241}Am, which can be accounted for during the assay.

The thermal power emitted by a nuclear material–bearing item is directly proportional to the quantity of radioactive material in it, and the total power generated by ionizing radiation absorbed in the item is measured by the calorimeter. The mass m of radionuclides present is calculated from the measured thermal power of an item using the relationship

$$m = \frac{W}{P_{eff}} \tag{12.41}$$

where P_{eff} is the effective specific power (Watts/gram) calculated from the isotopic composition of the item. For all multiradionuclide items, the P_{eff} is not a constant and needs to be corrected for the decay and growth of the constituent radionuclides. See Likes (1991) for details on decay correction of plutonium bearing items.

For monoisotopic items, the specific power (P) of the radioisotope is used in place of P_{eff}. For items that contain multiple radioactive isotopes, the effective specific power of an item, which contains i heat-producing radioisotopes, can be calculated by

$$P_{eff} = \sum_i R_i \bullet P_i \tag{12.42}$$

where R_i is the abundance of the ith radionuclide in the item, typically expressed as a mass fraction to a total elemental mass, and P_i is the specific power of the ith radionuclide in the item in watts/gram.

Two methods exist for determining P_{eff}: a computational method and an empirical method. The computational method uses Eq. (12.42) for determining P_{eff} and is appropriate when isotopic composition measurements can be made. The relative abundances of the radionuclides can be determined destructively using mass spectroscopy (ANSI, 1973, 1974; ASTM-C697, 2011) or nondestructively using gamma ray spectroscopy (Sampson, 1991; ASTM-C1030, 2018). When measuring items in sealed containers, high-resolution gamma ray spectroscopy is the only option for determining P_{eff} using nondestructive methods. The uncertainties on P_{eff} using gamma ray measurements for plutonium-bearing items are generally less than 0.5%. If mass spectroscopy is used to determine P_{eff} of plutonium-bearing items, the ^{238}Pu content should be determined using alpha spectrometry (ASTM-C697, 2011), and the ^{241}Am content should be determined radiochemically. The effective specific power uncertainty is normally 0.1%, for isotopically homogeneous items. The computational method using gamma ray spectroscopy for isotopic analysis is the dominant technique used in conjunction with calorimetry.

The empirical method of determining the effective specific power involves a calorimeter measurement to determine the total power produced by the sample and a chemical analysis to determine the total amount of nuclear material in the sample. Substituting these values into Eq. (12.41), P_{eff} can be determined. The empirical method is potentially more accurate and precise than the computational method. The method can only be implemented on discrete batches of process materials or when it is difficult

to determine the relative isotopic abundances of an item or batch of material. As with using mass spectroscopy in the computational method, the empirical method is a destructive technique that generates waste and requires long assay times to complete the analysis. These time and waste issues have increased the exclusive use of NDA techniques for the quantitative determination of nuclear material mass.

1. Assay error determination

The measurement of the two quantities that are used in calorimetric assay to determine the nuclear material mass of an item (item power and effective specific power of an item) is independent, so the relative uncertainty for the plutonium mass can be written as

$$\frac{\sigma_m}{m} = \sqrt{\left(\frac{\sigma_W}{W}\right)^2 + \left(\frac{\sigma_{P_{eff}}}{P_{eff}}\right)^2} \tag{12.43}$$

The uncertainty in the power measurement, σ_W, can be obtained from replicate power measurements of heat standards or from historical data. It should include both random and systematic error components. The uncertainty in P_{eff}, σ_{Peff}, comes from the uncertainty in the isotopic fractions, R_i, and isotopic specific powers, P_i. The uncertainties in the isotopic fractions are determined from uncertainties in the various techniques that might be used for the isotopic analysis, such as mass spectroscopy, alpha counting, or gamma ray spectroscopy. The uncertainties in the isotopic specific powers, P_i, as determined by different experiments, were previously given in Table 12.8.

2. Calorimetric assay performance

Calorimetric assay is considered the "gold standard" of NDA measurements for items containing more than 0.5 kg of plutonium of any form in a container less than 25.5 cm in diameter. Since calorimetry can measure entire items with very high precision and low bias, the results are often comparable with DA measurements in terms of accuracy and precision. Calorimetry is frequently used as a standard measurement to determine uncertainties and/or biases in other NDA techniques such as neutron counters (ASTM-C1207, 2011) and tomographic gamma scanner systems (Hyman et al., 1999; Lestone et al., 2000).

The accuracy and reliability of calorimetric assay are primarily dependent on the thermal power generated by the item and on the methods used to determine P_{eff}. The total measurement uncertainty on P_{eff} determined for pure homogeneous items using gamma ray spectroscopy is comparable with the power measurement uncertainty (Sampson, 1999). Major factors that can affect the precision of P_{eff} determined by gamma ray isotopic assay can be found in ASTM-C1030 (2018). Major factors that can affect the bias of P_{eff} determined by mass spectrometric methods can be found in ASTM-C697 (2011). For materials containing reasonable concentrations of plutonium (>100 g Pu/liter), the precision and bias of calorimetric assay are comparable with good chemical assay techniques (Welsh et al., 1995a). In this case, the largest source of calorimetry error is due to the uncertainty of the specific powers, P_i, of the individual radionuclides. For single radionuclide items, the uncertainties will be due only to the power measurement and the specific power of the radionuclide. The precision of a calorimeter measurement is dependent on the sensitivity of the calorimeter, baseline stability, and item power.

For impure or heterogeneous items, calorimetric assay can have lower uncertainties than DA techniques (Welsh et al., 1995b) because of DA sampling error. The power measurement integrates all of the heat produced by the item regardless of inhomogeneity, and for heterogeneous items, the determination of P_{eff} by gamma ray spectroscopy is a more representative average of the entire item than DA. In this case, where the isotopic composition of the plutonium is determined by gamma ray spectroscopy, the final uncertainty in the gram value determined by calorimetric assay is dominated by the uncertainty of the mass fractions, R_i, in P_{eff}.

To evaluate the precision and accuracy of calorimetric assay measurements throughout the Department of Energy (DOE) complex, the DOE created the Calorimetry Exchange program (CALEX), which distributed identical PuO_2 items containing 400 g of plutonium with 5.86% ^{240}Pu by weight to different Pu facilities throughout the complex. The plutonium content and isotopic composition reference values of the mother lot of PuO_2 material used for these standards were measured by coulometry and mass spectrometry/alpha counting by four analytical labs. The power of the CALEX standard during the time periods of measurements described below was about 1 W.

Measured data for 23 calorimeters at five DOE facilities are presented in Fig. 12.19 with the ratio of the measured mass value to the accepted mass value for the standard plotted as a function of the measurement number. The dashed vertical lines separate the data submitted by each laboratory. These data were collected for the CALEX program over a 15-month period starting in October 1993. All measurements have a bias of less than ±0.8%. The average bias is 1.0004 with a standard deviation of the average of ±0.0002. The error expected on a single measurement would be 0.3% one RSD.

The results of multiple calorimetric assay measurements by three facilities on the CALEX standards are shown in Table 12.10 (NBL, 1999). The calorimetry and gamma ray measurements used to determine plutonium mass variabilities and biases reported in Table 12.11 were taken over a 1-year period. The within-facility variability and the bias of the calorimetric assay were calculated from results reported

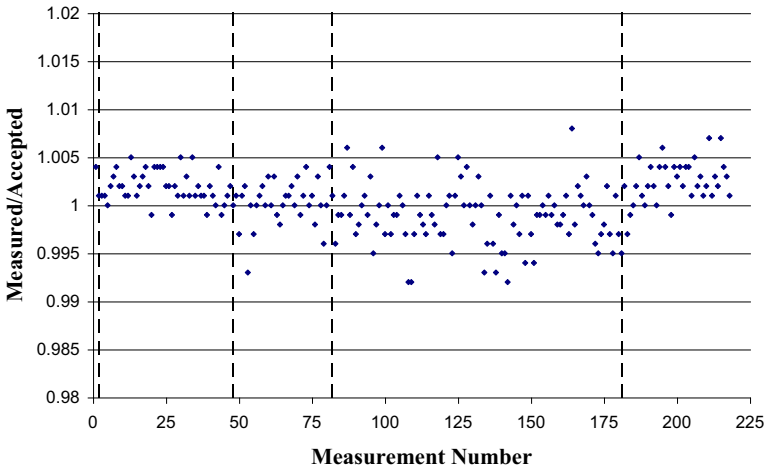

FIGURE 12.19 Calorimeter measurement biases for heat measurements of the CALEX standards. Measurements were taken over a 15-month period by five DOE laboratories using 23 different calorimeters.

by each facility decayed to a common date. Each facility used different gamma ray analysis codes for the isotopic measurements. For some, the reported values are the averages of measurements of the standard item with different calorimeters.

CALEX data taken at five different DOE facilities are presented in Table 12.11. The data were collected over an 8-year period from 1990 to 1998. Not all facilities reported results each year. Therefore, the averages contained data from a maximum of 8 years and a minimum of 5 years. Presented in Table 12.11 are the average percent measurement bias and percent RSD from repeated measurements for P_{eff} and item power. The percent bias and percent RSD are comparable for power and P_{eff} measurements on this item.

Data collected from a measurement control program can be used to calculate the precision and bias of the power measurement. A summary of the precision and bias of the power measurement obtained from replicate measurements of ^{238}Pu heat standards in production facilities over a 0.5−1.0 year period is shown in Table 12.12. Generally, the greater the thermal power of an item in a calorimeter, the better the relative precision. Extensive calorimetric assay precision and bias data can be found in references (Birden et al., 2000, NBL, 1999, Longmire et al., 1990, Fleissner and Hume, 1986, Welsh et al., 1995a,b, Lindsay et al., 1987).

There are a number of factors, which could affect the performance of a calorimetric assay. One potential factor is a heat distribution error (HDE), which is a variation in the calorimeter response due to the location of the heat source within the measurement chamber. For example, the same heat source may produce a larger calorimeter output in the bottom of the sample chamber than in the top. The HDE could lead to a bias if the location of heat within an item is unknown. HDE is quantified by performing multiple

TABLE 12.12 Examples of calorimeter power measurement precision and bias.

[b]*Measurements made in laboratory.*

measurements of the same heat source placed at different vertical positions within the calorimeter measurement well. The magnitude of an HDE will increase with increasing power. If an HDE is measured, the uncertainty associated with HDE must be included in the final uncertainty of the power determination.

Other factors, which can affect the precision and accuracy of a calorimetry measurement, include the presence of processes within the item that would add or subtract thermal power from the power being generated by the decay of the radionuclides being assayed. These processes can include phase changes, endothermic, or exothermic chemical reactions, such as oxidation. In addition, radioactive decay energy can drive endothermic reactions in aqueous solutions.

Because calorimetric assay relies on a knowledge of the radionuclides that are generating heat within an item, any radionuclides that generate heat within an item but that would not be detected using gamma ray spectroscopy would add additional thermal power to a measurement. This additional thermal power would be attributed to the known radionuclides present within the item. This would cause bias in the calorimetric assay of this item. In a similar manner, the accuracy of calorimetric assay can be degraded for items, which possess an inhomogeneous isotopic composition due to the increased uncertainty in the isotopic ratios.

Calorimetry measurement times are typically longer than other NDA techniques. The packaging conditions and matrix of the item cannot change the heat output of the material, but they are usually the determining factor for measurement time. Time series data collected with a twin-sensor water-bath calorimeter operated in passive mode are presented in Fig. 12.20 (Smith et al., 2001). The series of lines represent different matrix conditions. The effect of matrix on measurement time is apparent in Fig. 12.20. It can also be seen that the matrix has no effect on the magnitude of the final answer (i.e., the bridge potential at

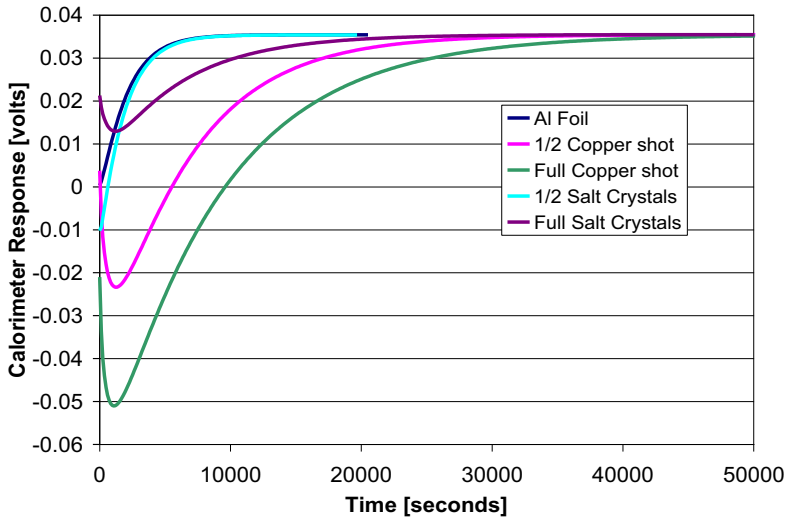

FIGURE 12.20 Twin-cell calorimeter measurements of a 1.25 W heat standard embedded in different matrices illustrating how different matrices affect time to equilibrium. The data have been adjusted so that the baseline value corresponds to 0 V. For the color version of the figure, the reader is referred to the electronic version of this book.

equilibrium). For each measurement presented in Fig. 12.20, the calorimeter can, including the matrix and source, was preequilibrated to the same temperature before insertion into the calorimeter. Preequilibration was done to minimize the time response due to starting temperature variability, therefore maximizing the time sensitivity to matrix. The different matrices containing the same 1.25 W heat standard reached equilibrium in a time range of 3−14 h. The matrices in order of increasing time to equilibrium were with the can 1/2 full of salt crystals, full of aluminum foil, full of salt crystals, 1/2 full of copper shot, and full of copper shot.

The time necessary for a calorimeter to reach thermal equilibrium during the assay of an item is dependent on a number of factors:

- initial temperature of item relative to final equilibrium temperature of the item/calorimeter (sample preconditioning can reduce measurement time by reducing this difference),
- type of heat-flow calorimeter used (passive or power-replacement),
- calorimeter size and thermal properties (thermal conductivity and total heat capacity) of the fabrication materials,
- thermal properties of the item and item packaging (usually more important than calorimeter properties), and
- the size and weight of the item and the calorimeter.

D. Applications

Calorimetric assay is presently the most precise and accurate NDA technique for the measurement of many physical forms of plutonium and tritium. Calorimetry has been applied to a wide variety of plutonium-bearing solids, including metals, alloys, oxides, fluorides, mixed plutonium−uranium oxides, mixed oxide fuel pins, waste, and scrap (e.g., ash, ash heels, salts, crucibles, and graphite scarfings) (Rogers, 1981; Likes, 1991). Calorimetric assay has applications in a number of different areas: shipper/receiver measurements, accountability measurements, calibration of NDA standards, process control measurements, outlier resolution, and product acceptance measurements.

Of the items listed above, calibration of NDA standards and outlier resolution can only be done nondestructively using calorimetric assay.

Calorimetric assay can be applied to a number of different radionuclides: plutonium, HEU, ^{233}U, ^{237}Np, ^{242,244,245}Cm, ^{250,252}Cf, ^{241,242m,243}Am, tritium, and fission products. Calorimetric assay can be accurately used for any of the above-listed items that will fit in the instrument measurement well and are free from any exothermic or endothermic chemical reactions. Fig. 12.21 presents the range of specific powers for some of the radionuclides listed above.

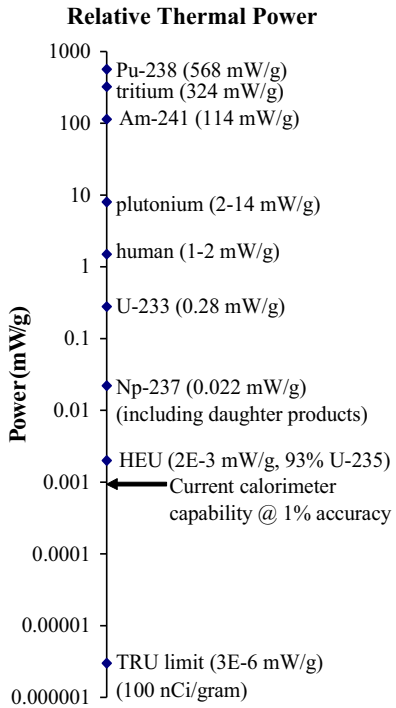

FIGURE 12.21 Specific power of actinides relative to current calorimeter capabilities.

Calorimetric assay is most frequently used to measure plutonium-bearing items with varying amounts of ^{241}Am. High-resolution gamma ray spectroscopy measurements are usually made to determine the plutonium isotopic and ^{241}Am mass fractions. An example of the importance of calorimetric assay of plutonium-bearing items at the Los Alamos National Laboratory (LANL) is presented in Table 12.13, originally presented in Bracken et al., 2002.

Calorimetry can be used to measure the quantity of tritium in containers. In most cases, tritium is the only radioactive isotope present; therefore, no isotopic measurements are required for the assays. A confirmatory gamma assay may be necessary to substantiate the lack of additional radionuclides for items with uncertain histories. High-precision and low-bias assays can be made on items containing more than approximately 0.01 g of tritium.

Uranium with a natural abundance of 0.7% ^{235}U generates too little thermal power to be accurately quantified by calorimetric assay. The major component of natural uranium, ^{238}U, has too long a half-life, 4.5×10^9 y, to generate sufficient thermal power. As the 7.0×10^8 y ^{235}U mass fraction increases during enrichment, the specific

power of uranium increases. Although the specific power of ^{235}U is higher than ^{238}U, the major contributor to the increase of effective specific power is the ^{234}U that is enriched along with the ^{235}U. The specific power for ^{234}U is nearly 0.2 mW/g, which is more than three orders of magnitude larger than for ^{235}U; this is due to its relatively short half-life of 2.45×10^5 years. For an enrichment of 93% ^{235}U, the ^{234}U mass fraction is about 1%. With a mass fraction of 1%, the ^{234}U component supplies about 96% of the total thermal power from the uranium, 1.85 mW/kg. This is a power density that can be measured to an accuracy of about 1% by some calorimeters. Calorimetric assay measurement results on HEU metal and oxide are shown in Table 12.14. These measurements were made with a 5″ diameter twin-bridge, water-bath calorimeter on well-characterized material (Rudy et al.,1997). The precision for the 1-kg items ranged from 12% to 18% RSD, whereas the thermal power for the 4-kg item, 7.8 mW, was measured with a precision of about 1% RSD. The low specific power of HEU limits calorimetric assay to matrices with high uranium content, such as metal, oxides, U alloys, and high-grade scrap.

William H. Geist

William Geist is a scientist in the Safeguards Science and Technology Group at Los Alamos National Laboratory. He received his PhD in Nuclear Physics from the University of North Carolina at Chapel Hill in 1998. Soon after receiving his degree, Bill became a full-time staff member at Los Alamos National Laboratory (LANL). Bill recently spent 3 years on assignment at the International Atomic Energy Agency (IAEA) in the Training Section teaching IAEA inspectors nondestructive assay (NDA) measurement techniques. Bill is an expert in developing and performing NDA measurements of plutonium and uranium materials for international safeguards, nuclear nonproliferation, and nuclear security applications. At LANL, Bill is currently serving as the Safeguards Technology Training Director, which includes responsibilities for running training courses on NDA methods for both domestic and international participants.

Peter Santi

Peter Santi received his PhD in Nuclear Physics in 2000 from the University of Notre Dame. After graduate school, he worked at the National Superconducting Cyclotron Laboratory at Michigan State University as a visiting research associate performing research in the area of nuclear astrophysics. From 2003 to 2015, he worked in the Safeguards Science and Technology Group at Los Alamos National Laboratory focusing on the development and implementation of nondestructive assay measurement techniques for Safeguards purposes. During this time at Los Alamos, he was a subject matter expert in performing calorimetric assay and project leader for certifying ^{238}Pu Calorimetry Heat Standards for the Department of Energy complex. Since 2016, he has been a senior instrumentation specialist working in the Safeguards Training Section at the International Atomic Energy Agency.

Philip A. Hypes

Phil Hypes received a BS in Physics from Loyola College in Maryland in 1993. He served as a US Army radiation specialist until 1998, when he joined the Safeguards Science and Technology Group at Los Alamos National Laboratory (LANL). At LANL, he has worked on projects involving gamma spectroscopy, calorimetry, and treaty verification. He completed an MS in Systems Research and Development through the National Technological University in 2004. He joined the IAEA and taught nondestructive assay to all new IAEA inspectors from 2005 to 2007. The IAEA received the Nobel Peace Prize during this time. When he returned to LANL, he became the lab's coordinator for IAEA projects. He also continued to teach in NDA courses. From 2012 to the summer of 2014, Phil was the team physicist on the VISIBLE team. Mr. Hypes now leads a transuranic waste management team in the Hazardous Materials Management group at LANL.

Chapter 13

PERPUSTAKAAN PRIBADI AN-NUR SUNARYA

Nuclear forensics

Michael J. Kristo
Lawrence Livermore National Laboratory, Livermore, CA, United States

Chapter outline

I. Introduction **921**
A. What is nuclear forensics? 921
II. The origins of nuclear forensics **921**
A. The policy implications of nuclear forensics 922
B. How the case begins 922
III. National objectives **924**
IV. Nuclear attribution **925**
V. Nuclear forensic interpretation **926**
VI. Validated signatures **927**

I. Introduction

A. What is nuclear forensics?

The field of nuclear forensics has been a topic of intense discussion in the scientific literature (Mayer et al., 2005, 2015a; May et al., 2006; Smith et al., 2008; IAEA, 2015a; Kristo et al., 2016; Keegan et al., 2016; Aggarwal, 2016), the public policy literature (Dunlop and Smith, 2006; Chivers et al., 2008; Talmadge, 2007; Levi, 2007; Mayer, 2013; Fedchenko, 2017), and the popular press (Broad, 2003; Allison, 2006, 2009; Ignatius, 2006; Stromberg, 2013; Conca, 2017; Scoles, 2015), since at least 2003. Nuclear forensic science, often referred to as "**nuclear forensics,**" has been defined as:

> *the examination of nuclear or other radioactive material, or of evidence that is contaminated with radionuclides, in the context of legal proceedings under international or national law related to nuclear security. The analysis of nuclear or other radioactive material seeks to identify what the materials are, how, when, or where the materials were made, and what their intended uses were (IAEA, 2015b).*

The "analysis" in the definition above includes both radiometric and nonradiometric measurement techniques.

II. The origins of nuclear forensics

It is impossible to define a birth date for nuclear forensics, since many of the techniques and methods used in nuclear forensics have deep roots in the US nuclear weapons program. However, the field rose to some prominence with the rash of interdictions of nuclear material following the breakup of the Soviet Union in 1992. According to the

Handbook of Radioactivity Analysis: Volume 2. https://doi.org/10.1016/B978-0-12-814395-7.00013-1

IAEA's Illicit Trafficking Database (IAEA, 2018), there were at least 11 major seizures of highly enriched uranium (HEU) or plutonium from 1992 through 1996, primarily in Russia and Europe. In response, the first organizational meeting of what was to become the Nuclear Forensics International Technical Working Group (ITWG), a group that offers technical solutions in nuclear forensics to requesting countries, was held at the Lawrence Livermore National Laboratory (LLNL) in 1995. The ITWG was chartered by the G-8 in 1996 and still reports informally to the G-8 Nuclear Safety and Security Group, although the ITWG includes representatives from countries around the world (Niemeyer and Koch, 2003; Smith et al., 2007; Schwantes, 2013). Even with these initial efforts, the field held little general interest for many years and was primarily the province of a few hardy pioneers, and their far-sighted government sponsors, at laboratories such as LLNL, the European Joint Research Center-Karlsruhe (formerly the Institute for Transuranium Elements (ITU)), the Centre L'Energie Atomique (CEA) in France, the United Kingdom Atomic Weapons Establishment (AWE), and others.

The terrorist attacks on New York City and Washington, DC, on September 11, 2001, greatly increased the visibility of nuclear forensics, as policy-makers became increasingly concerned about the possibility of well-organized terrorist groups, such as Al Qaeda, obtaining a nuclear weapon or using a radiological dispersal device (RDD or so-called "dirty bomb"). Thus, began a significant increase in funding for nuclear security, including nuclear forensics, in the United States, and also in other countries. At the same time, the US government began to grapple with how to best organize and execute a mission, which inherently has both research and operational components.

A. The policy implications of nuclear forensics

The basic problem of nuclear forensics is how to apply modern materials analysis techniques, knowledge of both commercial and military nuclear fuel cycles, and scientific principles to analyze unknown nuclear materials or devices and provide information of value to decision-makers. This problem is complex enough before one considers the wide range of potential materials and devices that might be encountered and the many different types of information that might be required.

When considering the full range of materials to be addressed by a nuclear forensics program, one must consider not only the full range of uranium and plutonium materials from the civilian and military nuclear fuel cycles, from uranium ore to reactor fuel or even weapon parts, but also highly radioactive materials that might be dispersed in an RDD, e.g., irradiated fuel rods and separated isotopes for medical or other purposes.

When considering the different types of information that might be required, one must think not only about the information needs of law enforcement but also that of national intelligence. Nuclear forensics has had a strong law enforcement focus from the very beginning, because the initial driving force behind the field was the ongoing interdiction of illicit nuclear material in Russia and Europe. In general, these interdictions were made by law enforcement or border personnel, and the ultimate goal was bringing each case to a successful prosecution. However, although the standards for admissibility of evidence are often quite high, the specific nuclear forensic results brought before a court of law are often quite few. Since, in most cases to date, the perpetrators were caught with the material in hand, it was only necessary to prove that the material was indeed illegal for them to possess. In the simplest cases, one might only need to know the basic chemical identity of the material, its mass (to prove that it exceeds some *de minimis* threshold), and enrichment level (for uranium).

National intelligence, which certainly includes law enforcement intelligence as well as nuclear intelligence, seeks to know more about the material: Where did it come from? What was its intended purpose? Where was legitimate control lost? What smuggling groups or routes were involved in moving the material? Providing this type of information requires much more sophisticated analysis and interpretation, yet the standards of evidence, while probably not as formal as those of law enforcement, must nonetheless be equally as high, because, while the legal system has courts of appeals to overturn bad decisions, some actions taken by national leaders based on such intelligence information have no such courts of appeals.

The US government has divided nuclear forensics into three mission areas (Oxford, 2007):

- interdicted predetonation materials,
- interdicted nuclear devices, and
- postdetonation.

However, the mission areas of nuclear forensics of interdicted nuclear devices and postdetonation debris are intimately tied to the design and construction of nuclear weapons, and information is at least sensitive, if not classified. Therefore, this chapter will devote itself to predetonation nuclear forensics of interdicted materials, except to note that postdetonation debris will be highly radioactive, with many short- to medium-lived fission and activation products. So, one should expect that radiometric methods of analysis will play a large part in the field of postdetonation forensics.

B. How the case begins

A nuclear forensic case can begin in many ways (see Table 13.1). Some cases begin quite simply with the discovery of unknown material, apparently lost or abandoned

TABLE 13.1 Selected interdictions of nuclear material around the world.

Year	Location	Country	Type	Enrichment/Pu-239 content	Mass	Interdiction
1978	New Mexico	United States	NU	0.72%	1500 kg	Theft/police investigation
1992	Augsburg	Germany	LEU	2.5%	1.1 kg	Police investigation
1992	Podolsk	Russia	HEU	90%	1.5 kg	Theft/police investigation
1993	Vilnius	Lithuania	HEU	50%	100 g	Police investigation/discovery
1993	Andreeva Guba	Russia	HEU	36%	1.8 kg	Theft/police investigation
1993	Murmansk	Russia	HEU	20%	4.5 kg	Theft/police investigation
1994	St. Petersburg	Russia	HEU	90%	3.05 kg	Theft/police investigation
1994	Tengen	Germany	Pu	99.75%	6 g	Police investigation/discovery
1994	Landshut	Germany	HEU	87.8%	0.8 g	Police sting operation
1994	Munich	Germany	Pu HEU	1.6% 87%	363 g 120 g	Police sting operation
1994	Prague	Czech Republic	HEU	87.8%	2.7 kg	Police operation/tip-off
1995	Prague	Czech Republic	HEU	87.8%	0.415 g	Police operation/tip-off
1995	Prague	Ceske Budejovice	HEU	87.8%	17 g	Police operation/tip-off
1995	Moscow	Russia	HEU	20%	1.7 kg	Theft/police investigation
1999	Ruse	Bulgaria	HEU	72%	4 g	Border guards
2001	Paris	France	HEU	72%	0.5 g	Police operation/tip-off
2003	Ignalina	Lithuania	LEU	2.0%	60 g	Theft/police investigation
2003	Georgia/Armenia border	Georgia	HEU		170 g	Border guards/radiation detection?
2003	Rotterdam	Netherlands	NU	0.72%	3 kg	Scrap metal
2006	Tbilisi	Georgia	HEU	~90%	80 g	Police sting operation
2007	Pribenik-Lacacseke border	Slovakia	NU	0.72%	426.5 g	Police operation/tip-off
2010	Tbilisi	Georgia	HEU	>70%	18 g	Police sting operation
2011	Chisinau	Moldova	HEU	NR	4.4 g	Police sting operation

HEU, highly enriched uranium; *LEU*, low enriched uranium; *NR*, not reported; *NU*, natural uranium.

by its rightful owner, such as the discovery of HEU in the basement of a bank in Vilnius, Lithuania, in 1993 (Potter, 1995). Police investigations, instigated either as a result of a known theft, a tip-off, or a sting operation, have also been a significant source of nuclear materials seizures (Potter, 1995; Wallenius et al., 2006, 2007; Mayer et al., 2007; Baude, 2007a; Zaitseva and Steinhausler, 2014). The traffickers are often caught as they seek to find a buyer for their material and unwittingly contact undercover law enforcement instead. On the other hand, the seizure of HEU oxide in Rousse, Bulgaria, in 1999 (see Fig. 13.1), was effected by border guards who correctly judged that Ozcan Hanifi fit the profile of a smuggler (Adamson et al., 2001; Moody et al., 2015). Many countries around the world have now erected large networks of passive detectors to prevent or detect the unauthorized movement of nuclear material. Although the majority of interdictions took place in the 1990s, following the fall of the Soviet Union, we can find evidence in the literature of nuclear forensic analysis of interdicted materials as far back as 1978 (Budinger et al., 1980), and we also have a number of recent interdictions, such as the interdictions of HEU in Georgia in 2003, 2006, and 2010 and in Moldova in 2011, which were widely reported in the popular press (Vogel, 2002; Sokova and Potter, 2008, Sheets, 2008; Borger, 2010a, 2010b; Kramer, 2011; Zaitseva and Steinhausler, 2014; Birch and Smith, 2015).

FIGURE 13.1 Highly enriched uranium oxide sample alongside its lead container ("pig") interdicted in Rousse, Bulgaria, in 1999. *Reproduced from Adamson et al. (2001).*

For all of these cases, the nuclear material is usually neatly packaged, ready for seizure by law enforcement personnel and transport to the nuclear forensics laboratory. Such cases call for an operational response, as defined in IAEA TECDOC-1313 (IAEA, 2002). However, one must also be prepared for the messier case in which the nuclear material might have been intentionally or inadvertently released within the localized crime scene or even to the broader locality. Such cases call for tactical, or even strategic, responses again as defined in IAEA TECDOC-1313, depending on the extent of the release. The Litvinenko ^{210}Po poisoning case (Dalheimer et al., 2009; Maguire et al., 2010), for example, while not, strictly speaking, a nuclear forensic case, nevertheless presented a situation in which the dispersal of radioactive material presented challenges for both forensics and public health.

The technical response to specific nuclear incidents also requires a graded approach. **Categorization** is the analysis performed to understand and address the threat posed by a specific incident, identifying the risk to the safety of first responders, law enforcement personnel, or the public, and determining whether there is criminal activity or a threat to national security. **Characterization**, on the other hand, is a more thorough analysis of the material, performed to determine the nature of the radioactive and associated evidence. **Nuclear forensic interpretation** is the process of drawing validated technical conclusions from the analytical results and correlating the characteristics of the material with material production history. While nuclear forensic interpretation is the end product for the nuclear forensic laboratory, it is an input into the nuclear attribution process. **Full nuclear forensic analysis** includes characterization of all materials, traditional forensic analysis, and nuclear forensic interpretation.

The IAEA document "Nuclear Forensics in Support of Investigations," Nuclear Security Series Number 2-G (IAEA, 2015b), documents a model action plan developed by the ITWG for use in designing a country's response to nuclear trafficking incidents.

III. National objectives

Although the techniques of nuclear forensics are sometimes used in unique applications such as "nuclear archaeology" (Schwantes et al., 2009; Mayer et al., 2010, 2011, 2015b; Meyers et al., 2013, 2014; Savina et al., 2017), a term used to describe the analysis and interpretation of nuclear samples of historical interest, the primary purpose of nuclear forensics is to support national objectives. As a relatively new field, many countries are struggling to understand nuclear forensics and define its role in meeting their

national objectives. This is made all the more difficult, because nuclear forensics supports two distinct sets of customers, those in law enforcement, who are interested in detecting, capturing, and prosecuting criminals, and those in national intelligence, who are interested in fully understanding the nuclear threat space.

Law enforcement, and subsequent prosecution, requires scientific evidence to support prosecution of nuclear smuggling cases. The evidence presented in court is likely to be the simplest properties of the material, properties that prove that the seized material is illegal, such as elemental or chemical identity, mass, and enrichment level, but these scientific results, and the laboratory system that produced them, must meet all of the national standards for admissibility of evidence. For example, Daubert (1993) and Kumho Tire (1999) are key cases used for determining admissibility of scientific evidence in the United States. The requirements of national intelligence, on the other hand, are less well defined. Law enforcement intelligence is interested in understanding smuggling networks and pathways, so that law enforcement entities can prevent crime, if possible, and detect and punish it, if not. Nuclear intelligence is interested in the state of nuclear capabilities of other countries or nonstate actors, such as terrorist groups. Both law enforcement intelligence and nuclear intelligence have broad areas of interest and are therefore interested in learning as much about the material as possible. Frequently, these wide-ranging intelligence requirements are framed as a set of questions:

- What is the threat posed by the material?
- Where did the material come from?
- Where did loss of legitimate control occur?
- What were the pathways of the material from loss of control to interdiction?
- Is there more material at large?

The overarching goal of nuclear forensics, then, should be to obtain scientific results that impact on the law enforcement and national intelligence requirements and to convey those results, and their technical interpretation, in a way that makes their meaning clear to those communities. One of the concepts that must be conveyed is that of "uncertainty," that is, the level of confidence in the results and their interpretation. The calculation of uncertainty for specific analytical results is fairly well understood in theory, if difficult to implement perfectly in practice (Currie, 1995; EPA, 2004; ISO, 2008). However, the uncertainty of technical conclusions, based on perhaps dozens of scientific measurements, is less readily apparent. In addition, conveying these uncertainty measurements to policy-makers, who typically have nontechnical backgrounds and who might have to make decisions of great import using these conclusions, can be extremely difficult.

The remainder of this chapter will describe how the various aspects of nuclear forensics work together to support these national objectives of law enforcement and national intelligence (see Fig. 13.2).

IV. Nuclear attribution

Over the past decade, the nuclear forensics community has distinguished between the terms "nuclear forensics," which is strictly technical in nature, and "nuclear attribution," which is

> *a process to identify the source of nuclear or other radioactive materials used in illegal activities, determine the point-of-origin and routes of transit involving such material, and ultimately contribute to the prosecution of those responsible. Nuclear attribution is the integration of all relevant forms of information about a nuclear smuggling incident into data that can be readily analyzed and interpreted to form the basis of a confident response to the incident. The goal of the attribution process is to answer policy-makers' needs, requirements, and questions in their framework for a given incident (IAEA, 2006).*

"Nuclear forensics," as defined, should focus solely on "intrinsic" information, that is, on results obtained from the analysis of the interdicted material and on validated technical conclusions (nuclear forensic interpretation) based on those results. "Nuclear attribution," on the other hand, utilizes the information provided by nuclear forensics but also incorporates "extrinsic" information—from law

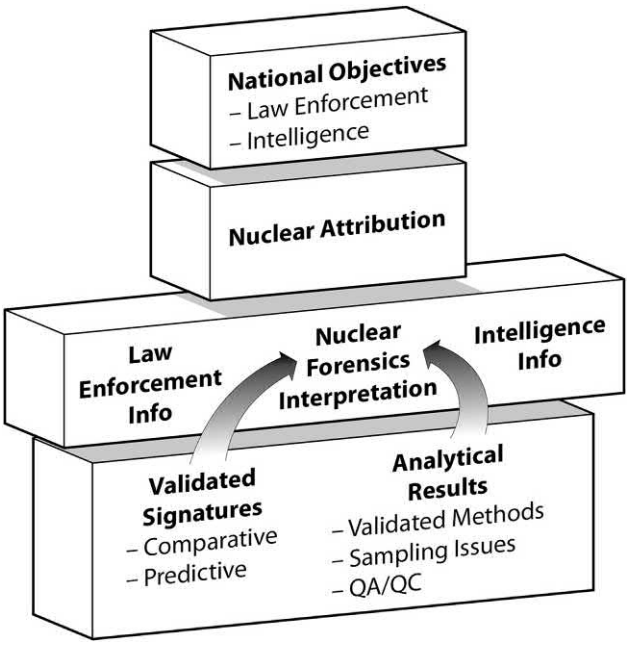

FIGURE 13.2 Hierarchy of nuclear forensic requirements and organization of this chapter.

enforcement, intelligence, and so on. Nuclear attribution, along with some expression of uncertainty in that attribution, is quite likely to be the finished product delivered to national decision-makers.

One of the primary goals of the separation of the processes of nuclear forensics and nuclear attribution is the insulation of the nuclear forensic scientist from any biases in their work that might be introduced through knowledge of the extrinsic information. At the same time, though, it is absolutely necessary that those responsible for nuclear attribution, typically senior officials in the government, have ready access to nuclear forensic experts, so that they can fully understand the implications and limitations of the information provided by nuclear forensics.

V. Nuclear forensic interpretation

Nuclear forensic scientists use the term "signatures" to describe material characteristics that potentially link samples to people, places, and processes and thus provide information about samples relevant to the set of intelligence questions described previously, much as a written signature can be used to link a document to a specific person. Quite simply, then, nuclear forensic interpretation is the evaluation of analytical results from a sample of interest using a set of validated "signatures" so as to provide technical conclusions to decision-makers. To generate high-confidence technical conclusions, one needs results generated using both validated analytical methods and validated signatures.

Nuclear forensic interpretation is a deductive process (see Fig. 13.3), much like the scientific method itself. At the beginning of the interpretation process, the nuclear forensic expert develops a hypothesis, or set of hypotheses, based on the initial analytical results. In most cases, these initial results will be consistent with multiple hypotheses, each of which may suggest additional signatures, which either might be, or must be, present if the hypothesis is true. The expert then devises further tests to verify the presence or absence of the signatures. On the one hand, if these tests show that the required signature is absent, then the nuclear forensic scientist must abandon his hypothesis or adjust it to fit the new results. On the other hand, if the tests show that the signature is present, then the scientist either has come to a unique technical interpretation, the desired result, or must devise additional tests to exclude the other remaining hypotheses. In the ideal case, only a single hypothesis or interpretation will eventually prove consistent with all results, although this is seldom true in practice.

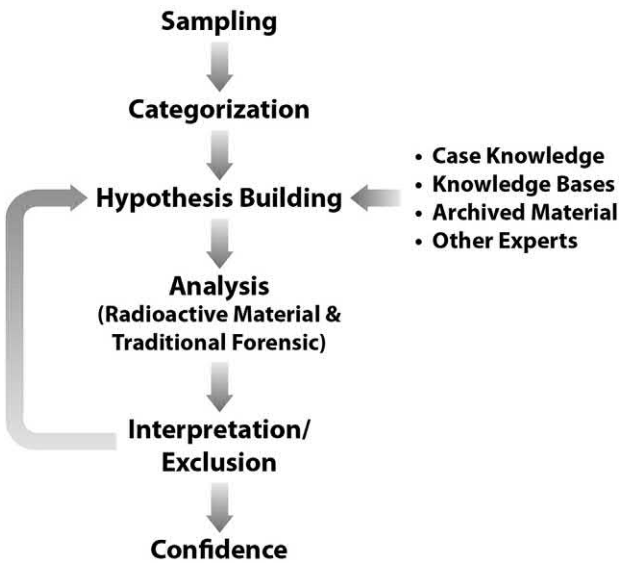

FIGURE 13.3 Flowchart of nuclear forensic interpretation process.

In general, one cannot rely on a single signature to answer all of the relevant questions in the case. Some signatures, such as those that derive from isotopic analysis, may only provide general clues that serve to place the material in a broad category like special nuclear material (SNM)[1] or, perhaps narrow the field of potential countries of origin. Other signatures, such as characteristic dimensions or markings, may provide specific clues that identify a specific facility or date of manufacture. In some cases, a result might only provide information useful for nuclear forensic interpretation when combined with other results. In the same way, independent signatures that reach the same conclusion increase the expert's confidence in the technical interpretation, whereas results that provide different or even conflicting conclusions decrease this confidence. Nevertheless, a result that seems confusing or insignificant at first may become crucial as the case develops.

Signatures can also work together to increase the specificity of the nuclear forensic interpretation. Figs. 13.4 and 13.5 represent the universe of potential sources and processes from which a given interdicted material may have originated, whereas the circles demonstrate how a given analytical measurement and associated signature serve to restrict those potential sources and processes. Although increasing the precision of a given measurement could further narrow the field of potential sources or processes that produced the material, as shown in Fig. 13.4, it is often more efficient to perform other types of measurements that use independent signatures, that is, measurements that verify the presence or absence of signatures different than those of the initial measurement. The confidence in, and the specificity of, the interpretation often increases as more independent measurements are made, as shown in Fig. 13.5.

1. Plutonium, uranium-233, or uranium enriched in U-235.

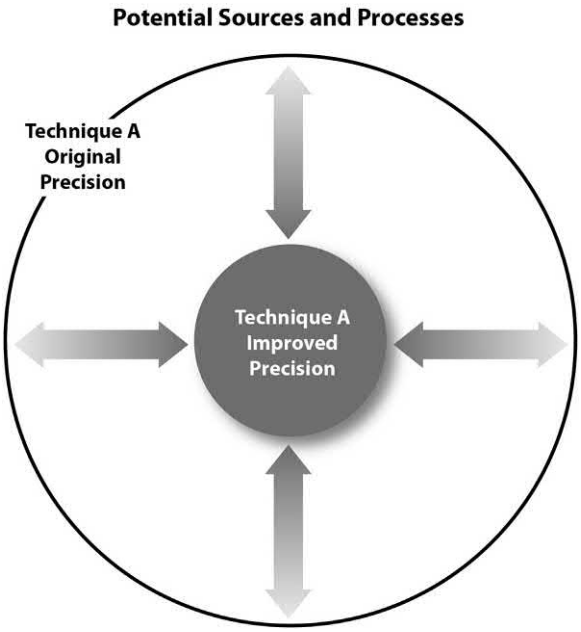

FIGURE 13.4 The effect of improved precision on nuclear forensic interpretation.

VI. Validated signatures

The validation of signatures involves rigorous testing, the extent of the testing depending on the confidence in the underlying scientific principles that drive the signature, for example, the principles of radioactive decay in age dating, and the extent to which the signature can be disturbed by factors outside our control, for example, the nature of the material, the extent and effectiveness of previous processing steps, and the presence of interferences. It is absolutely fundamental that the assumptions that underlie a signature be clearly stated. As far as possible, the nuclear forensic scientist must verify the correctness of those assumptions for the case at hand and, for those cases, where the assumptions cannot be verified, frame the conclusions, or adjust the uncertainties to reflect this lack of verification.

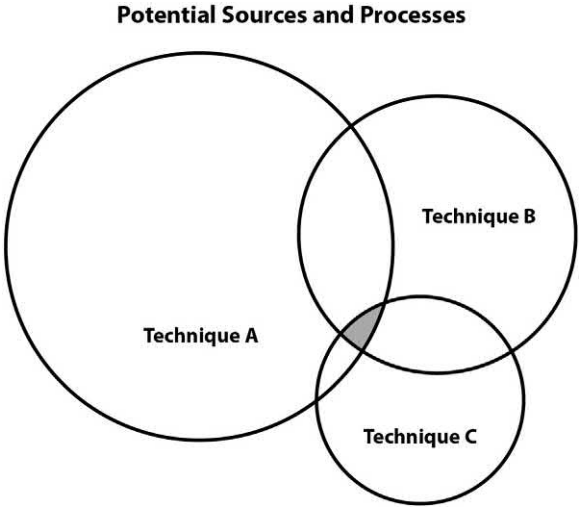

FIGURE 13.5 The effect of multiple measurements/signatures on nuclear forensic interpretation.

Each step of the nuclear fuel cycle creates some new signatures and erases other existing signatures, in the material. In general, materials at each stage of the fuel cycle will have their own characteristic set of signatures. It is certainly possible for some signatures to survive a given processing step and be present in multiple materials in the fuel cycle. However, a signature's persistence is something that must be validated and not assumed.

Signatures generally fall into two broad categories: comparative signatures and predictive signatures. Comparative signatures involve the comparison of an unknown (or "questioned sample" in law enforcement parlance) to one or more known samples, the essential question being whether the material characteristics of the unknown sample are consistent with one or more of the known samples. Predictive signatures, on the other hand, involve only an unknown sample, without reference to any known sample or database. Predictive signatures typically derive from underlying scientific principles, such as isotopic depletion and activation, in the case of nuclear reactor modeling used to understand the isotopic composition of irradiated material, or radioactive decay in the case of age dating.

A. Comparative signatures

Comparative signatures rely on the comparison of an unknown sample with one or more known samples. The simplest application of comparative signatures is the comparison of one sample to another. For example, the HEU oxide powders interdicted in Rousse, Bulgaria, in 1999 (Adamson et al., 2001; Moody et al., 2015), and in Paris, France, in 2001 (Baude, 2007a; Baude et al., 2007b), bear many remarkable resemblances. The two HEU oxide powders were essentially identical, except for differences in the concentrations of several of the common impurity elements. Furthermore, the powders were found in similar glass ampoules and conveyed by the traffickers in lead containers ("pigs") of similar manufacture and chemical composition and containing the same yellow wax. The seizure of two nearly identical samples almost 1500 miles apart should certainly raise concern among both law enforcement and intelligence officials about the existence of more such material outside of legitimate control. Sure enough, an HEU oxide powder was seized in Chisinau, Moldova, in 2011 (Kramer, 2011; Zaitseva and Steinhausler, 2014; Birch and Smith, 2015), inside a similar glass ampoule and a similar lead pig, protected by a similar yellow wax. So far, the analysis of the HEU oxide material

has not been reported, but the similarity of the packaging materials, seized in nuclear material interdictions a decade apart, certainly heightens the cause for concern.

Nuclear forensic databases, which may contain information on hundreds or thousands of samples, or nuclear forensic sample archives, which may contain tens or hundreds of physical samples, are the natural extension of more targeted sets of known samples. Clearly, the value of this comparative approach depends on both the relevance and comprehensiveness of the database and/or the sample archive. In the most general case, a database for nuclear forensics would include a comprehensive set of material characteristics from materials across the fuel cycle and across the globe. There has already been much discussion in the public policy literature about the importance of international nuclear forensics databases and whether such databases should be shared generally or closely held by each country (Chivers et al., 2008; Allison, 2009; Fedchenko, 2007). Due to the many problems involved in creating and maintaining an international nuclear forensics library, current international efforts are focused solely on the development of national nuclear forensics libraries (Engelbrecht et al., 2013; Davydov et al., 2016; Kimura et al., 2017). The ITWG, in conjunction with the Global Initiative to Combat Nuclear Terrorism, has developed and conducted the series of "Galaxy Serpent" exercises to foster an international understanding of nuclear forensic libraries and their value to nuclear security (Borgardt and Wong, 2014; Ball et al., 2015; Borgardt et al., 2017).

The importance of these national nuclear forensic libraries underscores the importance of international engagement in nuclear forensics. It is important to encourage all countries to develop their own nuclear forensic databases, whether they choose to keep them closely held or not. It is also important that all countries have high confidence in each other's databases, confidence that those databases contain the right materials characteristics for nuclear forensic purposes and that the analytical results contained therein are of high quality. If an interdicted sample is analyzed in France, for example, and compared against a database with analytical results from Russia, there must be strong assurance that both laboratories are providing equivalent results, i.e., that they would get the same answer (within the constraints of analytical uncertainty) when analyzing the same sample. Therefore, international scientific engagement in nuclear forensics, whether conducted in a multilateral setting, such as through the ITWG, or in a bilateral, country-to-country setting, should drive the standardization of methods, techniques, standards, and reference materials. International exercises or round robins are absolutely crucial for developing and testing the comparability of nuclear forensic data acquired by different countries.

ITWG Nuclear Forensics Exercises

In addition to actual casework, which occurs infrequently, nuclear forensic laboratories around the world have come to rely on the collaborative materials exercises conducted by the ITWG for keeping their skills in good practice.

- Six laboratories from the United States and Europe participated in the first exercise, held in 1999–2000, which featured reprocessed plutonium oxide material from the European civil nuclear cycle (Dudder et al., 2003b).
- Nine laboratories from the United States and Europe participated in the second exercise, held in 2000–2002 (Dudder 2003a,b), which featured an HEU oxide powder provided by the Czech Republic.
- Nine laboratories in the United States, Canada, and Europe participated (Kristo and Tumey, 2013; Hanlen, 2011) in the third exercise, which was a paired-comparison analytical exercise involving two HEU metal pins provided by the Y-12 National Security Complex in the United States.
- Sixteen laboratories around the world participated in the fourth exercise, which was another paired-comparison exercise involving two LEU oxide pellets and some LEU oxide powder (Schwantes et al., 2017, 2018).

Although the development of well-populated databases is a necessary step toward discovering and implementing valid comparative signatures, it is equally important to develop validated methods for performing the comparison of analytical results on unknown samples. These validated methods may consist of dozens of distinct analytical measurements, each with their own uncertainty, against these well-populated databases, which might have information on thousands of materials each with a similar number of measured properties. Currently, our ability to analyze interdicted samples and produce an extensive list of precise materials characteristics far exceeds our ability to interpret the results. Therefore, as we seek to develop the extensive databases necessary for nuclear forensics, we must also develop the comparative methods necessary to produce the required inferences from comparison of our analytical results with these large, multidimensional sets of data.

The identification of the sources of unknown uranium ores and ore concentrates (a product of the uranium milling process, sometimes referred to as "yellowcake") is an active area of interest in the international nuclear forensics community, both as a means to support international safeguard efforts and as a fruitful area for developing broadly applicable nuclear forensic methods without as many security or proprietary restrictions. Robel and coworkers (Robel et al., 2009, 2011) tested several multidimensional statistical techniques for comparative analysis against a data set consisting of 50 materials characteristics (mostly concentrations of trace impurities and uranium isotopic

composition) measured for approximately 1800 samples of uranium ore concentrate (UOC) from 21 known locations or sources. They found that principal component analysis was useful for initially understanding how results from a single source grouped together and how results from different sources related to one another. However, partial least squares discriminant analysis (PLS-DA) was inherently more suited to differentiating between different sources, because PLS-DA uses the source information in constructing its data model (Barker and Rayens, 2003). However, a single pass of PLS-DA was insufficient for discriminating between all of the sources in the database. Therefore, they developed an iterative PLS-DA procedure, which proved especially adept at identifying the production location of unknown UOC samples. By removing sources, which fell far outside the decision boundary of the initial PLS-DA model, and then rebuilding the model, they have consistently produced better and more definitive predictions than with a single-pass classification approach (Fig. 13.6).

Internal validation of the iterative PLS-DA model, in which data from a sample are removed from the comparison database and treated as the analytical data from the unknown (also called "hold one out" validation), achieved 91% accuracy in identifying the source of the UOC (facility or mine). In most cases, the inaccurate predictions chose the right country, but the wrong location within the country. External validation of the iterative PLS-DA model, in which separate physical samples from known locations were analyzed as unknowns, achieved 65% accuracy in predicting the correct source and 90% accuracy in predicting the right country. Furthermore, the iterative PLS-DA method performed better than the classification and regression tree and k nearest neighbor algorithms, with the best combination of accuracy and robustness, for this UOC data set.

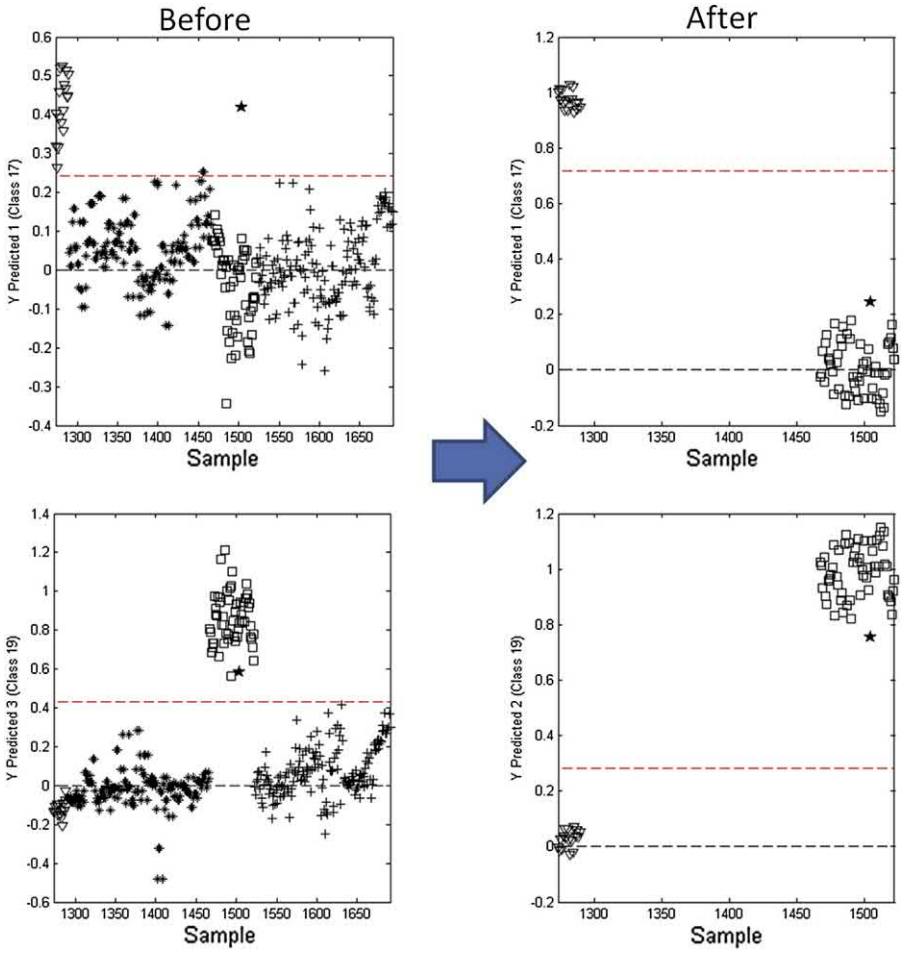

FIGURE 13.6 Each data point represents the analysis of an individual sample of material from a given class (source of uranium ore concentrate). Each class is represented by a unique symbol. The dashed line is the partial least squares discriminant analysis (PLS-DA) decision boundary for discriminating between the selected class and all other classes in the database. The figures on the left show that an unknown sample (represented by a star) is indistinguishable from material from either class 17 (triangle) or class 19 (square). The unknown is distinguishable from class 18 (asterix) and class 20 (cross) (models not shown). After removing class 18 and 20 from the database and regenerating the PLS-DA models, the figures on the right clearly and correctly demonstrate that the unknown is from class 19.

For any comparative method, though, it is important to provide some valid estimate of the confidence of its predictions. Internal and external validation exercises, like those described earlier, help one understand the overall reliability of the model. However, only preliminary work on calculating nuclear forensic probabilities or confidence levels for specific predictions has been reported (Kristo, 2011b). It is also important to understand how specific comparative methods behave when the true source of the unknown sample is not in the database. The iterative PLS-DA approach, for example, always returns a prediction, whether or not the true source can be found in the database. However, statistical parameters (Q and T_2) generated during application of the iterative PLS-DA approach provide a strong warning when the ultimate prediction does not fit well with the final model.

Current efforts in comparative approaches include the development of an integrated environment for inclusion/exclusion testing (Stork et al., 2017), the application of artificial intelligence and machine learning (Drummond, 2018), and a comparison of multiple methods for inverse prediction (Lewis et al., 2018). There have also been efforts to handle the particular problem of missing data, which can often occur when using historical data sets or production databases for performing comparative analysis (Langan et al., 2016).

B. Predictive signatures

With predictive signatures, one seeks to calculate identifying material characteristics based on a detailed understanding of the physical or chemical mechanisms responsible for producing the signatures and adequately modeling those mechanisms to predict the material signatures at a level of specificity required to provide information relevant to the national intelligence questions posed previously. The advantage of the predictive approach is that the processes (and possibly locations) of previously unanalyzed nuclear materials can be inferred from their measured characteristics, something of critical importance for types of materials that are not readily available, for example, materials from historical processes or tightly held materials from foreign countries. The disadvantage of the predictive approach is that significant effort must be expended to develop and validate the capability.

Predictive signatures rely, in a general sense, on our base of knowledge and on scientific inference, that is, how we apply our existing knowledge to the case at hand. Very little work has been done in building a nuclear forensics-specific base of knowledge; rather, nuclear forensics has been built primarily on other bases of knowledge that already exist. For example, nuclear forensics on materials found early in the fuel cycle, for example, uranium ores and ore concentrates, relies heavily on geochemistry, a field that studies the chemical and physical processes that govern the composition of rocks, water, and soils both on the earth and in the solar system as a whole. Nuclear forensics of materials found later in the nuclear fuel or found only in the weapons cycle relies on bases of knowledge developed by various companies as part of their role in the commercial nuclear fuel cycle and by the United States and other countries as part of their nuclear weapons programs.

The predictive approach to identifying the source of unknown samples of UOC, for example, involves interpreting signatures measured in a sample of interest to determine characteristics associated with both the parent ore and the mining and milling processes used to produce the UOC from the ore (Svedkauskaite-LeGore et al., 2008; Varga et al., 2011). The predictive approach is more challenging than the comparative approach since it requires a scientific basis for interpreting signatures. Fortunately, many of the chemical and physical processes that created the ore body, as well as the ore concentrate, are well understood through research in geochemistry and economic geology that can be used to develop predictive signatures. For example, the relative concentrations of the rare earth elements (REEs) can be typical of the type of ore body from which the uranium was mined (see Fig. 13.7 or Varga et al., 2010; Lin et al., 2015; Krajko et al., 2015; Spano et al., 2017). The uranium–lead radiometric dating system can be used to determine the age of a parent uranium ore body (Svedkauskaite-LeGore et al., 2007; Varga et al., 2009). The samarium–neodymium and rubidium–strontium dating methods can be similarly used and can also provide indication of the mineralogy of the parent uranium ore (Varga et al., 2009). The well-established

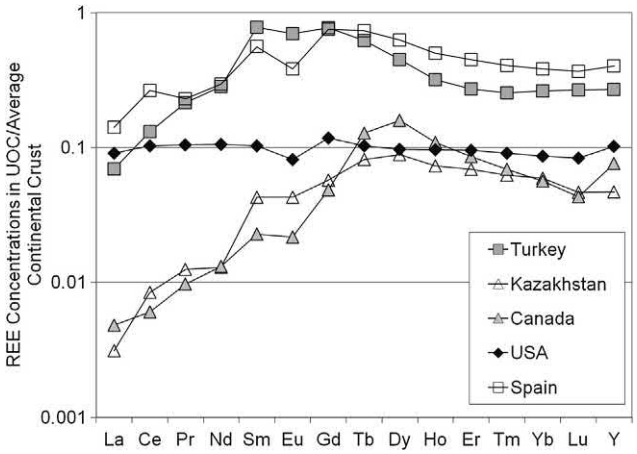

FIGURE 13.7 Different ore bodies contain different amounts of rare earth elements (REEs). This plot shows the concentration of REEs (relative to the concentrations of the same elements in the earth's crust) for uranium ore concentrate samples from different locations. Varga et al. (2010) has shown that the shapes of these REE curves are typical for certain types of uranium deposits.

geographic variation of ^{18}O in surface water (Craig, 1961; IAEA/WMO, 2006) influences the ^{18}O isotopic abundance in nuclear materials such as UOC and may provide geographic information (Pajo et al., 2001a, 2001b; Tamborini et al., 2002). Similar systematics in the isotopic composition of trace elements, such as S, Mo, and Nd, relate to geochemical processes (Han et al., 2013; Krajko et al., 2014, 2016; Migeon et al., 2018). The anion content of UOC (F^-, Cl^-, Br^-, NO^{3-}, PO_4^{3-}, SO_4^{2-}) also varies with location and is influenced by both the host rock and the milling process (Badaut et al., 2009; Keegan et al., 2012). Researchers have also studied the trace organic content of UOCs as a signature of process (Kennedy et al., 2013).

New predictive signatures are also being developed by establishing improved understanding of the factors that influence distribution of the isotopes of uranium. For example, the fractionation of $^{234}U/^{238}U$ through natural processes has been demonstrated to be indicative of the geological context of an ore (Kigoshi, 1971). Ores that have been leached by groundwater for long periods of time exhibit a significant depletion in $^{234}U/^{238}U$, whereas ores formed from deposition of those water leachates exhibit a significant enrichment in $^{234}U/^{238}U$. Modern mass spectrometry now provides results of sufficient precision that even natural variations in the $^{238}U/^{235}U$ ratio, once thought to be invariant in nature, can now be investigated. The depositional environment of an ore appears to strongly influence the $^{238}U/^{235}U$ ratio with low-temperature ores having higher ratios than deposits formed at high temperatures (Richter, 1999; Brennecka et al., 2010). In addition, naturally occurring ^{236}U can also be exploited as a nuclear forensic signature. ^{236}U is produced at very low levels in nature through neutron capture of ^{235}U. It has been demonstrated that $^{236}U/^{238}U$ ratios in uranium ores can vary widely and are influenced by the geologic context of the ore body (Wilcken et al., 2008; Srncik et al., 2011). All of these features of the isotopic distribution of natural uranium are potentially useful signatures for attribution of UOC.

As with all scientific work, it is extremely important to understand, and clearly state, all underlying assumptions when applying predictive signatures, since the validity of the nuclear forensic interpretation will always depend on the validity of those assumptions. For example, one of the most frequently applied predictive signatures in nuclear forensics is that of radiochronometry, the determination of the time since last purification using the laws of radioactive decay, a technique commonly known as "age dating" (Mayer and Wallenius, 2000; Morgenstern et al., 2002; LaMont and Hall, 2005; Williams and Gaffney, 2011; Stanley, 2012). Accurate age dating relies on several assumptions (ITWG, 2016). First of all, there must be a purification event that quantitatively removes the daughter (product) nuclide from the parent (precursor) nuclide. Incomplete purification leads to calculated ages (model ages) that are older than the true time since purification. Second, the sample must remain a closed system from purification until sampling and analysis, precluding both contamination from outside the system and internal segregation of either daughter or parent.

Age Dating

The principles behind age dating were enumerated in 1900 by Ernest Rutherford (see a detailed historical account by L'Annunziata, 2007, 2016). Age dating is a standard tool for disciplines such as geochemistry and cosmochemistry, and the use of multiple chronometers is a fundamental precept of these disciplines. In this context, agreement between chronometers indicates a simple (ideal or undisturbed) geologic history, whereas disagreement indicates that a sample has experienced a multistage history (see Faure 1998).

In most cases, nuclear forensic samples will not arrive at the laboratory with extrinsic information indicating how well these assumptions hold true for the particular sample. Therefore, it is incumbent on the analyst to test the validity of these assumptions as completely as possible. One of the best ways of doing this is to use multiple chronometers (chronometers based on different parent−daughter radionuclide pairs). If the ages given by the different chronometers "agree" with each other (concordant ages), then we have high confidence that the assumptions for accurate age dating have held true and that the model ages are, in fact, the true ages since purification.

If the chronometers do not agree with each other (discordant ages), then, at a minimum, we must be cautious in the way that the model age dates are interpreted. However, even in such cases, the results from multiple chronometers can themselves provide valuable information. For example, in the case of the HEU oxide powder seized in Bulgaria in 1999 (Adamson et al., 2001; Moody et al., 2015), the fact that two chronometers based on trivalent species gave ages slightly, but systematically older than other chronometers pointed to the use of the Purex process, which is very good at removing some elements (thus resetting those chronometers completely) and not as good at removing other elements, such as trivalent species (thus leading to anomalously older ages for chronometers based on the decay of those species). This inference was possible only due to the use of multiple chronometers.

The analysis of multiple chronometers in LLNL's analysis of samples from the third ITWG round robin (Bibby et al., 2010; Hanlen, 2011; Kristo, 2011a; Kristo and Tumey, 2013) yielded highly discordant model ages and signaled to the analysts that caution was necessary in interpreting these ages. However, these discordant ages

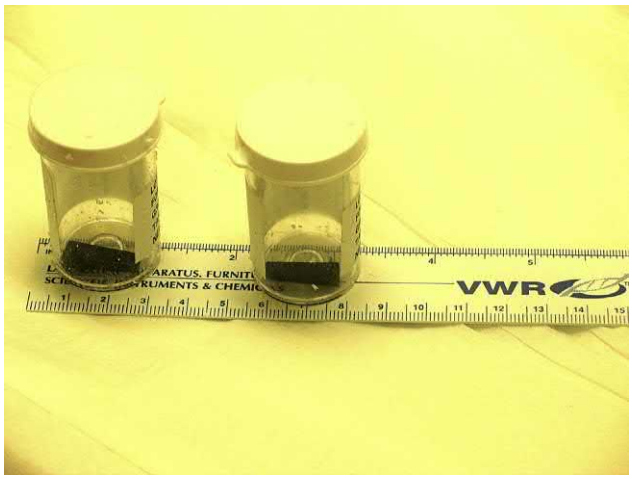

FIGURE 13.8 ITWG Round Robin 3 samples (trapezoidal pins of highly enriched uranium metal) as received. *Reproduced from Bibby et al. (2010).*

helped focus their attention on the complexities engendered by the uranium casting process (Martin and Miles, 1956; Feder et al., 1956; Whitman et al., 1957; Antill et al., 1959). Participating laboratories were each given two samples of HEU metal (5–6 g each—see Fig. 13.8). As part of its analysis, LLNL performed age dating using the $^{234}U/^{230}Th$, $^{235}U/^{231}Pa$, and $^{241}Pu/^{241}Am$ chronometers (see Table 13.2).

There are two striking features in these results. First, the model age calculated from the $^{234}U–^{230}Th$ system corresponds closely to the time since casting (which was only revealed to the participants after the exercise). Second, there is a total lack of agreement between any of the three model ages. The high concentration of carbon (~0.1–0.2 weight%) found in the samples and the presence of Zr and Er impurities, elements often used in graphite mold coatings, suggested that the uranium in each of the samples had been recast multiple times. It was therefore clear that the casting process must have caused a segregation of the Th in the material, such that Th was completely removed from the center of the initial casting (where the round robin samples were taken). However, this process did not result in the complete removal of other impurities, such as Pu, Am, or Pa. The segregation of radioactive impurities into the top of uranium castings (the so-called "hot top"), especially in the presence of high concentrations of carbon, has been observed for some time (Martin and Miles, 1956; Feder et al., 1956), but the behavior of these specific impurities, resulting from radioactive decay of the U isotopes, had not been studied. From the results of these analyses, it appears that, while Th was completely removed from the center of the casting by this process, the other species were either removed partially or not at all.

Without extrinsic knowledge of the sample, we have to be very careful in interpreting model ages. For instance, we did not know a priori anything about the casting shape (other than what was deduced from the shape of the solid pieces themselves) or the method of sampling. The samples could very well have been from the "hot top," for example, and resulted in the determination of an anamolously old model age. Even now, with knowledge of the casting shape and process, we still do not know how generalizable the interpretation of the ^{234}U-^{230}Th age as the casting age might be. We still lack the fundamental studies necessary to extrapolate this single-point measurement to the more general case where the conditions of casting might be expected to vary widely (with unknown effects on impurity segregation).

In summary, then, the measurement of multiple chronometers in nuclear forensics is critical for testing whether the fundamental assumptions of age dating have held true for the sample in question. If we obtain agreement between model ages from different systems, we can posit more confidently that the model age represents the true time since purification, since the likelihood that two or more chemical systems will be contaminated or fractionate in precisely the same way is very low. On the other hand, if we obtain disagreement between model ages from multiple systems, then we would know to exercise caution when interpreting those ages. However, such systematic variations in the ages can often provide insight into the chemical and physical processes used in preparing the material. Researchers at LLNL have been exploring the utility of additional

TABLE 13.2 Model ages calculated from both mass spectrometry and alpha spectrometry (Bibby et al., 2010).

Measurement	Sample	Units	Mass spectrometry	Alpha spectrometry	Years since casting
^{234}U-^{230}Th age	A	Years	6.894(41)	7.02(67)	6.10
	B	Years	6.074(36)	5.62(65)	6.82
^{235}U-^{231}Pa age	A	Years	33.73(36)		
	B	Years	35.77(37)		
^{241}Pu-^{241}Am age	A	Years	14.36(33)	12.3(1.3)	
	B	Years	17.47(37)	15.3(1.9)	

radiochronometers for U, including "grand daughter" radionuclides, such as ^{226}Ra and ^{227}Ac, which can further validate the fundamental assumptions or provide additional insights into the history of the material (Kayzar and Williams, 2016; Rolison et al., 2017).

To encourage the international application of radiochronometry in nuclear forensics, as well as to provide an intercomparison of results between laboratories, many countries have participated in bilateral and multilateral round robin comparison exercises (Varga et al., 2015a; Gaffney et al., 2016; Treinen et al., 2017). The fourth ITWG Collaborative Materials Exercise (CMX-4) demonstrated the current state of practice for radiochronometry (Kristo et al., 2018). 10 laboratories performed radiochronometry on three low enriched uranium oxide samples, providing 12 analytical results using three different parent−daughter pairs. The vast majority of the results were consistent with one another and consistent with the known processing history of the materials (see Fig. 13.9 for results from Sample ES-2). The results also demonstrate a situation in which the concordance of the ^{235}U-^{231}Pa and ^{234}U-^{230}Th chronometers confirmed the validity of the age dating assumptions, increasing confidence in the resulting conclusions. In this exercise, we have some knowledge of the history of the material, allowing us to assess the accuracy of the radiochronometry measurements in a general sense. However, both the United States and the European Commission have been actively developing radiochronometry reference materials to better assess accuracy in radiochronometry measurements (Varga et al., 2012; 2015a,b, 2018; Venchiarutti et al., 2015). The US approach focuses on certification of the model ages of existing nuclear materials, whereas the European Commission has focused on processing the nuclear materials to create a known date of purification, allowing the daughter nuclides to grow in from that point.

Although the uncertainty regarding assumptions clearly affects the uncertainty of the stated conclusion, determining that uncertainty in an unbiased way and then incorporating that uncertainty into the overall uncertainty of the conclusion is not straightforward and work remains to be done.

VII. Analytical results

Nuclear forensics is not amenable to a "cook book" approach that can be universally applied to all evidence; rather, it involves an iterative approach, in which the results from one analysis are used to guide the selection of subsequent analyses. However, the nuclear forensics community has defined three levels of analysis, namely,

- categorization,
- characterization, and
- full nuclear forensic analysis,

Each of the three levels serves a unique purpose in the investigation as described below. In all cases, though, laboratory sampling and analysis must be performed with due regard for preservation of evidence and perpetuation of chain-of-custody, since many of the analytical tools used in these analyses are destructive, that is, they consume some amount of sample during analysis. Therefore, the proper selection and sequencing of analyses is critical.

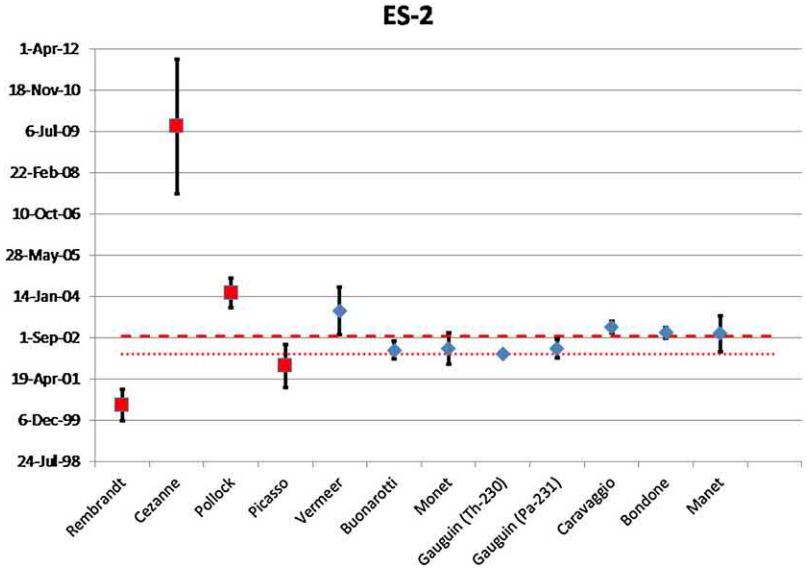

FIGURE 13.9 Age dating results for ITWG CMX-4 Sample ES-2 compared against known sample processing history. The dashed lines (----) indicate the range of probable processing dates according to the known history of the samples. Alpha spectrometry results are indicated by squares (■). Mass spectrometry results are indicated by diamonds (◆). All labs are designated by code names drawn from famous painters.

A. Categorization

Onsite nondestructive analysis (NDA) using field-portable gamma ray spectrometry, perhaps supplemented by X-ray fluorescence (XRF), aims to categorize the suspected radioactive material without affecting the evidence. The goal of categorization is to identify the bulk constituents of the material to assess the threat posed by the material and confirm whether the seized evidence is contraband, something which would form the basis for continued investigation. Such NDAs can quickly distinguish between naturally occurring radioactive material, SNM, radioactively contaminated material, or a commercial radioactive source.

Further analysis will be guided by this initial categorization. The next analyses to be performed will be based on the ultimate goals of the investigation (basic characterization vs. full nuclear forensics analysis—see below), the information uncovered so far, the potential signatures (physical, chemical, elemental, isotopic) that might lead to precise interpretation, the amount of sample available for analysis, and methods for measuring forensic signatures.

B. Characterization

Characterization aims to determine the nature of the radioactive evidence and provide detailed results for officials to make informed decisions. Characterization of the radioactive material includes complete elemental analysis, including major, minor, and trace constituents, as well as isotopic and chemical phase information for all major constituents. Characterization also includes physical characterization, including accurate measurement of the critical dimensions of solid samples, determination of particle size and shape distributions for powder samples, and high magnification imaging of the material by optical and scanning electron microscopy. Characterization does not include analysis of traditional forensic signatures nor detailed nuclear forensic interpretation (identification of candidate source locations and processes, for example). Characterization will take more time than categorization, but less time than the full nuclear forensics analysis, approximately 1–4 weeks after receipt of the samples.

C. Full nuclear forensics analysis

The goal of full nuclear forensics analysis is to analyze all radioactive and traditional forensic evidence to provide information for answering the questions of both law enforcement and intelligence, including identifying the material's origin, method of production, means by which legitimate control was lost, transit routes from diversion to interdiction, and probability that more material exists. Full nuclear forensics analysis would include detailed nuclear forensic interpretation and might include predictive techniques such as reactor modeling and comparison against nuclear forensics databases or sample archives, so as to identify the method of manufacture and probable sources of the material. Full nuclear forensic analysis will take the longest amount of time, up to 2–6 months after receipt of the samples.

VIII. Validated methods

Some analytical methods provide strictly qualitative information, for example, color, shape, identifying markings, but most analytical methods are quantitative, providing mean values and associated uncertainties for various characteristics of the material, for example, mass, dimensions, trace elemental composition. These means and uncertainties allow the application of the validated signatures to the material at hand. The analytical techniques described in the following sections are commonly used in nuclear forensic analysis. However, it is important that specific methods used to generate nuclear forensic results, either by these or other methods, be validated to ensure high-quality technical conclusions.

The validation of analytical methods involves rigorous testing to ensure that the strengths and limitations of the method are well characterized and that the results generated are fit for the intended purpose. In particular, characteristics of the technique, such as specificity, sensitivity, precision, and accuracy, should be determined and documented. **Specificity** refers to the ability of the technique to measure the analyte of interest in the presence of all other constituents in the sample. The presence of interferences, for example, will degrade the specificity of any technique. **Sensitivity** refers to the change in analytical signal with the amount of analyte present. If one combines the concept of sensitivity with the concept of "background," the amount of analytical signal present in the absence of analyte, one derives the **detection limit** of the technique, that is, the smallest amount of analyte that can be detected at a specified confidence level, and the **quantification limit**, the smallest amount of analyte that can be quantified at a specified confidence level. **Precision** usually refers to the variation in the analytical signal (or the quantity of analyte calculated from that signal) over time, with repeated measurements. When combined with other sources of uncertainty in the measurement, for example, uncertainties in the knowledge of dead time or uncertainty in the calibration standards, one can calculate the "combined uncertainty" of the measurement. **Accuracy**, of course, refers to how closely our reported results match the true value.

For an unknown sample, the true value is not known, so we rely on validation of the method and ongoing performance testing for estimates of the accuracy of the

technique. The method is typically validated through the analysis of known samples, such as certified reference materials (CRMs) from national or international standards laboratories or other standards with values traceable to those CRMs. However, despite ongoing efforts to develop reference materials for nuclear forensics (Inn et al., 2013; Venchiarutti et al., 2015; Mathew et al., 2016; Essex et al., 2018), appropriate CRMs or traceable standards are not available in all cases, necessitating the use of self-prepared standards or other well-characterized samples. We always seek to achieve accuracy within the stated uncertainty of our measurement. If we have a consistent bias (inaccuracy) in our reported results and this bias cannot be eliminated, by recalibration, for example, then we include this bias in the calculation of uncertainty. It is worth noting that these underlying uncertainties in the analytical measurement will eventually propagate through to the uncertainty in the nuclear forensic interpretation, combining with uncertainties in the signatures, and so forth.

Finally, it should also be noted that the use of validated methods alone does not guarantee high-quality results. Validated methods often require the use of scientific instruments, which must be properly maintained and the performance of which must be tracked on a regular basis and/or verified prior to analysis. Validated methods always require analysts, who are fully trained in the methods of analysis and who are conscientious in the application of good laboratory practice. Trained and conscientious analysts applying validated methods using properly maintained and verified instruments will result in high-quality analytical results.

A. Radioactive material analysis

The nuclear forensic scientist has a wide array of analytical tools to use for detecting signatures in radioactive material. These individual techniques can be sorted into three broad categories:

- bulk analysis tools,
- imaging tools, and
- microanalysis tools.

1. Elemental and isotopic bulk analysis tools

Bulk analysis tools allow the forensic scientist to characterize the elemental and isotopic composition of the radioactive material as a whole. In some cases, bulk analysis is necessary to have sufficient material to adequately detect and quantify trace constituents, which are often vitally important as signatures for certain manufacturing processes, for determining the time since chemical separation (age dating), and for determining whether the material has been exposed to a neutron flux.

a. Radiometric techniques

Each radioactive nuclide emits radiation of known types and energies at rates determined by the quantity present and its characteristic half-life (or decay constant). Therefore, by measurement of the type and intensity of radiation emitted from a sample, it is possible to quantify the amount of each radioactive nuclide present. There are three types of radiation that are commonly considered for measurement, alpha, beta, and gamma radiation, each with its own properties and methods of detection. Alpha radiation is commonly detected by silicon surface barrier detectors, beta radiation by scintillation techniques or gas ionization detectors, and gamma radiation by high-purity germanium (high energy resolution) or sodium iodide (lower energy resolution) detectors.

Gamma spectrometry. Gamma spectrometry (ITWG, 2013a,b,c) has a dual role in nuclear forensics. For on-site applications, high-resolution gamma spectrometry is mostly used only to quickly identify the material and obtain a rough idea about the isotopic composition of the material, i.e., categorization. Although field-portable high-purity germanium detectors are available, sodium iodide detectors are still often used for field applications. If a radiation source or RDD is detected, for example, gamma spectrometry can be deployed on the spot to identify the radioactive isotopes present (which includes, but is not limited to, the isotopes of uranium and plutonium), without dismantling the source or device. In the laboratory, high-resolution gamma spectrometry is used to provide an initial determination of the isotopic composition of uranium and/or plutonium, as well as detection and quantification of trace fission and activation products in the sample, for example, in uranium from reprocessed reactor fuel.

Alpha spectrometry. Alpha spectrometry (ITWG, 2012b) is used to quantify the abundance of alpha-emitting radionuclides, particularly those with relatively short half-lives. Because source preparation is crucial for achieving good energy resolution in alpha spectrometry, the target elements are usually separated and purified before deposition onto a flat surface. Quantification is achieved by spiking the samples with known amounts of an isotopic spike or tracer. Alpha spectrometry is especially suited for quantifying ^{232}U and ^{238}Pu due to their short half-lives and, in the case of ^{238}Pu, the potential interference from ^{238}U in mass spectrometry. However, conventional alpha spectrometry is not used to separate the peaks due to ^{239}Pu from ^{240}Pu, although some alpha detectors under development have sufficient energy resolution to do so (Horansky et al., 2008; Croce et al., 2011), nor is alpha spectrometry sensitive to ^{236}U. Therefore, full characterization of the isotopic composition of Pu and U should include both alpha spectrometry and mass spectrometric analysis. Alpha spectrometry may also be used to quantify ^{241}Am (daughter

of ^{241}Pu), which can then be used to calculate the date of the last plutonium purification performed on a sample (assuming complete purification), and ^{230}Th (daughter of ^{234}U), which can similarly be used to determine a last purification date for uranium materials.

Beta spectrometry. Because beta particles are emitted with a broad range of energies, beta spectrometry must be combined with chemical separation and purification of the target element to quantify a specific nuclide. In some cases, nuclides emit a gamma ray simultaneous with the emission of a beta particle; a combined beta−gamma measurement can provide additional specificity for the analysis.

b. Mass spectrometry

Mass spectrometry is used to determine both the elemental and isotopic composition of nuclear materials, offering extremely high precision and accuracy of analysis and the capability to determine both radioactive and stable isotopes. In mass spectrometry, atoms or molecules are converted into positively or negatively charged ions, which are then separated according to their mass-to-charge ratio and the intensities of the resulting mass-separated ion beams measured. Mass spectrometry can provide quantification (often called an "assay" when applied to major constituents of the sample) of elements either by using an isotopic spike (isotopic dilution mass spectrometry) or through calibration against standard solutions in the case of solution-based techniques such as inductively coupled plasma mass spectrometry.

Thermal ionization mass spectrometry (TIMS). In TIMS (ITWG, 2017a), a sample is deposited onto a metal filament, through which a current is passed to heat it to high temperatures inside the vacuum of the mass spectrometer. If the ionization potential of a given element is low enough compared with the work function of the filament, then a fraction of the atoms of that element are ionized via interaction with the filament surface at high temperature. Specificity of the TIMS analysis can be enhanced by both chemical separation steps and the ionization temperature. TIMS is capable of measuring isotopic ratios on picogram (10^{-12} g) to nanogram (10^{-9} g) samples or down to tens of femtograms (10^{-15} g) using special preconcentration techniques. TIMS routinely measures differences in isotope mass ratios in the order of 1 in 10^6. Multicollector TIMS instruments, with detectors able to measure multiple isotopes simultaneously, are now available for very precise measurements of isotopic composition. TIMS is the preferred technique for measuring the Sr and Nd isotope ratios mentioned previously and for measuring U and Pb isotopes with the highest possible precision and accuracy.

Inductively coupled plasma mass spectrometry (ICP-MS). In ICP-MS, the sample is aspirated as a solution into an inductively coupled plasma, where the high temperature of the plasma serves to atomize and ionize the sample with high efficiency. Multicollector ICP-MS instruments (MC-ICP-MS), with detectors able to measure multiple isotopes simultaneously, provide extremely precise measurements of U and Pu isotopic composition. In addition to measuring isotopic composition, ICP-MS is useful as a method for precisely quantifying trace elemental constituents of a sample with detection limits ranging from 0.1 parts per billion (ppb) to a few tens of ppb in solution. ICP-MS has difficulty measuring some elements due to background, interferences, or poor ionization efficiency, for example, C, O, and S.

c. Chemical assay

Chemical titration (ITWG, 2017c,d) and coulometry are standard methods for the determination of the elemental concentration of uranium, plutonium, neptunium, and other nuclear materials. In chemical titration, precisely measured amounts of a selective reagent are added to a known mass of sample in solution. The reagent, reacting with the element of interest according to a well-known stoichiometric reaction, is added until the element of interest has completely reacted, the "end point." The end point can be detected either via potentiometric (electrical) or spectrophotometric (optical) methods. In controlled potential coulometry, the element to be analyzed is selectively oxidized or reduced at a metallic electrode maintained at a suitably selected potential. The number of electrons used in the oxidation or reduction is a measure of the amount of element present in the sample. The precision and accuracy of these two assay methods can be better than 0.1% and can be very effective for the characterization of interdicted materials, provided that samples of at least a few tenths of a gram are available for this analysis.

d. Radiochemistry

Many samples are too chemically complex for all the radioactive isotopes present to be measured directly. By utilizing the differences in chemical properties of the elements, it is possible to devise schemes of chemical reactions to separate and purify elements, or groups of elements, allowing the measurement of radioactive nuclides of those specific elements by either radiometric methods, or mass spectrometry. The concentration of specific isotopes can be related back to the original sample by referencing to an internal isotopic standard called a "spike," added during the radiochemical preparation. This method of quantification is commonly known as "isotope dilution" and can be coupled with analytical techniques such as alpha spectrometry or mass spectrometry. The chemical separation and purification steps increase both the sensitivity and selectivity of the technique. Radiochemistry is especially important for the measurement of isotopes at low activity

levels. Radiochemistry, in combination with radioactive counting techniques or mass spectrometry, has the potential to measure down to 10^6 atoms or lower of certain isotopes.

e. X-ray Fluorescence Analysis

XRF can also be useful for broad and nondestructive elemental quantification of either solid samples or solutions. An incident X-ray beam excites characteristic secondary X-ray wavelengths and energies in a solid sample that are counted on a solid-state or proportional counter. The detection limits for XRF are generally in the range of 10 ppmw, although actinide matrices generate many X-rays that interfere with the lower-energy X-rays of lighter elements. Using wavelength-dispersive analysis of the X-rays (WDS) provides higher energy resolution than energy-dispersive analysis (EDS), which can be used to resolve some of these interferences (see X-ray Analysis discussion below). Analysis of light elements is also problematic due to low characteristic X-ray energies and consequently poor detection probabilities.

f. X-ray Diffraction Analysis

X-ray diffraction (XRD) (ITWG, 2015a) is the standard method for identifying the chemical structure of inorganic and organic crystalline materials. X-ray beams that impinge on regularly ordered lattices undergo constructive and destructive interference that depends on the spacing of the lattice, the wavelength of the X-rays, and the angle of incidence of the X-ray beam. By rotating the sample relative to a fixed X-ray source, variations in interference occur, leading to characteristic diffraction patterns. These diffraction patterns can be compared with reference spectra to identify the specific crystalline phase (see Fig. 13.10). No diffraction patterns can be generated from amorphous (noncrystalline) materials.

g. Gas Chromatography/mass spectrometry

Gas chromatography/mass spectrometry (GC/MS) is a technique useful for detecting and measuring trace organic constituents in a bulk sample. In GC/MS, the components of a mixture are separated in the GC and identified in the mass spectrometer. The primary component of a GC is a narrow bore tube (called a "column"), which is maintained inside an oven. In the simplest arrangement, the mixture is flash vaporized in the heated introduction port. The various components of the mixture are swept onto, and through, the column by the carrier gas (usually He). The components of the mixture are separated on the column based on their volatility and relative affinity for being on the column material versus the carrier gas. Columns are usually coated with a special material to enhance separation of the components of interest. In the ideal case, all components are separated and introduced into the mass spectrometer one at a time. At low flow rates, the column effluent can be introduced directly into the mass spectrometer. At higher flow rates, the GC requires an interface to match the flow requirements of the mass spectrometer, usually by selectively removing the carrier gas.

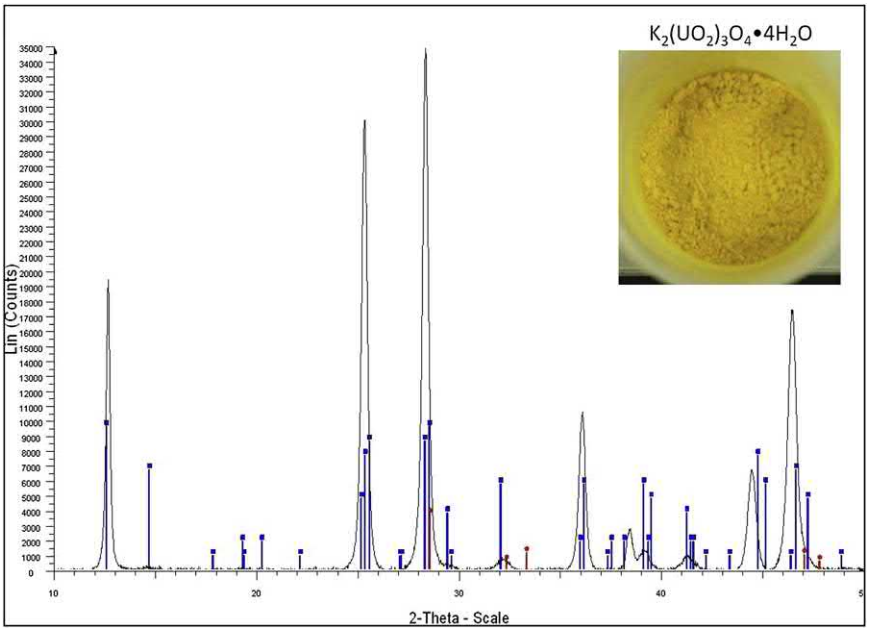

FIGURE 13.10 X-ray diffraction spectrum of interdicted uranium powder (shown in inset), identifying an unusual potassium-containing compound, related to potassium diuranate. *Reproduced from Borg et al. (2011).*

The mass spectrometer ionizes and fragments each component as it elutes from the column. Many different ionization methods can be used, but the most common for GC/MS is electron impact (EI). In EI, an energetic (usually 70 eV) beam of electrons bombards the sample molecules. Some of these electrons will hit a sample molecule and knock out an electron, leaving the molecule positively charged. This ionizing collision tends to impart some energy to the molecule. This energy is sometimes great enough to cause the ion to fragment (usually into an ion and a neutral fragment) in ways characteristic of the molecule's structure. The relative abundance of ion fragments of various masses (strictly mass-to-charge ratio, although the typical ion charge in EI is usually 1) is characteristic of the intact molecule. The mass spectrometer measures the intensity of ions of various masses, either by simultaneous or by sequential detection, depending on the type of mass spectrometer. The resulting plot of relative intensity versus mass-to-charge ratio is a "mass spectrum." There are now extensive libraries of EI mass spectra that help identify unknown compounds that are separated and detected by the GC/MS.

2. *Imaging tools*

While bulk analysis provides an integrated compositional measurement of the sample as a whole, and consequently may obscure important signatures in underlying components, imaging tools provide high magnification images or maps of the material that can confirm sample homogeneity or heterogeneity. Imaging techniques are especially important for assessing the morphology and microstructure of the material.

a. Visual inspection and photography

Visual inspection of a sample can often help in identifying the nature of a sample, especially in conjunction with data from the initial categorization. Size and shape can be sufficient to identify some items, especially if serial numbers or other identifying marks can be seen. For chemicals, the color and form of the material can be important clues.

b. Autoradiography

Autoradiography creates an image of a radioactive source by the direct exposure of imaging media (Parsons-Davis, 2018); the sample and the medium must be in fairly close proximity to one another. Traditional autoradiography used film emulsions, silver halide film being the most common. The resolution of this imaging system is strongly dependent on the thickness of the emulsion, the size of the silver halide grains dispersed in the emulsion, the optical densitometer performance, and the strength of the development process but is typically around 10 μm. The high sensitivity, accuracy, efficiency, and convenience of phosphor imaging are now commonly applied to autoradiography. In phosphor imaging systems, barium fluorohalide crystals doped with a europium activator are the photosensitive grain, and the image is formed via photostimulated luminescence. Incident radiation produces the latent image, which is subsequently "read out" through stimulation by laser light and detected by a photomultiplier tube. As with film, resolution is a function of emulsion thickness, grain size, optical readout system, and the properties of the sample being imaged. Because of the thinness of the medium, autoradiography is not sensitive to gamma radiation. Depending on the use of absorbers, autoradiography can be sensitive to alpha particles, beta particles, or both, but the resolution is typically around 50 μm (see Fig. 13.11).

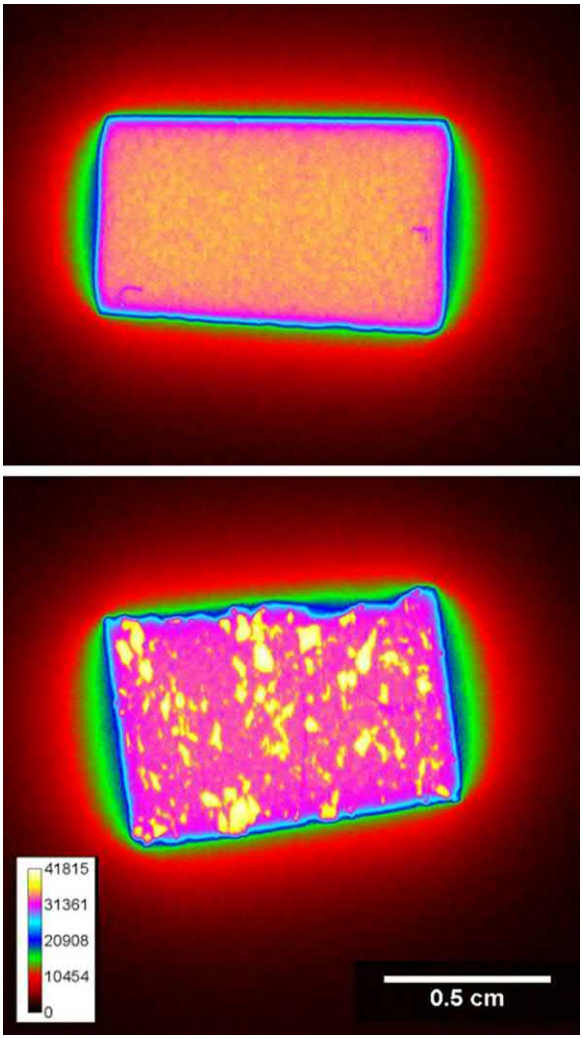

FIGURE 13.11 Cropped autoradiographs of two sawed low-enriched UO_2 subaliquots, which were mounted in epoxy and polished before being exposed to an SR IP for 25 h. The IP was scanned with 626 V, pixel size 25 μm. Sample 2 is characterized by heterogeneity in the distribution of activity on the 50−100 μm scale, whereas sample 1 shows a roughly homogenous distribution on the same scale.

FIGURE 13.12 Optical photomicrograph of the surface of one of the ITWG Round Robin 3 samples. The regular striations (~15/mm) on the surface were caused by slow cutting with a band saw. The rough-cut edge was also cut with the band saw, but at a much faster rate. *Reproduced from Bibby et al. (2010).*

c. Optical microscopy

Optical microscopy is often the first method to examine the sample at high magnification. An optical microscope uses magnifying light optics and reflected or transmitted methods of sample illumination to present magnified images of the sample to the user's eyes (see Fig. 13.12). Viewing samples under polarized light can also reveal additional information. Light microscopes can readily magnify an image up to ×1000.

d. Scanning electron microscopy

Scanning electron microscopy (SEM) can provide image magnifications up to ×100,000 with a conventional thermal filament source or ×1,000,000 with a field emission source. In SEM, a finely focused electron beam is rastered or scanned over the sample. The interaction of the energetic incident electron beam and the sample produce backscattered electrons, secondary electrons, and X-rays. By measuring the flux of one of these types of particles as a function of raster or scan position, an image or map of the sample can be reconstructed and displayed. Each type of particle conveys different information about the sample and, therefore, offers a different contrast mechanism. For instance, secondary electrons carry information about sample topology (see Fig. 13.13). Backscattered electrons carry information about average atomic number of the area being imaged and can be used to quickly detect spatially resolved phases of contrasting chemical composition.

e. Transmission electron microscopy

In transmission electron microscopy (TEM), an energetic electron beam is transmitted through an ultrathin sample (~100 nm thickness). TEM is capable of higher magnifications (several million times) than SEM and is able to image extremely fine structure (see Fig. 13.14), but at the expense of tight restrictions on sample thickness. In most cases, thin sections of the sample must be made. Transmitted electrons can undergo diffraction effects, which can be used like XRD to determine crystal phases in the material.

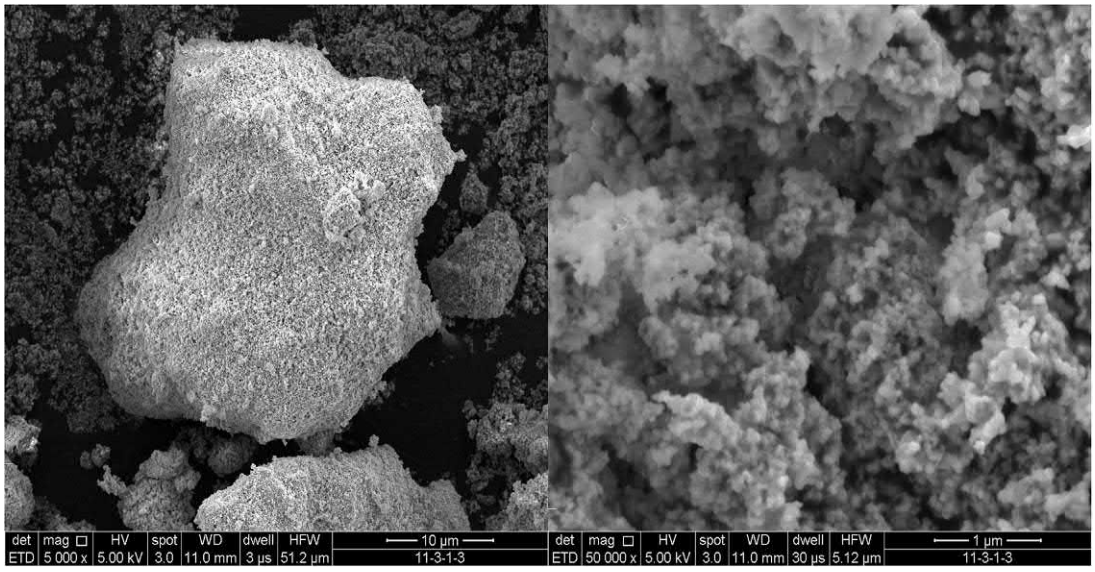

FIGURE 13.13 SEM photomicrographs of the interdicted uranium powder shown in Fig. 13.10. The morphology of the powder was consistent with a hydroxide precipitation process (probably KOH). *Reproduced from Borg et al. (2011).*

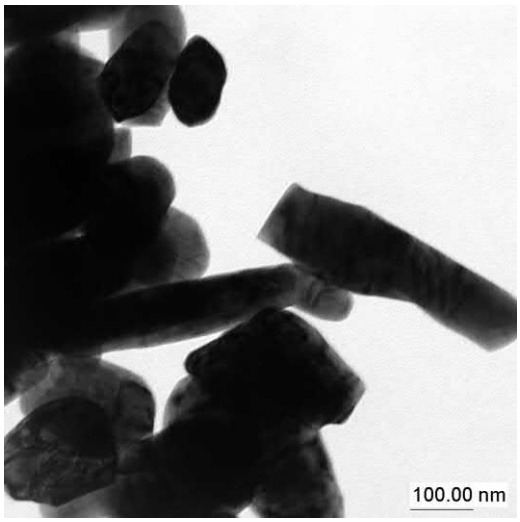

FIGURE 13.14 TEM image of the Bulgarian highly enriched uranium oxide sample, showing two distinct morphologies in the constituent particles. *Reproduced from Adamson et al. (2001).*

3. Microanalysis tools

If imaging analysis confirms that the sample is heterogeneous, then microanalysis tools can often quantitatively or semiquantitatively characterize the individual constituents of the bulk material. The category of microanalysis tools also includes surface analysis tools, which can detect trace surface contaminants or measure the composition of thin layers or coatings, either of which could be important for interpretation.

a. X-ray microanalysis

The X-rays generated during SEM, TEM, or electron microprobe analysis carry elemental information and are a convenient way of measuring the elemental composition on a fine spatial scale. The X-rays can be analyzed by either of two methods. First, an energy-dispersive spectrometer (EDS) uses a solid-state detector (typically a Si(Li) detector) to measure simultaneously the energy and rate of incident X-rays. Second, a wavelength-dispersive spectrometer (WDS) uses a synthetic analyzing crystal to sequentially diffract selected X-rays into a gas proportional counter. Due to the interaction mechanics of the electron beam with the sample, X-rays are generated over approximately a 1 μm, tear drop-shaped region, thus limiting the spatial resolution of X-ray analysis to around 1 μm. In TEM analysis, the sample thin sections limit the extent of the X-ray excitation region, enabling somewhat higher spatial resolution for X-ray analysis. The detection limits of X-ray analysis are approximately 0.01−0.1%, depending on the element. X-ray microanalysis is an assay technique to measure the elements at greater than 0.01% rather than a trace element analysis technique.

b. Secondary ion mass spectrometry

Secondary ion mass spectrometry (SIMS) (ITWG, 2015b) can be used for both elemental surveys and isotopic analysis of small samples, even particles. SIMS uses a finely focused primary ion beam, for example, O_2^+, O^-, Cs^+, or Ga^+, to sputter the sample surface. The sputtering process produces secondary ions (ions characteristic of the sample) that can be analyzed by a mass spectrometer. SIMS is capable of acquiring microscopic images of isotopic distributions (which can correspond to elemental images for known elements of known isotopic abundance). In the "microscope" mode, a relatively large primary ion beam bombards the sample, and the spatial position of the resulting secondary ions is maintained and magnified throughout the mass spectrometer. An imaging detector then displays and records the resulting isotopic image. In the "microbeam" mode, a finely focused primary ion beam is rastered or scanned across the sample in a manner similar to an electron microscope. The resulting secondary ion signal is then measured and correlated with the position of the primary ion beam to generate the isotope image. Sample ablation of the focused ion beam on the sample yields a depth profile through age, the sample surface that is extremely valuable to document compositional gradients or surface alteration.

High spatial resolution SIMS, using the CAMECA NanoSIMS, has proved useful in measuring the isotopic and elemental homogeneity of uranium oxide powders, which could prove a useful source of process signatures. Kips and coworkers have used the NanoSIMS to study the loss of F from uranium oxyfluoride particles in the environment as a function of temperature, humidity, and light level (see Fig. 13.15) (Kips et al., 2010; 2011a,b).

c. Infrared spectroscopy

Infrared (IR) spectroscopy is useful for the identification of organic compounds. Through the use of a specialized microscope, IR can be performed on samples as small as 10 μm and is an important microanalytical technique. Molecular bonds vibrate at characteristic frequencies. If a particular molecular vibration results in a change in the bond's dipole moment, then the molecule can absorb IR radiation of that characteristic frequency, exciting that vibration.

In IR spectroscopy, the sample is irradiated with a broadband of IR frequencies, and the intensity of the reflected or transmitted IR radiation is measured as a function of frequency. From the knowledge of incident intensity and reflected/transmitted intensity as a function of IR frequency, an IR absorbance spectrum can be reconstructed. Absorption at specific frequencies is characteristic of certain bonds. Thus, the IR spectrum identifies the various bonds and functional groups within the molecule. In

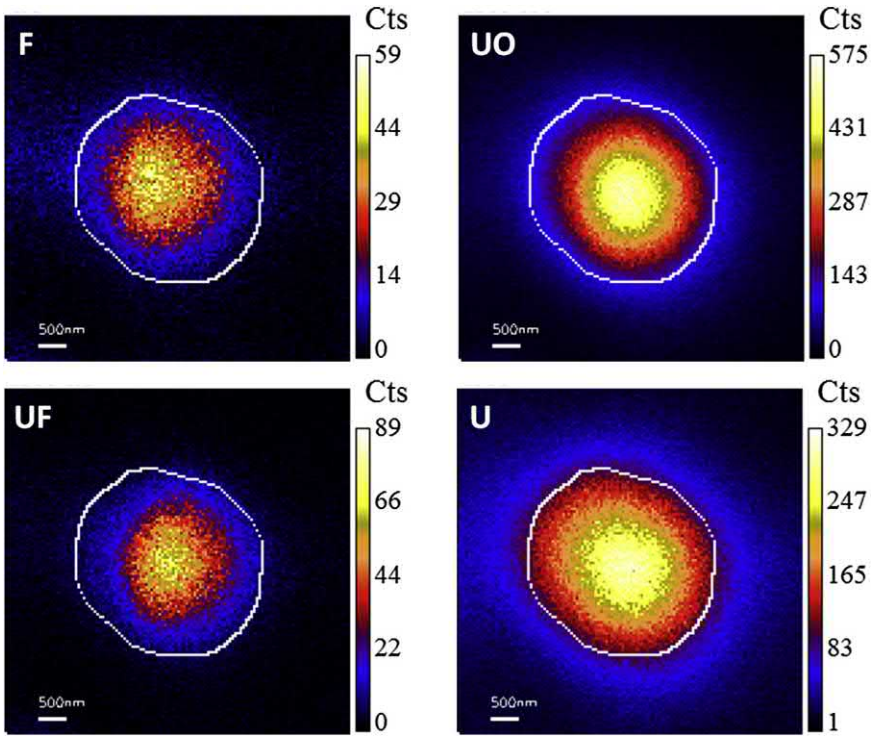

FIGURE 13.15 Ion intensity images using the CAMECA NanoSIMS at LLNL. The images are displayed in the false color mode, in which white corresponds to the highest ion intensity and black to the lowest ion intensity. These images clearly show that the uranium oxyfluoride particle (generated at the European Institute for Reference Materials & Measurements under laboratory conditions) is losing F from the outside of the particle inward (SIMS conditions: 45 pA O- primary ion beam, 16 keV impact energy).

addition, there are also vast libraries of IR spectra that help identify unknown compounds or, at least, place them into certain classes of molecules.

d. Raman spectroscopy

Raman spectroscopy is also useful for the identification of organic compounds and is complementary to IR spectroscopy, since some molecular vibrations are only Raman active and some are only IR active. Through the use of a specialized microscope, Raman spectroscopy can be performed on samples as small as 1 μm. If a particular molecular vibration results in a change in the polarizability of the molecule, then the molecule can absorb radiation of that characteristic frequency, exciting that vibration.

In Raman, the sample is irradiated with radiation of a specific frequency, and the intensity of the reflected radiation is measured as a function of frequency. Most of the radiation is reflected at the same frequency as the incident radiation. However, some radiation is reflected at specific frequencies of lower energy (Stokes lines) and some at specific frequencies of higher energy (anti-Stokes line). The frequency shifts between the Stokes and anti-Stokes lines and the incident radiation correspond to Raman active vibrations.

Characteristic Raman bands, such as the 863 cm^{-1} band for the uranyl moiety, are useful for deducing the chemical nature of the sample. Kips and coworkers have used Raman to understand how the chemical environment of the uranium atoms change as uranium oxyfluoride loses F to the environment (see Fig. 13.16).

The analytical tools commonly used in radioactive materials analysis and the information that these tools can provide are summarized in Table 13.3.

B. Traditional forensic analysis

1. Overview

Traditional forensic analysis, such as radioactive materials analysis, is an iterative process, in which the results from one analysis are used to guide the selection of subsequent analyses. The forensic analyst must carefully examine all of the items seized at the incident site to uncover as much information as possible; unlikely, and apparently unrelated, evidence are often the keys to the successful prosecution of a case.

There is a great variety of traditional forensic evidence, as well as methods of collection and evaluation. For example, evidence such as tissue, hair, fingerprints, and shoeprints can often associate a specific individual with a specific place or object. The analysis of fibers, pollen, or chemical substances found at the incident scene can

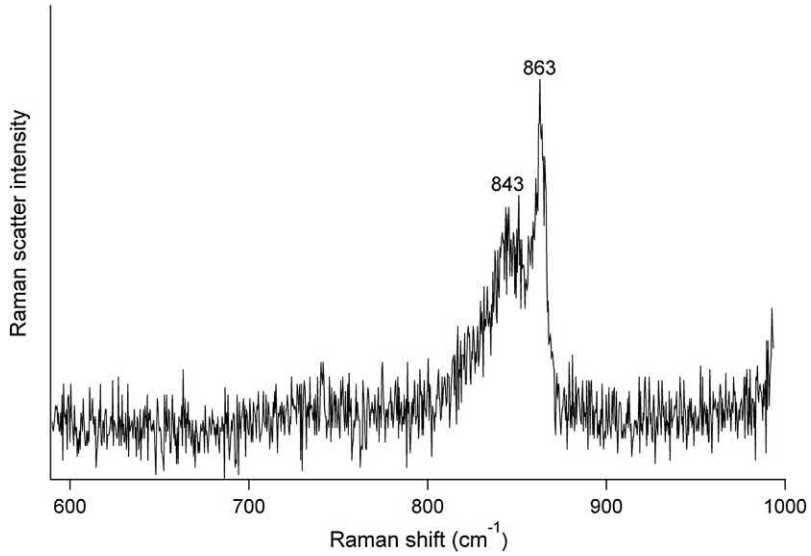

FIGURE 13.16 Raman spectrum of uranium oxyfluoride compound. The peak at 863 cm^{-1} is indicative of the uranyl moiety, whereas the peak at 843 cm^{-1} is indicative of degradation due to further hydration and loss of fluorine over time. *Reproduced from Kips et al. (2010).*

TABLE 13.3 Examples of analytical tools for nuclear forensics.

Measurement goal	Technique	Type of information	Typical detection limit	Spatial resolution
Survey	HRGS	Isotopic	ng–µg	
	Chemical assay	Elemental	mg	
	Radiochemistry/radiometric methods	Isotopic,	fg–pg	
		Elemental		
Elemental and	TIMS	Isotopic	pg–ng

	XRD	Molecular	~1 at%	
	GC/MS	Molecular	ppm	
	Visual inspection	Macroscopic		0.1 mm
	Autoradiography	Microscopic Structure		10–50 µm
Imaging	Optical microscopy			1 µm
	SEM			1 nm
	TEM			0.1 nm
Microanalysis	SIMS	Elemental	0.1 ppb–10 ppm	0.1–1 µm
		Isotopic		
	SEM/EDS or WDS	Elemental	0.1–2 wt%	1 µm
	FTIR	Molecular	0.1–1 wt%	10 µm
	Raman	Molecular	~1 wt%	1 µm

at%, atom percent; *fg*, femtogram, 10^{-15} g; *FTIR*, Fourier transform infrared; *GC/MS*, gas chromatography/mass spectrometry; *HRGS*, high-resolution gamma spectrometry; *ICP-MS*, inductively coupled plasma mass spectrometry; *mg*, milligram, 10^{-3} g; *ng*, nanogram, 10^{-9} g; *pg*, picogram, 10^{-12} g; *ppb*, parts per billion by weight; *ppm*, parts per million by weight; *SEM*, scanning electron microscopy; *SEM/EDS*, scanning electron microanalysis with energy-dispersive sensor; *SEM/WDS*, scanning electron microanalysis with wavelength-dispersive sensor; *SIMS*, secondary ion mass spectrometry; *TEM*, transmission electron microscopy; *TIMS*, thermal ionization mass spectrometry; *wt%*, weight percent; *XRD*, X-ray diffraction; *XRF*, X-ray fluorescence; *µg*, microgram, 10^{-6} g; *µm*, micrometer, 10^{-6} m.

provide information about motives or transportation routes. Documentary evidence provides useful information not only in the content of the communication itself but also in the incidental details of its creation (paper, ink, film type, extraneous noises, and accents).

Once again, all sampling and analysis must be performed with due regard for perpetuation of the chain-of-custody and preservation of evidence, since the sampling process itself could contaminate or destroy some evidence in the pursuit of other evidence. In addition, the collection of traditional forensic evidence on radioactively contaminated materials must also be performed in a manner consistent with good radiological safety practice.

2. Documentary evidence

Documents or recordings (from an answering machine, for example) can provide information, not only through the written or recorded information itself but also through other evidence that ties the document or recording to a person or place: detailed analysis of handwriting, type characteristics and anomalies on typed documents, photocopier characteristics and anomalies on photocopied documents, and mechanical impressions for typeset documents. Analysis of the paper used in a document can itself provide valuable clues. The analysis of paper associated with the Bulgarian seizure, for example, indicated a source somewhere in eastern Europe (Adamson et al., 2001; Moody et al., 2015). Examination of a recording would include an analysis of the language, dialect, and stray background sounds. If a computer, or a data storage media, for example, disk, is recovered from the incident scene, then the forensic analyst must try to recover all of the information stored there. Programs and files may document the perpetrators' plans and methods and/or implicate other people. Information stored in mobile phones could also provide useful information.

3. Impressions

Latent fingerprints, palm prints, or prints from other body areas, for example, ear prints from listening at windows, could tie a person to a location or an object seized in the incident. Shoe prints discovered at the incident site can also link a specific person to the incident site, through the unique tread pattern of their shoes. Similarly, tire treads could serve to link a specific car to the incident site.

4. Chemical analysis

Unique or special chemical substances seized at the incident site can provide valuable evidence. Controlled substances or poisons may provide useful information about the perpetrators or their motives. Accelerants used for arson or explosive residues provide evidence about methods and purpose. Characteristic dyes and petroleum products can tie the seized evidence to particular locations, perhaps serving as a marker for route interpretation.

5. Tissue and hair evidence

Human tissue recovered at the incident scene can also tie a specific individual to the incident scene or seized evidence. Blood can be typed through serology. Blood and other tissue can be subjected to either nuclear or mitochondrial DNA analysis, again helping to implicate an individual. Hair samples can provide information about race and body characteristics.

6. Weapons evidence

In the event that a bomb is detonated or seized, the bomb remains and explosive residues can provide a pattern for determining the type of bomb and its method of manufacture. Unique materials may pinpoint the exact perpetrator or, at least, restrict the number of potential perpetrators through purchase records for such material. In the event that firearms are seized, the examination of the projectile lead, cartridge cases, gunshot residues, and any altered function may tie the perpetrator to a given location, a fact useful in route interpretation, or it may provide evidence of method or purpose.

7. Tool marks

Alterations in objects that appear to be made by the perpetrators themselves are highly significant. The forensic analyst should look for fractures (particularly those that match up with other fractures in the evidence), odd marks in wood, the use of stamps and dies, and the modification of locks and keys. The forensic analyst should attempt to restore any obliterated markings. For example, the regularly spaced grooves on the ITWG Round Robin 3 samples (see Fig. 13.10) were indicative of cuts made by a slow-moving band saw.

8. Fiber examination

Fibers can serve to tie objects and perpetrators to specific locations as well. The forensic analyst must pay particular attention to fiber evidence, such as fabrics, cords, and ropes, and determine its type: animal (wool), mineral (glass), synthetic, or organic (cotton).

9. Flora and fauna

The forensic analyst should also examine all evidence for feathers, insects or other bugs, plant material, pollen, or spores that are indicative of a location other than the incident site. These botanical pieces of evidence can be important for route interpretation. A tineid moth found in an interdicted sample (see Fig. 13.17), for example,

FIGURE 13.17 Optical photomicrograph of a tineid moth found in an interdicted uranium powder sample. *Reproduced from Borg et al. (2011).*

provided evidence of sample location between loss of legitimate control and interdiction.

10. Other materials evidence

Other associated evidence should be carefully examined for possible clues toward methods and route interpretations. Such materials as glass, soil, dust, cosmetics, paints, inks and dyes, plastics, polymers, metal objects (such as the corroded staple shown in Fig. 13.18), and tapes often vary in chemical composition from place to place. Unique characteristics in these materials might tie the perpetrators to a specific location, again a fact that can be important for route interpretation. In the same way, unique minerals found on the evidence might be diagnostic of specific geology and location, that is, geolocation.

FIGURE 13.18 A somewhat unusual staple found in an interdicted uranium powder sample. *Reproduced from Borg et al. (2011).*

C. Application and sequencing of techniques and methods

The nuclear forensic scientist should, of course, consider issues such as specificity, sensitivity, detection limit, precision, and accuracy in choosing an appropriate analytical method to apply to the nuclear forensic sample. In addition, though, one must consider the cost of the analysis versus the benefit to be derived from the results. Cost includes real financial cost, of course, the cost of both instrument time and the analyst's time, the cost of consumables used during the analyses, and so forth. However, cost should also include the "cost" of any sample consumed during analysis. In the case of NDA, this cost may very well be zero, although one must always consider the potential of altering or contaminating the sample during NDA, rendering it useless for analysis by other techniques. In addition, if the amount of sample is quite large, this cost might be correspondingly quite small. Another potential cost might be time. For time-critical cases, the amount of time required for a specific analysis may be too long, and the analyst should consider other techniques that can provide answers more quickly. When considering the benefit of an analysis, the analyst should first consider the relevance of the anticipated results. Relevance really reflects the connection between the anticipated results and signatures of interest. In the case of comparative signatures, do we have the necessary database or sample archive against which to compare our results? In the case of predictive signatures, do we have the necessary scientific insights to interpret the meaning of our results?

The ITWG has achieved a general consensus on the proper sequencing of techniques so as to provide the most valuable information as early as possible in the interpretation process. This consensus was achieved through discussion and consultation at regular meetings, as well as from experience developed from three round robin analyses by nuclear forensic laboratories. The collection of time or environmentally sensitive samples must occur within the first 24 h after sample receipt. NDA should be conducted before destructive analyses whenever possible. Table 13.4 shows the generally accepted sequence of analysis, broken down into techniques that should be performed within 24 h, 1 week, or 2 months after sample receipt.

IX. Quality assurance

From the law enforcement perspective, nuclear forensic results must meet the standards of evidence of the jurisdiction where the case is to be prosecuted. In the United States, for example, the probative power and admissibility of scientific evidence in the courtroom has tended toward more restrictive interpretations of the Federal Rules of Evidence (Daubert, 1993; Kumho Tire, 1999), a trend also

TABLE 13.4 Sequence for techniques/methods as determined by the ITWG (Hanlen, 2011).

Techniques/ methods	24 hours[a]	1 week[a]	2 months[a]
Radiological	Health and safety assessment - Dose rate (α, γ, neutron) - Surface contamination - Radiography		
Physical characterization	Preliminary - Visual inspection - Photography - Weight and dimensional determination - Optical microscopy - Density	Detailed (microstructure, morphology, etc.) - SEM (EDX) - XRD	Detailed (nanostructure, morphology, etc.) - TEM - EMPA[b]
Classical forensics	Initial - Assessment of presence and collection of classical forensic evidence		Detailed - Analysis and interpretation of classical forensic evidence
Isotope analysis	Initial isotopic composition - Gamma spec on bulk material (i.e., is it HEU or not?)	Intermediate isotopic composition - HRGS - SIMS - TIMS - MC-ICP-MS - Alpha spectroscopy	Final isotopic composition - HRGS - SIMS - TIMS - MC-ICP-MS
	Initial age dating • HRGS Pu	Initial age dating - LA-ICP-MS	Age dating - HRGS - MC-ICP-MS - Alpha spectroscopy
Elemental/ chemical	Elemental/chemical (may take longer) - XRF	Elemental/chemical (may take longer) - ICP-MS - IDMS[c]	

HEU, highly enriched uranium; *HRGS,* high-resolution gamma spectrometry; *LA-ICP-MS,* laser ablation inductively coupled mass spectrometry; *MC-ICP-MS,* multicollector inductively coupled mass spectrometry; *SEM,* scanning electron microscopy; *SIMS,* secondary ion mass spectrometry; *TEM,* transmission electron miscroscopy; *TIMS,* therma ionization mass spectrometry; *XRD,* X-ray diffraction; *XRF,* x-ray fluorescence.

reflected in the 2004 NRC study of bullet lead analysis and the subsequent withdrawal of this method by the FBI (NRC, 2004; Finkelstein and Levin, 2005; FBI, 2005). The Daubert Standard, for example, consists of the following four factors, which a judge should consider when determining the admissibility of scientific evidence:

1. whether scientific evidence has been tested and the methodology with which it has been tested;
2. whether the evidence has been subjected to peer review or publication;
3. whether a potential rate of error is known; and
4. whether the evidence is generally accepted in the scientific community

The existence of a rigorous quality assurance system can help address several of these factors. According to the draft Quality Assurance Guidelines for Laboratories Performing Forensic Analyses of Radiological Materials (Garrett et al., 2012, personal communication):

> *Quality Assurance is an integral part of a laboratory analysis program. It provides a means to deliver valid, traceable results, an ability to identify and correct anomalies, consistency from analysis to analysis within a given technique, between techniques and temporally, and assurance that errors will be minimal and stochastic. The QA program is the element of an analytical program that provides assurance in the results generated by the analyses.*

From a nuclear forensic perspective, a QA program ensures defensible and consistent input to the interpretation process in support of attribution assessments.

Most forensic laboratories, including nuclear forensic laboratories, are seeking to accredit their quality assurance systems to the ISO 17025 standard (ISO/IEC, 2005). The Lawrence Livermore National Laboratory and Los Alamos National Laboratory, for example, have achieved accreditation in the field of nuclear forensics. The ISO 17025 standard is based on the essential structure of ISO 9000 with requirements in the following areas:

- Organization and management
- Document control
- Contracts and procurement
- Corrective action
- Control of records
- Audits
- Personnel qualifications and training
- Facility infrastructure and security
- Validation of methods, uncertainty, and measurement traceability
- Equipment
- Analytical procedures
- Calibration and maintenance
- Proficiency testing
- Documentation and reporting
- Sampling
- Sample control
- Safety
- Subcontracting services

The critical components for the analytical measurements are the requirements to validate the analytical methods prior to use, to calibrate and maintain the analytical instruments, and to qualify and train the personnel who use the methods and instruments. The method for determination of uncertainty and the traceability of measurements is an important part of each method (ITWG, 2017b). Although adherence to the Guide to Uncertainty in Measurement (ISO, 2008) is not a requirement of ISO 17025, it has, in fact, become the standard for determining analytical uncertainty. Finally, ISO 17025 requires proficiency testing, which serves to exercise the entire quality assurance system and serves to ensure comparability of results from different laboratories.

As mentioned previously, although the quality assurance requirements for the admissibility of scientific evidence into a court of law may be rigorous, scientific results used for intelligence purposes have a need for similar quality assurance, however, perhaps less formal than that required for law enforcement purposes.

X. Sampling

The quality of the analytical measurements is often limited by the quality of the sample. Uncertainties created in the field ripple through to uncertainties in the lab. A thorough analysis of issues regarding operations at the incident site can be found in IAEA TECDOC-1313 (IAEA, 2002) and the ITWG Guidelines for Evidence Collection in a Radiological or Nuclear Contaminated Crime Scene (ITWG, 2012a).

One must, of course, address the issue of personnel and public safety first. Since traditional forensic evidence is frequently commingled with the radioactive evidence, the collection of forensic evidence must be consistent with good radiological safety practice. Limiting time in the contaminated area and maximizing distance and shielding between the exposed personnel and radioactive sources can lessen the risk to personnel. Appropriate personal protective equipment (PPE), e.g., rubber gloves, safety goggles, will be required. In cases where dispersible radioactive material is present, an approved respirator may also be needed.

Ill-considered collection of traditional evidence could compromise the radioactive material evidence and vice versa. Therefore, it is essential that appropriate thought be given to the manner and relative timing of traditional forensic evidence collection and radioactive material collection. Good communication between nuclear forensic specialists and those responsible for collecting the evidence will help ensure that all factors are considered before a collection approach is adopted.

Finally, appropriate chain-of-custody procedures will be initiated and maintained during the evidence collection process. The resulting evidence must then be supervised and protected while awaiting transportation from the incident scene.

XI. Conclusions

Nuclear forensics is an emerging discipline, driven primarily by national objectives, to include both those of law enforcement and national intelligence. Nuclear forensics is one input into nuclear attribution, in which responsibility is assigned, along with other sources of information, such as law enforcement and intelligence. Nuclear forensics is used to generate technical conclusions by applying validated signatures to analytical results from the interdicted material. These validated signatures include both comparative signatures, in which the interdicted material is compared with the results from material of known origins, and predictive signatures, in which conclusions are generated without reference to other samples. Valid analytical results, in turn,

depend on appropriately validated analytical methods, proper analytical sampling, and a quality control/assurance program.

Acknowledgments

I would like to acknowledge the help and support of all of my colleagues in the nuclear forensic group at the Lawrence Livermore National Laboratory, but especially my mentors, Dr. Sid Niemeyer and the late Dr. Ian Hutcheon, who paved the way for the emergence of nuclear forensics as a distinct discipline of national importance. Dr. Ross Williams and Dr. Amy Gaffney have been instrumental in providing results that are helping us explore the strengths, and pitfalls, of age dating nuclear material. Dr. Kim Knight, Dr. Ruth Kips, Dr. Tashi Parsons-Davis, Dr. Jonathan Plaue, and Christie Ramon helped me by providing the optical, autoradiography, and SEM photomicrographs shown here. Finally, I would like to acknowledge our national and international colleagues, particularly those at the Joint Research Center-Karlsruhe (formerly Institute for Transuranium Elements) in Karlsruhe, Germany, for helping to develop this new field. This chapter was prepared by a contractor of the US government under contract number DE-AC52-07NA27344. Accordingly, the US government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for US government purposes.

Michael J. Kristo

Michael Kristo is an associate program leader for LLNL's Nuclear Forensics Materials Analysis Program and Group Leader for LLNL's Chemical and Isotopic Signatures Group. Dr. Kristo is the principal investigator on a wide variety of projects in the areas of nuclear forensics, nonproliferation, and international collaboration. He is particularly interested in the application of novel mass spectrometric techniques, imaging methods, and multidimensional statistics to nuclear forensics problems. Mike has a PhD in Analytical Chemistry from Michigan State University and a BS in Chemistry from the University of Notre Dame. After obtaining his PhD, Mike spent 4 years as an Air Force officer in the Air Force Technical Applications Center and 12 years as a scientist, analyst, and manager at Charles Evans and Associates, a commercial materials analysis company in Silicon Valley.

References 1012

I. Introduction

Data on the half-life, modes of decay, types of radiation emitted, radiation energies, and intensities of the predominate radiation emissions of radioactive isotopes are given in the following table. The isotopes are listed in order of increasing atomic number. Not all of the isotopes are listed here. The table includes commonly measured radionuclides, fission products, fission radioactivation products, radionuclides used in medical therapy and diagnosis, daughter radionuclides, and specific radionuclides referred to in this book. Some radionuclides of short half-life are listed because of their increasing applications and importance in the field of nuclear medicine. Decay products of the radionuclides are also provided. Radionuclides of atomic number $Z > 100$ are short-lived, many of which are isotopes of newly discovered elements. Only the longest-lived isotopes of these elements are listed in the table.

Information available on radionuclide decay modes and radiations is encyclopedic and complex. The most detailed sources of information are obtained from the National Nuclear Data Center, Brookhaven National Laboratory, Upton, NY, via the Internet database NuDat 2.7 (2018) [http://www.nndc.bnl.gov/nudat2/chartNuc.jsp] as well as the International Atomic Energy Agency (IAEA) database available via the Internet (IAEA Live Chart of Nuclides, https://www-nds.iaea.org/relnsd/vcharthtml/VChartHTML.html). Numerous volumes of the *Nuclear Data Sheets* published by Academic Press/Elsevier and edited by McCutchan (2018) are also available for additional information. Other important sources are Michael Lederer et al. (1978), Browne et al., (1986) and Firestone et al. (1996). Limited information of practical importance to scientists, who need to measure radionuclide activity, is provided in the table for ready access. For more detailed information and for radioisotopes not listed in the table provided here, the reader should consult the online references listed above. An explanation of the information in this table and examples of practical applications are provided in the following paragraphs.

A. Column I—nuclide

The radionuclides are listed here in order of increasing atomic number, Z, and under headings by element. When more than one radioisotope is given under the same element, these are listed in order of increasing mass number, A.

B. Column 2—half-life

The values of half-life given here are in units of microseconds (μs), milliseconds (ms) seconds (s), minutes (m), hours (h), days (d), and years (y). The values are those of the total half-life, which would be their decay rate if measured over a period of time.

C. Column 3—decay mode

The modes of decay are designated in this column as follows: α represents decay by alpha-particle emission; β^- signifies decay by negative beta-particle (negatron) emission; β^+ indicates decay by positive beta-particle (positron) emission; EC is electron capture; IT is isomeric transition; $\beta^- n$ is delayed-neutron emission in which β^- emitters

decay to unstable nuclides, which undergo instantaneous neutron emission; and SF refers to spontaneous fission. When more than one mode of decay occurs, the percentages of occurrence are given in parentheses beside the decay mode, and the total percentage should sum to 100. No percentage is given when only one mode of decay is cited, as it is understood that this is the only significant decay mode. Some radioisotopes are listed as decaying by $\beta^+ + \text{EC}$ without any percentage of occurrence given. In these cases, the β^+ decay mode is observed, and the later EC mode is inferred theoretically.

D. Column 4—radiation characteristics

The radiations listed are as follows: α is alpha-particle emission, β^- is negative beta-particle or negatron radiation, β^+ is positive beta-particle or positron emission, γ is gamma radiation, $\gamma^{\pm}$ is annihilation radiation, and n is neutron emission. Internal conversion electron and Auger electron emissions are grouped into the category of atomic electron emissions denoted by the symbol e^-. The average energies of the electron emissions in MeV are provided in brackets { } with the total intensity of the electron emissions given as a percentage enclosed in parenthesis alongside the brackets. Atomic electron emissions are listed when the average energy and intensity are significant in radionuclide detection and measurement. In certain cases, the specific energy lines of the most predominant atomic electron emissions are provided in MeV without brackets, and the intensities of the electron emission line provided as a percentage enclosed in parenthesis. X-rays are also given when emitted with significant intensity. Since x-rays are characteristic of the daughter nucleus, these are expressed with the symbol of the daughter nuclide as well as the atomic shell (K or L) of the daughter from which the x-rays originate.

The energies in MeV and intensities (percent) of the major radiations emitted are listed in this column. The energy values (MeV) are given without units and the known percent intensities of the emissions are enclosed in parentheses. The energies of beta particles are those of $E_{\max}$. The intensities of α- and β radiation emissions are added up to 100%. When the α- and β decay branches are numerous, only the major branches are listed. The principle γ-photon emission lines are listed with their percent intensities alongside enclosed in parenthesis. A percent intensity signifies the percentage of nuclides that would emit a given radiation. For example, the values γ 0.847 (100%) in the table for $^{56}_{27}$Co signifies that ^{56}Co nuclides emit a gamma ray of 0.847 MeV, and one gamma-ray photon of 0.847 MeV energy would be emitted in each ^{56}Co decay. Radiation intensities less than 100% would indicate the number of radionuclides out of 100 that would emit a given radiation type and/or radiation energy. Radiation intensities greater than 100% can also occur. For example, $\gamma^{\pm}$ 0.511 (180%) in the table under radiation characteristics of ^{22}Na signifies that annihilation radiation is produced (the energy of which is invariably 0.511 MeV), and the intensity of this emission is 180% in the case of ^{22}Na. Thus, for every 100 nuclides of ^{22}Na that decay, there is an expectancy of 180 photons of gamma rays as annihilation radiation. It should be noted here that the percent intensity (abundance) of annihilation radiation throughout this table is expressed as twice the value of the percent intensity of β^+ radiation, because each positron annihilation is accompanied by the emission of two gamma-ray photons of 0.511 MeV. Note that in the table alongside ^{22}Na, the percent intensity of β^+ radiation is 90%; that is, for every 100 nuclides of ^{22}Na that decay, 90 are expected to decay by positron emission.

E. Column 5—decay product

The daughter nuclide is listed in this column. More than one daughter is possible when more than one decay mode can occur. Under such circumstances the decay modes are listed with the corresponding symbol in parentheses (α, β^-, β^+, EC, or IT) alongside the decay product.

F. Some applications of radiation type, energy, and intensity data

A description of the radiation types and their energies and intensities may be used to judge which instrumental detection method could be employed to obtain an optimum detection efficiency for a particular radionuclide. As an example, from the table the nuclide $^{56}_{27}$Co may be cited. Both β^+ (two decay transitions with $E_{\max} = 1.46$ and 0.443 MeV) and γ emissions (several) are listed. However, the relatively low intensity of the β^+ emissions (19%) indicates that it may be less appropriate to assay for ^{56}Co by gas ionization or liquid scintillation counting of the positron radiation. Rather, solid scintillation counting of the more intense gamma rays and high-energy positrons may be preferable to obtain the highest counting efficiency possible. In contrast, another example can be taken from the table whereby we can conclude from the information provided that the liquid scintillation counting efficiency of $^{129}_{53}$I should be appreciably greater than the solid scintillation counting efficiency due to the greater intensity of beta radiation (100%) and atomic electrons (165%) than gamma rays (9%) emitted during ^{129}I decay.

The beta-particle energies and intensities may also be used to judge whether Cherenkov counting could serve as an appropriate means of radionuclide assay. For example, the table indicates that two beta-decay transitions can occur in the decay of $^{115m}_{48}$Cd. The principal transition occurs with the emission of beta particles of $E_{\max} = 1.62$ MeV at a 97% intensity. The other transition ($E_{\max} = 0.68$ MeV) is less significant, because it has a lower frequency of occurrence (3% intensity). In view of the threshold energy of 0.263

MeV for the production of Cherenkov photons by beta particles in water (see Chapter 6, Volume 2), and taking into account that beta radiation is emitted with a continuous spectrum of energies between zero and E_{max}, it can be estimated that an appreciable number of the beta particles emitted from ^{115m}Cd possess an energy greater than 0.263 MeV. Cherenkov counting of ^{115m}Cd should then be an appropriate technique for the assay of this nuclide, keeping in mind that liquid scintillation counting of the beta particles emitted from ^{115m}Cd would be a more efficient, although more expensive, counting technique.

In contrast to the preceding case, the energies and intensities of the beta particles emitted from $^{125}_{51}$Sb, listed in the table serve as an example of radiation data, which indicate that only a relatively small percentage of the beta particles emitted by this nuclide have energies greater than 0.263 MeV. Consequently, Cherenkov counting would not be an efficient method for the assay of ^{125}Sb; instead, liquid scintillation counting should be employed.

The nuclide $^{95}_{41}$Nb is another illustrative example that may be taken from the table. In this case, both beta particles and gamma rays are emitted with equal intensity, indicating that detection methods suitable for either the beta particles or gamma rays may be appropriate. However, liquid scintillation detection of the beta radiation would provide higher counting efficiencies than solid scintillation detection of the gamma radiation.

Illustrated in this table are numerous examples of the electron capture (EC) decay process, also known as *K*-capture, which is accompanied generally by the emission of gamma radiation, and the transitions produced in the electron orbital energy levels result in the emission of energy as x-rays. In such cases (e.g., $^{49}_{23}$V, $^{53}_{25}$Mn and $^{71}_{32}$Ge in the table) solid scintillation counting of the x-radiation may be the chosen assay method, although liquid scintillation analysis of atomic electron and x-ray-emitting nuclides is also possible (see Chapter 6, Volume 1).

The energy lines of alpha-particle emissions and their intensities, provided in this table, serve as useful references for the analysis of radionuclides by alpha spectrometry (see Chapter 5, Volume 1). The most predominant gamma energy lines and their intensities are vital in gamma spectrometric analysis with semiconductor detectors (see Chapter 4, Volume 1).

Table of radioactive isotopes

Nuclide $^{A}_{Z}X$	Half-life	Decay mode	Radiation characteristics: energies (MeV) [intensities (%)]	Decay product $^{A}_{Z}Y$

Appendix B

Particle range-energy correlations

PERPUSTAKAAN PRIBADI AN-NUR SUNARYA

Fig. B.1

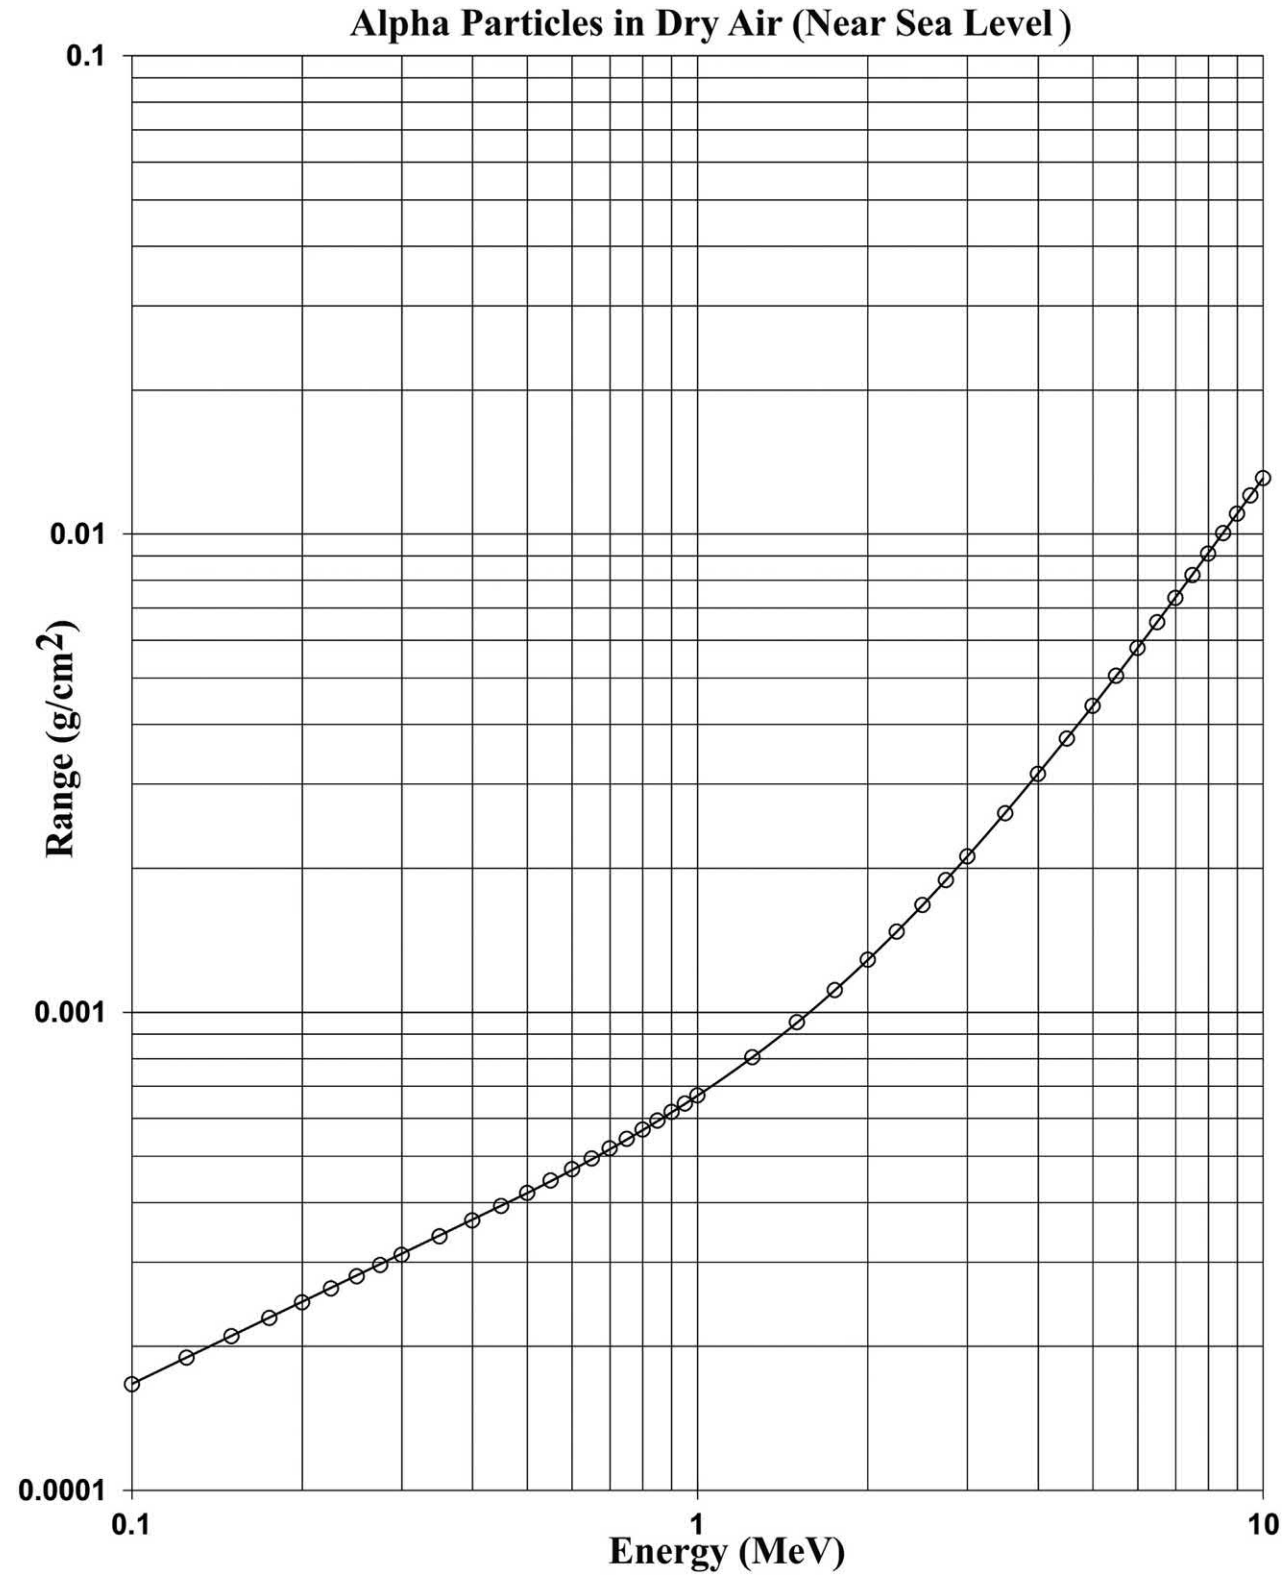

FIGURE B.1 Range-energy relationship for alpha particles in air. The range in cm can be obtained by dividing the above range by the density of air ($\rho = 0.001226$ g/cm^3 at STP). For example, the range of a 5.5 MeV alpha particle from the graph is read as 0.005 g/cm^2; and dividing by the density of air yields a calculated linear range of 4 cm. The range-energy relationship is plotted from data provided by the National Institute of Standards and Technology (NIST) Database ASTAR (2018) for CSDA (continuous slowing down approximation) ranges from which very precise calculated values of range in a large number of elements and compounds may be found: http://www.nist.gov/pml/data/star/index.cfm.

Fig. B.2

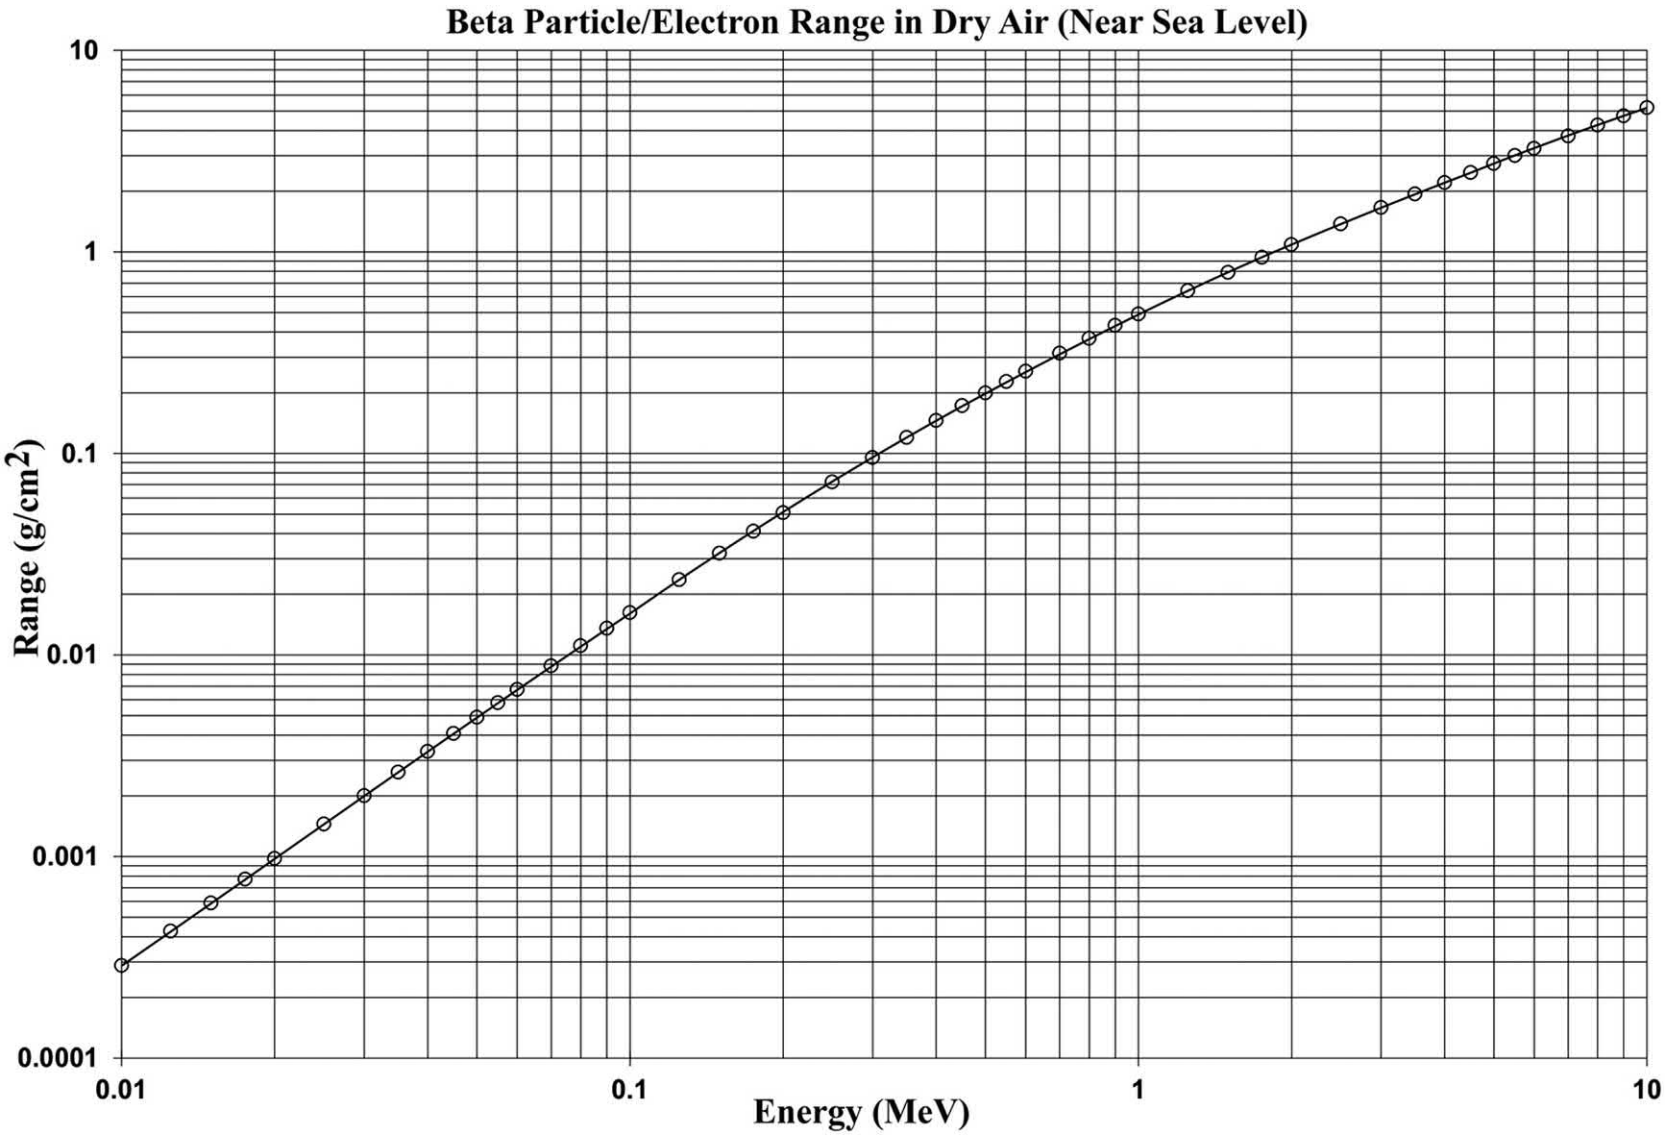

FIGURE B.2 Range-energy relationship for beta particles/electrons in air. The range in cm can be obtained by dividing the above range by the density of air ($\rho = 0.001226$ g/cm^3 at STP). For example, the range of a 1.0 MeV beta particle from the graph is read as 0.48 g/cm^2; and dividing by the density of air yields a calculated linear range of 390 cm. The range-energy relationship is plotted from data provided by the National Institute of Standards and Technology (NIST) Database ESTAR (2018) for CSDA (continuous slowing down approximation) ranges from which very precise calculated values of range in a large number of elements and compounds may be found: http://www.nist.gov/pml/data/star/index.cfm.

Fig. B.3

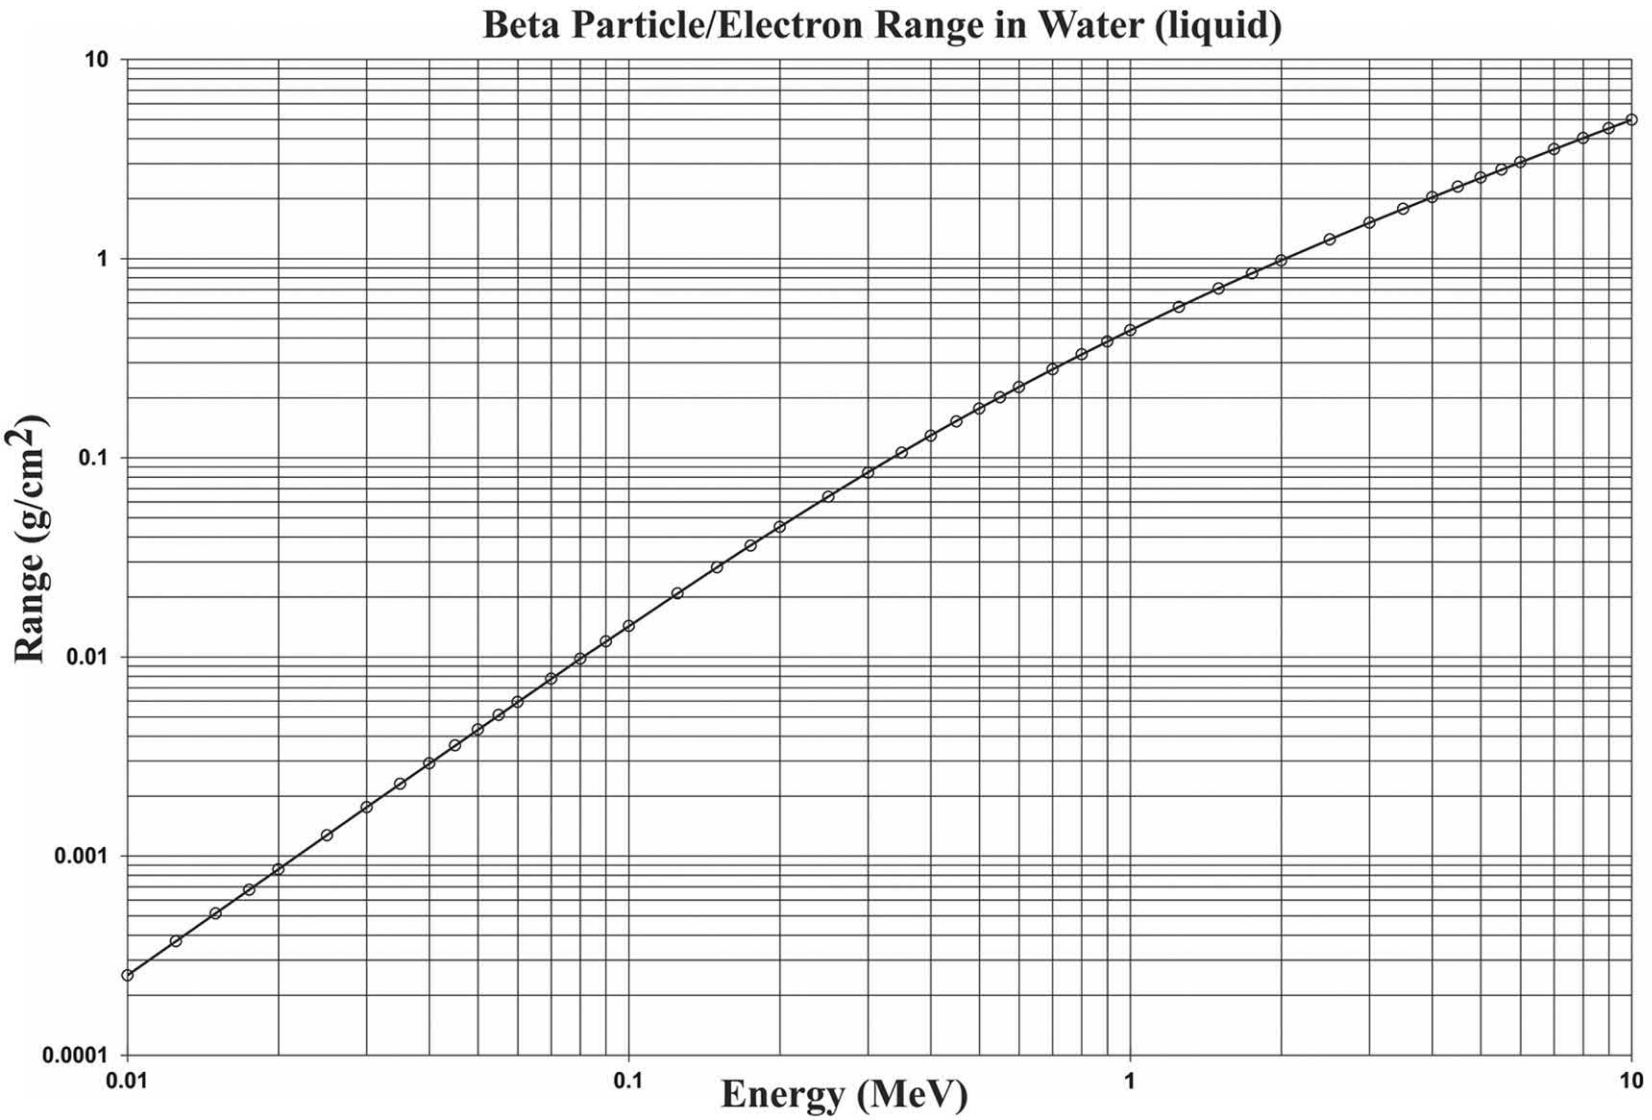

FIGURE B.3 Range-energy relationship for beta particles/electrons in water (liquid). The range in cm can be obtained by dividing the above range by the density of water ($\rho = 1.00$ g/cm^3 at STP). For example, the range of a 1.0 MeV beta particle from the graph is read as 0.43 g/cm^2; and dividing by the density of water yields a calculated linear range of 0.43 cm. The range-energy relationship is plotted from data provided by the National Institute of Standards and Technology (NIST) Database ESTAR (2018) for CSDA (continuous slowing down approximation) ranges from which very precise calculated values of range in a large number of elements and compounds may be found: http://www.nist.gov/pml/data/star/index.cfm.

Fig. B.4

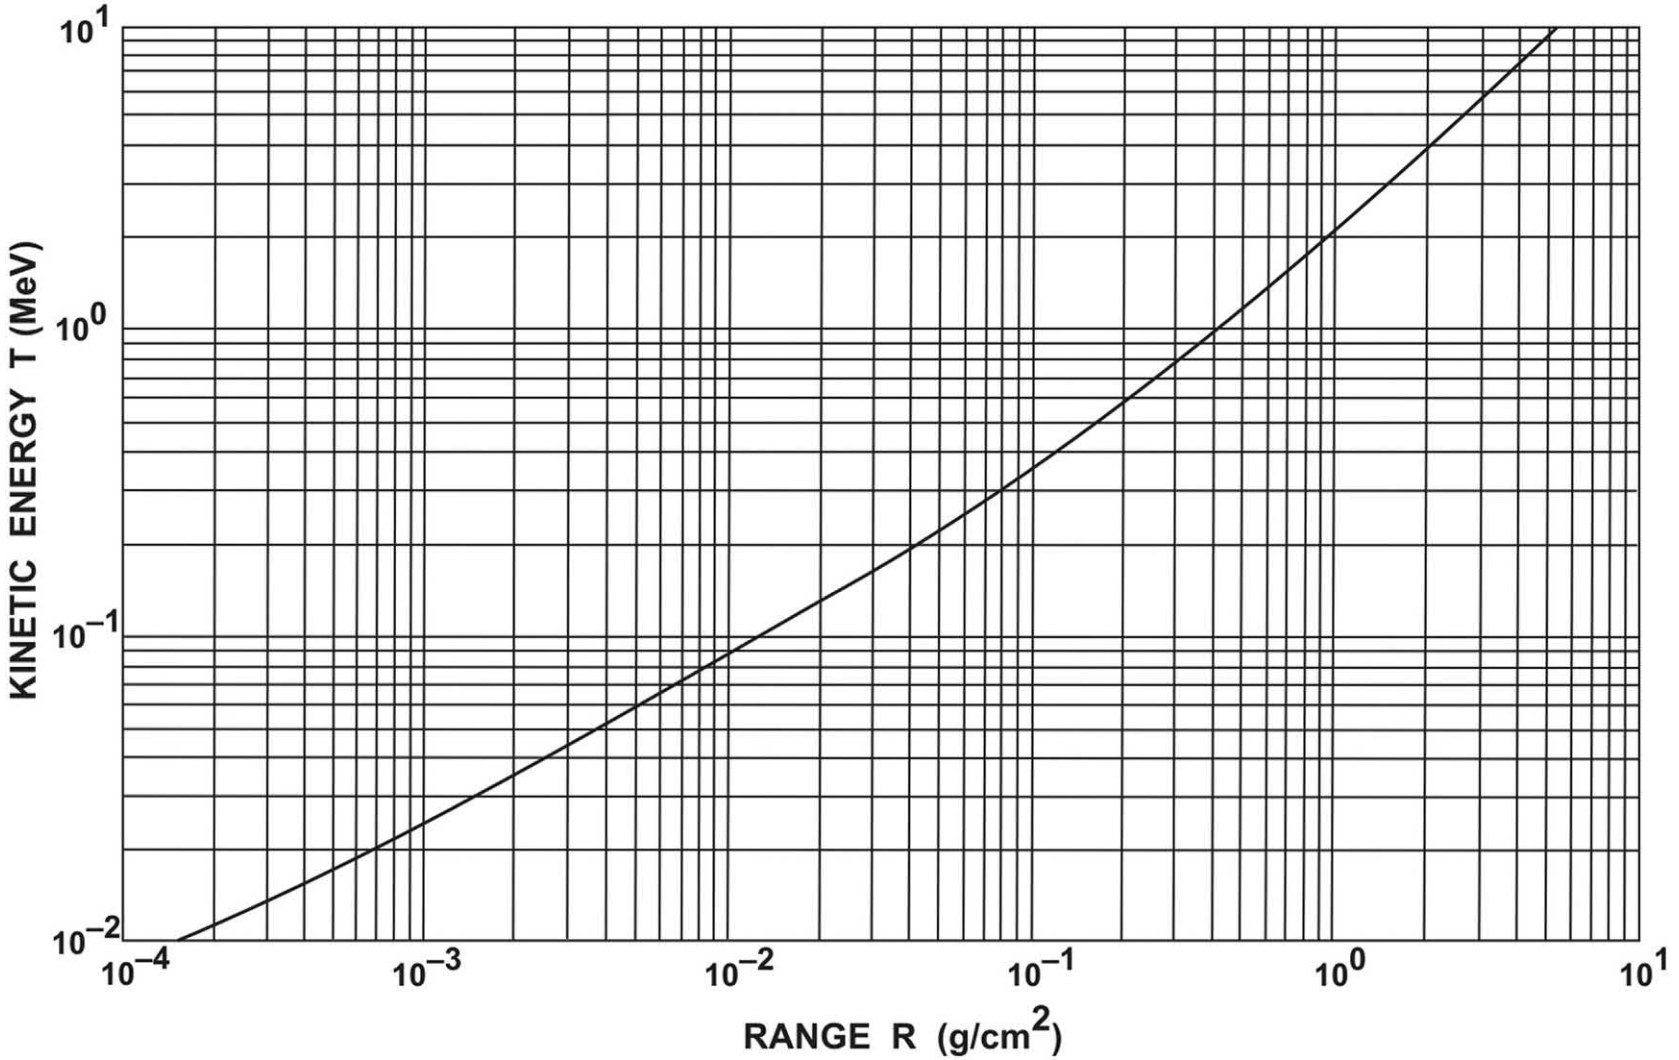

FIGURE B.4 Beta-particle range-energy curve for absorbers of low atomic number. The curve is described by the formulas $R = 0.412T^{1.27-0.0954 \ln T}$ for $0.01 \leq T \leq 2.5$ MeV and $R = 0.530T - 0.106$ for $T > 2.5$ MeV where T is the beta-particle energy in MeV. *From U.S. Public Health Service. (1970). Radiological Health Handbook. Publ. No. 2016. Bureau of Radiological Health, Rockville, MD.*

with organic MS and NMR, 793
Flow-cell radionuclide analysis, 729–820
Flow-cell sensors, scintillating extractive resins in, 766t
Flow cells
heterogeneous, 734–737
homogeneous, 734–739
Flow injection, 825–826
Flow scintillation analysis
in HPLC, 737f–738f
Flow scintillation analyzer, 734, 736f
chemiluminescence in, 760
Flow scintillation analyzers-NMR, 799–806
Flow scintillation cocktails, 763t–764t
Flow scintillation counting
principles of, 754–762
time-resolved, 760–761
Flow-scintillation detector, scintillator selection criteria, 762
Fluorine-18
autoradiography of, 695, 711
Cerenkov imaging of, 718
Fluorine-18-FDG
automated synthesis, 856
Fluorine-18, flow cell analysis, 741–744, 747
Fluorine-18 plus Technetium-99m
autoradiography of, 698
Forensic analysis, traditional, 941–944
Fork detectors, 876–877
Fraction collection, 730
Frank, Il'ja, 396–399
F ratio, 650
F-test, 636
Fukushima accident, 375
marine radioactivity and, 375
Fukushima NPP accident
^{137}Cs contamination from, 153f
radionuclides released from, 152
signal spike from ^{137}Cs, 154f
volatile radionuclides released, 153t
F values, 650

G

Galactic cosmic rays, 143
Gallium-68
automated generation and purification, 856
autoradiography of, 713–714
flow-cell analysis, 741–744, 745f
Medipix flow-cell analysis, 748–749
Gamma detector
sensitivity to beta radiation, 534
Gamma-ray attenuation, 878–879
Gamma-ray spectrometry
extended sources, 579–580
of marine radioactivity, 321–322
underwater, 321–328
underwater applications, 325, 326f
Gaussian distribution, 629–632
accumulated distribution function, 629–630
normalized random variable, 630
probability density function, 629
Geiger counter, 686f
Global fallout

Global fallout (*Continued*)
anthropogenic radionuclides in, 147t
Glow discharge mass spectrometry
environmental analysis by, 170

H

Half-life measurements
short-lived gamma emitters, 592
Heath method
critical point, 581
intrinsic efficiency, 580
total efficiency, 580
Heat flow calorimetry, 903–910
Heavyside, Oliver, 394
HERM electronics, 746–747
^{3}H-^{3}He ingrowth mass spectrometry
tritium trace analysis by, 170–171
High-performance liquid chromatography, 730–754
Histological imaging, 702
HPLC-FSA-NMR, 802–803
HPLC-mass spectrometry, 798
HPLC-NMR, 801
Hypothesis testing, 645–646, 653

I

IceCube Neutrino Observatory, 482–483
ICP mass spectrometry
radionuclides analyzed by, 168
Indian Ocean
Cesium-137 time series in, 369–370
Indium-111
autoradiography of, 711, 712f
Indium-111 plus Technetium-99m
autoradiography of, 698
Inductively coupled plasma mass spectrometry
of marine isotopes, 345–346
Inositol phosphates, soil
epimerization and origin in soil, 799–801
stereoisomers in soil, 799–801
In-situ gamma spectroscopy, 19–20
Intercomparison exercises, 360–362, 361f
Interlaboratory comparisons, 636–642
Internal gas counting
experimental aspects, 560
radionuclide standardization, 560–563
theoretical description, 560
International monitoring
European "Ring of Five", 234
International Monitoring System (IMS), 17, 233–234
Iodine-124
automated preparation and purification, 857–858
Iodine-125
autoradiography of, 671, 712, 713f
flow-cell analysis, 739–741, 747, 751
Iodine-129
anthropogenic, 156
flow-cell analysis, 768
marine environment analysis of, 349
natural occurrence, 87–88
sample preparation and analysis, 88
Iodine-129, on aerosols
analysis of, 196
applications, 196–197
origin and properties, 196–197
Iodine-131, flow-cell analysis, 740–741
Iodine in air, 16
Iodine-131, on aerosols
after Chernobyl accident, 196f
analysis of, 196
origin and properties, 196
Ionic liquids
definition, 429
Ionisation chamber
SIR reference system, 586
Ionization chambers
applications, 586–588
calibration of, 585–588
efficiency calculation, 588–590
half-life measurements with, 587
K_r factor of, 586
maximum accuracy, 584
Monte Carlo codes, 589
radon measurements, 588
Irish Sea
gamma-ray spectrometry of, 325–326
Iron-55
environmental occurrence, 73–75
flow-cell analysis, 751
Iron-55, environmental
sample preparation and analysis, 73–75
Irradiated Item Attribute Tester, 876–877
Isotopic composition measurements
ratio based, 884–885
Iterative PLS-DA, 928–929

K

Key Comparison Reference Value, 636
k factor, 644
Krypton isotopes
Atom-trap trace analysis, 186
Krypton-85 monitoring, 17

L

Lab-on-valve
radionuclide separations achieved, 830
Laboratory information management, 359–360
Lead-210
decay series, 105f
flow-cell analysis, 741, 769
gamma spectrometry, 105–106
in seawater, 332–334
in seawater and sediments, 333
Lead-210 and Po-210
alpha spectrometry, 106
Lead-212/bismuth-212
automated purification, 852
generation and purification, 851–852
Lead-210, bismuth-210 and Po-210
environmental occurrence and importance, 104–107
liquid scintillation analysis, 106–107
Least square fitting, 658
Linear regression, 651–653
Linear relationship, 651
Liquid scintillation analysis
of alpha-emitting transuranics, 60–62
Liquid scintillation analyzers, low level
definition, 42
Liquid scintillation counters
Beckman Coulter, 55
Hidex Oy, 54–55
Packard/PerkinElmer, 54
TDCR instruments, 54–55
Wallac Oy/PerkinElmer, 53–54
Liquid scintillation counting
alpha/beta discrimination, 51–58
alpha/beta misclassification, 57–58
Liquid scintillation counting, environmental
alpha/beta discrimination, 56
aqueous accepting cocktails, 55
definition, 42
energy resolution improvement, 112
extractive scintillators, 55–56
PERALS spectrometry, 110
software applications, 111–112
spectrum deconvolution, 109–112
spectrum unfolding, 110–112
TDCR method, 58
vial choice, 56
Liquid scintillation counting, low level
alpha/beta instrumentation, 52–55
applications, 42–43
background reduction, 43–51
cocktail choice, 50–51
counting environment, 51
counting region optimization, 48
counting vial holders, 49–50
counting vials, 49
passive/graded shielding, 44
process optimization, 48–49
pulse amplitude comparison, 45, 46f
pulse analysis, 51–52
pulse shape analysis, 45
pulse shape discrimination, 53–55
quasi-active detector guards, 47
region optimization procedures, 48
sources of background, 43
time-resolved, 45–47
Live-time
anticoincidence counting, 546–547
Live time clock, 546
Lower limit of detection, flow-cell detector, 758
Low-level alpha spectrometry
of marine samples, 340
Low-level beta spectrometry
of marine samples, 340–341
Low-level gamma spectrometry
of marine samples, 341–342
underground laboratories for, 342–343, 344f
Lutetium-177
autoradiography of, 711

M

Macroautoradiography, 675–678
  description of, 670
MALDI-MSI, 700–701, 701f
Marine environmental monitoring
  intercomparison exercises, 360
  management of data quality, 359–362
  radiological impact studies, 351–352
  reference materials in, 362
Marine environment analysis
  anthropogenic radionuclides, 335–336
  of cesium, 336–337
  ion-exchange separation, 330–331
  mass spectrometry in, 344–350
  particulate matter and sediments, 329–330
  of strontium, 337
  Th, U, and Pa electrodeposition, 331
  transuranics in, 336
Marine environment sampling
  particulate matter and sediments, 329
Marine radioactivity
  algae sampling, 320, 321f
  analytical methods, 316
  biota sampling, 319–320
  international studies of, 316–317
  mass spectrometric analysis, 316
  natural radionuclide analysis, 328
  from nuclear tests, 316
  particulate matter sampling, 320–321
  remotely operating vehicle detector, 323, 324f
  sampling and analysis, 317
  sampling techniques, 317–321
  sediment sampling, 318–319
  stationary detector systems, 323–324
  submarine groundwater discharge, 326–328
  towed detector systems, 323
Marine radioactivity databases, 362–365
Marine radioactivity studies
  sampling methods, 316
  worldwide, 365–372
Marine sediment and biota
  laboratory chemistry for, 339–340
Mass spectrometry
  ^{3}He in-growth spectrometry, 345
  of transuranic nuclides, 61
Mass spectrometry imaging (MSI), 700, 701f
Matrix-assisted laser desorption/ionization, 700–701, 701f
Mean, 632
  asymmetric distribution, 632
  symmetrical distribution, 632
Mean values, 663t
  accuracy, 634–635
Medical radionuclides
  alpha emitters, 850–854
  automated analysis and reactions, 848–858
  beta emitters, 849–850
  diagnostic, 854–858
  gamma emitters, 854–855
  positron emitters, 855–858
  therapeutic, 849–854
Medipix sensors, 747–750
Microautoradiography, 675
  of animal sections, 678f
  in bacteriology, 702
  of cells, 679
  description of, 670
  with emulsions, 678–680
  histology, 678
  performance, 678
  with QWBA, 702
  receptor studies, 679–680
  solid membrane detectors, 693–694
  staining in, 675
  techniques, 676
Microautoradiography - radionuclides, 678
Microradiography
  applications, 679–680
  use of ^{3}H and ^{125}I in, 678
  quantification in, 678–679
  resolution of, 678
  sensitivity of, 678
Microscopic autoradiography, 679
Minimal detectable activity, flow-cell detector, 758
Minimal detectable concentration, flow-cell analysis, 783
Minimum counting time, 657–658
Minimum detectable area, 656–657
Minimum detectable counting rate, 655
Minimum significant area, 656
Molecular imaging
  with Cerenkov radiation, 718–719
  in life sciences, 706–707
  in nuclear medicine, 706
  in pathology, 713
  validation, 713
  validation of imaging probes, 710–716
Molecular imaging - ex vivo, 671
Molecular imaging - PET, 702
Molecular imaging probes, 711
Monte Carlo technique
  international comparisons, 583
  ionization chamber simulation, 586
  low activity samples, 583
  sources of uncertainty, 582–583
M-P mean, 636
Multiplication
  leakage multiplication, 893
Multiwire proportional chamber, 686
Muroroa and *Fangataufa lagoons*
  gamma-ray spectrometry of, 324–325
Myo-inositol phosphates, soil, 801f
Myo-inositol, soil, 799–801

N

National nuclear forensics libraries, 928
Naturally occurring radioactive materials (NORMS), 2
Natural radionuclide analysis
  in marine environment, 328–335
Nautic Environment Marine Observatory, 323–324
Neptunium and other actinides
  analytical procedures, 223–225
Neptunium-237
  flow-cell analysis, 770
  ICP-MS analysis, 780t
Net counting rate, 655
Neutrino astronomy
  IceCube detector for, 482–483
Neutrino Cherenkov telescopes, 478–482
Neutrino flux measurements, total
  by neutral-current reaction, 478
Neutrino measurement
  atmospheric, 478
  Cherenkov counters for, 476–485
  Hyper-Kamiokande detector, 477
  large D_2O Cherenkov detector, 477–478
  Super-Kamiokande detector, 477
Neutrino measurement, all flavor
  by elastic scattering, 478
Neutrino measurement, ^{8}B
  by charged-current reaction, 478
Neutrino measurements, ultra-high energy, 483–484
  ANITA experiment, 484
  ARA detector, 485
  ARIANNA detector, 485
  Lunar Cherenkov technique, 485
  RICE detector, 484
  SALSA detector, 485
  TAROGE detector, 484–485
Neutrinos, high-energy muon
  principle of detection, 481f
Neutrino telescope
  ANTARES, 479–480, 481f
  BAIKAL, 479, 480f
  KM3NeT, 480, 481f, 482
Neutron-based safeguards
  coincidence counting, 896–899
  die-away time, 893–894
  efficiency, 893
  gate fractions, 894
  high-level neutron coincidence counter, 899
  known alpha technique, 899
  multiplicity counting technique, 899–902
  multiplicity shift register, 900–901
  neutron counter design, 894
  neutron counters, 893
  passive coincidence counting, 897–899
  point model assumptions, 900–901
  point model equations, 901
  ^{240}Pu effective mass, 897
  shift register electronics, 897–898
  singles counting, 894–896
  standard coincidence counting, 898
  well counters, 893–894
Neutron based safeguards measurements
  active coincidence counting, 899
  active neutron interrogation, 892
  active well coincidence counter, 899
  coincidence event, 891–892
  doubles, 891–892
  (α,n) neutron, 892
  ^{240}Pu effective mass, 891
  triples, 891–892
Neutron detector
  ^{3}He tube, 893
Neutron measurements
  in safeguards, 890

Neutron multiplicity counting, 902
Nickel-63
  environmental and waste samples, 74f, 77
  environmental occurrence, 75
Nickel-63, environmental
  sample preparation and analysis, 75–77
NMR chemical shift, 801–802
NMR shielding, 801–802
NMR spectroscopy, principles of, 801–802
Noble gas radionuclides
  key environmental, 183t
Noble gas radionuclides, environmental
  AMS of, 185–186
  applications of, 183
  gamma spectrometry of, 185
  gas proportional counting of, 184–185
  groundwater dating by, 184
  sample preparation of, 184
  sampling of, 183–184
Normal distribution, 631, 631t
  accumulated distribution computation, 631
  integration intervals, 630f
Northern blot analysis
  beta imaging, 706f
Novaya Zemlya bays
  gamma-ray spectrometry of, 325
NPP accident monitoring, 233–234
Nuclear accidents
  Chernobyl (Ukraine), 150–152
  Fukushima (Japan), 152
  radionuclides of interest, 6t
  Three Mile Island (USA), 149–150
Nuclear accident monitoring, 3

HANDBOOK OF **RADIOACTIVITY ANALYSIS**

FOURTH EDITION

VOLUME TWO

RADIOANALYTICAL APPLICATIONS

EDITED BY

MICHAEL F. L'ANNUNZIATA

The updated and further expanded **fourth edition** of the ***Handbook of Radioactivity Analysis*** is an authoritative reference providing the principles, practical techniques, and procedures for the accurate measurement of radioactivity—everything from the very low levels encountered in the environment to higher levels measured in radioisotope research, clinical laboratories, biological sciences, radionuclide standardization, nuclear medicine, nuclear power, and fuel cycle facilities and in the implementation of nuclear forensic analysis and nuclear safeguards. It includes sample preparation techniques for all types of matrices, including those found in the environment such as soil, water, air, plant matter, and animal tissue, and surface swipes.

Volume 2: Radioanalytical Applications describes in detail the latest advances in the applications of radioactivity analysis across various fields, including environmental monitoring, radiochemical standardization, high-resolution beta imaging, automated radiochemical separation, nuclear forensics, nuclear safeguards, and more.

Key Features

- Spans two volumes, ***Radiation Physics and Detectors*** and ***Radioanalytical Applications***
- Includes a new chapter on the analysis of environmental radionuclides
- Provides the latest advances in the applications of liquid and solid scintillation analysis, alpha- and gamma spectrometry, mass spectrometric analysis, Cherenkov counting, flow-cell radionuclide analysis, radionuclide standardization, aerosol analysis, high-resolution beta imaging techniques, analytical techniques in nuclear forensics, and nuclear safeguards
- Describes the timesaving techniques of computer-controlled automatic separation and activity analysis of radionuclides
- Provides an extensive table of the radiation characteristics of most radionuclides of interest for the radioanalytical chemist

Michael F. L'Annunziata, Oceanside, CA, USA

Michael F. L'Annunziata earned his undergraduate BSc degree in Chemistry in 1965 from St. Edward's University, and MSc and PhD degrees in 1967 and 1970, respectively, at the University of Arizona. His graduate thesis research in the 1960s was carried out under a research contract with the then US Atomic Energy Commission (US AEC). The research work dealt with the analysis of radionuclides and chemical remediation of the environment in the event of possible nuclear war and fission product fallout. His main research interests have been focused on the development of chemical and instrumental methods for the detection and measurement of radioactive nuclides and the utilization of radionuclides as tracers in biological research. L'Annunziata was formerly Head of Fellowships and Training at the International Atomic Energy Agency (IAEA) in Vienna, Austria; and he has served as a representative for the IAEA in fact-finding, planning, and implementation assignments on peaceful applications of nuclear energy for development in over 50 countries of the world from 1976 to 2007. He is the author and editor of several books, including *Radioactivity; Introduction and History, From the Quantum to Quarks* published by Elsevier in 2016, which received an Honorable Mention in the 2017 PROSE Awards and the *Handbook of Radioactivity Analysis* now in its fourth edition.
