About the Founding Editor

Michael F. L'Annunziata

Michael F. L'Annunziata, PhD, is the founding editor and coauthor of the *Handbook of Radioactivity Analysis*. He majored in chemistry with a BSc degree from St. Edward's University in 1965, and he was awarded MSc and PhD degrees from the University of Arizona, Tucson, in 1967 and 1970, respectively. His graduate thesis research in the 1960s, financed by the then US Atomic Energy Commission, dealt with the analysis of the radionuclides ^{89}Sr and ^{90}Sr and the remediation of soils contaminated with radiostrontium in the event of nuclear fallout, published as a thesis in 1967 (https://repository.arizona.edu/handle/10150/318640). After a short stint in the chemical industry (Amchem Products, Inc, Ambler, Pennsylvania) during 1970–71 as ^{14}C-tracer chemist, he joined the faculty at the Postgraduate College in Chapingo, Mexico, as a professor and thesis advisor during 1972–75, and during 1975–77, L'Annunziata was a senior research scientist at the Nuclear Center of the National Institute of Nuclear Research (ININ), Mexico, where he served also as a thesis research advisor to graduate students of chemistry of the Autonomous University of the State of Mexico in Toluca, Mexico, in the field of radionuclide analysis and applications. During 1977–91, he was a scientific officer in the Departments of Research and Isotopes and Technical Cooperation of the International Atomic Energy Agency (IAEA) in Vienna, Austria, where he served as IAEA Head of Fellowships and Training during 1987–91. From 1977 to 2007, he served as IAEA Expert in fact-finding, planning, and implementation assignments in peaceful applications of nuclear energy for development in more than 50 countries of the world in Asia, Africa, Europe, Latin America, and the Middle East. L'Annunziata was a member of the Board of Governors, International Science Programs at Uppsala University, between 1988 and 1991. His main research interests have been focused on the development of chemical and instrumental methods for the detection and measurement of radioactive nuclides as tracers in research. He was the first to postulate the soil microbial epimerization of myo-inositol to other inositol stereoisomers as a source of the stereoisomers of inositol phosphates in soils (PhD dissertation, 1970, https://dissexpress.proquest.com/dxweb/results.html?QryTxt=&By=L%27Annunziata&Title=&pubnum =) and in 1975 (*SSSA Journal* 39(2), 377–379) and first to demonstrate in 1977, with the use of the radioisotope carbon-14, the soil microbial epimerization of myo-inositol to chiro-inositol as a mechanism involved in the origin of the unique soil inositol phosphate stereoisomers (*SSSA Journal* 41(4), 733–736, https://dl.sciencesocieties.org/publications/sssaj/abstracts/41/4/SS0410040733). The first edition of the *Handbook of Radioactivity Analysis* was planned by L'Annunziata in 1995, and he edited and coauthored the subsequent editions, including the current fourth edition published by Elsevier in 2019. He has authored and coauthored 11 books since 1979 on radionuclide analysis and radiation physics among which his book entitled *Radioactivity: Introduction and History*, First Edition, published by Elsevier in 2007, was included on the Best Sellers List in Physics (*LibraryJournal Academic Newswire*) in 2008. His much expanded Second Edition entitled *Radioactivity: Introduction and History, From the Quantum to Quarks* (https://www.sciencedirect.com/book/9780444634894/radioactivity), published by Elsevier in 2016, was awarded an Honorary Mention in the 2017 PROSE AWARDS in the category of Chemistry and Physics.

Foreword

Radioactive sources play a significant role in promoting human development and health worldwide. Whether through its application to treat cancer, diagnose various diseases, develop new crop varieties, sterilize medical supplies, or provide clean energy, peaceful uses of radioactive sources are ubiquitous in our daily lives. These wide-ranging applications can only be implemented appropriately when radioactivity is measured precisely. Thus, the accurate measurement of nuclear radiation is indispensable for the peaceful applications of radioactive materials. For example, in fields such as nuclear medicine, whether for the treatment or diagnosis of disease, accurate measurements of radionuclides are essential. Dosimetric measurements are the cornerstone of safe and effective radiation therapy for the treatment of cancer whether for brachytherapy, proton beam therapy, or other sources of radiation therapy.

With more than 170 Member States in all continents of the world, the International Atomic Energy Agency (IAEA) serves as the global focal point for nuclear cooperation. The *Handbook of Radioactivity Analysis* will serve Member States as one of many tools available in the application of nuclear science and technology for peaceful purposes. The importance of this guidance is demonstrated by the wide range of areas in which the IAEA supports Member States to contribute to their well-being and development. Such examples include biological sciences research, insect pest control, health, fertilizer and water use efficiency, water resources and the environment including marine science and climate change, radiation technology, neutron diffraction, radiography and activation analysis, radiation processing in industry, radiation protection, nuclear power, nuclear safeguards, radiation preparedness and response, and research in the field of nuclear fusion, among others.

The *Handbook of Radioactivity Analysis* is now in its fourth edition since the successful first edition in 1998. Over the past two decades, this book has expanded in its scope from an initial 12 chapters to the current 22 chapters, encompassing the numerous modern applications and methods of radiation detection and measurement. The chapters in this book are written by experts from 16 countries around the world. This new edition will continue to serve as an important resource in our search to optimize radioactivity measurements both in research and in its applications, leading to the peaceful utilization of radioactive sources for health and development.

May Abdel-Wahab, MD, PhD, FACR
Director, Division of Human Health
Department of Nuclear Sciences and Applications
International Atomic Energy Agency, Vienna

Preface to the fourth edition

In 1996, I proposed to Academic Press the idea of a book that would provide readers with a reference source to state-of-the-art radiation detectors and methods of analysis of radionuclides and other sources of nuclear radiation. Thus, the first edition of this book was published in 1998 as a single volume with only 12 chapters, and the book has expanded in scope and depth over the past two decades with the current fourth edition and its 22 chapters in two volumes.

The numerous advances that have been made since the publication of the previous third edition warranted the partition of the *Handbook of Radioactivity Analysis* into two volumes. It was decided to separate the chapters into two categories, namely, Volume 1, *Radiation Physics and Detectors* and Volume 2, *Radioanalytical Applications*. The two volumes of this book were expanded greatly to provide material, which would serve as a valuable resource in teaching and a reference source to the researcher in his or her unique analytical requirements in the measurement of radioactive materials.

The first chapter in Volume 1, which was previously entitled *Radiation Physics and Radionuclide Decay*, was expanded to almost double in volume with a corresponding change in the chapter title to *The Atomic Nucleus, Nuclear Radiation, and the Interaction of Radiation with Matter*, which includes additional material helpful to supplement the academic curricula and aid in the decisions and calculations made by researchers in their measurement of nuclear radiation and radionuclide analysis. Current principles of operation of all classes of radiation detectors and their applications have been expanded and updated, including semiconductor detectors, gas ionization detectors, liquid and solid scintillation detectors, solid-state nuclear track detectors, Cherenkov detectors, calorimeters and bolometers, as well as advances in atom counting (i.e., mass spectrometry) for the measurement of radioactive and stable nuclides and radiation from other sources such as cosmic radiation, synchrotron radiation, and particle emissions from nuclear reactions.

In light of increased concern for radioactivity in the environment, a chapter was added on the *Analysis of Environmental Radionuclides* in Volume 2. Also, all chapters in Volume 2 have been expanded and updated with material required in the analysis of radionuclides and radiation in our land, air, and water resources, including the marine environment, as well as particle identification and measurement by Cherenkov counting, radiation counting statistics, radionuclide standardization, imaging techniques required in the applications of radionuclides in biological research and nuclear medicine, flow-cell analytical techniques, automation in radiochemical analysis together with analytical techniques required in the fields of nuclear safeguards and nuclear forensics.

Again, we have completed this book as an international effort by drawing upon the expertise of researchers and teachers from 16 countries of the world. Although coming from many branches of science, chapter authors all share one common objective, that being the most accurate measurement of radiation sources and radionuclides both natural and man-made, vital to all branches of science and human development. Readers interested in radiation physics, the applications of radionuclides and radiation sources, and how these have been vital to our well-being and development may refer to another text by the writer entitled "*Radioactivity: Introduction and History, From the Quantum to Quarks*" (ISBN: 978-0-444-63489-4), published in 2016 by Elsevier (https://www.elsevier.com/books/radioactivity/lannunziata/978-0-444-63489-4).

Women are the senior authors of three chapters in this new edition, which is evidence of the increasing role of women as leaders in this field of science. We may expect to see yet in the future an ever-increasing number of women, who will make great advances in this field of science following the pioneering examples of Marie Curie, Lise Meitner, Maria Goeppert-Mayer, Rosalind Franklin, Marietta Blau, and Chien-Shiung Wu, among others.

Mention of commercial products in this book does not imply recommendation or endorsement by the chapter authors or editor. Other or more suitable products may be available. Names of products are included for convenience or information purposes only.

I would like to thank the authors of each chapter, who have covered their fields of expertise with an unwavering commitment to meet the objectives of this book. Acknowledgment is extended to Kathryn Eryilmaz (nee Morrissey),

Aquisition Editor, at Elsevier in Cambridge for approaching me with the suggestion that we consider a fourth edition and for working with me during the planning stage of this book. Many thanks go to Hilary Carr, Elsevier Editorial Project Manager, for her constant support and advice throughout the writing and production of this book. I thank also Ashwathi P. Aravindakshan of Elsevier for her assistance in completing the legal requirements for the publication of this book. Appreciation is also extended to Prem Kumar Kaliamoorthi, Elsevier Production Project Manager, for his meticulous attention to every detail throughout the production process of this book. Thanks are also extended to Susan Dennis, Publisher of Elsevier Chemistry and Chemical Engineering Books, and Mona Zahir, Elsevier Editorial Project Manager, for their guidance and support during this project. Above all, I thank my wife Maria del Carmen (aka Reyna) for her understanding, encouragement, and unflagging patience.

Michael F. L'Annunziata, PhD

I. Introduction: objective of environmental monitoring

As recent history (e.g., IAEA, 2011; UNSCEAR, 2014; IAEA, 2015; IRSN, 2018) has shown to scientists and the public, transparent and comprehensible dose assessments, including estimation of doses as closely as possible to those actually received, are a fundamental basis of managing radiation protection. The most realistic assessment of doses is obtained by using measured activity concentrations in environmental media and measurements of external dose rates. Environmental monitoring provides data that permit the analysis and evaluation of radiation fields and radionuclide activity concentrations in environmental samples relevant to human exposure, primarily in air, drinking water, agricultural products, and natural foodstuffs, as well as in bioindicators that concentrate radionuclides and provide a measure of trends in activity levels.

Thus, environmental monitoring can be described as the exposition scenario–based systematic sampling and analysis of air, water, soil, and biota to assess environmental conditions. The objective of such monitoring is to obtain solid information that will serve as the basis for measures and political decisions. Environmental monitoring assessments can involve establishing baseline quality, uncovering environmental trends, identifying any variations, detecting new environmental issues, and determining the progress made to achieve environmental goals.

It is important to distinguish the specific aspects of environmental monitoring data obtained under normal

operating conditions from those obtained under emergency conditions since the criteria for evaluation are completely different. Under normal operating conditions, data are often important for the statutory control of releases, but the levels set are to be related to human tissue doses. In case of a possible accidental release of radioactivity, the monitoring program aims at answering questions, such as Has an abnormal release occurred? Is there action to be taken? and Which remedial measures should be brought about? Thus, distinction can be made between the following different situations:

Routine monitoring—emergency preparedness—emergency monitoring.

For each of these situations, the type of monitoring program to be established is influenced by the source of radioactivity as well as the scale of the spatial and temporal boundaries of the environment to be monitored. In the end, the goal of monitoring the environment always is to obtain a profound set of data that will serve as a basis that enables authorities to implement measures for either preserving environmental values or preventing their deterioration.

II. Types of monitoring programs

A. Routine monitoring

Routine monitoring programs aim at providing information on the overall dose received by the population at large. The setup of the monitoring is the result of an optimization process in which the availability of measurement resources, the relative importance of different exposure pathways, and the levels of activity and dose in relation to the regulatory constraints are taken into consideration. Routine environmental radiation monitoring programs are designed specifically for each facility, taking into account site-specific factors, such as climate, site location, the design of the facility and its barriers, geological and geomorphological conditions, the off-site environment, and the population distribution (IAEA, 2004); these programs are conducted both on and outside the site giving rise to potential exposure of the public to radionuclides in the environment.

The life cycle of the routine programs for environmental monitoring comprises preoperational studies, performed to establish "baseline" environmental radiation levels and activity concentrations for the purpose of subsequently determining the impacts of the source, monitoring during the operational phase, and decommissioning or post-operation monitoring, performed as long as the facility remains a potential source of radionuclides that could be released to the environment. The complexity of the program depends on the identities, quantities, and chemical and physical forms of radionuclides that may be released and on the characteristics of the monitored environment. Once a monitoring program has been implemented, it should be reviewed periodically to ensure that it continually fulfills the objectives.

The purpose of routine environmental monitoring of airborne radioactivity is to monitor domestic and foreign facilities. Sampling of soils, sediments, or deposits serves as an indicator of long-term buildup of radioactivity in the environment. Measurement of ingredients in foodstuff and water is intended to complete the monitoring program for the migration of radionuclides in the food chain or to check the contamination of the public at large by ingestion. Monitoring locations for ground- and surface water, sediment, biota, and foodstuffs are related to the potential migration pathways determined by preoperational studies, and the frequencies of sampling and measurements are specified with a view to the timely detection of significant changes in the release rates and concentrations of radionuclides and the associated levels of human exposure in accordance with the monitoring objectives.

It has to be noted that radon monitoring, which forms the main exposure to radioactive sources to members of the public (UNSCEAR, 2000b), is not implemented in environmental monitoring programs but conducted in special radon survey programs (e.g., Friedmann et al., 2007).

Recent attention has been paid to radiation risk to the people and the environment caused by exposure to ionizing radiation originating from naturally occurring radioactive materials (NORMs). NORMs touch many aspects of life, starting with occupational risk, through some "contaminated" goods, leisure activities including spa visits and ending with a huge amount of bulk waste often dumped in our vicinity (Kathren, 1998; IAEA, 2003). Such alterations to the natural state result in an increment of radiation risk to the people as well as to nonhuman biota. Each particular type of NORM determines a unique scenario of exposure usually differing from those caused by the artificial radionuclides (Martin et al., 1997).

The measurements must be adequate to determine radiation levels and trends of environmental radioactivity at levels just detectable, the parameters needed for subsequent dose assessment, and compliance with national or international standards, constraints, or limits laid down for the protection of the population. These limits and constraints have values that are typically less than exposure due to natural background radiation. It is, thus, necessary to be able to identify the source and to circumscribe the extent of the radioactive material with reasonable accuracy.

The objectives of routine monitoring programs are to

- provide information to assess the adequacy of protection of the public,
- meet requirements of regulatory agencies,
- verify radionuclide containment and/or waste management practices,

- meet legal liability obligations, and
- provide public assurance.

B. Emergency preparedness

Environmental monitoring may be conducted continuously to serve as a detection system. Emergency preparedness monitoring is part of a strategy for data and information acquisition. The overall emergency strategy includes two different modes of information, namely, (1) acquisition, as there are physical measurements of relevant data on one hand and (2) modeling of situations as a tool for interpolation and extrapolation in time and space where measurement data are sparse on the other hand. It is usually more satisfactory to make provision for detecting an emergency at its source, but detection by environmental monitoring may be required in some situations, for example, near frontiers. In a nuclear accident, the prompt monitoring of a large area may be needed. For this reason, automatic measuring stations that will continuously measure the dose rate in the environment installed around major facilities are capable of early monitoring. Continuously operated off-site systems have the advantage that they can provide rapid indication, not only that a release to the environment has taken place but also of the direction in which the released material is moving. Off-site systems do have the disadvantage that the detectors need to be considerably more sensitive than if sited near to the possible point of release and also need to be extremely reliable if duplication is to be avoided.

All of these systems may include such devices as continuous air samplers capable of measuring concentrations of airborne particles, gaseous iodine, and any other radionuclides of particular concern or water samplers for continuously scanning the sky or bodies of water for radiation. If a facility may contain large amounts of tritium, some special device to measure tritium may well be installed. In each case, the readings being telemetered back to a control center.

Systems intended to detect airborne releases by the use of air samplers introduce complex techniques, if early warning is required, because of the presence of the natural decay products of radon and thoron. However, if time can be allowed for these to decay, a simple measurement of gross alpha- or gross beta-activity will indicate whether conditions are seriously abnormal, although it must always be remembered that gross activity results cannot be interpreted in terms of hazard to man. The intended use of the resultant information gives guidance to the choice of monitoring priorities of such networks.

The objectives of emergency preparedness monitoring are as follows:

- Detecting any release
- Predicting plume trajectory
- Early government and public information
- Planning of urgent population protection countermeasures
- Planning of agricultural countermeasures and food restrictions

C. Emergency monitoring

Under emergency conditions, environmental monitoring is the most informative source of data. The measurements of the radiation levels or the levels of radioactive contamination are required for rapid assessments of the situation to inform those responsible for controlling the emergency so that countermeasures can be put in hand as a matter of urgency. Monitoring in emergency situations is also a valuable and fundamental tool to verify the effectiveness of the actions taken, for example, evacuation, closing the areas, use of stable iodine tablets, or banning the consumption of foodstuffs or water from defined areas.

History has shown that the requirements for the emergency monitoring program and the nature of relevant data will evolve with time. The procedures used in emergency monitoring can conveniently be grouped into three phases, namely, detection, initial survey, and subsequent surveys.

In the initial emergency response following an accident, where information is required with as little delay as possible, rapid and relatively simple, albeit crude, analytical methods may be preferred. This usually means a lesser sensitivity and thus a greater risk for errors. However, in any emergency situation, it is important that the results can be obtained relatively quickly. Under most conditions, this would amount to the use of dose rate and survey instruments.

Nevertheless, it should be ensured that the types of instruments available are suitable for the measurement purposes. For example, if the released material consists of only tritium or plutonium, then the typical beta–gamma survey instruments are not of much use and appropriate special instruments and/or monitoring techniques should be used.

At the early stage of an accidental atmospheric release, external exposure includes the contribution of radiation from the plume. Thus, initial surveys in the release phase of the accident will be focused on measurements of cloud shine and on the sampling of radionuclides from the plume to assess doses from external exposure and inhalation. In the postrelease phase, external gamma dose rate measurements are attributable mainly to radiation from deposits on the ground. Close to the installation, these measurements may also include the contribution of radiation from the source.

The external dose rate measurements should be supplemented as soon as possible by nuclide-specific analysis of representative samples of mobile environmental media and biota through which radionuclides could migrate and

reach the human habitat and thereby enter the human body. These are atmospheric air, soil water and groundwater, surface water, sediments, biota, and foodstuffs. Groundwater should be monitored through monitoring wells located at a sufficient depth around and downstream of the facility. These measurements may be pursued over longer periods of time. However, the assessment of the impact of short-lived nuclides such as iodine and ruthenium isotopes will be possible only if measurements are performed within a few weeks after the accident.

Once a release has ceased and deposition levels have stabilized, nuclide-specific deposition densities of all gamma-emitting radionuclides can be acquired rapidly by the use of *in situ* gamma spectrometry. Nevertheless, laboratory analysis of a large number of samples of soil, plants, water, agricultural products, and natural foodstuffs will be necessary to supplement the data provided by the *in situ* measurements.

During such subsequent surveys, it also will be necessary to perform a large number of measurements in different media in view of an accurate a posteriori assessment of the radiological impact. Such an assessment fulfills the need for adequate information of the public and may serve also further scientific investigations.

The specific objectives of emergency radiation monitoring in the environment are to

- provide accurate and timely data on the levels, extent, and duration of radiation and environmental contamination with radionuclides,
- provide detail of the physical and chemical characteristics of the hazard,
- assist in preventing and controlling the spread of contamination,
- assist decision-makers on the implementation of urgent, intermediate-, and recovery-phase population protection countermeasures, agricultural countermeasures, and food restrictions
- provide information for the protection of emergency and recovery workers,
- provide information for the public on the degree of the hazard,
- provide information needed to identify any people for whom long-term medical screening is warranted,
- confirm the efficiency of protective actions.

III. Fundamentals of environmental monitoring

A. Design of environmental monitoring programs

Monitoring design provides answers to the following questions: What will be monitored? What are the parameters to be measured? How will these parameters be monitored? Where, when, and how frequently will the parameters be measured. A monitoring program will be as valuable and effective as the questions identified are specific and focused and can be used to guide the development of a monitoring plan.

To be consistent with the objectives and the design of any monitoring program, one has to consider types and characteristics of critical radionuclides, modes of their release to the environment, including mechanisms for the transfer of radionuclides through environmental media, dispersion and reconcentration mechanisms, and their seasonal variation, existing levels of radionuclides in the environment and their variability, and exposure pathways that make the major contributions to individual doses, leading to requirements in terms of sampling, sample treatment, measurement technique, and the lower limit of detection or minimal detectable activity (IAEA, 2005). Moreover, the nature of the environment, as the location of the facility in relation to population centers and their composition and densities, surface waters, oceans, geological, meteorological, hydrological, and other natural conditions, which might influence the dispersal of released radionuclides, has to be taken into account.

A key feature in designing environmental monitoring programs is the identification of potentially critical radionuclides, pathways, and groups or individuals potentially affected.

In the considerations of the limitation of dose to the general public from ionizing radiation, doses to individuals, to critical groups, and to the general population are distinguished. As early as 1965, the ICRP (1965) defined a critical group as that "whose exposure is homogeneous and typical of that of the most highly exposed individuals in the exposed population." In 2006, the ICRP introduced the new concept of a representative person, defining it as "an individual receiving a dose that is representative of the more highly exposed individuals in the population" (ICRP, 2006). The term "representative person" describes an individual with characteristics that reflect those of the group that receives the highest doses from a particular source, known as the representative person for the radionuclide in question, and replaces the "average member of the critical group" defined in previous publications of the ICRP. In any case, critical groups or the representative person may be in the vicinity of the installation or at some distant location. To assess the annual effective doses for both critical group and representative person, methods recommended by the International Atomic Energy Agency (IAEA, 1982; IAEA, 2001) can be used. A more conservative concept to assess doses to the public is given in US Regulatory Guide 1.109 and based on the individual of maximum dose (US NRC, 1977).

Routes from a source of radionuclides and/or radiation to a target individual or a population through media in the environment are defined in the exposure pathways.

There are two main categories of exposure pathway:

- External exposure from radionuclides present in the air or in material incorporated in, for example, soils or sediment, determined by direct measurements of external dose or by soil analysis.
- Internal exposure from the inhalation, ingestion, or immersion of radionuclides present in air or incorporated in water or foods, respectively. Immersion and inhalation are monitored by air sampling. Ingestion of radioactivity is monitored by means of food sampling, for example, milk, fish, and shellfish, or indicator organisms or materials.

Generally, a range of potential pathways that may be more complicated in reality need to be considered (Table 1.1). The relative importance of different exposure pathways will be dependent upon

- the magnitude of the discharge,
- the route of discharge and factors affecting it (e.g., stack height, meteorological conditions, etc.),
- the physical state or properties (e.g., emission type, energy, physical half-life, gas, liquid, or solid),
- the chemical characteristics (e.g., organic or inorganic form, oxidation state, speciation, etc.)
- the dosimetric importance of radionuclides,
- environmental characteristics (e.g., climate, type of biota, agricultural production, etc.); locations, ages, diets, and habits of the exposed individuals or population.

Under conditions of normal discharges and chronic (prolonged) exposure, the pathways are usually permanent and well defined. In case of emergency releases, the contributions via different pathways to the doses received by workers and the public may be different from the normal and transient. These differences should be considered when establishing the monitoring program. To protect the public and workers from deterministic health effects following major accidents, radiological criteria in emergencies may be different from those applied under conditions of normal discharges (e.g., additional monitoring data may be necessary).

Under normal operation conditions, that is, for routine environmental monitoring, those radionuclides are to be considered, which are limited in discharge permits or are significant components of a group limit (e.g., strontium-90 limited under any other beta/gamma-emitting radionuclide group limit). Other radionuclides may be required as a result of international obligations or backgrounds. Proven surrogate radionuclides may be used (e.g., where the radionuclide fingerprint is relatively stable). Since routine monitoring programs are designed to verify compliance with environmental standards at levels just detectable and which are for records only by low-level measurements, it is essential to be able to identify the source and to circumscribe the extent of the radioactive material with reasonable accuracy.

Preoperational assessments of the expected inventories of radionuclides during operation of a facility, the possible discharge pathways and the likely amounts that will be discharged to the environment, with due consideration of the

TABLE 1.1 Important exposure pathways to be considered in the monitoring program.

External exposure pathways	
Source of radiation → human	Direct exposure from a source
Source of radionuclides→ atmosphere or water body → human	Exposure due to the plume or water
Source of radionuclides → atmosphere or water body → human skin	Skin contact exposure
Source of radionuclides → atmosphere or water body → soil or sediment or building surface or vegetation → human	Exposure from deposited radionuclides on the ground, on the shores of rivers, lakes, or the sea; on walls, roofs, and floors; or on trees, bushes, and grass
Internal exposure pathways	
Source of radionuclides → atmosphere → human	Inhalation of radionuclides in the plume;
Source of radionuclides → water body → human	Ingestion of radionuclides in drinking water
Source of radionuclides → atmosphere or water body → (soil or sediment) → vegetation → meat, milk, eggs, vegetables, or marine food → human	Ingestion of radionuclides in food or beverages
Soil or sediment → human	Inhalation of resuspended radionuclides
Source of tritium → atmosphere → human	Absorption of tritium oxide through the skin

effluent treatment systems that will be installed, will help to define spatial and temporal boundaries and select types and numbers of samples and measurement methods. A preoperational program intended to establish baselines might also identify suitable indicator organisms or indicator materials for particular radionuclides. Indicators such as seaweeds, lichen, or suspended particulate matter are selected not because they represent a component of the human diet but because they concentrate radionuclides and provide a measure of trends in activity levels and hence may provide more sensitive information of environmental contamination.

Environmental monitoring during the decommissioning of a facility, such as uranium mines and mills, uranium enrichment plants, fuel fabrication facilities, nuclear reactors (IAEA, 1998, 1999; 2001, 2002a, 2002b), nuclear fuel reprocessing plants, and other radionuclide processing facilities, will be similar to that for the operational stage, modified to take account of changes in the source term, all materials exhibiting significant levels of activity (FAO, 1996) are removed as decommissioning proceeds. For both current and historical discharges, in-growth of daughters may need to be considered (e.g., ^{241}Am from ^{241}Pu).

The most important radionuclides to be assessed following a release of radionuclides from a uranium-fueled reactor to the environment are ^{134}Cs, ^{137}Cs(^{137m}Ba), ^{131}I, and other gamma emitters; the beta emitters ^{89}Sr, ^{90}Sr, and tritium; and the alpha emitters ^{238}Pu, $^{(239\ +\ 240)}$Pu, ^{241}Am, and ^{242}Cm. This group of radionuclides is most likely to be of concern due to internal exposure from inhalation and ingestion of food and water and to the contamination of environmental materials, which are part of the immediate pathways, leading to contamination of food (Table 1.2). Biological concentration in freshwater and marine systems can result in very rapid transfer and enrichment of specific radionuclides. Radionuclides that enter such systems can, in certain cases, be rapidly accumulated by plankton and algae, which serve as food for higher trophic levels; thus, the radionuclides become concentrated in organisms such as oysters, clams, shrimp, etc.

Radionuclides of particular concern in freshwater and marine food chains include ^{54}Mn, ^{55}Fe, ^{59}Fe, ^{60}Co, ^{65}Zn, ^{95}Zr, ^{95}Nb, ^{103}Ru, ^{106}Ru, ^{110m}Ag, ^{125}Sb, ^{131}I, ^{134}Cs, ^{137}Cs, ^{141}Ce, ^{144}Ce, and some of the transuranic elements.

Many other radionuclides would be present in debris from a nuclear accident; their potential contribution to human exposure depends on the type of accident and the circumstances at the time of the accident. Since there are several types of fuel, the spectra of radionuclides that would be present in accidental releases could be somewhat different.

The levels of radionuclides in the environment and food and their variability have been extensively compiled by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR, 2000b, 2000c). These reports contain information about the transfer of radionuclides between atmospheres, waters, soils, biota, and person and about human exposure to the various nuclides (UNSCEAR, 2000a, 2008).

What site or environment will be monitored, what will be measured, where will it be measured, and when and how frequently will it be measured are essential elements of a monitoring design. However, as the development of the monitoring design almost always requires clarification and prioritization, documenting the design, including rationale for decisions, is critical when the design is implemented and when the collected data are used for reporting to national policymakers, international forums, and the public.

Identification and assessment of the potentially critical radionuclides, pathways, and groups or individuals is a substantial prerequisite in designing environmental monitoring programs, directly affecting the nature and extent of the measurements. The selection of the major contributing radionuclides and their significant pathways to the predefined target population or individual direct the monitoring programs to the most important subjects. The following principles for the development of a practical monitoring program involve steps that are reasonably independent of local circumstances:

TABLE 1.2 Radionuclides of interest and related media in case of a nuclear accident.

Samples	Radionuclides
Air	^{131}I, ^{134}Cs, ^{137}Cs
Water	^{3}H, ^{89}Sr, ^{90}Sr, ^{131}I, ^{134}Cs, ^{137}Cs
Milk	^{89}Sr, ^{90}Sr, ^{131}I, ^{134}Cs, ^{137}Cs
Meat	^{134}Cs, ^{137}Cs
Other foods	^{89}Sr, ^{90}Sr, ^{134}Cs, ^{137}Cs
Vegetation	^{89}Sr, ^{90}Sr, ^{95}Zr, ^{95}Nb, ^{103}Ru, ^{106}Ru, ^{131}I, ^{134}Cs, ^{137}Cs, ^{144}Ce
Soil	^{89}Sr, ^{90}Sr, ^{134}Cs, ^{137}Cs, ^{238}Pu, $^{(239+240)}$Pu, ^{241}Am, ^{242}Cm

- Define the objective.
- Evaluate sources of direct radiation and radionuclides, especially the composition, concentrations, release rates, points of release, and physical and chemical forms of nuclides.
- Identify the pathways leading to exposure to man from source data by the use of analytical models for the possible pathways and by the use of experience gained at other sites and data on local meteorology, hydrology, and population distribution and diet.
- Select the significant pathways that may be critical in terms of their contributions to exposure and determine the critical population groups.
- Consider the available analytical methods to select the most effective combination of in situ measurements, sampling, chemical separation, and radionuclide analysis, that is, one that yields the required information with least effort.
- Determine the consequent measurement requirements to provide data for dose assessment for both normal and abnormal conditions.
- Allow for flexibility in the design as operational experience is accumulated and indicates that other types of measurements or measurement frequencies may be desirable as the pathways and the other program requirements become better defined.

B. Sampling strategies

The term sampling refers to strategies in selecting a subgroup from a larger group and then uses this subgroup as a basis for making inferences about the larger group. The sampling strategy designed and adopted must deliver the necessary confidence and power to allow the appropriate inferences to be drawn. To do that, a number of important factors should be considered, including the nature of the control measure, the contaminant concerned, the nature and location of the inputs, and statistical aspects of sampling and analysis. The resulting measurements made following the strategy should meet the requirements for emergency or regulatory management, or simply for compliance purposes. The theoretical sampling strategy provides, as a minimum, a plan of what and where to measure, how many sampling units to collect, the time frame over which sampling units should be collected, and the sampling frequency. The consultation of experienced statisticians during the sampling design process may be appropriate.

Generally, sampling strategies can be classified as either nonprobabilistic or probabilistic. Nonprobabilistic sampling is used when the sampling location of most interest is already known or on suspected sites with no need to sample elsewhere, that is, judgmental sampling by subjective selection of sampling locations. Probabilistic strategies, based on statistical considerations, on the other hand are common when it is possible to sample only a small percentage of the whole. This type of sampling involves a selection process in which each element in the population has an equal and independent chance of being selected. Five main methods include the following:

1. Judgmental (sample is taken on the judgment of the sampling person)
2. Simple random (arbitrary collection of samples, having the same probability of being included),
3. Stratified random (random sampling based on additional information)
4. Systematic random (random sampling within subdivided smaller areas of the original area)
5. Systematic grid (subdividing the area of concern and collecting samples from the intersections of the grid lines)

By using statistical methods, probabilistic sampling attempts to increase the probability that generalizations derived from the sample will be correct. Of the many types of sampling strategies described in the literature, all are useful in certain situations, but none is perfect. For example, a significant danger of using only probabilistic sampling techniques in field survey is that a major site may be overlooked, resulting in a skewed analysis and nonrepresentative result. In any kind of environmental monitoring program, the sample representativeness is an important issue. Representativeness in this context means that the sample should reflect the conditions in the environment from which it is taken. A representative sample may be defined as one being able to answer questions in terms of radiological information for which the analyses are performed. To put it in a more mathematical way, a representative sample parallels the key variables and characteristics under examination and allows the collected results to be generalized to a larger population of which it is a subset.

In general, nonprobability sampling is less likely to produce a set of specimens that is representative of the population than valid probabilistic sampling, but representativeness of environmental samples is difficult to demonstrate and usually considered justified by the procedure used to select the samples (Gilbert and Pulsipher, 2005). It is necessary to keep in mind that site-representative samples are not necessarily representative in a statistical sense. Accuracy and precision, which are quality requirements on the analysis process, are of not much worth if the samples are not representative to characterize site conditions.

The inherent variability of environmental samples necessitates careful design of sampling strategy. Since under monitoring conditions the reasons for the variability cannot be fully understood, a predefined sampling strategy should be used that is closely connected with an appropriate

statistical evaluation of the measured activities. In general, activity levels in terrestrial samples are subject to spatial and temporal variability caused by various factors such as inhomogeneous spatial distributions of the deposited radioactive material in soil, redistribution of radionuclides by wind or by water erosion, differences in soil conditions and agricultural practices, and the superposition of different exposure pathways such as foliar uptake and root uptake. Although this may not eliminate the uncertainty associated with activity levels in environmental samples, it may reduce the uncertainty and enable it to be quantified by statistical means.

In the case of normal discharges from licensed facilities, sampling locations should be selected close to points where the maximum exposure or deposition is expected, preferentially in the main wind direction for airborne discharges or downstream from the release point for aquatic discharges and at the site boundary for direct radiation from the source (Table 1.3).

Details of statistically based sampling designs, the process of identifying survey unit sizes, laying out systematic or random measurement grids, and methods for collecting samples are given in existing guidelines (e.g., NRC, 1998a; NRC, 1998b; NRC, 1992; CIRIA, 2000; BSI, 2001; MARSSIM, 2002; IAEA, 2005; USEPA, 2006; ICRUM, 2006), in international standards (e.g., ISO 18589-2, 2007), and in classic statistical sampling textbooks, including Cochran (1977), Thompson and Seber (1996), Thompson (2000), and Barnett (2002).

There are some considerations in sampling radionuclides beyond those shared with other types of environmental sampling. The type of radiation emitted by a radionuclide affects sample selection and eventual treatment, because relatively nonpenetrating radiation such as alpha particles must be measured in very small amounts of material, while gamma rays can be conveniently detected in bulk or unprocessed material.

A common problem in collecting and storing a sample of gas or liquid is loss of the radionuclide to the apparatus and container surfaces. Selection of relatively nonretentive materials and minimization of areas and collection and sample transition times are recommended. Information on the magnitude and rate of uptake by surfaces is widely scattered and qualitative, however, and no materials as appropriate to the entire spectrum of encountered radionuclides are known.

To minimize losses during sample collection and storage, containers of appropriate composition should be used. The liquid contents can be frozen, acidified, or otherwise modified, by adding a complexing agent or stable carrier. While it is important to avoid losses to container walls during storage, it is also important that the pretreatment will not induce a change in the distribution of the radionuclides between the liquid and particulate matter or induce volatility losses of radionuclides.

The sampling frequency will depend on the item to be measured and the variations with time in the activity concentration in the media. In routine monitoring, the temporal fluctuations are generally relatively low, so the frequency may consequently be low. The time intervals between measurements should reflect the half-lives of the radionuclides that are to be monitored. If the sampling time on a filter is long in comparison with the half-life of the radionuclide concerned, this radionuclide may not be detected and the purpose of the monitoring is missed.

Samples are either taken manually from the environment or accumulated in unattended devices and analyzed in the laboratory or possibly in the field. Some collection devices have detector and recording systems that measure sample emissions during collection. Depending on the time response, online and off-line sampling/measuring devices are distinguished. For continuous monitoring systems, sampling and counting times are identical, thus providing the information nearly real time. A reduction of sampling/counting time of online systems is tied to an expense of statistical error, which in turn would demand an increase in the alarm levels. Shortcomings of online sampling systems are in the limited possibilities of physical or radioanalytical sample preparations used to accumulate the radionuclides or for nuclide-specific techniques, thereby leading to lower limits of detection, which are higher compared with off-line sampling and measurement.

Nevertheless, determination of radionuclide concentrations in environmental materials collected and brought into a laboratory for analysis is the primary approach in environmental radioactivity measurement. Samples that yield

TABLE 1.3 Pathways and related samples to be taken.

Release	Pathway	Samples
Atmospheric	Inhalation	Air
	Ingestion	Foodstuff
	External	Soil, direct measurement of ambient dose equivalent
Liquid	Ingestion	Marine food
	External	Water, direct measurement of ambient dose equivalent

information most directly on radiation exposures of populations such as air, food, and water are of greatest interest in monitoring programs. In some circumstances, field measurements are sufficient, as there are a wide variety of in situ measurement techniques available, including box counters, portal monitors, in situ gamma spectroscopy systems, and direct measurements with handheld instruments. In situ surveys are able to determine the radiation field properties, identify radionuclides, and determine their approximate concentrations but characterized by limited numbers of measurements with relative long count times. Thus, they may be combined with sampling and laboratory analysis. Laboratory determinations usually yield better descriptions of the analyzed material, greater analytical accuracy, and the required sensitivity for radionuclides that do not emit penetrating radiation. On the other hand, sampling requires greater efforts, provides information less promptly, and requires additional interpretation for relating analytical results to the required environmental information.

The general principles that apply to all sampling activities include the following:

- The selection of types and location of in situ measurements or sample collections and analyses, as well as the sample size and collection frequency to identify the radionuclides of interest, is to be based on information sources and modes of transfer through the environment of radionuclides.
- The radionuclide concentration, the sensitivity of the radiation instruments, the capability of analytical methods, and the coordination of sampling and laboratory schedules define the numbers of samples.
- All necessary parts of the sample are to be collected, and the samples have to be adequately preserved, so that loss of radioactivity between the time of sampling and analysis is known or negligible.
- Sufficient background samples are needed to provide information on preexisting nuclides from those under consideration.
- Sufficient replicate samples should be collected to determine variability of concentrations.

C. Sample preparation

High-sensitivity environmental analyses share common technologies, methods, processes, and information needs regardless of whether they are being used under normal operation conditions or in emergency situations.

Generally, sample preparation may include, but is not limited to, removing extraneous material, homogenizing, splitting, drying, compositing, and final preparation of samples, to distinguish the desired radionuclides from others that interfere with the final measurement by producing a response in a detector, to increase the specific activity so that the radionuclides can be measured with improved sensitivity or accuracy, and to reduce self-absorption in the sample matrix for measurement of alpha and pure beta emitters and low-energy photons.

Sample preparation without recourse to special chemical separations is limited to total alpha-, beta-counting and gamma spectrometry, but the samples have to be brought in suitable form for measurement, which means a uniform distribution of the radioactive substances throughout the sample and the same sample size, thickness, and configuration within each group of samples. The question of homogeneity becomes even more important as the range of the radiation becomes shorter, since self-absorption and the sample detector geometry may vary in different parts of the sample. Calibration of these samples is usually performed with locally made standards having the same physical properties and known quantities of the appropriate radionuclides, in addition to traceable standards.

Any radiochemical analysis usually starts with obtaining a solution by the destruction of organic material in the sample. Materials that contain little organic matter can be dissolved directly, since the dissolution treatment with oxidizing acids will also remove the organic portion. Most samples, however, must be oxidized first by wet ashing (reaction with oxidizing agents in solution), dry ashing, with oxygen, or at room temperature with electrically excited oxygen. When samples are heated, care is to be taken to avoid loss of the desired constituents by volatilization and splatter. For example, samples to be analyzed for radioiodine cannot reliably be heated in the dry state but should be wet-ashed unless iodine is in one of its more highly oxidized states.

When igniting samples containing much organic matter, such as food, the temperature should be raised gradually over an extended period to avoid flame-burning and to minimize glow-burning. Losses of small particulates by spattering can occur under these conditions. A partial oxidation of biological samples with nitric acid, followed by ashing in a muffle furnace, allows a lower final temperature (400−450°C) and will oxidize some of the volatile elements to less volatile forms.

Destruction of organic matter does not complete the sample preparation process if chemical separations are to be performed and the inorganic ash must also be dissolved. Complete dissolution of the sample is not necessary if it can be shown that the desired nuclide is completely leached.

Incompletely oxidized samples (gray ash) will be acceptable for gamma spectroscopy and many subsequent dissolution procedures. Usually, the dissolution process of residues will oxidize small amounts of organic matter remaining after ashing, such as the gray ash. The samples may be entirely or almost entirely dissolved in nitric or hydrochloric acids, or in their mixtures. Substances not easily dissolved with acids must be fused with appropriate

fluxes to obtain a solution. The higher temperature increases the reaction rates but may vaporize some radionuclides. A combination of acids and fusion, such as that as much as possible of the sample, is first dissolved by mineral acids, including hydrofluoric acid, and the insoluble residue dissolved by fusion is often convenient.

Any dissolution procedure should also include steps to ensure that any added carrier or tracer is in the same chemical form as the nuclide being analyzed. Whatever method is used to measure the recovery of a chemical separation procedure, isotopic exchange or chemical and physical equivalency between the radionuclide in the sample and the added carrier or tracer is essential. Isotopic exchange such as converting multivalent elements to their highest or lowest oxidation states (e.g., hypochloride oxidation of iodine or ruthenium, sulfite reduction of plutonium), or complexing or dissolving radium and barium sulfates (diethylene triamine pentaactetic acid [DTPA] or sodium carbonate fusion), should be undertaken, as early as possible in the analysis, before any chemical or physical operations are performed that might result in loss of the desired nuclide. For many nuclides, dissolution in mineral acids is sufficient to effect isotopic exchange.

Attention must also be paid to the chemical and physical form, that is, the ionic or nonionic form and oxidation state, of the radionuclide aside from the isotopic exchange question, even when the carrier or tracer is not used. To put it in a simple way, the radionuclide must be brought into a form in which it undergoes the expected reactions in the separation process.

The fundamentals of the conventional radiochemical methods are precipitation, coprecipitation, ion exchange, and solvent extraction (ISO 18589-4, 2009; ISO 18589-5, 2009). A great variety of methods have been developed in the past, but the most valuable development of the past years has been the development of extraction chromatographic materials, such as Sr-specific crown ether-based material, Sr resin, or the transuranium element−specific extraction chromatographic materials, (UTEVA, TRU, TEVA resins), developed by Horwitz et al. (1991, 1992a, 1992b, 1993, 1995). These materials have become commercially available as the registered products of Eichrom Technologies, Inc. and TrisKem International SAS, and these have replaced conventional methods based on a series of precipitations.

In addition to procedures for the individual determination of the nuclides, a great variety of combined procedures for the simultaneous determination of actinides and radiostrontium isotopes in a variety of environmental substances based on different combinations of ion exchange separation and extraction chromatography or the even pure extraction chromatography have been developed (Moreno et al., 1997; La Rosa et al., 2001; Mellado et al., 2001; Maxwell, 2006, 2007; Maxwell and Culligan, 2009; Maxwell et al., 2010; Michel et al., 2008; Łokas et al., 2010; Spry et al., 2000; Lee et al., 2011; Wand et al., 2004; Berlioz et al., 2005; Thakkar, 2002; Tavcar and Benedik, 2005; Martin and Odell, 1998; Hrnececk et al., 2005; Srncik et al., 2008).

Typically combined procedures are starting with the separation of Pu and Th by anion exchange resins from concentrated HNO_3 solution from Sr and Am, which are collected together with other sample components in the effluent. Following preconcentration, Am can be separated using a TRU column. Additional purification from lanthanide impurities may be based on an anion exchange resin or the TEVA resin, whereas Sr is separated on a Sr resin column. Recently, three review papers about the analytical methodologies for the determination of plutonium as well as ^{241}Am and ^{90}Sr/^{90}Y have been published (Vajda and Kim, 2010a,b,c).

Attention must be paid to some important details. For example, the concentration of ^{239}Pu in surface or ocean water from fallout is of the order of 20 μBq/L, or about $5 \cdot 10^{-17}$ M, and this concentration is obtained with $2 \cdot 10^{7}$ atoms. In soil, a common plutonium concentration from fallout is about 2 mBq/g. This activity can be obtained from one plutonium oxide particle with a diameter of 0.1 μm. At the very low concentrations frequently encountered, contamination of the sample with extraneous radionuclides during processing must be avoided, and the blank value must be known and kept low and constant. In addition to a low blank, high radiochemical purity in the separation is also needed for good accuracy and sensitivity. Reagents must be carefully checked for radioactivity. For example, the environmental concentration of thorium is approximately 10^3 times that of the chemically similar plutonium; thus, decontamination from thorium by a factor of 10^5 or more is required for a satisfactory plutonium analysis.

These difficulties encountered as a result of very low concentrations can be avoided by adding macroquantities of inactive isotopes of the same element, or of similar elements if no stable isotope exists. This procedure, the use of carriers for radioactive tracers, is frequently used for measuring the chemical yield of a separation procedure. The chemical separations are greatly simplified since now the element can be expected to exhibit its normal behavior, and the analytical problem is no longer one in ultratrace chemistry.

D. Measurement and quantification

For a long time, the outstanding measurement method in environmental monitoring has been the determination of gross alpha- and gross beta activities applying gas-flow proportional counters after preparing a solid sample of known thickness and area. The sample can be the residue remaining after evaporation of a water sample, soil, sediment, ashed vegetation, or other solid material. Since the

samples generally contain an unknown radionuclide mixture, an arbitrary choice must be made in selecting a standard for calibration of the counting system and determining the conversion of sample counting rates to disintegration rates. The arbitrary but necessary choice of a standard nuclide introduces the largest uncertainty in the disintegration rates inferred from counting rates of thick samples, since correction factors are energy dependent, but by convention, the same alpha counting efficiency is assigned for all the alpha emissions and the same beta counting efficiency is assigned for all the beta emissions (ISO 18589-6, 2009).

Advances in gamma spectrometry, in alpha spectrometry and in liquid scintillation counting (LSC) and spectrometry for alpha and beta emitters, have obviated many of the reasons for measuring total activity, but low-cost gross measurements, preferably applying alpha/beta, separated LSC measurements (Sánchez-Cabeza, and Pujol, 1995; Zapata-García et al., 2009; Palomo et al., 2011; Schumacher et al., 2014) may still serve as a rapid and cost-effective screening procedure.

A very effective tool for measuring the concentration of radionuclides in soil, water, air filters, and swipes is presented by LSC. Samples or an aliquot may be placed directly into an LSC vial of cocktail and counted without further preparation or first processed by ashing, radiochemical, or solvent extraction, or pulverizing to place the sample in intimate contact with the LSC cocktail. Actions such as bleaching the sample may also be adequate to make the cocktail solution transparent to the wavelength of light it emits. Additionally, very-high-energy beta emitters (above 1.5 MeV) may be counted using liquid scintillation equipment without liquid scintillation cocktails by use of the Cerenkov light pulse emitted, as high-energy charged particles move through water or similar substances. The use of pulse shape discrimination has allowed increases in sensitivity by electronic discrimination against beta and gamma emitters. However, beta energy spectra are 10−100 times broader than gamma spectrum photopeaks so that quantitative determination of complex multienergy beta spectra is hardly possible.

Environmental samples containing gamma-emitting radionuclides can be measured by means of gamma spectroscopy. Although scintillation counters using a sodium iodide crystal with a thallium activator, NaI(Tl), have been a mainstay of gamma ray spectrometry since 1948, they are superseded by semiconductor-based assemblies with the detector of choice for most applications to be a high-resolution hyperpure germanium crystal (HPGe), whereas silicon detectors are used for gamma spectrometry at low energies. Germanium has the advantages with respect to silicon of a smaller bandgap (Ge: 0.665 eV vs. Si: 1.12 eV at 77 K) for better energy resolution and a higher Z (32 vs. 14) for better photoelectric absorption. The germanium detector is not as efficient as the NaI detector, but it is capable of distinguishing between very closely spaced energies. The energy resolution measured as the full width at half the peak maximum (FWHM) for typical coaxial germanium detectors is between 1.6 and 2.1 keV for 1.33 MeV gamma rays, depending on the size and quality of the detector. The peak-to-Compton ratio is generally 40−100, again depending on the size and quality of the detector.

Alpha spectrometry systems, typically, consist of the silicon diode surface barrier detector housed in a light-tight vacuum chamber, a bias supply, amplifier, analog-to-digital converter, multichannel analyzer, and computer. The bias is typically 25−100 V. The vacuum is typically less than 0.1 millitorr. Since the sample and detector are in a vacuum, most commonly encountered alpha energies will be detected with approximately the same efficiency, provided there is no self-absorption in the sample. The system is appropriate for all alphas except those from gaseous radionuclides. Samples have to be prepared by means of chemical separation. A known amount of a (diluted) standard solution (tracer) may be added before separation to determine the overall recovery of the sample from the chemical procedures and/or quantification by isotope dilution. Following conversion to a particulate having very little mass and collection on a special filter (microprecipitation), or collection from solution by electroplating onto a metal disk, the sample is then placed in the vacuum chamber at a fixed distance from the diode and analyzed. For environmental levels, counting times are in the order of 80,000 seconds or more, providing detection limits in the order of 1 mBq/g or below. Typical energy resolutions are in the range of 10−20 keV.

Alpha counting procedures are capable of sufficient sensitivity to determine levels for monitoring and dose assessment. However, the potential of long-term buildup of long-lived radionuclides indicates that more sensitive methods may be required to determine the routes and rates of movement through the environment. For these purposes, mass spectrometry provides a unique and valuable tool (Ross, 2008 and Becker, 2007, 2010).

For the determination of ^{239}Pu and ^{240}Pu, which can give direct information on the content of fissionable ^{239}Pu, mass spectrometric methods such as inductively coupled plasma mass spectrometry (ICP-MS) and accelerator mass spectrometry (AMS) are necessary (Povinec et al., 2001). ICP-MS has been widely applied for this purpose, although care must be taken to remove interferences like $^{238}UH^{+}$, which can influence the determination of ^{239}Pu (Hrnecek et al., 2002; Chiappini et al., 1996; Muramatsu et al., 1999, 2001). A partial review of how to overcome spectral overlaps in elemental ICP-MS was presented by Vanhaecke and Moens (2004).

For plutonium isotopes, the main advantage of AMS compared with conventional MS (TIMS, ICP-MS) is the

complete destruction of molecular isobars (e.g., $^{238}UH^{+}$ for ^{239}Pu) by stripping to high positive charge states in the terminal of the tandem accelerator (Oughton et al., 2001). Additionally, this method permits the determination of higher mass plutonium isotopes such as ^{242}Pu and ^{244}Pu in environmental samples (Fifield et al., 1996; Hrnecek et al., 2005).

Mass spectrometric methods have been reviewed for the determination of transuranium elements, for example, by Betti et al. (2006). Hou and Ross (2008) extensively compared radiometric and mass spectrometric methods for long-lived radionuclides. They concluded that mass spectrometric techniques, although susceptible to isobaric interference and the need of extensive equipment and infrastructure, are valuable rapid analytical methods for the determination of many long-lived radionuclides, including ^{99}Tc, ^{237}Np, and isotopes of uranium, thorium, and plutonium (Table 1.4).

E. Quality assurance/quality control

As the results of environmental monitoring are of fundamental importance not only to assess environmental conditions but also to support decision-making, policy development and prioritization of policies based on solid information, the application of quality assurance and quality control measures during the data collection process, data storage and access is a fundamental component of any effective environmental monitoring program to ensure quality and comparability of the analytical results. As a minimum, an adequate quality assurance program satisfies the general requirements established by the regulatory body. To minimize laboratory incidents, such as the mislabeling of samples or biased analyses, quality control and quality assurance concepts have been developed to assist the laboratory personnel to achieve a higher degree of transparency of procedures, minimize potential sources of error, standardize the handling of samples, instruments, and data, and in the end, decrease the rate of nonconformance results.

Particularly in the case of sensitive materials, this has been recognized as early as the 1950s in the nuclear industry, and concepts have been developed to assure traceability of materials, and of course, reliability of results. Many different branches of industry have adopted, refined, and further developed these concepts, because it has been realized that a formal quality control and quality assurance system helps achieve a stable level of high-quality output. It was only in the late 1980s that similar strategies became attractive to research laboratories and, in particular, EURACHEM and ISO started to set up guidelines and norms for the implementation of these measures (e.g., the ISO 9000 series). Finally, the idea of a formal accreditation of laboratories following quality guidelines was developed and now is widely accepted that—through the advent of international trade and exchange—an internationally agreed procedure for accreditation of analytical laboratories through national accreditation bodies is a proper means to enhance acceptance and legal recognition of analytical results worldwide. The global quality standard for analytical laboratories is the ISO/IEC 17025 (ISO, 2017). These standards set out specific management and technical requirements.

While management requirements are mainly related to the operation and effectiveness of the quality management system and more or less identical to ISO 9001 requirements, technical requirements focus on the qualification and competence of staff, testing methodology, infrastructure and equipment, and reporting of results.

The sampling, sample handling and preparation, analytical procedures, and other factors, which might have an influence on the result, have to be documented carefully, for example, as standard operating procedures (SOPs), to allow reevaluation of results if doubts about their reliability come up. SOPs detail the work processes that are conducted or followed within an organization and document the way activities are performed. The benefits of a valid SOP are reduced work effort combined with improved data comparability, credibility, and legal defensibility and promoted quality through consistent implementation of a process even if there are changes in personnel.

In addition, particular attention should be paid to the requirements on method validation, in terms of accuracy, repeatability and reproducibility, the use of calibration standards that are traceable to national or international standards, instrument calibration, and performance testing.

In providing robust and sound analytical results, it is inevitable to understand that every measurement will always be subject to a certain amount of uncertainty. Uncertainty is a measure giving the quality and accuracy not only of a sample analysis but of the measurement program.

Uncertainty in environmental monitoring results arises primarily from design errors, the nonrepresentativeness of samples and/or measurements, human errors, and measurement uncertainty. These uncertainties cannot be fully eliminated but can be reduced as far as possible.

Nonrepresentativeness occurs when the sampling or field measurement is unable to capture the complete extent of variability that exists for the radionuclide distribution in a survey unit. Since it is impossible in every situation to measure the residual radioactivity at every point in space and time, the results will be incomplete to some degree. It is also impossible to know with complete certainty the residual radioactivity at locations that were not measured, so the incomplete survey results give rise to uncertainty. The greater the natural or inherent variation in residual radioactivity, the greater the uncertainty associated with a decision based on the survey results. Representativeness in sampling and/or in field measurements can be optimized by

TABLE 1.4 Detection limits, separation, and counting times for radionuclides of interest in environmental media.

Nuclide	Method	Detection limit (mBq/Sample)	Preparation time	Count time	Reference
$^{239+240}$Pu, ^{238}Pu[a]	Alpha spectrometry	0.02	2–4 days	5 days	Varga et al. (2007)
^{241}Pu	LSC	11	2–3 days	5 hours	Liong Wee Kwong (2004)
^{224}Ra	Gamma spectrometry	70	-	1000 minutes	Parekh et al. (2003)
^{226}Ra	Gamma spectrometry	80	-	2400 minutes	Parekh et al. (2003)
	LSC	0.3–1.4	2h (+30 days ingrowth of ^{222}Rn)	6 hours	Sanchez-Cabeza and Pujol (1998)
	Alpha spectrometry	0.2–0.5	2–4 days	2 days	Purkl S and Eisenhauer (2003); Karamanis et al., 2006
^{228}Ra	Gamma spectrometry	110	-	2400 minutes	Parekh et al. (2003)
	LSC	0.1	1–2 days (+48 h ingrowth of ^{228}Ac)	60 minutes	Nour et al. (2004)
	LSC (Cerenkov counting)	0.3	1–2 days (+48 h ingrowth of ^{228}Ac)	100 minutes	L'Annunziata and coworkers (see Aleissa et al., 2008)
	Alpha spectrometry	0.2	2–4 days (+12 months ingrowth of ^{222}Rn)	3 days	Purkl and Eisenhauer (2003)
^{90}Sr/^{90}Y	LSC (Cerenkov)	10	1–2 days (+20days ingrowth of ^{90}Y)	3hours	Suomela et al. (1993)
	LSC	10	1–2 days (+20days ingrowth of ^{90}Y)	3hours	Popov et al. (2006)

[a]*Same detection limits are achievable for all other actinides.*

means of an appropriate sampling and measurement scheme as described above.

Whereas incorrect calibration may be detected and corrected at a later stage, errors in the treatment of the samples cannot readily be detected and corrected. Furthermore, the storage of samples allows the repetition of measurements on the samples that are obviously not correct. Regular training and exercises should be conducted for the staff to maintain the experience of personnel as an important precondition for high-quality work, especially under stress in emergencies.

Human errors may give rise to, for example, improper recording, loss of samples, incorrect labeling, cross-contamination during sample preparation, and contamination of measurement devices. Adequate training of personnel and quality assurance procedures should be used to reduce human errors, even in emergency conditions.

IV. Monitoring for internal exposure

A. Air

Monitoring of airborne radioactive material in either particulate or gaseous form in air is of particular importance to estimate radiation exposures from external radiation or inhaled radionuclides; it provides the first opportunity to identify the spectrum of radionuclides making up the contamination and transfer of the deposited radionuclides through the food chain. Except for radon, the noble gases are not of great concern for internal exposure but contribute to the external exposure (Mück and Henrich, 2001).

Since the natural radioactivity concentrations under normal conditions are significantly higher than the artificial activity concentrations, accumulation methods are required. If the concentration is needed, the volume of air is measured in terms of flow rate. When the radionuclide activity per total amount of the element is to be determined, a passive device, such as a bag of silica gel or zeolite suspended in air to collect tritiated water, may be satisfactory. Retention efficiency must be tested under operating conditions, and possible adverse effects on the collection efficiency by other gases at various concentrations should be tested. The chemical form of the radionuclide especially influences the collection efficiency. Data on atmospheric stability, wind speed, and wind direction under which the samples were collected should be noted.

1. Aerosols

Aerosol monitoring includes sampling and measuring units that collect dust by drawing air through a filter material. The filters coupled to air pumps are capable of accumulating particulates from a large volume of air onto a small surface; their radioactive content can be determined with good measuring efficiency. Electrostatic precipitators, cyclone collectors, and cascade impactors are in use to collect particles and classify them according to size.

Since the radionuclide concentrations are reported per unit volume of air (Bq/m^3), the air should be drawn through the filter at a known rate for a known period of time, preferably using an integrating flow meter to give the total volume. When high dust concentrations occur during sampling, it may not be possible to maintain a constant air flow through the filter. The collection efficiency may change during operation if too many solids accumulate.

Several types of filter material (glass fiber, paper, cellulose) are used for collecting aerosol materials. The type of filter is selected according to the needs for high collection efficiency, particle size selectivity, retention of gaseous iodine with the particles, and ease of radiochemical analysis. It may be desirable to change filter media for specific purposes or to use several filters in series.

Lozano et al. (2011) propose the use of quartz filters to collect alpha-emitting natural radionuclides.

Pure cellulose papers are useful for samples to be dissolved and analyzed radiochemically, but the analytical filter papers used to filter solutions are inefficient collectors for aerosols and clog easily. Of particular value for samples to be analyzed radiochemically are filters composed of polystyrene fibers. They are efficient and capable of sustaining high air flow rates without clogging, are readily destroyed in analysis by ignition at low temperatures ($\sim 300^{\circ}C$) or by wet ashing with oxidizing agents, are also soluble in many organic liquids, have the disadvantage of very low mechanical and tensile strength, and must be handled carefully. Fiberglass filters can function efficiently at high flow rates but require fluoride treatment for dissolution and generally contain some radionuclides, for example, ^{40}K, to complicate low activity analysis. Overviews of filter media, classification, performance data, collection efficiencies, and practical selection tables are available (e.g., Purchas and Sutherland, 2002; Ruzer and Harley, 2005; and Papastefanou, 2008).

2. Online versus offline systems

Aerosol filtration can be accomplished by either moving filter bands in online systems or offline with fixed filter sheets. Both solutions have their advantages and drawbacks, and obviously, they require different measuring arrangements and different data evaluation algorithms.

The concept of moving filter bands means that the adsorbing surface is (partially or totally) renewed from measurement to measurement. Thus, the sampled volume is relatively less than that of a fixed filter sheet with the same air rate ($\sim 25\ m^3$/hour compared with $100-1000\ m^3$/hour), and so does the accumulation of a suspected artificial radiocontamination as well. On the other hand, the amount

of accumulated natural radioactivity will also be less in this case. Radionuclides on air filters are dominated by the naturally occurring, short-lived particulate decay products of radon (1−20 Bq/m^3 in outdoor air) and will also include cosmogenic ^{7}Be.

The moving band concept has significant advantage over the fixed filter systems if the concentration of artificial radioactivity in the sampled air steeply increases. This step-function-like phenomenon can occur in local monitoring systems where the possible source of contamination is close to the sampling station. In regional systems, the activity concentration of artificial radionuclides may increase due to atmospheric dispersion of radioactivity emitted from a (probably) distant source. This dispersion process is governed by laws of long-distance diffusion so the increase cannot be as vivid as it is assumed for cases of local monitoring. Therefore, a slow buildup rate is expected so the "early warning" requires accumulation of radioactivity—this condition means the supremacy of fixed (or slowly moving) filter systems over those of fast filter increment. Moving filter facilities allow automatic operation up to 6 months and are particularly used in automatic monitoring networks. One automatic station design of the IMS (International Monitoring System) Radionuclide Network uses a small robot to cut the filter in pieces after the collection process, which are afterward stacked into a neat pile for gamma measurement. The cutting edge works well on glass fiber filter material but badly on organic ones (Medici et al., 2004).

Fixed filter devices only permit sampling periods of maximum 1 week and thus require considerable operational service. High sampling rates are achieved with high capacity blowers and large area filters. The filters are usually compressed to provide a standard counting geometry and are measured by gamma spectrometry. Most institutes perform correction from natural radioactivity by waiting 2−5 days before measuring the filter. Detection levels of a few μBq/m^3 can be obtained, for example, 10−30 μBq/m^3 for ^{140}Ba with an airflow of 1000 m^3/hour (Schulze et al., 2000). Subsequently the filters may be dry- or wet-ashed for radiochemical analysis of pure alpha or beta emitters (e.g., ^{239}Pu and ^{90}Sr) using alpha spectrometry or LSC, respectively.

Widely used measuring methods of online systems are as follows:

- Gross beta: That is, total beta radioactivity with correction for natural radioactivity (mostly influenced by radon daughters). The measuring instruments used are Geiger−Müller, gas flow proportional counter with different active surfaces, and plastic scintillators with ZnS coating, mostly in anticoincidence configuration. Depending on the methods used, the lower detection limits range between $5\cdot10^{-5}$ and 1 Bq/m^3. Distinction between natural and artificial radioactivity can be done very effectively by simultaneous coincidence counting of alpha decay and by assuming that there is no contribution of artificial alpha emitters. In this way, concentrations of artificial radioactivity down to 0.1 Bq/m^3 can be detected. One may also perform a second delayed beta-counting after, for example, 12 h (most short-lived daughters will then have decayed, except ^{212}Pb).
- Gross alpha: That is, total alpha minus natural alpha radioactivity. The measurement is done by gas flow proportional counters, with or without anticoincidence or passivated, ion-implanted planar silicon detectors (PIPS). Lower detection limits range between $1\cdot10^{-5}$ and $4\cdot10^{-2}$ Bq/m^3.
- Nuclide specific: To ensure optimum early warning, these instruments are designed to allow the simultaneous alpha−beta measurement and the nuclide-specific measurement. In the automatic mode, modern instruments are capable of reaching low detection limits by means of high-purity Ge detectors.

General aspects pertaining to online monitoring systems (IEC, 2002a, 2002b) and regarding both continuous and discontinuous sampling (ANSI, 1999; ISO-2889, 1975) of discharges to the atmosphere can be found in international standards.

3. Gaseous effluents

Effluents can be present in air in gaseous forms that are not collected on particulate filters. Thus, special cartridges of activated charcoals or zeolites, both of which also may be silver impregnated, are necessary for efficient collection. Flow rates through these cartridges are normally lower than those for normal aerosols. Drawback of these filters is that, depending on the concentration, they become saturated and have to be replaced. However, silver zeolite cartridges are very expensive, and charcoal cartridges are more commonly used.

Radioactive gases can be measured in many types of counters with suitable sample chamber or the gas being placed inside the detector and spectrometers, including coincident detection of different radiation types. To prepare a gas sample for counting, it should be separated from the air and purified. This process consists of separations by charcoal and molecular sieve columns and purification by drying and chemical reactions to remove the impurities (Cummings et al., 1971; Stevenson and Johns, 1971; Johns, 1973; Medici et al., 2004; Bowyer et al., 2002).

^{3}H and ^{14}C gas samples are usually not counted as gases, as ^{3}H is usually converted to water and ^{14}C gas samples are converted into benzene or similar liquid for counting in liquid scintillation counters. To use the liquid scintillation technique for radioactive gases, they must be soluble in the liquid scintillation medium.

a. Iodine measurement

Iodine in air can be bound to aerosols or in the gaseous state, each requiring special measuring techniques. Iodine sampling is carried out by means of "traditional" filter papers or charcoal drums. The filter paper captures the iodine attached to aerosols, the charcoal captures the gaseous iodine, and the combination of the two measures the total amount of iodine in air.

Filter sheets containing charcoal and iodine-specific impregnated material are available. The advantage of the latter is obvious: the filters can be replaced easily and automatically, and their measuring geometry provides much better counting efficiency.

As far as regional monitoring is concerned, the "expected" iodine radioisotopes are the relatively long-lived fission products ^{131}I, ^{132}I, and ^{133}I. All of them are beta and gamma emitters, so iodine filter sheets are coupled to the appropriate detectors described above. If further radiochemical processing of filter sheets is possible and required, the extremely long-lived ^{129}I can also be analyzed (Hou et al., 2009). ^{131}I concentrations in the order of hundreds of mBq/m^3 can be measured in 1 hour. In the case of an accident, the ratio of gaseous ^{131}I to ^{131}I attached to particulate matter can vary between 2 and 20.

b. Radon measurement

There are many different methods available for the measurement of radon and its short-lived decay products, active as well as passive, short term as well as continuous or time integrating monitors. Some of them are very sophisticated and promise an accuracy of the measurement in the order of a few percent. Many of those are very sensitive not only to radon but also to environmental parameters and therefore fail, for example, in a wet environment. Others are less accurate, but they give reliable information on radon under difficult conditions. Instruments are called active, when any kind of external or internal power supply is needed for operation. Instruments are passive, when no external power supply is necessary for operation.

For the detection of radon gas, only the instrument has to be designed in a way that the noble gas, separated by means of an aerosol filter from its decay products and other aerosols present in air, is permitted to enter the sensitive volume where the radon is allowed to decay for a defined period of time. Thus, the radon measurement is basically a radon and radon progeny measurement. In that case, all suitable detectors are applicable to detect charged particles and photons emitted from the decaying radon and its decay products. For reasons such as the selected alpha and / or beta particles and the insensitivity to photons, only ionization chambers, alpha spectrometers and scintillation methods (e.g. Lucas Cells) are used for the active measurement of radon gas.

Ionization chambers provide a theoretical sensitivity in the order of 10^{-14} A/becquerel at equilibrium. The detection limit is variable with the volume of the ionization chamber and the measuring time, which is in the order of 30 minutes to hours. Typically using a 1-L ionization chamber, one can detect about 5 Bq/m^3 with an uncertainty of 10%–20% (Pohl and Pohl-Rueling, 1976; Friedmann, 1983).

Lucas cells are containers coated inside with ZnS(Ag) and having a quartz window transparent to scintillation photons. The container is filled with radon containing air, and scintillation photons are measured after equilibrium with the short-lived radon progenies is reached. Since each alpha particle emitted from a decaying radon atom is followed by two others from the decaying radon progenies, the theoretical conversion factor is 3 pulses/becquerel. Practically, this factor is between 2 and 2.5 scintillations/becquerel.

For time-integrated measurements mainly passive instrumentation, such as adsorption on charcoal, diffusion chambers with and without filters, thermoluminescent detectors, or solid-state nuclear track detectors are used currently. Solid-state nuclear track detectors are made of materials such as cellulose nitrate (LR115), polycarbonate (Makrofol, Lexan), or allyldiglycol polycarbonate (CR39). The reading of these types of detectors is done after an (electro-)chemical etching process by optical devices, for example, as track density, changes in optical transparency, or by scintillation technique. As etching agent a solution of mainly potassium hydroxide or sodium hydroxide in different concentrations and varying ratios of ethanol are used, depending on the detector quality, the kind of etching process, and alpha energies to be detected.

Excellent reviews on solid-state nuclear track detectors are given by an OECD/NEA group of experts, published in OECD (1987), by Ilić and Durrani (2003), Guo et al. (2012), and in Chapter 3, Volume 1 of this book.

c. Noble gases other than radon

Krypton and xenon are inert noble gases and, therefore, usually one of the first radionuclides that can be emitted in processes that produce fission products. Due to their inert nature, krypton and xenon radioisotopes are unlikely to contribute significantly to internal exposure but are parts of the external exposure due to the plume after an accidental release to the air.

Furthermore, krypton and xenon do not have a major deposition rate from the atmosphere and therefore can travel long distances following a release and be detected with sufficiently sensitive instruments. In addition, the half-lives of some of their isotopes (^{85}Kr half-life: 10.8 years and ^{133}Xe half-life: 5.3 days) are nearly optimal for detection, because they are short enough that they do not build up in the atmosphere from decay of geological uranium or anthropogenic sources, yet they are long enough to

survive windborne travel distance from the source at detectable levels.

The major sources of ^{85}Kr are nuclear fuel reprocessing plants located in the northern hemisphere. Due to its long radioactive lifetime, ^{85}Kr has spread out all over the globe; typical background levels in the northern (southern) hemisphere are currently about 1.3 Bq m^{-3} of air. The yearly global release rate of ^{85}Kr to the atmosphere exceeds the removal rate by radioactive decay, resulting in a slow but continuous increase of atmospheric concentrations worldwide, which has been of some scientific concern (WMO, 1996). The well-known source term and its chemically inert properties make ^{85}Kr a useful tracer for studies of the regional and the global air circulation (Jacob et al., 1987; Zimmermann et al., 1989; WMO, 1996). Monitoring of ^{85}Kr may have some importance for nuclear safeguards (Kalinowski et al., 1998). Clandestine production of plutonium for nuclear weapons can be detected by the monitoring of ^{85}Kr in the air.

About 20 radioactive isotopes of xenon are formed in fission of heavy elements such as uranium or plutonium. Most of these isotopes decay within seconds, but a few have half-lives of several hours to several days and, thus, are detected in the environment near nuclear facilities such as medical isotope production facilities (Saey et al., 2010), near operating nuclear reactors, and also following nuclear explosions. This is one of the basic reasons why monitoring of radioactive noble gases in the atmosphere has been performed for decades. Radioxenon backgrounds range from well below 1 mBq m^{-3} in much of the southern hemisphere (Bowyer et al., 1997) to 1000 mBq/m^3 near medical isotope production facilities. However, most of the world has backgrounds in the range of 1−100 mBq/m^3. Radioactive xenon has four isotopes that are commonly detected by many groups and by the International Monitoring System (IMS) of the Comprehensive Nuclear-Test-Ban Treaty (Saey and De Geer, 2005). These isotopes are ^{131m}Xe ($t_{½} = 11.9$ d), ^{133}Xe ($t_{½} = 5.2$ d), ^{133m}Xe ($t_{½} = 2.2$ d), and ^{135}Xe ($t_{½} = 9.1$ h).

The basic techniques for measuring radioactive krypton or xenon isotopes in the atmosphere have been available for a number of years using a variety of methods (Ludwick, 1966; Schölch et al., 1966; Bernstrom and DeGeer, 1983; Kunz, 1989; Bowyer et al., 1996). Sensitive detection of krypton and xenon isotopes is commonly performed after separation of the gas from large volumes of air from the major interfering constituents of air, such as N_2, O_2, Ar, CO_2, H_2O, Rn, etc. by collecting the gas on adsorbents (e.g., through activated charcoal under reduced pressure at liquid nitrogen temperature) followed by the use of gas chromatography using CH_4 as a carrier gas to both further separate the xenon from radon and to insert the krypton or xenon gas into a favorable counting geometry. Several sources explain the state-of-the-art for this process in some detail (e.g., Stockburger et al., 1977; Ringbom et al., 2003).

Mainly, four automatic xenon measurement systems have been developed: the Automatic Radioanalyzer for Isotopic Xenon (ARIX), from the Khlopin Radium Institute (KRI), Russia; the Automated Radioxenon Sampler-Analyzer (ARSA), from the Pacific Northwest National Laboratory (PNNL), United States; the Swedish Automatic Unit for Noble Gas Acquisition (SAUNA), from Totalförsvarets Forskningsinstitut (FOI), Sweden; and the Système de Prélèvement d'Air Automatique en Ligne avec l'Analyse radioXénons atmosphériques (SPALAX) from Departement Analyse, Surveillance, Environnement du CEA (CEA/DASE), France. An overview of the system features can be found in Bowyer et al. (2002); Ringbom et al. (2003); and Fontaine et al. (2002).

B. Soil, sediments, vegetation, and deposits

Sampling of soils, deposits, and vegetation and subsequent measurement of radionuclide concentration is an appropriate method for evaluation of levels of ground contamination due to dry or wet deposition, the contribution to the evaluation of levels of total deposition per unit area on all surfaces, the prediction of dose rates, and time dependence of dose at the location, and with use of transfer coefficients, a rough estimate can be obtained for the future contamination of vegetables. Additionally, ground contamination may be a source of resuspension of radioactivity that may cause inhalation hazards and additional dispersion of radioactivity.

1. Laboratory based

a. Soil and sediments

Soil sample analysis is a common method of environmental monitoring. Sampling depths vary with the purpose of the study and the soil characteristics. The conventional sampling technique of soils is core sampling. Because the concentration of deposited radionuclides usually decreases rapidly with depth in undisturbed soil, one may have to sample as a function of depth, with both the collection area and the depth noted. For radionuclide availability studies, samples should be taken in crop areas with a coring tool to a depth of 5 cm or to the depth of the plow line.

Migration in the soil depends on the radionuclide and its chemical form and the soil type, but most artificial radionuclides are found in the upper 30 cm soil layer. Because of the possibility of large microscale variations of deposition, it is very important to take a sufficient amount of soil samples to obtain a reasonable estimate of the deposition of radioisotopes at a given site. The sample should also be

defined according to soil characteristics, agricultural status, and vegetation cover. The latter should be analyzed separately. Sampling tools vary, but any device that will cut a straight core will be satisfactory. Samples should be taken with coring tools of known diameter so that the ground area represented by the sample is accurately known. In general, about 10 cores (or a total surface area of at least 200 cm^2) are taken and composed to make a single sample.

Sediment is an indicator and accumulator of radionuclides that are insoluble and adsorbed on insoluble material in the aquatic system. Conventional collection is by a dredge dropped from a boat. The dredge mechanism is activated by contact with the benthos. For river sediments, it is of interest to describe the stream flow conditions that lead to benthal deposition and the movement of the sediment, as well as the characteristics of the sediment such as particle size distribution, soil type, ion-exchange capacity, and organic content. Collected samples are treated similarly to soil samples except that the accumulation from and interaction with the aquatic environment must be considered rather than deposition from air and uptake by grass.

Drying at low temperatures (50°C) to avoid the loss of radionuclides from the soil and hand mixing of soils or sediments prior to subsampling should be acceptable for gamma spectroscopy where a relatively large subsample is used (e.g., 150−500g). However, drying, grinding, and sieving prior to subsampling should be carried out where a small subsample (e.g., 5−10g) is to be taken for radiochemical analysis. Commercially available grinders, mills, pulverizers, mixers, and blenders are suitable. Hardened metals are best for the grinding surfaces, and it is not likely that radioactive contamination will be introduced into a sample with this equipment, except by cross-contamination from a high radioactive sample. To prevent this, thorough cleaning of equipment between samples is advisable. At this stage, a portion may be taken for gamma ray spectrometry.

If vegetation and organic debris are not discarded, the roots, mat, and vegetation should be cut into very fine particles so as to be distributed evenly; if they are to be discarded, these materials should be collected and weighed. Stones should be collected, weighed, and discarded. It can be assumed that the large rocks contain an insignificant fraction of the activity and are in effect voids in the sample. This has been shown experimentally for plutonium (Krey and Hardy, 1970). The mass of the discarded material should be taken into account, but not in calculating the specific activity of the soil. It provides, however, additional information to indicate the overall makeup of the growing area. In either case, the soil should be crushed, ground, or pulverized to a particle size predetermined by the analytical requirements. The need for preparing the material will also depend on the nature of the soil; for example, beach sand may not need grinding. In general, the soil should pass a mesh size of 2 mm. Activity in soil samples is reported on a dry weight basis in Bq/kg and on an area basis in Bq/m^2.

The question of complete dissolution versus leaching of soils is still being debated for certain analyses. Plutonium from worldwide fallout can be successfully leached with acids, if a plutonium tracer in the same chemical form is used to monitor the yield. Other forms of plutonium, such as those produced in a laboratory or fuel reprocessing plant by high temperature ignition, require digestion methods (e.g., high-pressure microwave, plasma, etc.) or repeated treatments with hydrofluoric and mineral acids for complete dissolution.

In typical radiochemical procedures to analyze for Pu, Am, and Sr in soils, 10 g of ashed material is taken for the analysis. If no stable strontium is present in the sample, 10 mg of strontium carrier and spikes of ^{243}Am and either ^{236}Pu or ^{242}Pu tracers are added. The selection of the amount of the spikes depends on the expected activity concentrations present in the sample, but typically 10−50 mBq of each are added. The use of HF will be recommended for sample dissolution to facilitate the total decomposition of the matrix, since ^{90}Sr might be contained in the lattice of the silicate material or in refractory oxides. The sequential treatment with mineral acids usually results in the dissolution of greater than 99% of the sample, and the resulting solution is filtered through a 0.2-μm polypropylene membrane filter. The leachate solution is used for the radiochemical separation of Pu from Am and Sr by anion exchange followed by the preconcentration of Am and Sr by coprecipitation with calcium oxalate. Am is separated from Sr by extraction chromatography using TRU resin. For further purification of the Am fraction (separation from rare earth elements), anion exchange chromatography is used. The final Sr separation and purification is performed by extraction chromatography using Sr resin (Vajda et al., 1992; Moreno et al., 1997). The measurement of the ^{90}Sr activity is performed by LSC using a low-energy window, which includes the entire ^{90}Sr spectrum plus some tailing from any ingrown ^{90}Y, and a high-energy window chosen above the ^{90}Sr maximum β-energy, which is used to measure ^{90}Y to correct the ^{90}Y tailing in the ^{90}Sr window. The recovery factor for ^{90}Sr (assuming a total isotopic exchange between the stable strontium isotopes and the measurand ^{90}Sr) is determined by gravimetry, and the calculation is based on a standardized strontium carrier solution. The quantification is performed by isotope dilution alpha spectrometry using ^{242}Pu or ^{236}Pu and ^{243}Am tracers.

b. Vegetation

Analysis of vegetation, such as grass and leaves, animal feeds, especially forage and field corn, provides important data for determining radionuclide concentrations in food

chains. Some materials have particular utility for identification: Spanish moss on trees being a natural filter for airborne particles, ground mosses, and lichens integrating radionuclide deposition over many years, and the leaves of perennial plants being useful for identifying nuclides collected in a particular growing season.

The vegetation cover from at least 1 m^2 of ground should be collected. The aim should be to obtain at least 0.5 kg. Smaller samples may be collected whenever the required radionuclide detection limit can be attained. Grass should be cut at the appropriate height (1−5 cm) to obtain an estimate of what a grazing animal would consume by simulating its grazing behavior. In drier climates or during sparse growing seasons, it may be necessary to sample nearer to the soil surface. Care must be taken to prevent the cut material from being contaminated with soil. It should be recognized that samples of vegetation cut this way will not represent exactly what the grazing animal consumes.

The vegetation may be analyzed in a fresh state, or if time permits and the loss of radioiodine is not of concern, it may be dried. Generally, grass is dried at temperatures not exceeding 105°C for 24 hours. The dried matter should be ground so that all particles pass through a 2-mm sieve. Samples must be weighed in a consistent manner so that the concentrations can be compared among samples. Activity on grass is reported on the basis of two weights (Bq/kg wet mass or Bq/kg dry mass) and area (Bq/m^2); hence, sample mass should be determined at collection and air-dried, oven-dried, or ashed. There is general agreement that vegetation requires complete dissolution.

If samples are collected to derive transfer coefficients or to represent certain exposure pathways, sample selection must be guided by factors such as growth patterns, wind direction frequencies, soil types, and farming practices. The amounts required for such analyses may refer to the entire sample, to the edible part, or to the part that collects or concentrates the radionuclides of interest. One should consider the pathway of radionuclides to the analyzed fractions, such as surface deposition, root uptake, and translocation from other parts of the plant.

c. Deposits

Dry and wet depositions of radionuclides are measured to follow the movement of radionuclides from air to terrestrial and aquatic media. In principle, a collector with an open surface ranging from 0.05 to 10 m^2 accumulates dust or precipitation for a specified time, and this material is analyzed for radionuclide content. The materials used for the collecting areas vary (stainless steel, plastic, polyester, PVC). To obtain concentration as well as deposition values, the amount of rainfall is measured after each collection. Typical sampling periods range from daily, over weekly to monthly. In normal circumstances, variations in time and space for the data from a number of sampling locations are gradual. For this reason, daily, weekly, or even monthly variations per sample location are not of radiological significance.

The container or collector surface should be washed to collect radionuclides that tend to adhere to surfaces or lined with a plastic sheet that is analyzed with the container contents. Water may be funneled through a filter or ion exchange system for collecting some radionuclides. Dry deposition is determined separately on material such as gummed paper or fibers that simulate grass. The same radionuclides are usually deposited in rain and collected with airborne particles, but relative amounts depend on the initial vertical distribution, particle sizes, and other characteristics.

Collectors intended to measure representative deposition should be placed so as to avoid effects by local factors, for example, air turbulence, shielding by buildings and vegetation, and sources of dust, fumes, and moisture.

2. In situ gamma spectroscopy

Introduced in the 1960s to determine natural background and weapons test fallout emitters in soil, the relevant gamma dose rate in the air above, and the relative contribution of the ^{238}U and ^{232}Th series and ^{40}K to the dose rate (Lowder et al., 1964a, 1964b; Beck, 1966; Beck et al., 1964), in situ (i.e., field) spectrometry soon appeared as a powerful tool to provide rapid and spatially representative estimates of environmental radioactivity. In essence, this technique consists of the collection of gamma spectra using a field-portable detector mounted on a tripod above the ground surface (typically 1 m) and subsequent elaboration of the full absorption peak areas multiplied by ad hoc coefficients calculated according to two fundamental assumptions:

- The source—in this case the soil—can be modeled as an infinite half-space (thus within the field of view of the detector, the ground surface should be relatively flat and free of any large obstacles, and the radionuclide activities are assumed to be uniform within this zone).
- The vertical distribution of radionuclides can be reasonably assumed to take account of attenuation by the soil matrix (typically uniform distribution for natural radionuclides and exponential distribution for artificial ones).

Under these conditions, it is possible to use a standard point source calibration performed in the laboratory (Beck, 1972; Beck et al., 1972; Cutshall and Larsen, 1986; Miller and Shebell, 1995). The calibration based on the relation of the absorption peak counting rate registered by the detector (N_f) to the exposure rate in air (I) above the ground, or the concentration or inventory of a particular nuclide (A) is

$$\frac{N_f}{I} = \frac{N_0}{\Phi} \cdot \frac{N_f}{N_0} \cdot \frac{\Phi}{I} \quad \text{or} \quad \frac{N_f}{A} = \frac{N_0}{\Phi} \cdot \frac{N_f}{N_0} \cdot \frac{\Phi}{A}$$

where

N/Φ is the counting rate from a particular spectrum absorption peak due to a unit primary photon flux density of energy E incident on the detector along the detector axis (normal to the detector face).
N_f/N_0 is the correction required to account for detector angular response,
Φ/I is the primary photon flux density with an energy E at the detector resulting from the decay of a particular radionuclide per unit exposure rate at the detector from all primary and scattered photons originating from this nuclide and any others present from its radioactive decay series.
Φ/A is the total photon flux density at the detector location per unit concentration or inventory of the nuclide.

The first two terms depend on the particular detector; Φ/I and Φ/A values depend only on the source composition and geometry and can be used for any spectrometer calibration. The factors are derived from γ-ray transport calculations. Tabulations of these data along with other pertinent information on the makeup of the environmental γ-radiation field can be found in Beck et al. (1972), Beck and de Planque (1968), and Beck (1972). A complete set of exposure rate values *(I/A)* close to 200 common fission and activation radionuclides at various exponential depth distributions in the soil can be found in Beck (1980).

With this calibration and the coefficients elaborated following Beck's method, the dose rate—produced by the unscattered and scattered fluence of gamma rays—can be estimated, and the radionuclide inventory calculated. Minimum detectable concentrations using a typical 25% relative efficiency p-type germanium detector and a 10-minute count time at typical background radiation levels for ^{60}Co, ^{137}Cs, ^{152}Eu, ^{226}Ra (based on measurement of progeny), and ^{228}Ac (to infer ^{232}Th) are all reported to be in the order of 1.8 Bq/kg (NRC, 1995).

The original method cannot be used for all kinds of source geometry, for example, indoors or urban outdoors, because it is not feasible to elaborate the buildup factors or produce calibration curves from which to derive the radionuclide activity concentrations in the source. Further limitations of the technique are mainly associated with the need of a priori assumptions about the distribution of nuclides in the soil, an important source of uncertainties of activity concentration estimates and dose rate evaluations, since dose rate is obtained as a sum of different radionuclide contributions to unscattered and scattered gamma flux at the detector.

Indoor and outdoor buildup factors and the estimate of the actual radionuclide distribution in soil have been obtained following two approaches: Monte Carlo simulation and the use of algorithms aimed to the direct elaboration of spectra. A parametric calibration was elaborated, based on the efficiency and geometric dimensions of the detector (Helfer and Miller, 1988). Another improvement was the introduction of a stripping method that subtracts partial absorption and the contribution from cosmic ray events from a collected spectrum. An important step for the diffusion of this technique was the publication of ICRU Report 53 (ICRU, 1994), which addressed the main aspects of in situ gamma spectroscopy.

Hence, since the pioneering work of Beck et al. (1972), the use of in situ gamma spectrometry measurements has become a well-established technique for documenting levels of environmental radioactivity in soils (e.g., Miller and Helfer, 1985; Helfer and Miller, 1988; Miller et al., 1994; Zombori et al., 1992; Lettner et al., 1996; Abelquist et al., 1996; Tyler et al., 1996), power reactor plumes (Gogolak, 1984), forests (Gering et al., 2002; Plamboeck et al., 2006), urban areas (Medeiros and Yoshimura, 2005; Clouvas et al., 2001, 2003; 2006; Svoukis and Tsertos, 2007), large areas (Cresswell et al., 2006; Tyler, 2004; Guillot, 2001; Hendriks et al., 2001), indoor gamma dose rate estimates (Miller, 1984; Miller and Beck, 1984; Clouvas et al., 1998, 2000), and building materials (Risica et al., 2001; Risica and Nuccetelli, 2001; Bochicchio et al., 2004).

C. Water

In addition to potential contamination with anthropogenic radionuclides, radium isotopes, ^{222}Rn, several short-lived daughter products of radon, and finally, two longer-lived decay products, ^{210}Pb and ^{210}Po, and to some extent uranium are of some concern in natural waters. Due to its low solubility, thorium is not generally considered to be a major environmental hazard. Radiological water quality guidelines have been developed regionally (ANZECC/ARMCANZ, 2000; NHMRC, 2004; USEPA, 2000; EU, 1998) and globally (WHO, 2008; WHO, 2011) for potable, livestock, watering irrigation, and recreational uses.

Sampling and preparation of water samples for analysis presents a number of problems not shared by other sample types and for which clearly defined answers are not available. The problems are caused principally by two situations: the samples are two-phase systems (i.e., the water contains some insoluble material) and the sometimes unpredictable behavior of many substances at very low concentration. The variable composition of natural waters adds to the problem.

Because a radioactive element of interest often is present in submicrogram quantities, a significant fraction may no longer exhibit their expected ionic behavior and be lost by adsorption on the surface of suspended particles or on

the surface of containers used in the examination. Even an ion as simple as cesium can be lost in trace amounts in glass containers by exchange with the potassium in the glass. Radionuclides at low activities may also exhibit many properties of colloids, and the term "radiocolloid" has been applied to such mixtures. For a discussion of radiocolloids, in general, see Crouthamel and Heinrich (1971), Olofsson et al. (1981, 1983), or Vilks and Bachinsk (1997). To reduce the effect of radiocolloid adsorption, an appropriate amount of the corresponding nonlabeled compounds (carrier) should be added to the system to lower the radiocolloid formation by the chemical dilution of the radioactivity (Keller, 1993).

To reduce the possibility of the loss of radionuclides on the walls, the sample is usually acidified. Most environmental water is close to neutral, and acidification to 0.1−0.5N is adequate. At this acidity, radioactive substances in particles in the sample can be leached (perhaps slowly) and appear in the solution, resulting in a considerable increase in the original soluble radioactivity. Also, iodine ions will slowly oxidize to iodine, and radioiodine in solution may be lost by volatilization if nitric acid is used. To prevent sorption of radionuclides on container walls between sampling and analysis, freezing may be a suitable method, but this is practical for small samples only, and the treatment of the insoluble portion still remains. If the sample has been stored before analysis, particularly at its natural acidity, it is advisable to transfer the sample to a second container with a solution—usually an acid—in which the sought-for activity is soluble. The wash solution can be added to the original solution or analyzed separately. The effectiveness of the washing procedure must be verified experimentally.

So, it would appear that the safest pretreatment procedure, if the suspended and dissolved fractions are desired separately, is to filter the water through membrane filter paper while collecting the sample in the field and acidify the sample immediately thereafter. The acid can be present in the receiving flask during filtration. In this way, the water is not in contact with the container walls until after acidification. If this procedure is impractical, the sample should be filtered as soon as possible after collection and the sample acidified immediately prior to filtration. Any inactive carriers or radioactive tracers used in the analyses should be added as soon as possible, preferably before acidification, filtration, or evaporation.

An efficient method for separating traces of actinide elements from solution introduced in the 1960s by Eakins and Gomm (1968) utilizes filtration through glass fiber paper at pH 5. Most actinides are absorbed almost completely on the glass fibers, indicating that silica in solution can adsorb many ions from solution.

A precaution observed in direct gamma spectrometry of water samples is the change in counting geometry that will occur if finely divided species become fixed on the container walls during counting. Such samples can be filtered, evaporated, or acidified, if the suspended material is soluble in dilute acid.

For gross activity measurements applying gas flow proportional counters, the water sample is dried by oven evaporation just below the boiling temperature or on a hot plate. The sample should be less than 3 mg cm^{-2} in thickness. The main error in this procedure is the loss of particles, which might become airborne during the drying process.

Although there are a number of international standards describing test methods for gross alpha and/or gross beta determination in water samples, for example, ISO 10704 "Water quality—Gross alpha and gross beta activity—Test method using thin source deposit" (ISO 10704, 2018); ISO 9696 "Water quality—Gross alpha activity—Test method using thick source" (ISO 9696, 2017); ISO 9697 "Water quality—Gross beta activity—Test method using thick source" (ISO 9697, 2018), the gross activity method is considered to be a screening procedure at best. For example, Oural et al. (1988) have shown that gross-alpha activity can underestimate actual activity because of partial volatilization of radon, short-lived radon daughters, and polonium during evaporation on the planchet. Until the short-lived radon daughters decay to a level supported by radium in the water, a time-dependent alpha activity results, which has little correspondence with actual water chemistry (Oural et al., 1987, 1989). Although nuclide-specific measurements are preferable in environmental monitoring, there are some attempts of gross counting applying LSC (Happel et al., 2004; Kleinschmidt, 2004; Wisser et al., 2006, Zapata-García et al., 2009), as it provides a rapid screening method with the ability to give at least hints of the radionuclide that has to be analyzed in the case of an unknown contamination.

Various methods have been described for the measurement of radium isotopes and ^{222}Rn. Besides gamma spectroscopy (e.g., ISO 13164-2, 2013; ISO 13165-3, 2016), liquid scintillation techniques are most common. The classical reference method for radon in water measurements has used a radon bubbler and the Lucas cell. Liquid scintillation techniques for ^{222}Rn in water, first described by Prichard and Gesell (1977), have the advantages of minimal sample preparation time, small sample sizes, and automatic sample changing, with achievable detection limits in the order of 0.37 Bq/L (Spaulding and Noakes, 1992), actually depending on the background, counting time, and acceptable degree of uncertainty. LSC instruments capable of alpha/beta discrimination are being used in the determination of radon and its daughters in ground water and drinking water since the 1990s (e.g., Schönhofer, 1989; Chalupnik and Lebecka, 1993; Irlweck and Wallner, 1993; Prichard et al., 1991) as well as

in surface water (Salonen, 1993). A standard method based on a two-phase extraction to determine ^{222}Rn in water samples is given in ISO 13164-4 (2015), the detection limit of which is 0.5 Bq/L at a measuring time of 1 hour and for a test sample of 10 mL.

Liquid−liquid extraction, ion exchange chromatography barium sulfate, and barium carbonate precipitation are the usual separation techniques used for radium. Specific extractants especially for use with alpha LSC, such as extractive scintillators (RADAEX) (McDowell and McDowell, 1994) or impregnated filter papers (Empore Radium Rad Disks) (Smith et al., 1997) for radium, have been developed. The extractive scintillator consists of an organic extractant solution, such as toluene, xylene, or mesitylene solution of a high-molecular-weight neocarboxylic acid together with the crown ether (dicyclohexano-21-crown-7), used in a mole ration 2:1 combined with a flour, PBBO, and naphthalene as energy transfer agent. This extractant separates radium from barium, strontium, and calcium by factors of 9.3, 12, and 58, respectively (McDowell and McDowell, 1994).

Analysis for ^{226}Ra may involve inferring the radium activity from a measurement of the ingrown daughter, ^{222}Rn (Parks and Tsuboi, 1978; Prichard et al., 1980; Cooper and Wilks, 1981; Horiuchi and Murakami, 1981; Nobrega et al., 1987; Chu and Khalique, 1990; Schönhofer et al., 1991), or applying pulse shape analysis to the determination of ^{226}Ra alpha particles (Cross and McBeth, 1976; Coombs, 1980; Noguchi et al., 1984; Burnett and Tai, 1992; Blackburn and Al-Masri, 1992; Saarinen and Suksi, 1992).

^{228}Ra determination may be based on counting ^{228}Ac (Petrow et al., 1964; Nour et al., 2004, L'Annunziata and coworkers (see Aleissa et al., 2008)) or the ^{228}Th alpha-emitting daughter, liquid scintillation beta−gamma coincidence spectrometry, and ^{220}Rn emanation (Orr, 1988), which is similar to ^{222}Rn emanation techniques used for ^{226}Ra. However, the latter approaches are limited by the slow ingrowth of the ^{228}Th ($T_{1/2} = 1.9$ years).

A time-saving method for the measurement of ^{226}Ra, ^{228}Ra, and ^{210}Pb in drinking water by applying Empore Radium Rad Disks and low-level liquid scintillation spectrometry has been developed by Schönhofer and Wallner (2001). Radium is concentrated by filtration of the sample through a membrane loaded with element-selective particles. The extracted nuclides are eluted with 0.25 M alkaline EDTA solution, which is then mixed with the LSC cocktail. Lead is coextracted, and therefore, ^{210}Pb interferes with ^{228}Ra to a certain extent. The collection efficiency for both lead and radium isotopes is about 100% (Schönhofer and Wallner, 2001; Wallner, 2002).

To determine low-level activity concentrations of ^{210}Po in water samples, large volume samples (>1 L) have to be provided. The samples have to be preconcentrated since direct evaporation (Katzlberger et al., 2001) of large volumes is very time-consuming and susceptible to losses of polonium (Oural et al., 1988).

Therefore, coprecipitation with iron hydroxide followed by a solvent extraction step with an extractant such as diisopropyl ether to remove Fe from the sample solution (Narita et al., 1989) or MnO_2 (Carvalho, 1997; Martin and Hancock, 2004) has commonly been used. Additional chemical purification using Sr resin (Vajda et al., 1997; Miura et al., 2000; Vrecek et al., 2004) or various solvent extractions prior to the final autodeposition of Po may be applied.

Besides gamma spectroscopy of evaporated water samples, analysis of ^{210}Pb in water samples can be based on autodeposition of the Pb-210 decay product Bi-210 on nickel according to the electrochemical series of metals. Due to its electrochemical characteristic, Po-210 is collected as well. The method consists of a chemical acid pulping, followed by a decay products buildup, the deposition and the measurement of the ^{210}Bi beta radiation. The deposition from HCl is more smoothly and quantitative to HNO_3 or H_2SO_4 (Figgis, 1961). In 1982, Richard J. Velten and Betty J. Jacobs developed a standard method for ^{210}Pb determination in drinking water (EPA, 1982) for LSC or low background end window counting. The method consists of a precipitation as chromate, purification from ^{210}Bi by selected dissolution of lead sulfide from a hydrochloric acid solution (1.5 N), and conversion of lead to the carbonate.

Activity concentrations in the range of less than 20 mBq−50 mBq/L can be achieved with measuring times between 3 and 12 hours with the standard method of ISO 13163, 2013 "Lead-210—Test method using liquid scintillation counting" (ISO 13163, 2013). The sample volume needed for this method is 0.5−1.5 L.

Tritium, produced during atmospheric thermonuclear tests, is used as a global transient tracer for studying dynamics in the hydrological cycle, recharge, renewal rate, flow velocity, and in conjunction with radiocarbon to determine groundwater age (Libby, 1953; Bergmann and Libby, 1957; Fontes, 1983; Günay, 2006; Lloyd, 1981; Sanchez-Cabeza and Pujol, 1999; Lehmann et al., 1993; Yurstsever, 1983; Wen et al., 2005, 2008; Borio et al., 2005).

Because natural levels of tritium are only marginally measurable by direct β-counting methods, the water samples are purified by distillation, followed by an isotopic enrichment procedure using electrolysis through direct current (Florkowski, 1963, 1992; Morgenstern et al., 1992). After the neutralization procedure by addition of $PbCl_2$, or CO_2, a new distillation is performed. Afterward, one aliquot of 8 mL is withdrawn to a scintillation vial with 12 mL of Ultima Gold LLT scintillation cocktail (PerkinElmer, Inc.) at a sample pH value ranging from 5 to 7.

Tritium (and its daughter ^{3}He) can also be measured using mass spectrometry, but other dissolved gases (H_2O, CO_2, O_2, N_2, etc.) must be removed first (Faure, 1986; Clark and Fritz, 1997).

Due to the specific characteristics of tritium (gas, relatively easily oxidized to HTO), combined with omnipotent presence of water vapor, the assay of low levels of tritium requires consideration of various types of contamination, the magnitude of which is depending strongly on specific procedures of sample handling, on the ambient tritium concentrations during sampling, storage and analysis, and the type of containers used to store the samples before the analysis. Sample contamination may originate from some types of watches with fluorescent tritium dials, tritium sources used in gas chromatography, targets used in neutron generators, or medical experiments where tritium is used as a tracer (Okada and Momoshima, 1993).

Tritium activity concentration is commonly reported in Tritium Units (TU). The TU is the ratio of tritium atoms to stable hydrogen-1 atoms or $[^{3}H]/[^{1}H]$, prior to weapons testing, and represents the number of tritium atoms per $1 \cdot 10^{18}$ hydrogen atoms. Hence, one TU is equivalent to 0.118 Bq kg^{-1} of water. With the electrolytic enrichment technique, detection limits in the order of 0.1−0.01 TU (11.8−1.18 mBq/kg) are achievable. If detection limits in the order of 10 Bq/kg (Bq/L) are to be achieved, distillation (probably multiple distillations) will suffice using low-level LSC instruments.

1. Wastewater

Wastewater often contains larger amounts of nonradioactive suspended and dissolved solids than water, and often, most of the radioactivity is in the solid phase. At the sampling of radioactive industrial wastes or similar materials, the high possibility of deposition of radioactivity on surfaces of glassware, plastic containers, and equipment, which may cause a loss of radioactivity and possible contamination of subsequent samples collected in inadequately cleansed containers, has to be considered.

Generally, the use of carriers in the analysis is ineffective without prior conversion of the solid phase to the soluble phase, since the radioelements may exhibit unusual chemical characteristics, because of the presence of complexing agents or the method of waste production. For example, tritium may be combined in an organic compound when used in the manufacture of luminous articles; radioiodine from hospitals may occur as complex organic compounds, compared with elemental and iodide forms found in fission products from the processing of spent nuclear fuels; uranium and thorium progeny often exist as inorganic complexes rather than oxides after processing in uranium mills; the ^{90}Sr titanate waste from a radioisotope heat source is quite insoluble compared with most other strontium wastes. Valuable information on the chemical composition of wastes, the behavior of radioelements, and the quantity of radioisotopes in use appears in the literature (e.g., Ghiloufi, 2009.)

2. Rain

The rainwater may be directly fed to a bottle or to an ion exchange column where the nuclides are fixed. Measurement of the activity in the collected rainwater and of the amount of rainfall allows the calculation of the average total deposition during the sampling period.

Contamination of rain water samples by airborne soil and surface dust can be minimized by locating the sampling stations on the roofs of buildings. Overhanging vegetation should be avoided. The most suitable size for the collector depends on the amount and frequency of precipitation in the area, as well as the frequency of collection. For areas receiving 5−25 cm precipitation per month, a collecting area of 0.1−0.2 m^2 is suggested. All materials in the collector must be transferred with great care to ensure that all the radioactive material is collected. The sides and bottom of the container should be scrubbed several times with a rubber spatula and rinsed with distilled water. If the containers are reused, care must be taken to avoid a buildup of contamination that will influence subsequent samples.

3. Groundwater

For most people, the source of water for domestic consumption and other uses is groundwater, often obtained from shallow, private wells, but more often obtained from public, community wells tapping the aquifer.

Besides possible contamination from effluent discharges, groundwater is prone to naturally occurring radionuclides. If valid judgments are to be made about the hazards and management of the radionuclides in ground water, it is necessary to understand the specific behavior of these radionuclides in the aquifer chemical systems, and that requires detailed knowledge of groundwater pH, reduction−oxidation potentials, with rock materials (Foss and Brooker, 1991). Chemical reactions, such as ion exchange, chemical complexing, and equilibration reactions with minerals and physical processes, such as alpha recoil (Osmond and Cowart, 1976; Osmand et al., 1983, 1984), can cause considerable departures from decay equilibrium within the uranium decay series.

Because of their greater mobility, uranium and ^{226}Ra are usually depleted relative to ^{230}Th on the surfaces of soil or rock particles (e.g., minerals and particulate organics). ^{238}U, ^{234}U,

and ^{226}Ra are, therefore, present in greater abundance in ground water than ^{230}Th. ^{222}Rn enters water by alpha recoil and/or leaching and migrates. ^{210}Po and ^{210}Pb also migrate to a lesser extent and are in disequilibrium to other isotopes in the U-238 series (Upchurch et al., 1991).

4. Surface water

Surface water comprises river, lake, or sea water and is one of the environmental compartments to which radioactive effluents from nuclear installations are authorized to be discharged. Radionuclides in surface waters can be found in the water phase or associated with suspended particles and can eventually become incorporated into sediments and living species. Natural radionuclides in river water include ^{3}H at levels of 0.02−0.1 Bq/L, ^{40}K (0.04−2 Bq/L), radium, radon, and their short-lived decay products (<0.4−2 Bq/L). The main fraction of ^{3}H in surface water, however, is due to human activities.

Some of the sampling methods are automatic and continuous and are designed to give an early warning in case of an accidental release. In all cases, additional information on the river flow rate is very important. Samples can be taken continuously (or daily) and are then bulked into monthly or quarterly analysis, or alternatively, spot samples are taken periodically and analyzed individually. The time and frequency of sampling is very important for rivers with large differences in seasonal hydrological variations.

Treatment of the water may consist of filtration, the filtered water and the suspended material being measured separately, ion exchange and subsequent washing of the ion exchange column, or evaporation (for direct measurement of the residue). Chemical separations are needed for ^{90}Sr, whereas ^{3}H is measured after multiple distillation or electrolytic enrichment. Usually, residual beta (total beta less ^{40}K activity) contamination is reported, although there is a clear tendency to perform nuclide-specific measurements by means of gamma spectrometry and LSC.

5. Drinking water

Drinking water is monitored because of its vital importance for human consumption, even though a severe radioactive contamination of this medium is rather improbable. Samples may be taken from ground or surface water supplies, from water distribution networks, mineral waters, etc. Spot samples are taken a few times a year and analyzed individually or samples are taken daily and bulked for monthly or quarterly analysis.

Sample treatment usually consists of sample evaporation for direct measurement of the concentrate or separation on ion exchange columns. More elaborate chemical separations are required for ^{90}Sr determination, whereas ^{3}H is generally measured following multiple distillation of the sample.

D. Foodstuff

Samples of food are of greatest interest because their analysis yields values of the radionuclide intake that contribute directly to dose. Foods that contribute 5% or more to the total diet intake should be collected for analyses. Food sampling should be undertaken first at the producer's and subsequently at the retail market. In general, food products should be prepared as for home use, bearing also in mind that like vegetation, all foodstuffs require complete dissolution. Analysis of individual foodstuffs can indicate whether and which countermeasures should be taken to reduce doses, whereas food sampling of mixed diets provides an estimation of total uptake. If, however, mixed diet samples are to be used, a separate mixed diet of baby foods should also be analyzed.

Following an emergency, it is important that specific food types are continued to be monitored, particularly foodstuffs coming from areas with high contamination and those accumulating radionuclides of interest, such as cesium or strontium.

1. Milk

Consumption of milk and dairy products has been shown to be one of the most important pathways for uptake of radionuclides from environment to man, as milk is likely to be contaminated by radioactive iodine and cesium within the first days after a release of volatile radionuclides. Milk can be collected from individual farms or from individual animals, raw milk at farms at processing centers, or bottled milk at the supermarket. It is, of course, essential to note the date of collection of the milk. At large processing centers, milk is pooled from several sources with different collection days at the local farms. The date of processing should therefore be taken as the reference date for sampling.

Liquid milk must be preserved for long-time storage. For periods of 1−2 weeks, milk is usually stored in a refrigerator near the freezing point. Storage at frozen-food temperatures (about −15°C) is suitable for longer periods. A preservative, such as formalin or sodium azide (3.5 mL of 5% aq. solution per liter), can be added to prevent souring if a longer period of storage is anticipated.

Before gamma spectrometric analysis, the milk samples are dried at low temperatures with stirring to avoid the formation of a protein skin on the surface, by adding milk in small quantities to the container in which evaporation occurs so only a small quantity is being heated at any one time, by coagulating the protein before evaporation, by heating the milk with rennin, or by freeze-drying. Chemical separation is applied for the determination of ^{90}Sr activity and separation of the water phase with subsequent distillation for the separation of ^{3}H.

In an emergency situation, the rapid analysis of ^{89}Sr and ^{90}Sr in milk is essential to protect humans from radiation exposure due to the intake of contaminated milk. Some methods using ion exchange resins have been attempted for rapid determination of radiostrontium in milk to avoid the usual process of drying, ashing, and acid leaching (Vaney et al., 1989; Baratta, 2000). Brun et al. (2003) summarized rapid methods of radiostrontium analysis in milk, compared several methods in terms of analysis time, and reported a procedure combining cation exchange resin, Sr-resin, oxalate, and $BaCrO_4$ precipitations to be appropriate for the analysis of ^{90}Sr within 48 hours (2002). However, it was difficult to apply this method to milk samples containing both ^{89}Sr and ^{90}Sr.

There have been some efforts to measure ^{89}Sr and ^{90}Sr simultaneously, such as using spectrum-unfolding methods (Hong et al., 2001), other full spectrum methods (Heilgeist, 2000), the three energy window approach (Eikenberg et al., 2005), and the constrained optimization function in three energy windows with MATLAB software (Chobola et al., 2006). All of these approaches tend to fail when the $^{89}Sr/^{90}Sr$ activity ratio is reasonably high, since small variations in the quenching level shifts the spectrum toward the low energy region, leading to significant counting errors in the ^{90}Sr energy region. Using two energy windows, Kim et al. (2009) reported relative bias due to spectrum shifting higher than 20%, when the $^{89}Sr/^{90}Sr$ activity ratio exceeded 10.

Cerenkov counting procedures for the determination of ^{89}Sr and ^{90}Sr have been reported by Melin and Suomela (1995), who applied an additional step to separate ^{90}Y after measuring ^{89}Sr, and Heckel and Vogl (2009). Both methods only have been demonstrated for low $^{89}Sr/^{90}Sr$ activity ratios, which would be exceeded likely in samples collected under emergency conditions.

Kim et al. (2010) introduced a combined counting method using Cerenkov and liquid scintillation where the sample was sequentially measured in Cerenkov and scintillation counting modes. ^{89}Sr and ^{90}Sr activities in milk samples of $^{89}Sr/^{90}Sr$ activity ratios as high as 35 could be measured within 1 day with less than 20% and 40% relative biases, respectively. A review paper on the analytical methodologies for the determination of radiostrontium isotopes has been published by Vajda and Kim (2010).

2. Meat and fish

Animals whose meat is consumed by the public can be collected at the normal time of slaughter. It is strongly recommended that rare wildlife (e.g., endangered species) should not be used in environmental sampling and measurement.

The animal usually is dissected to separate the edible portions of those tissues that are to a degree specific for radionuclides of interest. Unless the animal is very small, tissue from each animal is considered as a separate sample. Where the sample includes considerable water, it must be weighed at uniform water content. Because radionuclide concentrations in animal tissue tend to range widely, a sufficient number of animals must be collected to define the normal range of radionuclide concentrations.

Following an accidental release, meat becomes one of the main sources of radiocesium for humans. Contamination of meat is mainly the result of animal grazing, but contaminated drinking water might also be an important pathway, while inhalation is not likely to be a significant pathway to meat. Meat sampling should normally be done in such a way that the composite sample is representative of a large number of animals, although after heavy fallout, screening measurements of individual animals may be necessary.

Another pathway for the uptake of radiocesium by man following an accident constitutes contamination of fish, especially those from nutrient-deficient lakes. Obtaining a representative sample from an area containing many lakes may require some compromise since collection of samples from a large number of the lakes may be impracticable. Ocean fish will not take up as much radiocesium as freshwater fish, because of the dilution through the depth of the ocean and the effective dilution associated with the high potassium content in the water, but particulate-associated radionuclides can be enriched to high levels.

In a detailed program, fish are collected by species; in a less detailed program, fish typical of categories such as bottom feeders, insect eaters, and predators may be collected. Again, numerous replicate samples are desirable because of the usual difficulty in knowing whether a fish caught at a location had lived there for an extended period. Thus, the presence or absence of a radionuclide does not permit any definite conclusion concerning the presence of the radionuclide in water at that location. For some fish, more specific information concerning their location may be available; for example, dams, salinity gradients, and temperature gradients can be effective barriers in their movement. Besides their origin, fish are sorted per species and size (Saxen, 1990).

Shellfish such as clams or oysters, some species of macroalgae, and other filter feeders quickly take up the contaminants from the seawater and can also be used as biological indicators, having the advantage of being relatively stationary. The shells, meat, and, in some case, the fluid are analyzed separately. However, shellfish being filter feeders contain much sediment in the intestine. If this material is not also separated, the results can be seriously misleading.

The samples should be cleaned, and the edible portions should be retained for analyses. Masses are determined by subtracting the inedible portion from the total since loss of moisture from the edible portion during the time of preparation may amount to a sizable fraction of the mass. For fish, poultry, and meat samples, the bones are easily separated after heating for 1 hour at 150°C. The mass of the

sample must be referred to the mass of the genuine material after subtracting the mass of the bones. Subsequently, the samples are reduced to a homogeneous condition with an electric food-type blender. For direct measurements, 1 kg of fresh sample is generally sufficient.

When ashing foods, the temperature should be raised slowly until the upper limit of the temperature prior to ignition has been reached. It is important to recall that foods with high phosphorus content tend to ignite. When the upper limit has been reached, the temperature can be raised more rapidly to 450°C and samples can be ashed for about 16 hours. Temperatures higher than 450°C may result in losses of volatile radionuclides, for example, radiocesium. With proper adjustment, ignition can be avoided for all materials except those with large amounts of fat. Usually, 10−25 g of ashed samples is sufficient for analyses.

3. Vegetables, fruits, and cereals

Green leafy vegetables are very prone to external contamination during their growing season. In the early stages of fallout, green vegetables can be a very significant pathway for short-lived radionuclides. After harvesting, grain and rice are subjected to contamination only during storage, and only the outer layers would be contaminated. If fallout occurs during the growing season, radionuclides will be transported into the grain and rice through the plant growth process. It is relatively easy to select representative samples of grain and rice at harvest time. If the fallout occurs during the winter, grain will be contaminated only through root uptake in the next growing season.

In certain countries, as much as 50% of the dietary calcium may be derived from cereal grains, whereas fruits and vegetables may add another 25%. No special techniques are required for the sampling. Before analysis, however, samples should be treated in the same way as if being prepared for human consumption. Samples collected for an analysis should weigh approximately 500 g each.

4. Mixed diet

Radioactivity in mixed diet is measured to get "integral" information on the uptake of radionuclides by man via the food chain. For monitoring of mixed diets, it is more appropriate to provide the activity consumed per day per person (Bq d^{-1} p^{-1}) than expressing the radioactivity content of foodstuffs per unit weight. Samples are taken as ingredients or as complete meals, mostly at places where many meals are consumed (i.e., factory restaurants, schools). Treatment usually consists of mixing the sample prior to gamma spectroscopic measurement of ^{137}Cs and chemical separation to determine the ^{90}Sr activity. The most important natural radionuclide is ^{40}K (typically 100 Bq d^{-1} p^{-1}). Knowledge of the contamination of the individual ingredients together with the composition of the national diet can also lead to a representative figure of the mixed diet.

V. Monitoring for external exposure

The simplest and least expensive and thus most widespread method of radiological environmental monitoring of human exposure due to external sources of gamma radiation is the continuous and remote-controlled measurement of external gamma dose rate or gamma dose integrated over a certain time period. It is nonnuclide specific and provides information covering large areas but is not suitable for the distinction between artificial and natural radioactivity. The actual level of natural gamma dose rate is affected by numerous influences and conditions. Apart from regional variations, there are both slow and fast temporal variations due to the dependence of radon daughter concentrations in air and soil on meteorological parameters. All of them must be thoroughly determined and investigated before setting warning and alarm levels for the detection of artificial radioactivity. Nevertheless, alarm levels can be set at dose rates of the order of 100 nSv/hour above background.

A. Dose rate monitoring

Dose rate measurements in environmental monitoring are of specific importance since real-time information about the progression of a radioactive cloud is provided. To be able to cover the measuring range from natural radiation levels up to high dose rate levels encountered during accidental releases, two counters are usually built in a detector, one for low-range measurements and one for high-range measurements.

The most frequently used detectors are energy compensated, gas-filled counter tubes, mostly Geiger−Müller counters, ionization chambers and proportional counters, and scintillation detectors (e.g., NaI(Tl), plastic). Modern systems perform automatic background correction and are equipped with local electronics for data transfer and storage.

Depending on specific monitoring objectives, account may be taken of the occupations of different population groups in typical urban areas and their vicinity. For screening purposes, the dose rate is usually measured above undisturbed soil for large-scale radioactive contamination of the environment. When detailed monitoring of external radiation fields in inhabited areas is carried out, the dose rate should be measured in typical areas that are accessible to the public: in dwellings, public buildings, production areas, gardens, and recreation areas (beach, park, etc.).

For areas uniformly contaminated with radionuclides, the measurement data on dose rates are averaged across the monitored area, the background dose rate estimated and subtracted from the measurement data.

B. Dose monitoring

To obtain a cumulative dose measurement of the direct gamma radiation, integration dosimeters, such as film badges and thermoluminescence dosimeters (TLDs) are used, mostly on the perimeter fence of nuclear installations diameter and a number of concentric rings outside the site boundary of the facility placed in a moisture-resistant polyester pouch inside a polypropylene mesh cylindrical cartridge.

TLDs are commercially available that exhibit a linear dose response and are capable of accurately measuring the absorbed dose. The radiation-sensitive element of a TLD is a small quantity, typically less than 100 mg, of an inorganic crystal doped with metal impurities, which provide the crystal with the energy storage capacity as well as the luminescent properties, required to function as a thermoluminescent phosphor upon exposure to ionizing radiation. The most commonly used TLD phosphors are lithium fluoride (LiF), calcium fluoride (CaF), lithium borate ($Li_2B_4O_7$), calcium sulfate ($CaSO_4$), and aluminum oxide (Al_2O_3) activated with trace quantities of transition metal or rare earth metal ions.

A typically TL dosimeter has four thermoluminescent elements to measure radiation exposure, one of which uses an "open" window of 3 mg/cm^2 to minimize attenuation of beta radiation; the second incorporates a 160 mg/cm^2 plastic filter, the third and fourth are covered by an 850 mg/cm^2 lead filter (in addition to 160 mg/cm^2 of plastic) to attenuate low-energy photon radiation in a manner that is intended to compensate for the overresponse of calcium sulfate in this portion of energy spectrum. These values are in addition to the filtration imposed by the polyamide backing (11 mg/cm^2) on one face and the Teflon window (28 mg/cm^2) on the opposite face of each.

The TL response of the phosphor to ionizing radiation is indicated by measurement of the glow curve, which is the plot of the TL intensity versus temperature, measured as the phosphor is heated. Field dosimeters receive exposure both while in transit to and from the placement contractor and while in storage at the contractor's facility, as well as while they are at their monitoring locations. To determine the field exposure, it is necessary to estimate this additional exposure, which is designated transit exposure. Likely sources of transit exposure include shipments of medical and other radioisotopes in the mail, as well as natural terrestrial and cosmic radiation.

VI. Mobile monitoring

Aerial and vehicle-borne measurements are used for mapping of areas contaminated by nuclear fallout, direct sampling in the plume, natural sources concentrated in the environment by human activities, or locating of lost sources. Airborne and mobile gamma ray methods permit large-scale primary surveys for gamma-emitting radionuclides, since vast areas can be scanned very fast. Mobile laboratories allow on-site measurements that otherwise would have to be performed in a laboratory facility following a time-consuming transfer to the facility.

A. Aerial measurements

Helicopters or aeroplanes can be equipped for aerial mapping, which includes the following:

- Isodose and exposure contours calculated to a given height above ground
- Soil concentrations of specific radionuclides
- Total activity inventories of radionuclides of interest
- Gamma ray spectra

In general, there are several different flying parameters, such as speed of the aircraft, altitude, and line spacing depending on objectives of survey (Table 1.5). Depending on the situation and national authority requirements, a fixed-wing aircraft survey is usually performed at a height of about 200 m. Helicopter flying altitudes for a first survey are typically 90−120 m above ground depending on landscape (trees, buildings, power lines, etc.). Thus, the detector's field of view is in the range of 200−400 m^2.

TABLE 1.5 Possible flight patterns for helicopter surveys.

Name	Description	Applicability
Parallel Track Search	Parallel straight tracks with a length of some kilometers with a distance between the tracks of 300 m	Survey in flat or hilly landscape
Line Search	Flight along specified lines (e.g., roads, railway tracks, rivers) with parallel tracks with a distance of 300 m	Survey along traffic lines
Contour Search	Flight along geographic contour lines	Survey in deeply cut or mountainous terrain
Penetration Search	Flights from landmark to landmark on different tracks	Rapid detection of contaminated area borders

In the case of an accidental release to the air, it may prove very useful to carry out an aerial mapping at higher altitudes, in particular above the mixing boundary layer (e.g., 1500 m) for the three-dimensional circumscription of the cloud. After the passage of the plume, a rapid geographic mapping of the ground deposition can be carried out most easily and rapidly at low altitude.

A major requirement for both aircrafts is that the flying altitude should be kept as constant as possible. In structured terrain, the helicopters usually try to follow that structure. For helicopters, flying speed is typically between 60 and 150 km/hour in accordance with the characteristics of the helicopter, airplanes usually go faster (180−220 km/hour). Actual flight line spacing and altitudes depend on the activity and number of sources and the sensitivity of the monitoring system.

The systems are based on the measurement of the gamma flux density at the position of the detector, which may be specially developed gas-filled probes, single or banks of scintillation detectors (NaI(Tl), plastic) of large volumes, or even semiconductor detectors of the HPGe type. The readout may be simple count rates or calibrated to dose rate or means of gamma spectrometry. Measurements are made at least once every second, and the system live time is automatically logged and output with the data stream.

Ancillary equipment usually includes GPS navigation (real-time differential), radar altimeter, barometer, and thermometer. The radar altimeter, temperature, and pressure are used to correct gamma ray data for the height of the detector above the ground. Gamma rays are attenuated by air. The density of the air, which is, in turn, affected by the prevailing temperature and pressure, affects the degree of attenuation. Real-time differential GPS navigation is accurate to within about 5 m. The radar altimeter is accurate to about 2%. The GPS navigation equipment and radar altimeter record the instantaneous position and height of the aircraft every second. Temperature and pressure are also recorded every second.

In the case of a rather uniform ground contamination, the true exposure rate at a nominal height of 170 m is about one-tenth of that at 1 m above the contaminated ground surface, this factor being approximately independent of the initial gamma energy in the range of 0.4−1.5 MeV (Chamberlain et al., 1961). The increased count rate produced by a ground deposition of about 10 kBq/m^2 may, therefore, be of the same order of magnitude as the variations in count rate attributable to different geological formations. In addition, the recorded counts may vary significantly if the aircraft is not able to fly at a fixed altitude. Due to these reasons, estimates of the activity on ground are difficult. It is even more difficult for a point source than for a uniform contamination unless hovering above the source is possible. To be able to estimate the soil contamination due to individual radionuclides, the gamma spectrometer, the response of the detector as a function of the photon energy, and the angle of incidence (including possible shielding of the helicopter or fixed-wing aircraft itself) have to be known. Therefore, the spectrometer has to be calibrated for aerial measurements prior to any use.

The main corrections that must be applied to airborne gamma ray data are background correction, stripping correction, height correction, and sensitivity correction (reduction to elemental concentrations) (IAEA, 2003b). For each of these corrections, the approach taken to calibration is empirical. There are three main procedures for acquiring calibration data:

- high altitude background calibration flights, usually flown offshore in an area where there is low atmospheric radon, at a range of heights—typically 1.0, 1.5, 2.0, 2.5, 3.0, and 3.5 km above the water,
- ground calibrations over radioactive sources to determine empirically stripping ratios, and
- calibration flights over a calibration range to determine height attenuation coefficients and sensitivity coefficients (IAEA, 1991)

Airborne gamma ray spectrometers should be fully calibrated every 12 months (Grasty and Minty, 1995).

B. Mobile laboratories

A number of car-mounted detection systems for the detection and location of radioactive sources in large areas have been developed. Additionally, mobile laboratories have been equipped with all the equipment needed for in situ measurement of dose rates, and for the collection of air samples with aerosol filters and charcoal cartridges, and possibly of soil and biological samples, and for their immediate counting and spectrometric analysis. These instruments are basically similar to the corresponding handheld devices or laboratory instruments discussed so far or in following sections, respectively; they may, however, be powered by car batteries or mobile generators. For the sake of completeness, it should be mentioned that human body counters may be a very useful part of the mobile equipment.

Instrument manufacturers have designed systems specifically for carborne use or adaptable to a variety of platforms (vehicle, helicopter, or fixed wing) as listed in Table 1.6. Depending on the speed of the vehicle and strength of the source, the signal received by the detector at a distance is only for a short duration and may be very weak compared with natural background. For a fixed distance, the primary photon fluence due to a point source falls sharply as the detector moves along. The recently developed car-mounted systems use this falling for a crude localization of point sources. Concerning aerial measurements, the closer the flight line is to a pass directly over the

TABLE 1.6 Air- and vehicle-borne detection systems.

Product	NaI-SS	MDS	FHT 1376 MobiSys
Manufacturer Vendor	*ORTEC*	*Thermo Electron Corporation*	*Thermo Electron Corporation*
Primary use	Carborne	Airborne	Carborne
Purpose	Detection of radiation sources	Detection of radiation sources	Detection of radiation sources
Hardware	1 each 4″ × 4″× 16″ NaI(Tl) detector. • 2 each 25 mm diameter × 500 mm long ^{3}He tubes. Includes 4″ polyethylene (HDPE) moderator and to save weight, 0.5″-thick PE facing the operator. • 1 each ORTEC digiBASE electronics integrating both NaI and neutron pulse counting in a single device. • 1 each laptop computer with expansion slots for extra devices, e.g., wireless networking. • GPS with USB interface, mapping software	5 L volume scintillation detector; proportional detector; model FHT 752E, He-3 neutron detector (optional); six-channel GPS	5 L plastic scintillator, optional FH 40 GL-W survey meter, GPS
Detection capability	At 15 km/hour: ^{137}Cs 370 kBq (10 μCi) at 3 m,^{60}Co 629 kBq (17 μCi) at 6 m,^{252}Cf neutron 1.3 MBq (36 μCi) at 5 m	Scintillation detector: measurement range: 1 nSv/hour to 20 μSv/hour (0.1 μR/hour to mR/hour), energy threshold: 50 keV, sensitivity (^{137}Cs): 20,000 cps/μSv/hour, able to detect 2 μSv/hour (0.2 μR/hour) increase above background, at 120 km/hour in 100m height: 370 MBq (10 mCi); proportional detector: measurement range:10 nSv/hour to 1 Sv/hour (1μR/ to 10 R/hour), energy response: 36 keV to 1.3 MeV; neutron detector (optional): sensitivity: 10 cps/μS/hour for^{252}Cf	Sensitivity: Typical 20,000 cps/μSv per hour (^{137}Cs); Detection limits: Gross: approximately 2 nSv/hour equivalent count rate relative to background level (^{137}Cs); NBR: 20% artificial dose rate contribution to the current natural gamma background level typically
Display	Laptop	Laptop	Laptop
Readout	Waterfall plot, count rate versus time, count rate versus position, spectrum at a position	Not specified	Total gamma dose rate (1 nSV/hour to 20 μSv/hour measured by the NBR-detector), artificial gamma dose rate (NBR), raw data count rates for offline analysis; total gamma dose rate (100 nSv/hour to 100 mSv/hour) measured by the optional FH 40 GL-W survey meter
Power	12 V DC	12 V DC, 8 hours on supplied battery (detector package only)	12 V DC
Size (mm)	“Pelican type” containers	400 × 600 × 350	520 × 280 × 200 mm
Weight	50 kg	15.0 kg	14 kg
Operating temperature	Not specified	0 to 50°C	Not specified

TABLE 1.6 Air- and vehicle-borne detection systems.—cont'd

Product	NaI-SS	MDS	FHT 1376 MobiSys
Humidity	Waterproof housing and wiring	5%–95% noncondensing	
Ruggedness	Plastic housing	Zarges military grade Carry Case, NATO approved	
Special		All models also function with any standard probe from the FH40G series of digital survey meters. MAPTRACK software, included with the MDS, provides a real-time data feed into any standard version of ESRI 's ArcView/ArcGIS software (ArcView 3.3, ArcGIS versions 8 and 9)	Natural background rejection (NBR) and the advanced digital filter (ADF) technologies; implemented in German, English, and French. Other languages are available upon request

Product	Matrix MRDS	GR-660 carborne	GR-660 Airborne	Mobile microspec
Manufacturer Vendor	*Thermo Electron Corporation*	*SAIC*	*SAIC*	*Bubble Technology Industries*
Primary use	Fixed, mobile, or venue-driven	Carborne	Airborne	Carborne and airborne
Purpose	Detection of radiation sources	Detection and measurement of radiation sources	Detection and measurement of radiation sources	Detection and measurement of radiation sources
Hardware	NBR probe, neutron probe, no more specification given; GPS accurate up to 3 m	GPX-256: 4 L NaI 256 in^3 (maximum 2); SAIC Exploranium GR-320 (Resolution: 256 or 512 channel); optional: neutron detector	GPX-1024 NaI (16 L) minimum recommended; maximum 16; Exploranium radiation detection system GR-820 (Resolution: 256 or 512 channel)	Various sizes of NaI for gamma spectroscopy, Phoswich scintillator for beta, liquid scintillator and ^{3}He counter for neutrons, MCA
Detection capability	Capable of detecting and monitoring radiation sources ranging from 20 to 1500 KeV, sensitivity for internal probes not specified	Not specified	^{241}Am:15–40 kBq/m^2;^{137}Cs: 1–4 Bq/m^2;^{60}Co: 0.5–3 kBq/m^2	Not specified

Display	Laptop	Touch screen color display	LCD	Laptop
Readout	Not specified	Not specified	Not specified	Dose rate, cumulative dose, spectrum, mapping with on-board GPS
Power	Incorporating smart battery management technology, battery power up to 3 hours, vehicle AC power enabled	8–35 VDC, 85–260 VAC converter included	8–35 VDC, 85–260 VAC converter included	Built-in rechargeable NiMH (12h) or external 12–32 V power supply
Size (mm)	Not specified	793 × 216 × 177	444 × 533 × 508	Analyzer: 330 × 230 × 162
Weight	Not specified	33 kg	33 kg	Analyzer: 4.1 kg; Probe 1.5–4.0 kg
Operating temperature	Not specified	Not specified	Not specified	−20 to + 40°C
Humidity	Not specified	Not specified	Not specified	Not specified
Ruggedness	Complete vibration and shock tested	Not specified	Not specified	MIL810E; MIL461E
Special	Capacity to integrate an unlimited number of sensors of Thermo's full line of radiation probes through expansion modules; data uplink capabilities via WiFi technology 2.4 GHz, secure, binary communication, unaided signal distribution up to 1 mile wireless, aided signal unlimited area	Export program to convert to a wide selection of formats, including ASCII, Map Info and Arcview GIS software	Survey planner (airborne)	

source, the higher the rate of falling of fluence. Detectors mounted on a vehicle's roof increase the field of view (Killeen, 1979); nevertheless, the field of view of a carborne system is much closer to that of a portable rather than airborne system, and the speed of operation is much slower than that of an airborne system. Consequently, the resolution of the data along a carborne traverse is much greater than that of an airborne flight line.

However, the data are also much more susceptible to local variations such as soil composition, soil moisture content, surface water (e.g., puddles), transported versus in situ material, weathering, and outcrop exposure (IAEA, 2003a). In addition, buildings, trees, and topographic effects in even moderate terrain may have a significant effect on carborne data. Variations in the system background levels may be higher than for an airborne system, due to collection of dust, mud, etc., inside and outside the vehicle. Grasty and Cox (1997) showed that the efficiency of a carborne detector at locating nearby sources is highly dependent on the geometry of the detector, the shielding elements within the vehicle, and the spectrometer system. The shielding effect of the vehicle can be advantageous if sampling of the underlying road material is not desired. Lead shields can be utilized as well. Detection limits are determined by the detector volume and the velocity of the vehicle, which govern the signal-to-noise and the spatial wavelength resolution, respectively. System sensitivities can be determined by recording carborne data centered over a 15–20 m diameter area where the ground concentrations have been averaged from a grid of calibrated ground spectrometer measurements. A test line to monitor the system should be established in a stable area off-road (e.g., grass field) and "driven" on a daily basis. For determination of background count rates, Grasty and Cox (1997) suggest connecting the detector to a portable spectrometer and taking the measurements over a large body of water with a metal or fiberglass boat.

In the case of a nuclear emergency response, a more elaborate calibration scheme is required to account for the deposition and decay of anthropogenic radionuclides. Karlsson et al. (2000) compare ^{137}Cs measurements from nine carborne systems (11 detectors) acquired over a 200 km traverse and at four specific calibration sites, all during the same day. Even though each system was calibrated, the levels of ^{137}Cs, reported as equivalent surface activity, varied by a factor of 2. These differences were attributed mainly to different calibration procedures, but also possibly to geometry, shielding, or displacement of the systems.

Road-based measurements will typically follow an irregular network. Preparing grid images from such data can be difficult, but the minimum curvature algorithm (Briggs, 1974) is suitable if the gridding parameters are well chosen. The resultant images should be prepared with the road traverses superimposed so that the most reliable portions of the grid are easily determined. Profile presentation of the data, possibly incorporating manual contouring, may be more appropriate where the network is sparse.

Rudolf Engelbrecht

Rudolf Engelbrecht graduated in radioecology and radiochemistry at the Technical University of Vienna after which he joined the Austrian Research Center, Radio Protection Department. Since 2010, he has been the head of the Radiochemical Analytics Group of the Department of Radiation Safety and Applications of the Seibersdorf Labor GmbH, Austria. Since 2019, Rudolf has been with the Austrian Agency for Health and Food Security, GmbH in Vienna. His research activities can be summarized as radioanalytical methods as a prerequisite for risk assessments with some emphasis on the determination of committed effective dose. Methods comprise whole-body counting and excretion analysis as well as radiochemical analysis of environmental media. Most recent research focuses on the evaluation of exposure to technologically enhanced naturally occurring radioactive materials by alpha and gamma spectrometry.

I. Introduction

Environmental liquid scintillation counting (LSC) is the measurement of both natural and anthropogenic radionuclides in the environment. In the vast majority of environmental applications, radionuclide concentrations are low and the contribution of instrument background to the precision of the measurement is significant. During the 1980s, a new generation of commercially manufactured liquid scintillation analyzers (LSAs) was introduced. These instruments were classified as "low level" because the background reduction features that were incorporated into them enabled the quantification of much lower radionuclide activities than were previously possible, i.e., the E^2/B (Figure of Merit (FOM)) factor is increased (where E = efficiency and B = background), and this results in an improvement in the minimum detectable activity (MDA). Well-documented examples of such improvements include (1) the extension of the effective age limit for radiocarbon dating from approximately 40,000 years to 55,000 and even up to 70,000 years (Polach et al., 1983; McCormac et al., 1993; Cook, 1995; Hogg, 2004; Hogg et al., 2007) and (2) the detection of approximately 1 Bq/L of ^{3}H in natural waters without electrolytic enrichment (Rank, 1993) and from 0.01 Bq/L down to 0.001 Bq/L with enrichment factors of 26 and 175, respectively (Morgenstern and Taylor, 2009).

In addition to the introduction of background reduction features, the incorporation of multichannel analyzers (MCAs) and microprocessor technology into modern LSAs has added spectrometric and sophisticated data handling capabilities that have made LSC a much more attractive analytical tool for environmental analyses. Because of these advances, low-level LSC is now commonly used for the following applications:

1. **Measurement of naturally occurring radionuclides, in many cases with respect to health issues**. Many are now routinely measured at natural environmental levels in a range of sample matrices including waters, sediments, soils, air, etc. These include isotopes of Ra, U and Th, ^{210}Pb, and ^{222}Rn (Möbius et al., 1993; Venso et al., 1993; Al-Masri and Blackburn, 1995; Pates et al., 1996a, 1996b; Tinker and Smith, 1996; Salonen and Hukkanen, 1997; Aupiais et al., 1998; Sato et al., 2000; Wallner, 2001; Salonen, 1993a, 1993b; 2009, 2010a; Fons-Castells et al., 2017; Mikalauskiene et al., 2018).
2. **Monitoring the environment for radionuclide releases associated with nuclear fuel cycle activities (fuel enrichment, fuel fabrication, power generation, and fuel reprocessing)**. This would mainly focus on beta-emitting radionuclides without significant gamma emissions, including ^{3}H, ^{14}C, ^{36}Cl, ^{55}Fe, ^{63}Ni, ^{89,90}Sr, ^{90}Y, ^{99}Tc, and ^{241}Pu, but could also include analysis of alpha-emitting radionuclides (Wilken and Joshi, 1991; Verrezen and Hurtgen, 1992; Ryan et al., 1993; Cook et al., 1995; Lee and Lee, 1999; Spry et al., 2000; Heilgeist, 2000; Tolmachyov et al., 2001). In addition, the analysis of effluent waters and other matrices for alpha activity is now widely reported (Cadieux et al., 1994; Dacheux and Aupiais, 1997; Mitchell et al., 2005). Some radionuclides in decommissioning of nuclear facilities can be measured by LSC,

i.e., ^{3}H, ^{14}C, ^{36}Cl, ^{41}Ca, ^{55}Fe, ^{63}Ni, ^{59}Ni, ^{90}Sr, ^{99}Tc, ^{129}I, ^{93}Zr, ^{93}Mo, and ^{241}Pu (Hou, 2005a, 2005b, 2007; Hou et al. 2005b, 2007; Vesely et al., 2008).

3. **Rapid methods developed for emergency preparedness and homeland security purposes**. The power of liquid scintillation spectrometry in the rapid collection of information in emergencies was demonstrated by Schönhofer and Weisz (1987) by the analysis of water samples collected from airplane wings at Vienna. The importance of LSC in rapid decision-making was pointed out by Schönhofer (1988). Numerous papers were published on rapid Sr/Y analyses by LSC of food and milk (Suomela et al., 1993; Günther et al., 2009; Kim et al., 2009; Kim, 2011 and references therein; Guerin et al., 2017a), air and water (Heckel and Vogl, 2009; Tayeb et al., 2015, 2016) and soil (Lee et al., 2011). Rusconi et al. (2004) discussed rapid analyses of drinking water for gross alpha and beta, ^{226}Ra, ^{234}U, ^{238}U, and ^{235}U. Eikenberg et al. (1996) measured gross alpha activity in urine. Piraner and Jones (2009) and Dai et al. (2013) applied LSC in urine analyses for radiological emergency preparedness. Portable instruments allow fast on-site detection of environmental radionuclides (Möbius, 2002).
4. **Studying the environmental processes**. This would mainly be carried out using radionuclides of natural origins and would include (1) ^{14}C dating (Thomson et al., 1995; Zaretskaia et al., 2001), (2) groundwater movement and dating using ^{3}H (Rank, 1993; Morgenstern and Taylor, 2009), and (3) marine sediment mixing, productivity, and particle flux studies using ^{234}Th (Pates et al., 1996b; Kersten et al., 1998; Nour et al., 2002; Anand et al., 2017) and ^{210}Pb/^{210}Bi/^{210}Po (Biggin et al., 2002).
5. **Analysis of ^{14}C content in air, plants, biofuel, biobased materials, and CO_2 emissions**. Conventional radiocarbon dating techniques with liquid scintillation spectrometry offer feasible analysis methods (Noakes et al., 2006; Dijs et al., 2006; Culp and Noakes, 2009, 2011; Yunoki and Saito, 2009; Norton, 2009; Norton and Woodruff, 2011; Idoeta et al., 2014; Graven, 2015; Keller et al., 2016; Niu et al., 2018).

The general theory of LSC is discussed in Chapter 6, Volume 1, while the focus of this chapter is confined to a discussion of the features that have enhanced the performance of LSAs and the application of these techniques to the measurement of environmentally significant radionuclides.

II. Low-level liquid scintillation counting theory

A. Sources of background

Instrument background is derived from many sources including natural radioactivity in the instrument's construction materials, e.g., the photomultiplier tubes (PMTs), natural radioactivity in the vial walls or cap, cosmic ray interactions with the vial walls and vial contents, and thermal ionizations in the PMTs, etc. These can be divided broadly into two categories termed quenchable and unquenchable background (Horrocks, 1985). Quenchable background comprises approximately one-third of the total, and it is primarily due to cosmic rays and other high-energy radiations that penetrate the lead shielding, the reflector, and the wall of the vial before interacting with the scintillation cocktail (Horrocks, 1985; van Cauter, 1986). In addition, radioactive contamination of the scintillation cocktail can add to the quenchable component. Quenchable background increases with increasing cocktail volume and is reduced by quenching agents (Horrocks, 1985). The pulse height spectrum extends beyond the ^{3}H and ^{14}C energy ranges, and the light pulses so produced are similar to those of true beta events.

Background events originating outside the cocktail are unaffected by quenching agents and thus are referred to as unquenchable (Horrocks, 1985). Unquenchable background events contribute approximately two-thirds of the total LSA background (van Cauter, 1986). The primary source is high-energy cosmic radiation and natural radioactivity in the vials, which interact with the vial and PMT glass surfaces to produce low-photon-yield Cerenkov events and fluorescence, which are primarily confined to the ^{3}H energy region. Unquenchable background can be distinguished electronically from valid scintillation events because the pulse pattern that results is characterized by a series (burst) of trailing low-photon-yield afterpulses that follow the initial prompt pulse (van Cauter, 1986). Typical pulse patterns due to quenchable and unquenchable events are illustrated in Fig. 2.1.

B. Background reduction methods—instrument considerations

Until the introduction of commercially manufactured low-level LSAs in the 1980s, almost all background reduction methods were attempted by the instrument users. They consisted mainly of modifications to existing instrumentation and included the following: increasing the amount of passive shielding, reducing the voltage applied to the PMTs, masking the PMTs or the vials to minimize PMT cross-talk, or using alternative low background materials for vials (mainly quartz or Teflon) or vial holder (e.g., Delrin) construction (Tamers, 1965; Calf and Polach, 1974; Noakes, 1977; Haas, 1979; Gupta and Polach, 1985). In addition, a number of experimental devices incorporating cosmic guard detectors were fabricated (Von Pietig and Scharpenseel, 1964; Alessio et al., 1976; Punning and Rajamäe, 1977; Iwakura et al., 1979; Jiang et al., 1983). However, it was not until background reduction features

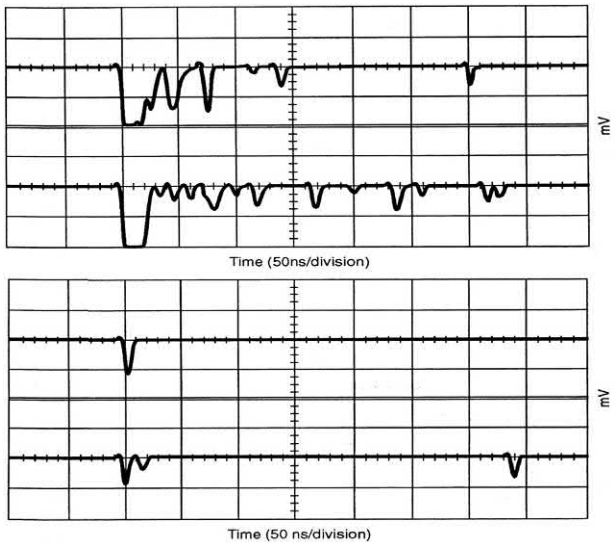

FIGURE 2.1 Typical photomultiplier tube (PMT) pulse shapes from (upper plot) unquenchable and (lower plot) quenchable events. were combined with modern microprocessor technology that the full potential of low-level LSA instrumentation was realized. Modern low-level instruments employ one or more of the following features to reduce background.

1. Enhanced passive/graded shielding

Some instruments employ large amounts of lead shielding. For example, the Wallac 1220 Quantulus has a shield of approximately 630 kg. This is composed primarily of low specific activity lead with graded cadmium and OFHC copper inner linings (Kojola et al., 1984). Also, the Beijing Nuclear Instrument Factory reported an LSA with a passive shield comprising a 7.5 cm thickness of lead and 4 cm of stainless steel, which has a total weight of 1500 kg (Guan and Xie, 1992). The Japanese Aloka LB-5 total weight with its lead shield is 900 kg. The low-level LSA manufactured by Simmax (China) also has a heavy lead shielding of 900 kg. These shields reduce the background from environmental gamma photons associated with building and instrument construction materials, as well as the "soft" cosmic muon component of background, and the graded cadmium and copper lining in the Quantulus shield absorbs secondary X-rays and thermal neutrons. However, passive shielding alone does not fully absorb high-energy gamma photons and the hard cosmic-ray component. Anticoincidence shielding (an active guard detector) or a quasi-active guard in combination with some type of pulse shape analysis are the most effective ways to reduce background (Kojola et al., 1984; Guan and Xie, 1992; Noakes and Valenta, 1996; Edler, 2017).

2. Active guard detectors

An active shield or guard detector consists of a volume of scintillating material (e.g., a plastic scintillator such as NE-110, a liquid scintillator, a large sodium iodide or a bismuth germanium oxide (BGO) crystal) and either one or two additional PMTs. This guard surrounds the detector assembly, and its PMTs are in anticoincidence with the sample PMTs (e.g., Kojola et al., 1984). Events detected only by the guard detector in the Quantulus can be saved as raw spectra for monitoring purposes. The sample events, which are simultaneously measured with the guard events, can be saved as a rejected sample event spectrum. At the same time, a net sample spectrum is also saved. Typically, the guard will reject much of the residual environmental gamma radiation, and more than 99% of the soft cosmic component and harder cosmic muon flux. This can reduce PMT cross-talk from Cerenkov light-induced pulses, which are primarily caused by the interaction of cosmic muons with the PMTs. Several types of active shields are employed in commercially available LSAs. For example, the Wallac 1414 Guardian employs an elastic plastic scintillator, the Wallac 1220 Quantulus uses a mineral oil–based liquid scintillator (Fig. 2.2), the single PMT counter ICELS (Theodórsson and Gudjónsson, 2009; Tudyka et al., 2010) uses a large sodium iodide crystal, the Aloka LB5 has a plastic shield, and the Quantulus GCT 6220 guard detector uses BGO crystal (Edler, 2017). These anti-Compton devices are true background event detectors. Quasi-active guard detectors are presented in Section 2.B.4.

3. Pulse discrimination electronics

a. Pulse shape analysis

A beta scintillation event is comprised of a fast (prompt) and a delayed component. The majority of the light (derived from excited singlet states) is within the prompt component (typically 2–8 ns in duration). The delayed component (produced largely by the annihilation of triplet states) may persist for several hundred nanoseconds. The relative amounts of light in the prompt and delayed components are dependent on the specific ionization induced by different types of particles. The pulse shape analyzer in the Quantulus is an analog device that integrates the tail of each pulse and compares this with the total pulse integral to produce an amplitude-independent parameter that relates to the pulse shape (Oikari et al., 1987). It is on this basis that PSA can be used for particle detection, which includes alpha–beta discrimination. Although the most effective use of PSA is for alpha counting, the technique has also been used for background discrimination (Kaihola, 1991). The background of glass vials is characterized by long scintillation light pulses or fluorescence due to the interaction of cosmic or other environmental radiation with the vial (much of the latter originates from the inherent radioactivity of the vial itself). PSA is used to separate these long scintillation events from the shorter scintillations of true beta events (Fig. 2.3). PSA values are adjustable within a finite range and the optimum value (in which E^2/B is maximized) can be determined automatically or empirically determined by the user. This optimum will be specific for vial type and chemistry. As in all pulse shape discrimination schemes, there is a finite probability of a slight decrease in counting efficiency due to the misclassification of events. Several of the leading LSA manufacturers, including Wallac, Hidex, and Beckman Coulter Instruments Inc. use some form of PSA that is capable of background reduction.

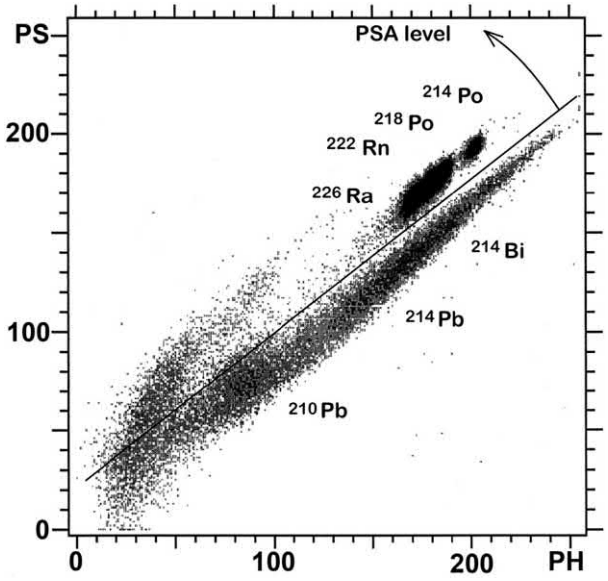

FIGURE 2.3 3D scatterplot of alpha and beta events from ^{226}Ra separated by the Wallac pulse shape analyzer (PSA), as recorded by an experimental LSC and displayed in pulse-height/pulse-shape coordinates (Kaihola et al., 1994). Slow fluorescence events from a glass vial form a streak above the beta background band in low channels. The spectra from a 1024 Ch MCA were saved in 256 Ch resolutions, and the event rate was originally illustrated by colors (Kaihola, unpublished).

b. Pulse amplitude comparison

This technique compares the ratio of the pulse amplitudes produced by the two PMTs (Soini, 1975). Photons produced in the cocktail from a radioactive decay event are evenly distributed, and the number impinging on each photocathode will be similar. Thus, the ratio of the sample pulse amplitudes will vary around a value of 1. Photons produced in the vial wall or in the PMTs will show greater variation, e.g., if scintillation is produced through the interaction of a cosmic muon with a PMT, the amplitude of the pulse observed by one PMT will differ from that observed by the other and the PAC ratio will deviate significantly from unity. Therefore, the pulse amplitude ratios will be less evenly distributed. Effectively, this is a PMT cross-talk reduction feature, and it is used in low-level LSA instruments manufactured by Wallac (Fig. 2.4). The PAC values are adjustable within a defined range and the optimum is empirically determined. Again, the use of PAC can lead to a small reduction in high-energy beta particle counting efficiency due to misclassification of events. PAC should not be applied for the measurement of low-energy beta-emitters and Cerenkov radiation as a small number of photons is generated per event, and a great disparity is observed in the number of detected photons at the PMTs.

c. Time-resolved liquid scintillation counting

This is another pulse shape discrimination technique, and it is used by the Packard Instrument Company (now PerkinElmer, Inc.) to reduce background count rates by discriminating the unquenchable component of background from true beta events and the quenchable background, on the basis of the number and energies of afterpulses that follow a prompt pulse event. Unquenchable background is the result of low photon yield Cerenkov events consisting of a prompt component followed by a delayed component comprising a burst of afterpulses (of single photoelectron magnitude) that can continue for as long as 5 microseconds (Dressler and Spitzer, 1967; Jerde et al., 1967; Roodbergen et al., 1972). The prompt pulses derived from true beta events will also be followed by afterpulses, which are caused by the collision of electrons with gas molecules inside the PMTs. The resulting ionized gas molecules take a significant time to migrate back to the photocathode where they produce secondary light

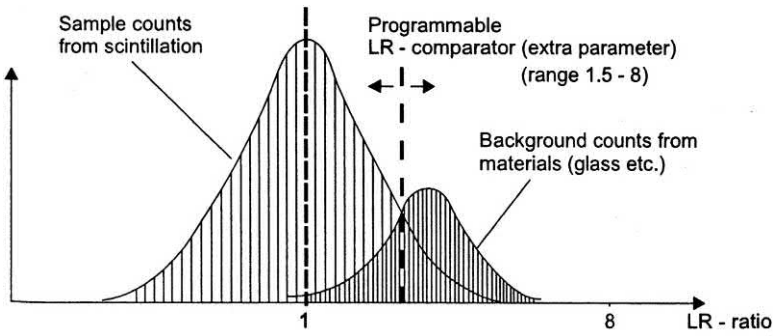

FIGURE 2.4 Schematic representation of the pulse amplitude comparator feature used by Wallac. *©1984−2011, PerkinElmer, Inc. All rights reserved. Printed with permission.*

pulses (afterpulses), and this can occur over a period of several microseconds, thereby emulating a background event. In addition, the higher the energy of the initial event, the greater will be the number of electrons liberated and the higher the probability of afterpulse production. Nevertheless, a greater number of afterpulses will usually result from an unquenchable background event than from a true scintillation event, for a given energy. Therefore, the solution is to incorporate a system that allows some afterpulses and in addition, this acceptance criterion is scaled with event energy. The acceptance criteria are stored in the form of a "burst look-up table" that correlates the acceptable number of afterpulses versus event energy. Valenta (1987) designed burst counting circuitry to discriminate unquenchable background events from true beta events on the basis of the number of burst afterpulses that follow the prompt pulse, relative to the amplitude of this prompt pulse. The total number of afterpulses is termed the pulse index, and this is used to produce three-dimensional information that is comprised of energy and time-resolved information (number of afterpulses) for each detected event. Fig. 2.5A demonstrates that a background sample produces a significant number of afterpulses or bursts at the low-energy end of the spectrum. In contrast, an unquenched ^{3}H sample generates few afterpulses and only at the high-energy end of the spectrum (Fig. 2.5B) while an air-quenched ^{3}H sample prepared in the laboratory (Fig. 2.5C) generates almost no afterpulses. Graded shielding is not required on these Tri-Carb LSAs because TR-LSC is effective at eliminating the background that is caused by the interaction of secondary X-rays with the counting chamber. In addition, background due to Cerenkov radiation and fluorescence, which is the result of the interaction of beta radiation from ^{40}K in the glass of the PMTs and counting vial, is also effectively eliminated.

Because true beta events are followed by afterpulses, there is a finite probability that valid events may be rejected, thus TR-LSC may reduce counting efficiency. In some applications, rejection of valid events is more probable, e.g., (1) in deoxygenated samples, (2) when using long fluorescence life-time (slow) scintillators that produce a significant delayed component, i.e., those cocktails that contain di-isopropyl naphthalene (DIN) and phenyl-ortho-xylylethane (PXE), and (3) with higher energy betaemitters (energies greater than or equal to ^{14}C) where the delayed component persists, even in the presence of oxygen. The

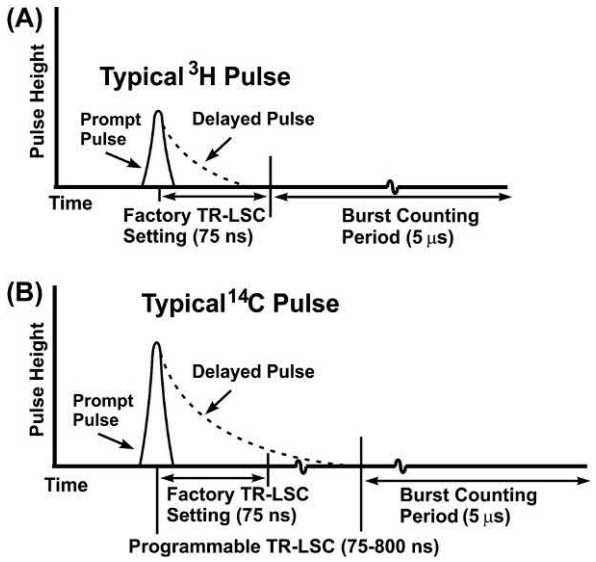

FIGURE 2.6 Schematic representations of (A) nonprogrammable TR-LSC and (B) programmable TR-LSC (Passo and Roberts, 1996). *Reprinted by permission of Radiocarbon, University of Arizona, Tucson.*

ability to optimize TR-LSC for all three of the above conditions was made possible by the introduction of programmable TR-LSC. TR-LSC has a preset delay of 75 ns between the onset of the prompt pulse and the commencement of afterpulse or burst counting. Programmable TR-LSC, on the other hand, provides the ability to adjust the delay between 75 and 800 ns (Passo and Kessler, 1993). Graphic representations of nonprogrammable and programmable TR-LSC are shown in Fig. 2.6.

4. TR-LSC quasi-active detector guards

a. Slow scintillating plastic

An additional feature to reduce background was incorporated into earlier Packard Tri-Carb XL models employing TR-LSC. This feature was in the form of a modified detector assembly that consisted of a long fluorescence lifetime scintillating plastic that surrounded the sample vial in the counting chamber (Valenta and Noakes, 1989). This plastic detector guard was optically coupled to the face of each PMT and was coated with a reflective material. It had very good optical transmission in the 400−500 nm range and the decay time of the slower component of the scintillating plastic was approximately 250 ns. When the slow fluor in the plastic (external to the sample) was excited by a high-energy gamma or muon event, which satisfied the instrument coincidence requirement, the phosphorescence of the slow fluor provided an extended burst of afterpulses that aided the background discrimination. Thus, the plastic acted as an active guard (but without dedicated PMTs). One factor that had to be stressed when using the plastic guard was that the emission spectrum of the cocktail should not significantly overlap the absorption spectrum of the guard. An appropriate secondary scintillator (e.g., POPOP, *bis*-MSB) was used to ensure that significant spectral overlap was avoided.

b. Bismuth germanate

A quasi-active detector guard, based on BGO ($Bi_4Ge_3O_{12}$), was developed by the Packard Instrument Company (Noakes and Valenta, 1996) and incorporated into the Tri-Carb 2770TR/SL, 3170TR/SL, 3110TR, 3180TR/SL models (Fig. 2.7) and the Quantulus GCT 6220 model (Edler, 2017). BGO is a nonhygroscopic scintillator that exhibits low afterglow, and its efficient gamma photon stopping power ($Z = 83$; density $= 7.13\ g\ cm^{-3}$) makes it an effective cosmic guard. BGO gamma detectors were first introduced commercially (circa 1979) for use in Computerized Tomography (CT) applications and, because of its high gamma cross-section, BGO has also been used in Positron Emission Tomography (PET), high-energy calorimetry, and medium-energy physics (Bicron Corporation, 1988). As a detector guard for LSA, BGO is used to discriminate against the gamma and muon components of cosmic background. Events that interact with BGO produce pulses, which are of much longer duration (at least a factor of 10) than beta and alpha pulses in the cocktail.

If an event interacts with the detector and satisfies the coincidence requirement, TR-LSC is then used to discriminate the longer cosmic background pulses from beta pulses. Similar to the slow scintillating plastic guard already discussed, the BGO guard completely surrounds the sample vial in the modified detector assembly. However, this detector assembly is not optimal for analysis of beta−gamma-emitting radionuclides where the gamma photons are coincident with the beta particle and sufficiently energetic to interact with the BGO guard as this increases the probability of misclassification of beta events as background. The same applies to high-energy beta particles from ^{90}Y, which can penetrate through the plastic vial into the guard resulting in a reduced ^{90}Y:^{90}Sr ratio in the lowest level counting modes.

5. Counting region optimization

The detection limit of a measurement is determined by the signal-to-noise ratio. In LSC, the signal-to-noise ratio is expressed as the square of the detection efficiency divided by the background (E^2/B) and is termed the FOM. Counting region optimization is used to maximize the E^2/B and thereby improve the detection limit.

a. Region optimization procedures and requirements under constant quench conditions

A blank (background) and a standard sample containing the radionuclide of interest are required to optimize the counting region for that radionuclide. The requirements for proper region optimization include the following:

(1) The standard containing the radionuclide of interest should have sufficient known activity and must be in the same cocktail and quenched to the same degree as the unknown samples. Equivalent quench ensures that the region chosen gives the optimum E^2/B for the sample. Different quench levels will shift the counts in or out of the region and thus affect the counting efficiency in that region. The assumption is made that the unknown(s) will be quenched to the same degree. In reality, there will be slight differences in quench and, for this reason, once the optimum region is determined, quench correction should be applied to calculate the absolute activity. The quench curve should relate counting efficiency in the optimized region (for a series of known activity standards that are quenched to different degrees) to the quench indicating parameter (H-number, SQP(E), t-SIE, etc.). Production of this type of quench curve will account for the minor quench variations in the samples. Wallac 1400 LSC series employ a digital overlay technique (DOT) where chemically and color quenched reference spectra, stored in the memory of the counter, are fitted to the sample spectra. Rundt (1992) gives a comprehensive review of this technique.

(2) The blank should be quenched to the same degree as the standard and the unknown samples and prepared in the same way. Minor fluctuations in the degree of quenching will result in only small changes in the blank counts. Therefore, it is generally not necessary to construct a quench curve for the blank. Small changes in the blank spectrum will not adversely affect the optimum window determination.

By using a representative standard and an appropriate blank, a reasonable approximation to the optimum counting window can be determined for unknown samples near background levels. In some cases, it may be possible to use the unknown sample as the standard if the activity is several times the background. In this case, the count time should be long enough to minimize the error associated with the measurement. However, counting efficiency must still be determined. In many modern LSAs, region optimization can be performed automatically.

b. Region optimization under variable quench conditions

For samples that have highly variable quench, it may not be practical to maintain a fixed counting region and still maintain maximum counting sensitivity. A practical solution is to determine the equivalent, unquenched spectral endpoint by counting the least quenched sample in the batch of unknowns or by counting the least quenched standard of the quench set. Quench standards and samples are counted using this region setting with Automatic Quench Compensation (AQC is a Beckman patent), Automatic Efficiency Compensation (AEC is a derivative of AQC and is a Packard Feature), or an equivalent technique. AQC adjusts the upper limit of the counting region to the observed spectral endpoint of the quenched sample. By adjusting the region in this manner, background is reduced and high counting efficiency is maintained. For variably quenched samples, the use of AQC represents the best choice for maintaining high sensitivity, provided that the sample activity is sufficiently high to produce a good spectral endpoint. Accuracy of AQC and AEC will be reduced for a variable quench situation at very low count rates. The DOT technique employed by Wallac shifts from spectrum libraries to conventional fixed window counting, when total collected counts are less than 500 for the spectrum window.

6. Process optimization

The term “optimize” or “optimizing” is used in many areas to simply describe the process of determining the best or optimum windows (see Counting Region Optimization above) on an LSA, for a given sample geometry. While the counter is certainly an integral part of producing results, it is just that, a part. It is one step in a “process”, and it is this process which should always be considered for “optimization”. The process would include collection, storage, and preparation/extraction of the sample, the preparation for counting, and the actual sample counting. The goal of the optimization would be to attain the required results (precision, accuracy, and sensitivity) with the lowest cost per sample in terms of technician time, materials/equipment, and counter time. If the equipment is new, the counter performance must be determined prior to evaluating the process. The first step is to consider the process requirements:

1) What is the required lower limit of detection (LLD)?
2) Is waste production an important consideration?
3) Does the sampling process have restrictions (size, time, etc.)?
4) Is equipment time restricted?

5) Is sample preparation/extraction time limited?
6) Is sample storage limited?
7) Is cocktail/vial cost per sample important?

The second step is to define the current performance (LLD) of existing resources. Typical performance data for three counters are presented in Table 2.1. The third and final step is to consider all the factors from step 1 and employing the performance data from step 2, to arrive at the most efficient (optimum) procedure for the application. Given all of the process variables, this can become quite a challenge. By using a decision tree, such as the example in Fig. 2.8, the operation can be arranged into a fairly straightforward exercise. Counter setup and sample preparation can be widely varied and still meet the same sensitivity requirements. For example, assume that a laboratory currently uses the first counter from Table 2.1 (Counter A) and that the required LLD for the process is 3.7 Bq/L for ^{3}H. A new counter arrives (Counter C), and it must be integrated into the system. As shown, the performance of the new counter is significantly better and, if the same counting protocol is maintained, the samples will be "over counted". This additional performance can be exploited as shown in Table 2.2, to reduce either the required count time or sample volume.

C. Background reduction methods—vial, vial holder, and cocktail considerations

1. Vials

Any natural radioactivity in the walls or cap of the counting vial will obviously increase the background count rate and for this reason, glass vials with a low ^{40}K content are desirable. Plastic vials display lower background than glass, partly due to their lower radioactivity (especially much lower ^{40}K content) and also to their lower density, which results in a lower probability of particle/photon interactions with the vial walls. However, care must be exercised over the choice of scintillation cocktail when using plastic vials. Typically, cocktails based on diisopropylnaphthalene (DIN) and phenyl-ortho-xylylethane (PXE) will not attack the plastic vial, whereas cocktails containing solvents such as benzene, pseudocumene, and toluene can diffuse into the plastic wall. Low diffusion plastic vials that have a thin Teflon coating reduce solvent diffusion to some extent but do not completely eliminate it. Static charge may build up on plastic vials and this can lead to spurious high count rates (the typical static symptom). To prevent any buildup of static charge, it is suggested that vials with an antistatic coating should be used. The antistatic vials are slightly more expensive, but the costs associated with recounting samples usually more than offset any price difference. A built-in deionizer also removes static charge effectively. Vials manufactured from silica (Hogg et al., 1991; Hogg and Noakes, 1992; Wilson et al., 1996) and Teflon (Polach et al., 1983; Kalin and Long, 1989) are quite commonly used for radiocarbon dating and have been demonstrated to produce significant background reductions. Their main drawback is the comparatively high cost compared to low ^{40}K glass while a lack of uniformity of response has also been noted by Einarsson (1992) for silica vials. Additionally, great care must be taken in their cleaning between sample additions; however, under certain circumstances, e.g., where samples are very small or their ages are approaching the limit of detection, they can prove very beneficial. The buildup and removal of UV absorbing coating on glass vials from benzene has been investigated by Haas (1995). Copper–Teflon vials of 20-, 15-, 7-, and 3 mL sizes were originally designed for radiocarbon dating, as benzene permeation in solid Teflon is negligible. Copper caps provided additional shielding for external radiation, and this benefit was observed in standard liquid scintillation counters (Verrezen and Hurtgren, 2003). Gold-plated copper in caps and bases have been recently replaced by black polyoxymethylene (POM), as no advantage was gained in the Quantulus from this additional passive copper shielding.

2. Vial holders

Inert vial holders made from materials such as Delrin have been used to enable instruments such as the Quantulus to accept nonstandard-sized vials (particularly those made from silica) and indirectly, their use brings about background reductions (Hogg and Noakes, 1992; Kaihola et al., 1992). The slow scintillating plastic used as the material for construction of the quasi-active guard in the Packard Tri-Carb XL models was also used to produce vial holders that would accommodate 7-mL vials. The vial holders

TABLE 2.1 Instrument performance summary for ^{3}H analysis using 10 mL water and 10 mL scintillation cocktail.

Counter	Opt. window (keV)	Efficiency (%)	Bkgd (cpm)	Count time (min)	LLD (Bq/L)
A	0.0–3.5	21.82	2.08	200 (2 × 100)	3.7
B	0.0–5.5	20.03	1.53	200 (2 × 100)	3.4
C	0.0–4.0	23.71	0.95	200 (2 × 100)	2.3

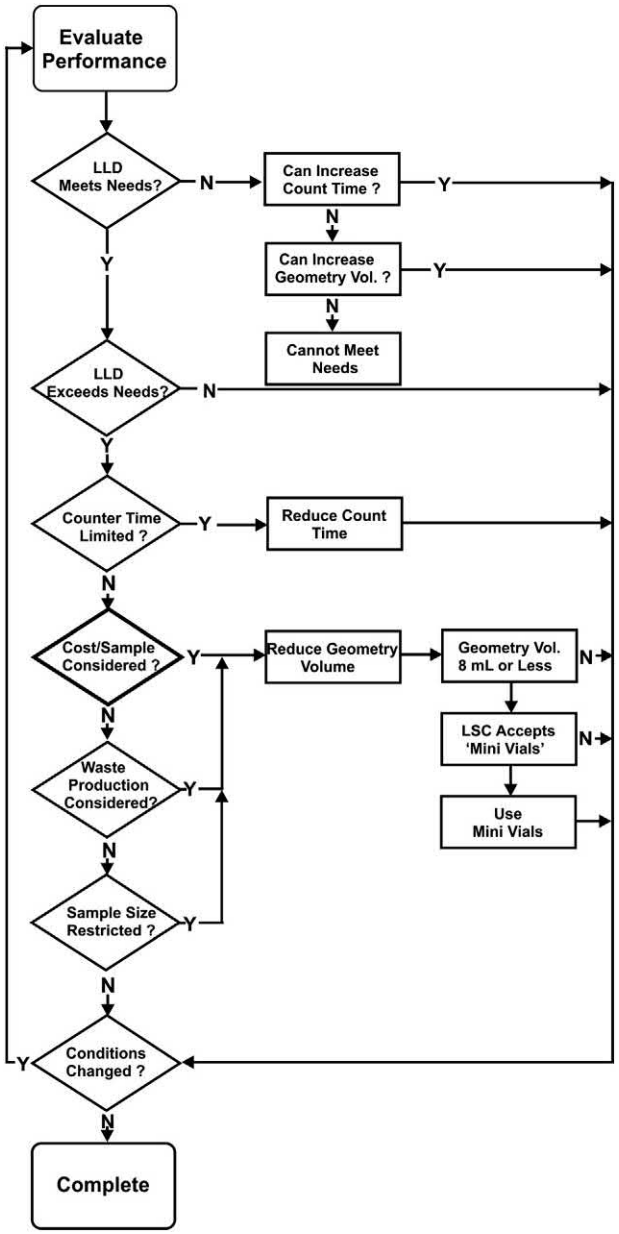

FIGURE 2.8 Process optimizing decision tree.

enhanced the background reduction even further when used in conjunction with the plastic guard; however, they were expensive and could be damaged by some solvents. They are very useful for applications such as radiocarbon dating where the total sample volume is often <7 mL. Where the sample size was not limited, the use of 20-mL vials (and therefore no vial holder) was preferable as the MDA from the smaller sample would be poorer. In addition, these vial holders are also used effectively in TR-LSC instruments that do not contain the plastic guard (Cook et al., 1989). Similarly, vial holders manufactured from BGO and designed to accommodate 7-mL vials were also used to provide additional background discrimination although, again they were expensive. These vial holders worked well in an instrument that had the BGO guard detector and electronics, but also performed quite well in other TR-LSC systems operating in the low-level count mode (Cook, 1995). Owing to their limited use and high cost, very few of these types of vial holder is now commercially available.

3. Cocktail choice and optimization

Overall, liquid scintillators should be prepared with reagents that are low in natural radioactivity. Ultima Gold LLT has been introduced by PerkinElmer with negligible ^{40}K content. When dealing with aqueous samples, the detection limit is also influenced by the loading capacity. The selected cocktail(s) should be evaluated to determine the sample to cocktail mixing ratio that will give the best performance. The cocktail should be tested at various sample loads through its rated capacity, while holding the total geometry constant. Each mixing ratio is tested using a background/standard pair to determine optimum windows and evaluate the LLD. In the example presented in Fig. 2.9, Ultima Gold LLT is evaluated from 10% to 60% sample loading, with a constant counting geometry of 20 mL.

The best performance for this example occurs at a 50% sample load (ratio = 1:1). Regardless of the total sample/cocktail volume, the best counting performance (LLD) will be achieved using an optimum 1:1 mixing ratio. The

TABLE 2.2 Example of optimizing to performance requirements for ^{3}H.

Counter	Sample vol. (mL)	Cocktail vol. (mL)	Efficiency (%)	Bkgd (cpm)	Count time (min)	LLD (Bq/L)

detailed legend box in Fig. 2.9 outlines the optimum counting windows for each percent sample loading.

D. Background reduction methods—environment

To achieve optimum performance from an LSA, it is important to ensure that the instrument is stable. Lack of stability may be manifested by changes in efficiency, background, and the quench indicating parameter, etc. Stability is generally aided by placing the LSA in a stable counting environment, where temperature and humidity are controlled, the atmosphere is not corrosive, the power supply to the instruments is of good quality and direct access of sunlight to samples is prevented. As a general guide, samples should be allowed to stand for several hours (4–6) in the counter prior to counting, as this minimizes chemiluminescence and/or photoluminescence. The effects of chemiluminescence can also be reduced by the use of a chilling unit that cools the sample counting chamber.

Static is generated in the counter by the rubbing together of nonconducting materials in a dry environment, hence the requirement for controlling humidity. If the vial entering the counting chamber has a static charge, spurious photons will be generated as the charge dissipates. Static can be minimized by humidifying the counter or the counting room, by using antistatic vials and by employing the static controlling device, i.e., a deionizer, which is common to LSAs that have an automated sample changer. One should observe that the deionizer may not be fully effective when smaller vials are measured inside 20 mL-sized vented vial holders.

Temperature has played an important role in the operation of early liquid scintillation counters. The noise rates (singles rates) of early PMTs were much greater than today's and very dependent on operating temperature. For this reason, older instruments were refrigerated to reduce this noise level, and reductions in background count rates were significant beyond the effect of the coincidence circuitry. Refrigeration is not as critical for background reduction in modern instruments because of the introduction of lower-noise bialkali tubes and improvements in tube manufacturing. Today, refrigeration is often used for reasons other than cooling the PMTs. Temperature control may be necessary for special sample preparation (e.g., where a gel cocktail is required and gelling may be impaired within certain temperature ranges), in severe operating conditions to stabilize counting conditions, for minimizing chemiluminescence, or reducing static buildup.

As previously discussed, the contribution to background from high-energy radiation, which can penetrate passive shielding and interact with the vial walls and PMTs, etc., can be minimized by the use of active guard detectors and pulse shape analysis techniques. An alternative method for the reduction of high-energy radiation, which is particularly effective for instruments without the above features, is to choose a location that provides additional shielding against cosmic or environmental radiation. Examples of this include (1) Felsenkeller in Dresden (40 m overburden, 110 m water equivalent, Niese et al., 1998), (2) a specially designed counting laboratory at the University of Arizona that has 10 m of overburden (Kalin and Long, 1989), (3) a counting laboratory within the Warragamba Dam wall in Australia (Calf and Airey, 1982), (4) the IAEA Marine Environment Laboratory (Povinec et al., 2006), (5) the Gran Sasso laboratory under 3800 mwe (Plastino and Kaihola, 2004), and (6) Wallac's surface low-level laboratory (Kaihola et al., 1986). A review of underground laboratories was published by Niese (2008).

The Wallac surface low-level laboratory was constructed from low background materials and contained in a Faraday cage, where environmental gamma flux was 5% of the level observed outside. This leads to halving of ^{3}H background in the Quantulus (Kaihola et al., 1986). Mainly inherent PMT radioactivity is a reason preventing a lower reduction of sample background than expected from the level of environmental radioactivity.

III. Alpha/beta discrimination

A. Alpha/beta separation theory

The ability to measure the activity of alpha-emitting radionuclides by LSC has been recognized for many years. It has also been known that alpha- and beta-emitting radionuclides produce different pulse shapes at the PMT anode and may be separated on this basis (Buchtela et al., 1974; Thorngate et al., 1974; McKlveen and Johnson, 1975). Pulse shape discrimination techniques are well known and have been extensively applied to the rejection of gamma background in neutron spectrometry (Horrocks, 1970; Winyard et al., 1971) and to the isolation of fission events in LSC (Horrocks, 1963). These techniques are often referred to in the literature

by different instrument manufacturers as either pulse shape discrimination, pulse shape analysis, or pulse decay analysis. Different names arise because the techniques of pulse shape discrimination can vary, but all are based on electronic circuits that measure some aspect of pulse decay time.

Alpha/beta discrimination became commercially available in conventional LSAs since the late 1980s in the Quantulus. The 4π counting geometry of LSC yields approximately 100% counting efficiency for alpha-emitting radionuclides, which, coupled with the low alpha background count rates, provides an alternative to gross alpha/beta by gas flow proportional counting. For certain applications, alpha/beta LSC can also be a very useful alternative to conventional alpha spectrometry, which utilize passivated implanted planar silicon (PIPS) and silicon surface barrier (SSB) detectors; however, the much poorer resolution of LSC relative to semiconductor detectors can be a major disadvantage. This is because the relatively large amount of energy is required to produce a single photoelectron at the PMT photocathode.

To understand how the separation of alpha from beta events is accomplished, it is necessary to examine the processes at a molecular level. Alpha and beta events may be distinguished from one another in a liquid scintillator by examining the electronic pulses that are produced at the PMT anode of the detector. As described in the previous section, these pulses are made up of two components: the prompt and the delayed components, which occur in different proportions in alpha and beta pulses (Horrocks, 1974a). Fig. 2.10 demonstrates the difference in pulse shape between ^{36}Cl (beta-emitter) and ^{241}Am (alpha-emitter) in Insta-Gel cocktail (PerkinElmer, Inc.) containing 20% weight/volume naphthalene. These pulse shapes were measured at the PMT anode using a storage oscilloscope set on averaging mode to produce an average pulse shape. The photons incident on the cathode of the PMT originate from the radiative decay of excited singlet and triplet states of the fluor molecules in the cocktail. The prompt component arises from the fast, exponential decay of excited singlet states, while triplet states can produce photons only upon collision with another molecule in the triplet state, resulting in a longer lifetime of several hundred nanoseconds, thus producing the delayed component of the pulse (Brooks, 1979). The higher specific ionization of alpha particles causes a greater proportion of excited molecules to be in triplet states, and hence alpha pulses have a longer duration. The longer duration of alpha pulses is the basis of alpha/beta separation by pulse shape discrimination.

Most of the environmentally significant alpha-emitting radionuclides emit particles in the 4–8 MeV energy region, while the betas of interest typically have E_{max} values below 2.5 MeV. Separation of alpha from beta events is necessary, because the energy to light conversion yield

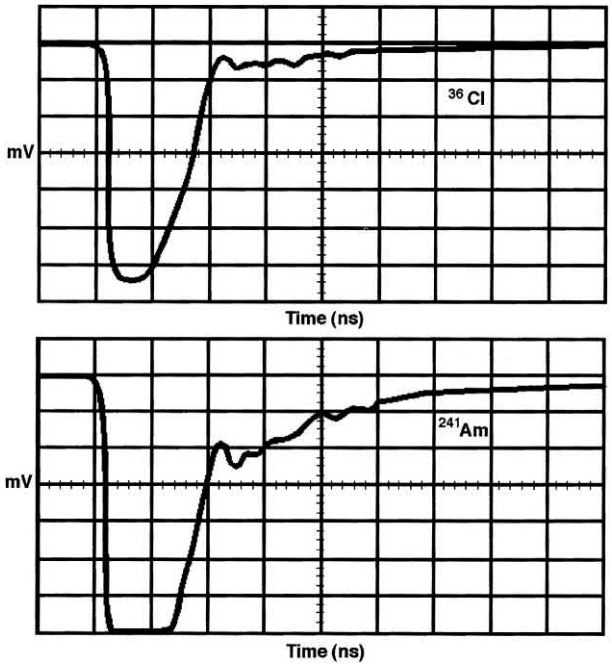

FIGURE 2.10 PMT pulse shapes for ^{36}Cl (beta) and ^{241}Am (alpha). *©1994–2019, PerkinElmer, Inc. All rights reserved. Printed with permission.*

from alpha particles is approximately a factor of 8–10 lower than from betas, with the result that alpha spectra are typically in the beta region. Fig. 2.11 illustrates the spectral overlap that is observed between ^{241}Am, which produces alpha particles in the region 5.4–5.5 MeV and ^{36}Cl, which has an E_{max} of 710 keV.

B. Alpha/beta instrumentation

Two types of LSC instruments can distinguish α from β events. These are the PERALS spectrometer (photon/electron-rejecting alpha liquid scintillation) and conventional LSAs with pulse-shape discrimination (PSD/PSA) electronics. Although both can simultaneously produce resolved α and β spectra, they are designed with different

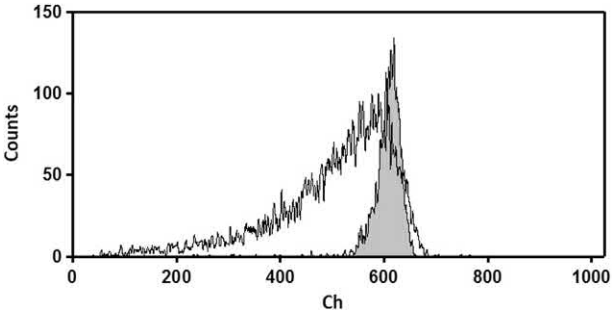

FIGURE 2.11 Logarithmic Quantulus Multi Channel Analyzer display for ^{36}Cl and ^{241}Am (gray) spectra.

purposes in mind and, hence, are generally best suited to different types of applications.

1. The PERALS spectrometer

This instrument was designed by the W. Jack McDowell, G. N. Case, and co-workers (McDowell and McDowell, 1994) as a method of α spectrometry in addition to conventional solid-state detection, and has its own characteristics, advantages, and disadvantages. Optics, sample preparation techniques and sample geometry are geared to producing the maximum α−α energy resolution by enhancing light output, as well as reducing interference from β and γ emissions. A cross section of the PERALS detector is illustrated in Fig. 2.12. As a result, the optics and geometry are not optimized for β spectrometry, and the lack of passive shielding and coincidence circuitry result in increased background in the β spectrum. McDowell and McDowell (1994) suggest that this instrument is really best suited for α measurements alone. A key element of the PERALS system is extractive scintillators, whereby an organophilic complexing agent, usually specific to a single element, is incorporated into the scintillation cocktail. This serves two purposes: (1) specific radionuclide extraction may be accomplished and (2) quenching caused by water, acid, or other sample impurities is minimized thereby maximizing light output which leads to improved energy resolution. A series of extractive scintillators for the analysis of a range of actinides and other naturally occurring radionuclides has been developed (McDowell and McDowell, 1994) and used successfully both with PERALS and other LSAs utilizing PSD. The authors also recommend purging all samples with nitrogen or an alternative oxygen-free gas to improve energy resolution even further by reducing oxygen quenching.

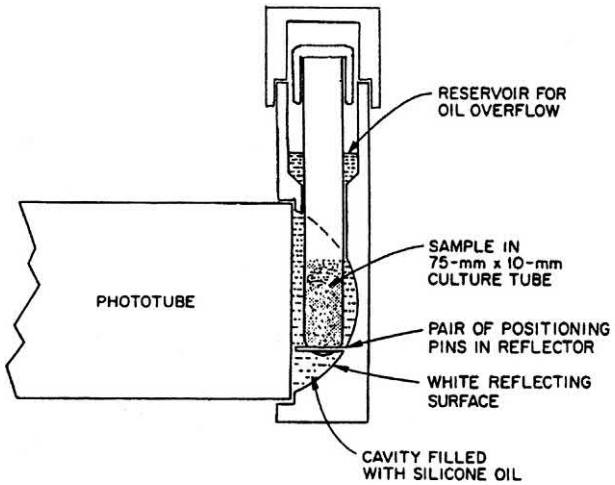

FIGURE 2.12 Cross-section of the PERALS© spectrometer (McDowell and McDowell, 1993). *Reprinted by permission of Radiocarbon, University of Arizona, Tucson.*

The advantages of this system are (i) high alpha-beta discrimination, producing > 99.9% rejection of β−γ events while maintaining a >99% counting efficiency for the α events, (ii) improved alpha resolution (200−300 keV FWHM) compared with a standard LS counter, and (iii) the observed backgrounds in the α spectra are typically lower than in a conventional counter. The sample vial is optically coupled to the PMT by silicone immersion fluid. This arrangement inhibits automatic sample changing.

2. Conventional LS spectrometers with pulse-shape discrimination

The major manufacturers of LSAs produce instruments capable of PSD for simultaneous determination of α and β activity. The α energy resolution that can be achieved by conventional LS spectrometers is 300 to >500 keV FWHM depending on sample quench level. The best reported resolution is 270 keV for the Quantulus at 5.5 MeV in an extracted sample (Yu-Fu et al., 1990). These conventional instruments have definite advantages for gross α−β analysis, for instance automatic sample changers are standard features, which are advantageous for routine analyses or for relatively short counting times. In some instances, the use of extractive scintillators is not practical or adds unnecessary complications to the sample preparation. For example, radon can be prepared for analysis by simply shaking a sample of water with a water-immiscible cocktail. However, the use of conventional LSAs does not preclude McDowell's methods. Finally, these instruments also allow the use of an α-emitting isotope as a yield tracer in the analysis of a β-emitting isotope and vice versa (e.g., Pates et al., 1996b).

As stated before, each manufacturer has its own method of PSD and these methods are referred to by different terminologies. This can be confusing, so we include here a discussion of various methods of PSD used with each instrument and explain the terms used.

a. Wallac Oy

Wallac Oy (now PerkinElmer, Inc.) has manufactured several α/β LSAs: Wallac 1219 Rackbeta SM, 1411, 1415, 1414 WinSpectral α/β and the Wallac 1414 Guardian DSA systems. These models have now been discontinued and only the Wallac 1220 Quantulus ultra low-level liquid scintillation spectrometer is still in production (Fig. 2.2). Wallac terms its version of PSD as pulse shape analysis (PSA), because all events, including discriminated events, can be saved as raw spectra. The pulse decay discriminator (PDD) settings are called PSA levels. Wallac's concept is similar to the one adopted by Brooks (1979), viz. PSA initiates the integration of the scintillation pulse tail charge after 50 ns from the leading edge and compares it with the total charge in the pulse (Oikari et al., 1987). The pulse length information is thus normalized to the pulse height to achieve

amplitude independence (*i.e.*, energy-independence). The optimum PSA level is a numeric parameter that is represented schematically by a line that separates the alpha from beta events. Events falling above the line are classified as α-events, and those below as β-events (Fig. 2.3). Both the 1414 Guardian and the 1220 Quantulus have active guard counters, in addition to other features that contribute to background reduction (See Section II for details).

b. Packard Instrument Co (Now PerkinElmer, Inc.).

The Tri-Carb 3100TR series of LSAs have an optional PSD feature called pulse decay analysis (PDA), with a TD called the pulse decay discriminator (PDD). PDA distinguishes between α and β events using the zero-crossing method of PSD, which is so named because each scintillation pulse is doubly differentiated and the time at which this new curve crosses the zero line is compared to the PDD value (Fig. 2.13). Pulses that cross in a shorter time are classified as β events and those that cross in a longer time are classified as α events. Again, this method should be amplitude-independent. These instruments can also reduce background by activation of the burst-counting circuitry (BCC) feature (see Section II for details). Time resolved pulse decay analysis (TR-PDA) is the combined use of TR-LSC background discrimination and pulse decay analysis. By applying TR-LSC to PDA, alpha events that are misclassified as beta are discriminated out by TR-LSC since the long delayed component of alpha pulses resemble background events. Thus, alpha events misclassified as betas will be eliminated from the beta MCA. In addition, the misclassification of beta events will also be reduced since the TR-PDA causes a shift to a higher optimum PDD value. At higher PDD values, fewer beta events can satisfy the time requirement for an alpha pulse and this reduces the beta spill into the alpha MCA. The net result of TR-PDA is a reduction in the misclassification of beta and alpha events. An added benefit of TR-PDA is that TR-LSC background discrimination allows simultaneous low-level beta counting, when suitable cocktails are selected to avoid excessive loss of alpha events in background reduction.

c. Hidex Oy

A small, portable liquid scintillation counter and luminometer, Triathler was introduced by Hidex Oy in 1997, which allows measurement of several vial sizes in manual mode (Haaslahti et al., 2000). Low noise and radioactivity of a small single phototube reduces beta background to a moderate level with only a 10-mm thick lead shield and total weight of 9 kg. The counting window needs to be narrowed only for energy beta range to remove interfering PMT noise. Direct dpm counting method calibration curves are available for single label samples and quench monitoring with a ^{152}Eu external standard. An MCA is included with data acquisition firmware, and spectra are analyzed in Excel/Windows environment with an external computer. A pulse shape analyzer produces 3D spectra, and the selection of regions of interest can be made after measurements. Separation of alpha and beta events is done similarly to the Wallac PSA, which classifies the signal after 30 ns of pulse onset as the tail component of the pulse. Normalization of tail charge to the total charge of the pulse removes energy dependence of pulse length. This PSA level is called pulse length index (PLI).

This Instrument has been used for the analysis and control of environmental and man-made radionuclides, for instance on-site ^{222}Rn measurements in drinking water (Villalba et al., 2005). Several fast methods were presented for the analysis of environmental radionuclides using the Triathler, including ^{90}Sr by Li et al. (2009) and ^{226}Ra, ^{228}Ra, ^{224}Ra, ^{222}Rn, and ^{210}Pb by Möbius et al. (2006). Optimum results have been demonstrated with good α/β separation and consequently low background and the lowest LLD for ^{226}Ra down to 5 mBq/L in 1 hour counting time using 3M Rad Disk filtering in sample preparation.

The Triathler can also be equipped with an inbuilt NaI(Tl) crystal for detection of gamma radiation.

Another LSC model was introduced by Hidex Oy in 2008, which is a 3 PMT TDCR version, called Hidex 300 SL. The instrument total weight is 125 kg, of which the

lead shield comprises 90 kg. A robotic loading arm picks samples from a tray holding either 40 × 20 mL vials or 96 × 7 mL vials. Pulse shape analysis is a standard feature and a small external anticoincident guard detector reduces instrument background and thus allows greater sensitivity in monitoring environmental radionuclides. Substantial reduction of random PMT noise, sample luminescence signal and also glass vial Cerenkov background signal is achieved in triple PMT coincidence counting.

Swab and urine samples were tested with the 300 SL by Sas et al. (2010), Sas and Janda, (2017) with ^{90}Sr, ^{241}Am, and ^{239}Pu as model radionuclides. Dai et al. (2012a) developed a nasal swab method for quick screening of alpha and beta contaminations in the event of radiological/nuclear emergency. Murali et al. (2009) have presented alpha/beta discrimination for ^{90}Sr–^{90}Y/^{241}Am samples and Wisser et al. (2006) for gross alpha/gross beta samples. Wanke et al. (2012) compared the Hidex 300 SL system with a noncommercial instrument for metrological measurements. Deviations of the results between the instruments were found to be about +0.1% for ^{3}H, +0.22% for ^{55}Fe and only 0.02% for ^{109}Cd from the reference figure.

Krąpiec and Walanus (2011) ran an instrument without guard and external standard in triple coincidence mode for radiocarbon dating. Trailing edge of the pulse height spectrum corrected better for quenching correction in benzene than the TDCR method. For near-background samples the muon peak trailing edge performed better than that of the ^{14}C spectrum.

The 3 PMT TDCR LSAs, including the Hidex 300 SL, are described in detail in Chapter 6, Volume 1.

d. Beckman Coulter Inc.

The Beckman LS 6500 series include the optional capability for PSD, in which α and β scintillation pulses are distinguished by a ratio technique. The area of each pulse is found at times t_1 and t_2, corresponding to the prompt and delayed components respectively. The ratio of these areas is compared with the ratio of known α and β pulses, resulting in a TD called the R-value (Dodson, 1991). The R-values are plotted versus cpm response and the optimum TD setting is the R-value that provides the minimum spillover of alpha and beta events. Typically, this minimum is represented graphically as the minimum value between the alpha and beta R-value spectra. Beckman Coulter terminated LSC production in 2010.

C. Cocktail and vial considerations

1. Cocktail choice

a. Aqueous-accepting cocktails

Aqueous accepting cocktails are typically used in standard β-spectrometers and are quite suitable for gross alpha-beta measurements and where alpha/alpha resolution is not critical. They are infrequently used in the PERALS system. The reasons for this are as follows. The presence of surfactants and other additives in these cocktails (and, of course, the aqueous sample itself) causes a significant degree of quenching and therefore a reduction in light output. This in turn has an adverse effect on the degree of alpha-beta separation and alpha-alpha resolution. Thus, the degree of separation is always a trade-off against sample loading. In addition, standard cocktails for beta counting applications employing fast solvents such as xylene, pseudocumene, toluene, and alkylbenzenes do not result in pulse shapes to be sufficiently different for producing optimum separation of alpha from beta events. To overcome the poor separation, 20% naphthalene has been added to standard cocktails for alpha/beta separation applications (Oikari et al., 1987). Naphthalene improves alpha/beta separation by acting as an intermediate in the energy transfer process between the solvent and fluor (Brooks, 1979; McDowell and McDowell, 1994). This more energetically favorable route increases the production efficiency of excited fluor molecules. The production rate of fluor triplet states is especially enhanced, because energy transfer to triplet states relies on a physical approach and is affected by the concentration of both the fluors and the intermediate (naphthalene) in the cocktail. As more triplet states become occupied, the delayed component of the PMT anode pulse increases and has the effect of stretching the alpha pulses relative to the beta pulses. The ability of naphthalene to act as an intermediate in this way is the result of the extensive delocalization of its electrons. During the late 1980s and early 1990s, a range of cocktails based on the solvent di-isopropylnaphthalene (DIN) was introduced (Thomson, 1991). DIN has many advantages over the traditional cocktails including the fact that it is nontoxic, nonflammable, and biodegradable, and it is similar to naphthalene in its ability to stretch alpha pulses relative to betas and therefore to enhance alpha/beta separation. Cocktails based on DIN, PXE, or DIN together with a second "safe" solvent have now almost completely taken over from fast cocktails containing naphthalene. Furthermore, experiments to assess the suitability of (i) secondary fluors with a range of fluorescence lifetimes and (ii) some alternative scintillating cocktail solvents have failed to improve upon the alpha/beta separation efficacy provided by commercially available cocktail formulations (Pates et al., 1996c; Passo et al., 2002).

b. Extractive scintillators

Extractive scintillators are an elegant combination of two technologies (liquid scintillation and liquid-liquid extraction) in which an organophilic extractant is incorporated in an organic solvent in the presence of a fluor and naphthalene. Extractive scintillators enable extraction of the nuclide

TABLE 2.3 Properties of the commercially available extractive scintillators.

Extractive scintillator	Elements extracted	Applications
ALPHAEXα	Th, Pa, U, Np, Pu,	Any original matrix after conversion to:
	Am, Cm, Bk, Cf, Es,	1 M HNO_3 for Th, U(IV, VI); pH 2−3
	Fm, Md, No	1 M nitrate for others
URAEXα	Uranium selectivity	From 1 M sulfate at pH 2
THOREXα	Thorium and uranium	From 1 M sulfate at pH 2
POLEXα	Polonium selectively	From 7.5 M H_3PO_4, 0.01 M HCl
RADAEXα	Radium selectively	From 0.3 to 0.5 M $NaNO_3$ at pH 11-12
RADONSα	Radon selectively	Radon from water or aqueous solution
STRONEXα	Strontium selectively	From 0.3 to 1.0 M $NaNO_3$ at pH 9−11

of interest from an aqueous sample directly into the scintillator, and since virtually nothing except the radionuclide of interest is transferred, there is reduced quenching compared with that observed in aqueous-accepting cocktails. This results in improved separation of β−γ from α events and improved α−α resolution. There is also a reduction in the variations in quenching between samples, and this facilitates nuclide identification. Products for the extraction of uranium, thorium, plutonium, polonium, radium, and so on are all marketed by ETRAC Laboratories Inc., Knoxville and Oak Ridge, Tennessee (Table 2.3). A typical formulation for extraction of uranium would comprise 96.3 g of Adogen 364 (tertiary amine), 160 g of purified naphthalene, 4 g of the scintillator PBBO [2-(4′-biphenylyl-6-phenylbenzoxazole)] made up to 1 L with toluene (Bouwer et al., 1979). A comprehensive guide to the PERALS and extractive scintillators can be found in McDowell and McDowell (1994).

2. Vial choice

Experiments have shown that no significant improvements in the separation of alpha from beta events have been observed when using plastic vials, although peak resolution is improved. In addition, a progressive deterioration in separation with time (commencing within 48 hour of sample preparation) was observed when using plastic vials. This is due to the so-called plastic vial effect, i.e., the impregnation of cocktail into the vial wall, which then starts to scintillate producing longer pulses than the sample mixed with cocktail. Therefore, plain polyethylene vials should not be used for extractive cocktails. This effect is not seen in glass, Teflon-coated plastic, and Teflon vials. There was also no significant difference in pulse separation between 7 and 20 mL vials. Alpha spectra from glass vials are skewed to have a low-energy tail. This is caused by multiple internal reflections and subsequent losses of photons before light reaches the phototubes.

Alpha/beta separation with glass vials can be improved significantly by etching the outside wall of the vial (McKlveen and McDowell, 1984; Oikari et al., 1987). Careful optics design improves the light output and also improves spectrum resolution (Kossert et al., 2009; Nähle et al., 2009). Monte Carlo simulation of the light passage in LSC optics was done by Hurtado et al. (2009).

D. Alpha/beta calibration

To optimize alpha-beta separation performance, it is essential to determine the optimum TD setting at which there is equal and minimum spill of alpha pulses into the beta MCA and beta pulses into the alpha MCA. Fig. 2.14 illustrates the percent spillover or percent misclassification of ^{241}Am and ^{36}Cl samples in a Packard instrument. The determination of an optimum TD requires two standards, preferably, one of the pure alpha-emitter of interest and one of the pure beta-emitter of interest. For the most accurate results, the standards must be as nearly identical as possible to the unknown samples in their chemistry, volume, vial type, and so on. To achieve the optimum setting, each standard is counted individually at a range of TD settings. Some instruments perform this operation automatically while others perform it semiautomatically. It is possible to favor counting either alpha or beta events by adjusting the TD value appropriately to minimize interference from the other radionuclide (DeVol et al., 1996; Sanchez-Cabeza and Pujol, 1995; Pujol and Sanchez-Cabeza, 1997; Warwick and Croudace, 2002a, 2002b; Salonen, 2006).

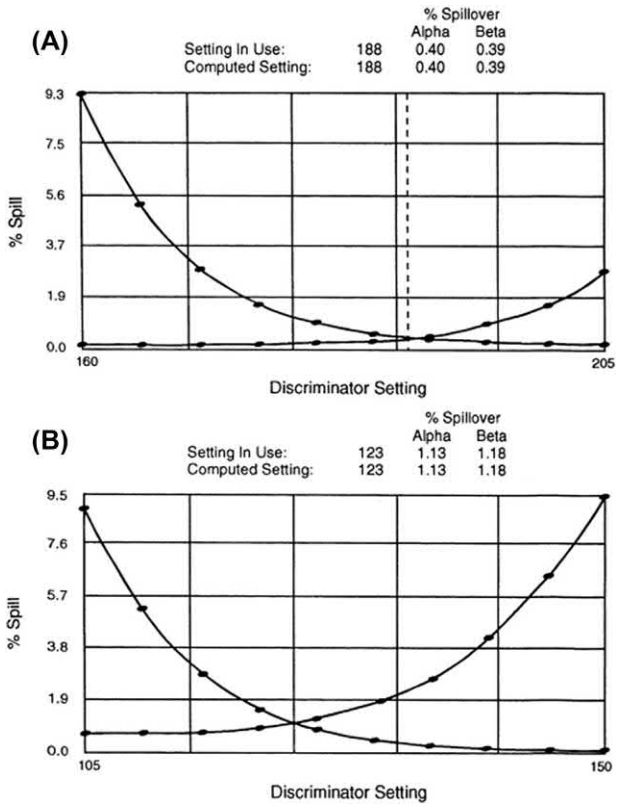

FIGURE 2.14 Percentage misclassification of ^{36}Cl and ^{241}Am in a Packard 2550TR/AB under (A) normal laboratory prepared levels of quenching and (B) artificially high levels of quenching. *©1994–2019, PerkinElmer, Inc. All rights reserved. Printed with permission.*

1. Misclassification Calculations

The calculation required to determine the actual cpm is essentially the same as that used in dual label studies and can be defined as follows:

X_α = alpha misclassification as beta
X_β = beta misclassification as alpha
A_T = true count rate due to alpha disintegrations
B_T = true count rate due to beta disintegrations
A_O = observed count rate in alpha MCA
B_O = observed count rate in beta MCA

Alpha into beta misclassification (X_α) is defined as the ratio of counts accumulated in the beta MCA to counts accumulated in both the alpha and beta MCAs as measured with the alpha standard.

$$X_\alpha = B_O/(A_O + B_O)$$

Similarly, beta into alpha misclassification (X_β) is defined as:

$$X_\beta = A_O/(A_O + B_O)$$

as measured with the beta standard.

It is important to understand that the count rate observed in each MCA is a function of both alpha and beta disintegrations because of the occurrence of some misclassification. This relationship can be defined as:

$$A_O = A_T - A_T X_\alpha + B_T X_\beta$$

$$B_O = B_T - B_T X_\beta + A_T X_\alpha$$

The first equation states that the observed count rate in the alpha MCA (A_O) is due mainly to counts from alpha disintegrations (A_T); however, this value will be reduced by the total number of alpha disintegrations counted in the beta MCA ($A_T X_\alpha$). Furthermore, beta counts falling into the alpha MCA must also be taken into account. This is accomplished by adding the $B_T X_\beta$ term. The calculation of the observed beta count rate (B_O) is the reverse of the calculation for the observed alpha count rate.

Solving for A_T and B_T and substitution of the A_T expression into the B_T expression and vice versa, we obtain the final equations for A_T and B_T:

$$A_T = \frac{A_O - A_O X_\beta - B_O X_\beta}{1 - X_\beta - X_\alpha}$$

and similarly

$$B_T = \frac{B_O - B_O X_\alpha - A_O X_\alpha}{1 - X_\alpha - X_\beta}$$

Example *of Misclassification calculation.* The calculation is further illustrated by counting mixtures of ^{36}Cl and ^{241}Am ranging from approximately 500 dpm of ^{36}Cl and 50,000 dpm of ^{241}Am to approximately 50,000 dpm of ^{36}Cl and 500 dpm of ^{241}Am in a total volume of 10 mL of cocktail (with appropriate background samples) at the optimum TD value.

The results were as follows:

Misclassification of alphas into the beta MCA (as a fraction) = 0.0071 = X_α
Misclassification of betas into the alpha MCA (as a fraction) = 0.0063 = X_β
Background in alpha-MCA = 0.69 cpm (0–2000 keV)
Background in beta-MCA = 39.6 cpm (0–2000 keV)

Table 2.4 lists the gross and background-corrected raw instrument data. Table 2.5 compares the actual alpha and beta activities in the vial with the calculated spill-corrected activities derived from the raw data.

2. Quenching and quench correction of percentage misclassification

In the PERALS system, all aspects of sample preparation (but principally the use of extractive scintillants) are geared toward minimizing quenching and maximizing the constancy of composition of samples. In standard LS counters,

TABLE 2.4 Gross and net (background corrected) raw data.

	Observed gross counts		Net counts (background subtracted)	
Sample no.	Beta-MCA	Alpha-MCA	Beta-MCA	Alpha-MCA

7	507	49,595	411	51,135

when aqueous-accepting cocktails are employed, variations in quenching are much more likely and have to be accounted for in any calculations.

Fig. 2.14A and B represent misclassification plots determined in a Tri-Carb LSA instrument for the same activities of standards but under different quench conditions. Fig. 2.14A represents relatively unquenched conditions compared with Fig. 2.14B. Both the optimum TD value and the percentage misclassification of events change under these different conditions. It should be noted, however, that this effect will vary according to the isotopes being measured and may also vary, in a more limited fashion, from instrument to instrument. When the degree of quenching for a particular set of samples varies, there are two possible approaches. The first approach is to produce a single pair of alpha-beta standards that are similar in their quench-indicating parameter value to the least-quenched sample and then to progressively quench them and reoptimize the TD at each quench level. This produces a series of optimum TD values and percentage misclassifications for a range of quenching. The degree of sample quenching in each sample may then be measured by making a short count on each sample to determine the value of the quench-indicating parameter. Subsequently, the samples have to be counted at their individual optimum PDD conditions; however, this could conceivably require a separate counting protocol for each sample. The alternative approach is again to prepare a pair of standards that are equivalent in quenching to the least quenched samples, determine the optimum TD and then progressively quench the standards. However, in this approach, the misclassification is always determined at the original TD setting. This allows the construction of a plot of percentage misclassification versus quench-indicating parameter for a single TD setting. All samples may then be counted within a single protocol and a correction for misclassification as a function of quench is applied. This approach would be in addition to a quench curve that relates quenching to detection efficiency.

IV. Triple-to-double coincidence ratio (TDCR) counting

A. TDCR liquid scintillation counting

The TDCR method is an absolute standardization technique based on LSC developed for the determination of the activity of pure β-emitting and pure electron capture (EC) nuclides. The TDCR method requires a LSA equipped with three PMTs and two different coincident outputs, and the integration of theoretical calculation of counting efficiency is based on a physical and statistical model of the distribution of scintillation photons and their detection probability by the LSA. The principle of the TDCR method, the configuration about the TDCR detector system, the TDCR efficiency calculation technique as well as the applications of the TDCR method in radionuclide metrology have been described in detail in Chapter 6, Volume 1.

For the early applications, the TDCR method was exclusively employed in metrological laboratories for radionuclide standardization. Since the introduction of the first commercial TDCR LSA (Hidex 300 SL) by Hidex Oy in 2008, the TDCR method has been used more widely to radionuclide measurements in other applications such as environmental monitoring, radiological protection and biomedical studies.

As the nonlinearity of the scintillation response caused by the ionization-quenching phenomenon can be dealt with the TDCR method, the measured TDCR values have been used for quench correction. In TDCR LSC, triple and double coincidences are both measured. Since triple coincidences are more affected by chemical and color quench than double coincidences, a correlation between the quench level (or

counting efficiency) and the measured TDCR value can be established for quench correction. For pure beta-emitting radionuclides, the TDCR value usually approximates the overall counting efficiency. The TDCR efficiency calculation technique has been approved to be suitable for routine analysis of beta-emitting nuclides in samples with different quench levels (Simpson and Meyer, 1994).

For electron capture nuclides, such as ^{55}Fe, ^{41}Ca, and ^{139}Ce, there can be more than one counting efficiency corresponding to a given TDCR value, as the decay spectra are not continuous due to the contribution of two or more separated groups of scintillation energy from conversion electrons and gammas. Thus, the introduction of a new parameter into the algorithm of counting efficiency determination would be required to yield a single-valued efficiency versus TDCR curve (Broda, 2003).

Unlike external standard methods, TDCR is a universal method applicable for both chemical and color quenching, for aqueous and organic samples and for different cocktails and range of isotopes. In TDCR LSC, an external standard for monitoring quench level is not needed. The TDCR efficiency calculation technique enables the determination of pure beta-emitting and pure electron-capture nuclides in samples of various states of quench. Alternatively, quench correction can also be made with a curve fit option. Using a set of quench standard samples for the analyte nuclide, a standard quench curve of counting efficiency versus the TDCR value is first established, and the counting efficiency of an unknown sample can then be determined from the measured TDCR value of the sample. Once established, the TDCR quench curves are quite generic and do not need to be redone. In the Hidex 300SL LSA, a standard quench curve can be stored with the curve fit option, which can be automatically employed to determine the real counting efficiency based on the TDCR value of the sample.

The LSC instrument based on TDCR technique has been widely utilized for the determination of beta-emitters in a variety of environmental and biological samples for environmental monitoring, environmental tracing, radiocarbon dating, waste characterization and nuclear medicine etc. The TDCR method was demonstrated to be easy and sufficiently accurate for the determination of beta-emitting radionuclides in environmental and biological samples. The TDCR LSC has been used for the measurements of radionuclides including the following examples:

- ^{3}H, ^{210}Pb, ^{228}Ra, ^{99}Tc, ^{89}Sr, and ^{90}Sr in environmental water samples (Atkinson et al., 2014; Eikenberg et al., 2014; Guerin el al., 2017b; Dai and Kramer-Tremblay, 2014; Tayeb et al., 2016),
- ^{241}Pu, ^{90}Sr, and ^{63}Ni in radioactive waste and decommissioning samples (Taddei et al., 2013; Jaggi and Eikenberg, 2014; Priya et al., 2014), as well as
- ^{51}Cr, ^{90}Sr, and ^{32}P in various biological samples (Zoriy et al., 2016; Dai et al., 2013; Guerin el al., 2017a; Miura and Minai, 2017; Vernon et al., 2018).

Krąpiec and Walanus (2011) tested the Hidex 300SL for the determination of ^{14}C in radiocarbon dating. While the TDCR quench correction worked very well for determining the activity of ^{14}C in quench standards with high activity levels, it may not be preferred for the correction of benzene impurities in very low activity samples for radiocarbon dating. Thus, based on the observed position of the right slope of the ^{14}C or muons spectrum, a quench correction method was proposed and seemed to be more optimal for ^{14}C dating.

Using the Hidex TDCR LSA, several investigations have been carried out for the measurement of ^{55}Fe (an electron capture nuclide) in radioactive waste, irradiated steel, and urine samples (Taddei et al., 2013; Priya et al., 2014; Guerin and Dai, 2015). As an obvious discrepancy was observed between the measured TDCR value and the counting efficiency of ^{55}Fe, quench correction needed to be conducted by fitting with a quench calibration curve. The quench correction is particularly important for activity measurement of ^{55}Fe by LSC, because ferric ions in the sample could cause a strong color quenching and seriously reduce the counting efficiency. By obtaining a simple power function of counting efficiency versus the TDCR value with a set of quench standards, satisfactory results of quench correction for ^{55}Fe has been achieved (Guerin and Dai, 2015).

B. TDCR Cerenkov counting

The TDCR method can be used not only for activity measurement of typical beta-emitting isotopes by LSC but also for the determination of high-energy beta-emitting nuclides (e.g., ^{89}Sr, ^{90}Y, ^{32}P, ^{106}Rh, ^{204}Tl) by Cerenkov counting (Kossert, 2010).

In Cerenkov counting, fast electrons from beta decay moving in a dielectric and transparent medium (e.g., water) would produce Cerenkov photons, which can be directly detected using a LSC system with no use of scintillation media. The energy threshold of a radionuclide for Cerenkov light production in water is 263 keV. Although the efficiency of Cerenkov counting is usually lower in comparison with LSC, it has some significant advantages over LSC: (1) samples are counted directly without the need to add scintillation cocktail, which not only allows for a larger sample volume but also helps reduce time and cost on sample preparation and disposal problems; (2) the Cerenkov method can be used as a natural discrimination from low-energy beta- and alpha-emitting nuclides; (3) since Cerenkov photons are produced directly in sample solutions, no inhibition of the photon emission process due to fluorescence is involved; thus, Cerenkov counting is free of

chemical quenching. However, Cerenkov counting efficiency could be affected strongly by color quenching. Even very light color barely visible to the naked eye can produce a significant quench effect with a noticeable reduction in counting efficiency.

The color quench for Cerenkov counting is usually corrected by the internal standard method or quench curve method. The use of internal standards for color quench correction is applied by adding a known activity of the same radioisotope to the sample (after its counting) and recounting to determine the counting efficiency. Although this method is accurate, it is time consuming and cancels one of the main advantages of the Cerenkov method of keeping the original unadulterated sample. In most modern liquid scintillation systems, the quench correction for LSC is often performed by the quench curve method using external gamma-emitting radioisotopes such as ^{137}Cs, ^{226}Ra, ^{133}Ba, or ^{152}Eu. However, as a photon energy of >430 keV for the external source would be needed to produce Compton electrons above the threshold for the production of Cerenkov radiation (263 keV), those liquid scintillation counters containing ^{137}Cs and ^{133}Ba sources would not be applicable to quench correction in Cerenkov counting (Kamp and Blanchard, 1971; Takiue et al., 1996). Using a quench indicative parameter based on the integral area of the spectra measured with the external ^{152}Eu source of a Quantulus 1220 system, an ESAR (external source area ratio) method was proposed for color quench correction in Cerenkov counting (Tsroya et al., 2009, 2012). This method has been utilized for the determination of ^{90}Sr/^{90}Y activity in milk and urine samples (Tsroya et al., 2013a; 2013b).

In the TDCR technique, however, there is no need for constructing of quench correction curves using an external gamma source, because the effects of color quenching on Cerenkov efficiency can be automatically corrected based on the measured TDCR values. Unlike the conventional double coincidence counting techniques, the TDCR technique uses a triple coincidence counting method. For radionuclide standardization by Cerenkov counting with detection systems using two PMTs, Grau-Carles and Grau-Molonda (2006) have developed a free parameter model of light emission to compute Cerenkov counting efficiency. By adapting the Frank and Tamm theory for the production of Cerenkov photons, this free parameter model was extended for standardization with the TDCR detection systems (Kossert, 2010; Kossert et al., 2014). Based on the Monte Carlo code Geant4, Bobin et al. (2010) has also constructed a stochastic TDCR model to determine the Cerenkov efficiency using the experimental TDCR value. These TDCR Cerenkov models have been successfully tested for the activity standardizations of ^{90}Y, ^{89}Sr, and ^{68}Ge in nuclear medicine applications (Kossert et al., 2016; Thiam et al., 2017). The TDCR Cerenkov method would allow for calculation of the counting efficiency without an external or internal standard source.

Using a Hidex TDCR liquid scintillation counter, the TDCR Cerenkov method has been successfully used for quantitative determination of high-energy beta-emitters in environmental samples. An empirical correlation between the Cerenkov counting efficiency for ^{90}Y and the measured TDCR value was established for the correction of color quench effect on the determination of ^{90}Sr/^{90}Y in aqueous samples (Tayeb et al., 2014). The direct TDCR Cerenkov counting can serve as a rapid screening method for high-energy beta-emitting radionuclides in environmental water samples without any radiochemical separation procedure. For the measurements of ^{90}Sr−^{90}Y in groundwater samples collected in a contaminated riverbed, Olfert et al. (2014) compared the results by TDCR Cerenkov counting to those by LSC followed through radiochemical separation, and good agreements have been achieved. To date, the TDCR Cerenkov counting is still new to radioanalytical chemists, and only a few papers were published about its applications in environmental measurements (Olfert et al., 2014; Tayeb et al., 2015; Yang et al., 2017). In addition, Coha et al. (2016) studied the effects of measurement conditions on Cerenkov counting efficiency using three commercially available LSAs (including Triathler, Tri-Carb 3180, and Hidex 300 SL) with one-, two-, and three PMTs, and concluded that the TDCR Cerenkov counting would be well suited for routine quantitative determination of high energetic beta-emitting radionuclides in low-level environmental samples.

V. Analysis of alpha-emitting transuranic nuclides

A. Environmental occurrence and importance

The transuranium elements, neptunium (Np), plutonium (Pu), americium (Am), and curium (Cm), are products of nuclear weapons tests and nuclear fuel cycle operations particularly from reprocessing plants (Pimpl, 1992). With the exception of Pu and Am, which have been widely studied as part of global fallout following atmospheric weapons testing and nuclear accidents, the others are of environmental importance around fuel reprocessing and disposal sites (Hou and Roos, 2008; Qiao et al., 2009). The most common transuranium nuclides investigated in environmental studies are ^{238}Pu ($t_{1/2} = 87.74$ y), ^{239}Pu ($t_{1/2} = 2.41 \times 10^4$ y), ^{240}Pu ($t_{1/2} = 6563$ y), ^{241}Pu ($t_{1/2} = 14.4$ y) ^{241}Am ($t_{1/2} = 432.2$ y), and ^{244}Cm ($t_{1/2} = 18.1$ y). With the exception of ^{241}Pu, the other radionuclides are long-lived α-emitters and highly radiotoxic. ^{241}Am is a unique tracer in oceanographic and sedimentation studies, and its maximum concentration in the environment is estimated to be attained in the middle of the 21st

century (Hou and Roos, 2008) due to the decay of ^{241}Pu. The analysis of ^{241}Pu is discussed in other sections.

The differences in the plutonium isotopic ratios are used to trace the origin of the environmental contamination (Kershaw et al., 1995; Turner et al., 2003; Carbol et al., 2003; Ketterer et al., 2004; Kwong et al., 2004; Alamelu and Aggarwal, 2007; Hou and Roos, 2008; Varga et al., 2008; Zheng et al., 2013). For instance, the activity ratio of ^{238}Pu/$^{239+240}$Pu differs depending on whether the contaminations originate from releases from nuclear fuel reprocessing plants (0.25), nuclear tests (0.026), weapon grade uranium (0.014), or the Chernobyl accident (0.47). Owing to the high radiotoxicity of transuranium nuclides, the disposal of nuclear wastes is of particular concern, and strict restrictions govern the limits allowed for them in the environment. Environmental monitoring of transuranium nuclides around nuclear facilities is common and their determination in high-activity waste in nuclear fuel reprocessing cycles is important, as it will influence the method of final disposal (Prosser et al., 1994; Feng and He, 2009).

B. Sample preparation and analysis

Numerous methods have been applied to determine α-emitting transuranium nuclides in environmental and nuclear samples, which have been compiled and assessed in four comprehensive reviews by Hou and Roos (2008), Qiao et al. (2009), and Vajda and Kim (2010a, 2010b). These reviews deal with pre-treatments, pre-concentration, chemical separation, and various measurement methods, which are mostly tedious and challenging because of the complex environmental sample matrices and other radionuclides present. The chemical separation schemes are complicated, because the concentrations of transuranium nuclides are very low, their oxidation states have to be considered and they must be purified completely from other actinides in advance to avoid the interference of other radionuclides. The other actinides (such as U and Th) and fission products are usually present in much higher concentrations in most samples than those of transuranium nuclides. To achieve the best possible energy resolution by α-spectrometric analysis, the sample must be prepared as a thin-layer counting source. Likewise, their determination in high-activity waste is not trivial because of the low concentrations, the presence of β- and β/γ-emitting radionuclides and high salt concentrations.

1. Alpha spectrometry

The traditional methods for determining α-emitting transuranium nuclides in environmental samples are based on α-spectrometry. However, ^{239}Pu and ^{240}Pu isotopes cannot be distinguished by the standard α-spectrometers due to their similar α-particle energies; they exist as a sum peak in the α-spectrum. Likewise, due to their overlapping α-peaks, ^{244}Cm and ^{243}Cm isotopes are also indistinguishable by α-spectrometry. The typical radiochemical separation methods for transuranium elements are based on ion exchange, solvent extraction and extraction chromatography (EC). The EC techniques are commonly employed in the separation schemes partly owing to the availability of actinide-specific resins, TEVA, TRU, UTEVA, and DGA, which can be used with ion exchangers and Sr resin to the simultaneous determination of several actinides, Th, U, Pu, Am, Cm, and Np, and other radionuclides such as ^{226}Ra, ^{210}Pb, ^{137}Cs, and ^{90}Sr from a single sample (Alvarez and Navarro, 1996; Moreno et al., 1998; Pilviö et al., 1999; Pilviö and Bickel, 2000; La Rosa et al., 2001; Thakkar, 2001; Mellado et al., 2002; Wang et al., 2004; Tavčar and Benedik, 2005; Oh et al., 2009; Maxwell, 2006; Maxwell and Culligan, 2009b; Maxwell et al., 2014; Harrison et al., 2011; Luo et al., 2018). Sequential separation brings considerable savings in time needed for pre-concentration, pre-treatments, and the chemical separation, which is simpler and faster using EC than merely ion exchange (Dai and Kramer-Tremblay, 2011; 2014). Lee et al. (2011) developed a rather simple procedure for the determination of Pu, ^{90}Sr, and ^{241}Am in soil samples and obtained high chemical yields (71%−75%) for these nuclides in terrestrial soil samples. It was based on an anion exchange resin connected with a Sr-Spec column. ^{236}Pu, ^{242}Pu, ^{239}Np, and ^{243}Am (for Am and Cm) are the most commonly used yield tracers. The detection limits using α-spectrometry are of the order of 0.02−0.09 mBq for ^{238}Pu and ^{239,240}Pu and of 0.1−0.2 mBq for ^{241}Am with a few days of counting time (Hou and Roos, 2008; Qiao et al., 2009; Vajda and Kim, 2010a, 2010b; Dai and Kramer-Tremblay, 2014).

2. Mass spectrometry

Currently, long-lived transuranic radionuclides are often determined by mass spectrometric techniques, including ICP-MS (Chen et al., 2002a; Hou and Roos, 2008; Qiao et al., 2009; Vajda and Kim, 2010a, 2010b; Shi et al., 2011; Zheng et al., 2013), thermal ionization mass spectrometry (Callis and Abernathey, 1991; Cooper et al., 2000; Elliot et al., 2006; Shibahara et al., 2016) and accelerator mass spectrometry (Fifield et al., 1996; Child et al., 2008; Dai et al., 2012b, 2016). In this case, the isotopic ratio of ^{239}Pu and ^{240}Pu are also determined, but chemical separation prior to their detection by mass spectrometry is necessary. The detection limits for long-lived actinide isotopes with a half-life of $>10^4$ years by mass spectrometric techniques (especially AMS) are better than those obtained by α-spectrometry.

3. Liquid scintillation counting (LSC)

LSC using α/β discrimination has been used to measure transuranium nuclides in high-activity wastes (Yang, 1990;

Feng and He, 2009) and in bioassay samples (Yang et al., 1995; Eikenberg et al., 1999) following chemical separation by solvent extraction or extraction chromatography (EC). Yang (1990) used di-(2-ethylhexyl) phosphoric acid (HDEHP) and trialkyl phosphine oxide (TRPO) as extractants to separate Np, Pu, and Am from reactor waste samples. Yang et al. (1995) determined Pu in urine by extracting it with 30% TRPO in xylene from 1M HNO_3 solution where urine residue was dissolved following the removal of organic compounds. The chemical yields were between 80% and 95%. Feng and He (2009) proposed a new method for the determination of ^{237}Np, $^{238-240}$Pu, and ^{241}Am in high-active waste. It is based on combined α-spectrometric and LSC measurements and on the extraction of transuranic elements with TRPO and tenoyl-tri-fluor acetone (TTA). The source for the α-spectrometric measurement was prepared simply by evaporating the TRPO in xylene onto a stainless steel disk to determine the activity percentage of each α-emitter while their total activity was quantified by LSC using a sample prepared from the same solution. The activities of various transuranium nuclides were calculated using the results of these measurements. The complicated separations were then avoided and the advantage of the high counting efficiency by LSC was achieved. Moreover, only one step of extraction with TRPO is needed, if it is not necessary to know the relative amounts of ^{238}Pu, $^{239+240}$Pu, and ^{241}Am. Otherwise, another extraction step is needed to separate Pu from Am completely, because the α-peaks of ^{238}Pu (5.456 and 5.498 MeV) and ^{241}Am (5.443 and 5.486 MeV) overlap each other. This separation is performed using 0.5 mol/L TTA in xylene whereby the Pu (IV) is efficiently extracted into the organic phase while Am remains in the aqueous phase. The activity ratio of ^{238}Pu/$^{239+240}$Pu is obtained from the α-spectrometric measurement using a sample prepared from the organic phase as previously described. The extraction efficiencies with the TPRO and TTA extractants are nearly 100%. Eikenberg et al. (1999) used Actinide resin, with a trade name of DIPEX, for separating transuranium nuclides (Pu, Am, Cm) from urine. Their procedure was rather simple including partial oxidation of organic matter, sorption of the actinides on the resin, separation of the resin from the solution and stripping of the actinides from the resin with isopropanol. This was decomposed by oxidation with acids to have a transparent residue dissolved in 2 mL 0.5 M HCl, which was mixed with the LS cocktail. The chemical yields for various actinides, including U and Th isotopes and ^{233}Pa, were between 70% and 100%, whereas Ra (<5%) and Po (<3%) were purely adsorbed on the resin. One advantage of using LSC with α/β discrimination is that it eliminates any β-interferences that might have been co-extracted. Yang (1990) observed that α-activity can be quantitatively analyzed in the presence of a 10^5 excess of β-activity in high-activity waste. Detection limits depend on the sample volume used for the analysis and on the amount of beta interference that is present. Detection limits for Pu with the α/β LSC are of the order of 3−10 mBq/L for a 100−120 minute count time.

The PERALS LSC system in combination with extractive scintillators has been applied for the determination of a number of transuranium nuclides (Metzger et al., 1995; Dacheux and Aupiais, 1997, 1998; Aupiais, 1997; Aupiais et al., 1999). The detection limits are comparable to those achieved by ICP-MS or α-spectrometry.

VI. Analysis of beta-emitting radionuclides

LSC is the major technique for measurement of pure beta-emitting radionuclides, including the radionuclides that decay by electron capture. The most important radionuclides in view of environmental radioactivity, tracer application in various disciplines and nuclear waste management are ^{3}H, ^{14}C, ^{55}Fe, ^{63}Ni, ^{89}Sr, ^{90}Sr, ^{129}I, and ^{241}Pu. The updated analytical methods for these radionuclides using LSC are presented below.

A. Tritium (^{3}H)

1. Environmental occurrence

Tritium is a pure, low-energy beta-emitter ($E_{max} = 18.6$ keV) with a half-life of 12.32 years (Lucas and Unterweger, 2000). Tritium in the present environment has three major sources: (1) natural production in the upper atmosphere through cosmic ray reaction of nitrogen (^{14}N(n,^{3}H)^{12}C) and oxygen in the upper atmosphere (Hou, 2018); (2) residual activities from atmospheric nuclear weapons testing (Libby, 1963); and (3) on-going nuclear fuel cycle operations. Since the partial atmospheric nuclear test ban treaty in 1963, the worldwide levels of tritium in the environment have been decreasing at a rate approximately equal to its half-life (Okada and Momoshima, 1993). Generally, nuclear fuel cycle operations are of concern to the immediate locale only, with relatively minor contributions to more general environmental tritium levels. Regulated monitoring of specific sites and hydrological studies are the principal applications of environmental tritium analysis, and, of course, as the "background" levels decrease, there is a corresponding requirement for the measurement of lower and lower activities (Eyrolle et al., 2018).

Tritium activities in the field environmental tracer application are commonly described in terms of tritium units (TU), where 1 TU = 1 atom of tritium per 10^{18} atoms of hydrogen or 1 TU = 7.14 dpm/L of water = 0.119 Bq/L of water. The natural activities (without direct contamination from nuclear facilities) in precipitation vary from about

25 TU at high latitudes to about 4 TU in the equatorial zone (Geyh and Schleicher, 1990; Duliu et al., 2018).

2. Sample preparation and analysis

a. Sample handling

Samples taken for the purpose of tritium analysis should be sealed in airtight containers at the point of sampling (glass or high-density plastic is preferred), as the hydrogen from water or water-bearing samples is readily exchanged with atmospheric hydrogen in the form of water vapor. In the case of biological samples and some water-bearing biologically active samples (sludge and silt) that cannot be processed immediately, freezing is a good way to preserve the sample composition. Frozen samples should be thawed completely and the external areas of the container is dried prior to opening in order to minimize sample exposure to condensation of atmospheric water (onto the sample) or isotopic exchange with water vapor in the air. When samples are exposed, it should be assumed that contamination is a possibility, and steps to prevent or monitor this are required.

b. Sample preparation

The term "sample preparation" of this section refers to the processes required to render the separated sample of water form into a pure state (purified water or benzene), that is, ready to be mixed with the scintillation cocktail or fluor in preparation for LSC. Generally, three methods of preparation are employed for environmental tritium measurement of water. These are direct addition, electrolytic enrichment, and benzene synthesis, and the method of sample preparation depends on the type of analysis to be performed and tritium level in the samples. Biological and soil samples always require a tritium extraction/separation step regardless of the sample preparation method to be employed. Water samples require purification (distillation is the normal approach) prior to electrolytic enrichment and benzene synthesis analysis, but this step can be omitted with the direct addition method if the water is relative pure (no color and no high salt content). Tritium exists in biological samples as part of the water component (FWT, free water tritium) or as part of the organic structure (BT, bound tritium). The free water tritium is often separated from the sample by freeze drying and collecting the evaporated water. To analyze the bound tritium, the sample is dried (freeze drying or low-temperature oven drying at $\sim$60−80°C) and then combusted. The water of combustion is collected, purified as required, and analyzed by the direct addition method.

Direct Addition. Some water samples are relatively pure as received (*e.g.*, municipal drinking water) and can be counted without any purification steps. For routine operations this can be a significant consideration, because the purification step greatly increases the sample preparation time. Purification is recommended if (1) color is visible (includes cloudiness from suspended solids), (2) organics are present, (3) the sample history or source is unknown (may contain interfering chemicals causing high quench), and (4) high salt content (seawater and some ground water), which causes a high quench and much less sample size can be used. For a relatively pure water sample, it can be directly mixed with a scintillation cocktail and counted.

Electrolytic Enrichment. This procedure is based on the principle of selective isotopic enrichment using electrolysis. Because of the slightly higher binding energies, molecules of THO are not decomposed to form H_2 and O_2 as readily as H_2O or DHO (T = tritium, D = deuterium). Water samples are distilled, then made slightly alkaline (Stencel et al., 1995) by addition of Na_2O and placed in an electrolysis cell. A constant current (e.g., 10 A) is applied to the cell, and electrolytic decomposition of the water reduces the sample to about 1−5% of the initial volume. Isotopic fractionation, due to the higher binding energy, typically concentrates over 90% of the tritium in the remaining water. The concentrated sample is purified by distillation or vacuum distillation to remove the alkaline (NaOH) and counted after addition of scintillation cocktail. This procedure usually takes 5−10 days to complete depending on the size of cell/sample; therefore, multicell designs containing 20−40 cells are very common. During electrolysis, the temperature of the water sample in the cell needs to be cooled to a low temperature (2−4°C) to reduce the loss of water sample by evaporation. Modern electrolytical enrichment systems often include temperature control of samples ($\sim$2−4°C) and electronic regulation of the electrolysis process. Fig. 2.15 illustrates a schematic diagram of a cell for the electrolytical enrichment of tritium (Plastino et al., 2007). Each cell in the system must be characterized for isotopic separation performance, which is done by adding a known quantity of tritium to the cell to determine the "recovery of tritium". The recovery of tritium is related to the performance of each cell, but for the same quality, the performance of the cells should be similar. Fig. 2.16 shows a measured recovery of tritium in an electrolytical system with an initial volume of 500 mL and final remaining volume of 13−16 mL, a relative constant recovery of tritium was obtained regardless of the cells and volume of remaining water in 13−16 mL. However, it should be mentioned that if the volume of the remaining water is less than 13 mL, a significantly reduced recovery of tritium was observed. Therefore, the smallest volume of the remaining water has to be more than 13 mL for this system. The performance of the electrolytical enrichment system is often checked yearly, cells are spiked with a known activity of tritium water standard, and the recovery of tritium in each cell is checked against a known standard and the final remaining water volume. The enrichment factor (EF) is simply the recovery (RE) multiplied by the

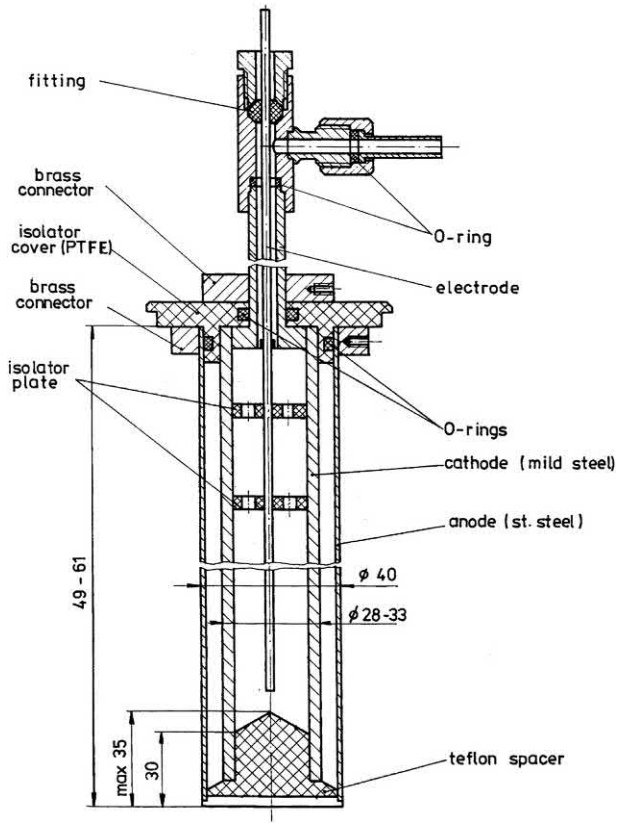

FIGURE 2.15 Electrolysis cell for enrichment of tritium in water.

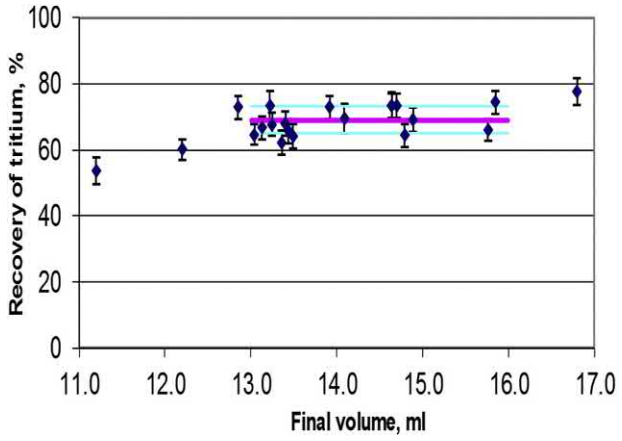

FIGURE 2.16 Recovery of tritium in electrolytical enrichment system with initial volume of 450 mL water.

initial weight (W_i) of sample divided by the final weight (W_f) of sample and is expressed as a numerical value (*e.g.*, enrichment factor = 15). The electrolysis cells are generally designed to handle 100−500 mL samples, with enrichment factors of 15 to >30.

$$EF = RE(W_i \div W_f)$$

For example, a 250-g water sample is enriched and 10 g of sample remains; the recovery is 91%. $EF = 0.91(250 \div 10) = 22.75$.

Benzene Synthesis. The third method of preparation is the synthesis of high-purity benzene from water samples (De Filippis and Noakes, 1991). Sample water is added to calcium carbide in an evacuated reaction vessel, to form acetylene (C_2H_2). The acetylene is then cyclotrimerized to high-purity benzene using a chromium or vanadium catalyst. For LSC of benzene, there is no requirement for the addition of a scintillation cocktail, as the fluors can be added in solid form directly to the counting vial. One sample per day per vacuum apparatus can be handled, with the production of 8−15 mL of high-purity benzene. Regardless of a larger volume of sample counted and less quenching of benzene compared to water, the method is only marginally more sensitive than direct addition because of no improvement in the hydrogen/tritium content in benzene (<8%) compared to H_2O (about 11%). Since the detection limit of tritium is not significantly improved, this method is generally not used. The method is included here only for completeness and will not be discussed further.

c. Tritium extraction/purification techniques

Low-level counting of tritium requires that water samples be reasonably pure and free from interfering substances. Given the wide variety of sample matrices that environmental monitoring programs may encounter, various cleanup/separation techniques are employed. If there is any doubt about the purity of a sample, it is always best to take proactive action, as repeating the analysis invariably costs more (manpower, equipment, and time) than the initial sample cleanup.

Filtration. Simple filtering of a "dirty" water sample often produces clear water by the removal of particles in suspension, which will cause physical quench during LSC measurement. This should be used only when the source of the sample is well known, such as a routinely sampled stream or well water, and there is little chance of the presence of interferences. This type of cleanup should be used only for samples containing suspended mud or silt. An alternative would be to allow the suspended material to settle down and then decant/suck the clear water sample for measurement. However, this action cannot remove the soluble interferences, such as salt and organic and colorful substance (e.g., humic substances), which need other purification action.

Distillation. Plain or vacuum distillation is useful for the purification of water samples that do not contain volatile materials but may have chemical contaminants that would render them unsuitable for analysis.

Ion Exchange. Mixed-bed ion exchange columns designed specifically for tritium analysis are commercially

available. A typical column (Eichrom Industries, Tritium Column) is composed of a prefilter and beds of anion, cation, and organic specific resins. It is designed to give results comparable to those of simple distillation. The column needs to be pre-conditioned with background water (tritium dead water) and then the sample is passed through for "cleanup". This type of column is a useful tool but should be used only with sample media that have been pretested and the cleanup performance verified. Simple water samples (groundwater, seawater, etc.) are likely candidates for this method. More complex samples, such as rainwater and lake water containing high organic substances, can become highly colored and require a more aggressive procedure.

Active Charcoal Adsorption. This is the method often applied to remove soluble organic substances before distillation or ion exchange purification, especially for a sample with a high content of organics, especially urine sample. Active charcoal powder in a ratio of 1:15−30 (by mass) to sample is mixed and allow to stand for 1−5 hours, the mixture is then filtered to remove the charcoal with adsorbed organics. The water is further distillated or treated with ion exchange chromatography for LSC measurement.

Freeze Drying. Freeze drying is the process whereby a sample is frozen and then exposed to high vacuum. The water contained in the sample goes from the solid phase directly to a vapor (sublimation), and if the vacuum is drawn through a cold trap, this vapor can be collected as pure water. Routine application of this process for the purposes of extracting pure water for tritium analysis is generally accomplished using custom glassware and cryogenic (liquid nitrogen, LN_2) cooling. The sample is first frozen to solid using a Dewar of LN_2; the Dewar is then moved to a collecting flask (cold trap) and a high vacuum applied. The ambient room temperature supplies sufficient heat to accelerate the sublimation process, which may take several hours (depending on the volume of water required). The water sample is collected in the cold trap (as deposited ice) and is simply melted and recovered for analysis.

Azeotropic Distillation. An azeotrope is a liquid mixture that has a constant boiling point and its vapor has the same composition as the liquid. Several compounds, such as toluene, benzene, and cyclohexane, form suitable azeotropes with water. These compounds have a cyclic structure, immiscible in water, so are resistant to exchange with external hydrogen. Cyclohexane is the preferred compound, as it is the least hazardous and provides a suitable level of performance in the extraction of water and measurement of tritium. The water azeotrope formed with cyclohexane (boiling point 80.7°C) contains 8.5% water, has a boiling point of 69.8°C. Azeotropic distillation (Moghissi et al., 1973) provides a simple method for extracting water from a wide variety of media (e.g., honey, milk, vegetation, soil, fish) for tritium analysis using LSC. Because these materials are largely composed of free water, an azeotropic distillation will generate, from a mixture of sample and cyclohexane, not necessarily azeotropic in proportion, an azeotropic vapor and, hence, distillate. The distillate separates into two layers with water in the bottom layer. Using suitable glassware, the distillate is collected and the water portion is taken for analysis.

Combustion: The organic bound tritium in biological samples and the strong binding of tritium within the crystal of grains of soil and sediment are often separated using combustion with oxygen flow and high temperature. In this case, tritium in organic substance is converted to water vapor and collected by condensing (Huang et al., 2014; Croudace et al., 2012). The firmly binding tritium in the crystal of soil and sediment grains and metals can be separated also by converting it into water vapor by combustion (Croudace et al., 2014; Warwick et al., 2010). The converted tritium in water vapor form is condensed and collected as liquid water, which is further purified with the methods presented above, and finally measured using LSC.

d. Background water

A tritium-free water needs to be used as blank (background water) to measure the background of the LSC. The quality of this water is the cornerstone of any program undertaking environmental tritium analysis, as it is used for subtraction of the measurement background. Deep wells and glacial aquifers are likely sources of tritium-free water due to their long period of isolation from atmospheric exposure. Identifying a suitable source of background water can be a challenging task, and communicating with laboratories with existing environmental tritium monitoring programs and hydrologist can save considerable effort and time in locating these sources. To evaluate the suitability of reference background water, it is simplest to use the electrolytic enrichment technique. A sample of the water is enriched by 15−30 times and analyzed by LSC, as a sample, using the original blank water as the background. This allows detection of any tritium present, at a much LLD (typically < 0.1 Bq/L). Suggestions on handling the background water supply are as follows: (1) obtain large batches (1−2 years supply), as it is more efficient and economical to validate, (2) store in airtight glass containers, and (3) implement procedures for handling, validation testing, and maintenance of testing and usage records.

e. Standards

Standards are used to measure the counting efficiency of tritium by the LS counter at different quench levels and volumes of water sample. A traceable tritium standard should be purchased in the form of HTO or other less quench compound. Aliquots are accurately dispensed/weighed and diluted to give solutions of known activity.

Common practice is to prepare stock solutions of high activity, which are then diluted to working standards. As a guideline, a small volume of the working standard solution (<1.0 mL) should contain sufficient activity to yield less than 0.1% counting error (at 1 sigma), when counted using the sample protocol. Keeping the tritium standard close to the guideline offers several advantages: (1) since a minimum of activity is used, potential cross contamination to samples is reduced; (2) some counters employ special background enhancing features that are sensitive to high count rates, and if the count rate of the standard exceeds the limit, inconsistent results can occur; (3) the lower the activity level employed, the more cost effective the use of the purchased tritium standard will be.

Suggestions for handling tritium standards are as follows: (1) store and prepare in airtight glass containers (i.e., dedicated volumetric flasks); (2) use stock and working solutions; (3) keep records of all certificates and preparation and testing of all stock and working solutions; and (4) dispense standards in a properly ventilated area, well away from any samples.

f. Quality control

The purpose of the quality control program is to demonstrate that the parameters involved in the production of results are within expected tolerances. The counting efficiency and background count rate are obtained for each batch of samples by including standards and background samples. These are satisfactory for demonstrating the equipment performance but do not validate the sample handling or preparation. Two other sample types are used to demonstrate that sample handling does not adulterate or contaminate the sample and that the preparation of samples for counting is acceptable:

(1) Process blank samples. Samples with low levels of tritium can easily be contaminated by external sources. A process blank sample is basically a sample of background water (tritium dead water) that is treated using the same processes as the sample. This sample is then counted along with the rest of the sample batch and compared with the regular background/blank to demonstrate the absence of contamination during the process. For example, if a batch of milk samples is freeze dried to extract water for tritium analysis, a process control sample would also be freeze dried and included in the sample batch.

(2) Quality control (QC) samples. The purpose of the QC sample is to introduce a sample with known activity into the handling process. Whenever a purification or extraction technique is performed, a QC sample is added to the batch and processed as a regular sample. Because the QC sample has known activity, this demonstrates the performance of the entire analytical and counting process. The QC sample is prepared by adding a measured amount of standard stock or working standard solution to a quantity of background water. The activity level required varies with the count conditions, but should be calculated to yield a 2 sigma counting error of the order of 10%. Charting the data from QC samples gives a historical baseline against which current results can be judged. This aids in detecting trends, poor sample preparation, and counting or counter problems.

g. Quality assurance

Quality assurance tests are independent tests performed to provide confidence in the analytical results, which is implemented by involving known and unknown (blind) samples from external agencies. A good example of this for tritium would be the Laboratory Intercomparison Program administered by some national and international organizations (e.g., the U.S. Environmental Protection Agency, and International Atomic Energy Agency). Water samples are distributed to the participating laboratories as "blind" samples for analysis. The analysis results are reported back to the organizer of the intercomparison, which are evaluated against the spiked value or average of the reported results. This serves as a check on the accuracy of the analysis process and gives insight into the performance of the laboratories. Intercomparisons with other laboratories using known and unknown samples are also useful when they can be arranged.

B. Radiocarbon (^{14}C)

1. Environmental occurrence

^{14}C has a half-life of 5730 years and decays by beta emission ($E_{max} = 156$ keV) to the stable nuclide ^{14}N. It is ubiquitous in our environment and also one of the most common radionuclides measured by LSC. Its occurrence in the environment is from three main sources: (1) natural production via the interaction of cosmically produced neutrons with atmospheric nitrogen in the upper atmosphere, (2) atmospheric nuclear weapons tests (principally during the 1950s and 1960s), and (3) discharges from facilities associated with the nuclear fuel cycle (principally nuclear power plants and fuel reprocessing plants). Additional minor sources include (1) discharges from facilities that synthesize radiolabeled compounds for biomedical, biological, and agricultural tracer studies; (2) discharges from hospitals, universities, research centers, and so on, of the labeled materials used in tracer studies; and (3) natural production by spallation reactions in surface rocks and soils.

The environmental applications of ^{14}C measurements can be divided into the following main categories:

1) Radiocarbon dating. The relatively constant natural production rate of ^{14}C in the upper atmosphere, its uniform uptake as $^{14}CO_2$ into living plant material, conversion to

plant carbohydrates, and subsequent transfer through the food chain are the basis of the radiocarbon dating technique. The end result of the food chain transfer is almost uniform labeling of all living organisms. ^{14}C dating is used in a wide range of scientific disciplines including archeology, geology, soil science, climate reconstruction, and oceanography, and LSC is a widely used measurement technique for ^{14}C dating (Thomson et al., 1995; Pessenda et al., 2001; Walker et al., 2001) besides the most sensitive accelerator mass spectrometry.

2) Environmental measurements. Typically, these measurements are performed on samples from the environment around facilities associated with the nuclear fuel cycle and facilities that produce labeled compounds. Although ^{14}C is not among the most abundant of the anthropogenic radionuclides that enter our environment as a result of nuclear fuel cycle activities, its long half-life, high environmental mobility, and ability to enter the food chain mean that it delivers one of the highest collective effective dose equivalents to the global population, hence the level of ^{14}C in the environment is critical for environmental monitoring of nuclear facilities (Buzinny et al., 1998; Gulliver et al., 2001; Isogai et al., 2002; UNSCEAR, 2008).
3) Food adulteration studies. Petroleum derivatives are occasionally used to adulterate natural food and drink products without the buyer's knowledge. Because petroleum-based products are sufficiently old, they contain no ^{14}C, and depletions in ^{14}C content are normally indicative of adulteration. Examples of this include the adulteration of wines, spirits, wine or cider vinegars, and other natural products (Schönhofer, 1989a, 1992).
4) Estimation of fossil fuel CO_2 emission. Carbon dioxide is the main greenhouse gas released to the atmosphere as a result of human activities. A 30% rise in CO_2 concentration has been observed since the start of the industrial revolution, which is mainly attributed to the increased use of fossil-based fuel for energy production and transportation. Since the ^{14}C in the fossil fuel is very low compared to biogenic materials, measurement of atmospheric ^{14}C levels and its distribution has been proposed for directly estimating the amount of fossil CO_2 releases, and has been widely applied in the past years (Keller et al., 2016; Turnbull et al., 2014; Niu et al., 2018; Graven, 2015).
5) Biogenic fuel composition measurement. For reducing the fossil CO_2 releases, one effort has been implemented by the addition of biogenic fuel (with present atmospheric ^{14}C) to the fossil fuel (with dead ^{14}C) in some levels. To monitor the level of biogenic fuel in the mixed fuel, ^{14}C in the fuel is measured using the LSC method.

2. Sample preparation and analysis

a. Sample preparation

Benzene synthesis. This is the preferred technique for radiocarbon dating because of its higher precision and sensitivity, although it is also used for environmental and food adulteration studies. Benzene synthesis involves the following steps: Carbon is first converted to CO_2 by combustion in a pure oxygen atmosphere for organic carbon samples or acid hydrolysis for inorganic carbon samples (e.g., shells and biogenic deep ocean sediments). The collected CO_2 is subsequently converted to lithium carbide by reaction with molten lithium, and on cooling, the addition of water causes the production of acetylene (Barker, 1953). The acetylene is then cyclotrimerized to benzene using a chromium- or vanadium-based catalyst (Noakes et al., 1963). Benzene is an ideal counting medium for the following reasons:

1) It is a clear aromatic solvent capable of dissolving sufficient fluor.
2) It has excellent energy transmission properties.
3) It has a high carbon content (92.3%).
4) It is relatively easy to synthesize.
5) It exhibits low quench.

In most instances, solid fluors would be added directly, rather than a scintillation cocktail. This minimizes volume additions and therefore any increase in quenchable background. The trend in the radiocarbon dating discipline has been to use only a primary fluor and to use it at relatively high concentrations (12−15 mg per gram of benzene) to facilitate weighing. This procedure would be common for researchers using instruments such as the Wallac 1220 Quantulus. This is now possible, because the wider wavelength response of modern PMTs has negated the requirement for a secondary fluor (wavelength shifter). A primary and a secondary fluor (*bis*-MSB) are recommended for users of Packard instruments with nonprogrammable TR-LSC. The recommended concentrations are 2.8 mg of *butyl*-PBD and 3.0 mg of *bis*-MSB per gram of sample benzene, and highly accurate techniques for dispensing such small weights are available (Cook et al., 1990a, 1990b; Anderson and Cook, 1991; Cook and Anderson, 1992). A primary fluor alone can be used with programmable TR-LSC provided the burst delay is increased beyond 75 ns. This method is mainly applied for the ^{14}C dating or the precise measurement of ^{14}C in low level or background level environmental samples. With the rapid development of accelerator mass spectrometry and its wide application, ^{14}C measurement for dating purpose is now mainly carried out by the AMS technique.

CO_2 Absorption. Direct absorption of CO_2 using quaternary amines is a widely used technique, particularly where the activities are enriched relative to natural

production. Carbo-Sorb E (PerkinElmer, Inc.) and Solusol (National Diagnostics) are examples of high-capacity carbon dioxide absorbers that are compatible with LSC cocktails. Direct absorption into inorganic bases is an alternative means of absorbing the CO_2 in which aqueous solutions of up to 1 M sodium hydroxide or methanolic solutions of 2 M sodium hydroxide have been used. However, these have three distinct disadvantages: they are strong quenching agents, they have low trapping capacities compared with the amines, and they produce severe chemiluminescence.

For CO_2 samples absorbed into base solutions, cocktails that can accept high-ionic-strength solutions are added. For low-precision measurements, the advantages of the absorption technique are that sample preparation is less time consuming than for benzene synthesis and the sample preparation apparatus is relatively simple. The major disadvantage of the CO_2 absorption technique is the relative small amount of carbon that can be absorbed. For example, 10 mL of Carbo-Sorb is approximately the maximum quantity that would be miscible with Permafluor E + scintillation cocktail in a 20 mL vial. This is capable of absorbing 58 mmol of CO_2, which is equivalent to 0.7 g of carbon. In comparison, it is possible to add approximately 19 g of carbon into a vial via benzene synthesis, although 3−7 g is more typical. Detailed information on the absorption technique has been reported (Qureshi et al., 1989; Canducci et al., 2013). This is the most often applied technique for the preparation of samples from nuclear facilities or surrounding environment, which have a relative high ^{14}C concentration. Thus, a small amount of sample (carbon) is sufficient for LSC measurement. Hou et al. (2005, 2007) have reported a method for the determination of ^{14}C in samples from nuclear decommissioning, such as graphite, concrete, and metals. ^{14}C was released from the sample matrix as CO_2 by oxidation combustion with O_2 flow at a temperature higher than 1000°C with Pt as catalyzer to convert all CO to CO_2. It was also confirmed that both organic and inorganic carbon in the sample can be completely converted to CO_2 in this condition. The released $^{14}CO_2$ was trapped using 8−12 mL of Carb-Sorb E solution filled into a column to ensure a high absorption efficiency. The trap solution was then mixed with Permafluor E+ scintillation cocktail for LSC measurement. The entire separation was implemented with a Sample Oxidizer (PerkinElmer Inc.), which makes the separation complete within 2 minutes. The major disadvantage of this method is the relatively small sample amount (0.2−1.0 g) that can be treated, which limits the analysis of large samples and the detection limit of the method. A tube furnace was also reported for separation of ^{14}C from solid samples using combustion. In this case, the sample amount can be increased to 20 g, which improves the detection limit (Hou, 2018). Fig. 2.17 illustrates the two systems for ^{14}C sample preparation. This method was also demonstrated to be applicable to other solid samples, such as soil, sediment, vegetations, tissues, exchange resin, filter, and plastic materials (Hou, 2018).

A method for the determination of ^{14}C in water samples was reported using evaporation and combustion for carbon separation and LSC for ^{14}C measurement (Hou, 2007). In environmental water samples, ^{14}C is present as both inorganic (carbonate) and organic associated form, evaporation with addition of stable carbonate as carrier is first used to concentrate ^{14}C and convert it to solid. The residue with concentrated ^{14}C was used for the analysis using the same procedure as other solid samples described above. In this way, the interfering radionuclides can be also removed, and only ^{14}C trapped in amine solution for LSC measurement.

Direct counting. On occasion, when adulteration of alcoholic drinks and biogenic fuel are studied, direct counting of the alcohol or fuel may be performed. Schönhofer (1989a) has demonstrated that direct counting of uncolored spirits with an ethanol concentration of about 40% v/v is feasible. A 1:1 ratio of spirit to cocktail (Quickszint 400 by Zinsser) was found to be suitable. For colored spirits and wine, distillation was required to concentrate and purify the ethanol. A 1:1 mixture of cocktail to 85%−90% ethanol was used.

For ^{14}C measurements in vinegar, acetic acid has been isolated by continuous extraction with di-isopropyl ether and subsequent distillation. Subsequently, 4 mL of concentrated acetic acid in 6 mL of Quickszint 400 cocktail were measured (Schönhofer, 1992).

b. Standards of ^{14}C

For ^{14}C dating purpose, the Primary Modern Reference Standard for radiocarbon measurements is wood from the AD 1890 tree ring (and therefore uncontaminated by fossil fuel CO_2 − Suess Effect), whose activity was measured in the 1950s and corrected for ^{14}C decay to the year of growth to determine the absolute activity. Radiocarbon ages are expressed in years B.P. (before present − where present is the year 1950). In practice, all laboratories use a Secondary Modern Reference Standard against which sample activities are determined. The secondary standard most commonly in use is Oxalic Acid SRM 4990C, which is distributed by the National Institute of Standards and Technology (Gaithersburg, USA). This reference material consists of a 1000-lb lot of oxalic acid prepared by fermentation of French beet molasses using *Aspergillus niger*; 0.7459 times the specific activity of this material (normalized to a $\delta^{13}C$ value of −25‰) is equal to the activity of the AD 1890 wood, which in turn equates to 226 Bq/kg of carbon.

For the measurement of ^{14}C in environmental and nuclear samples, ^{14}C standard solution is often applied. In this case, ^{14}C labeled organic compounds are the most

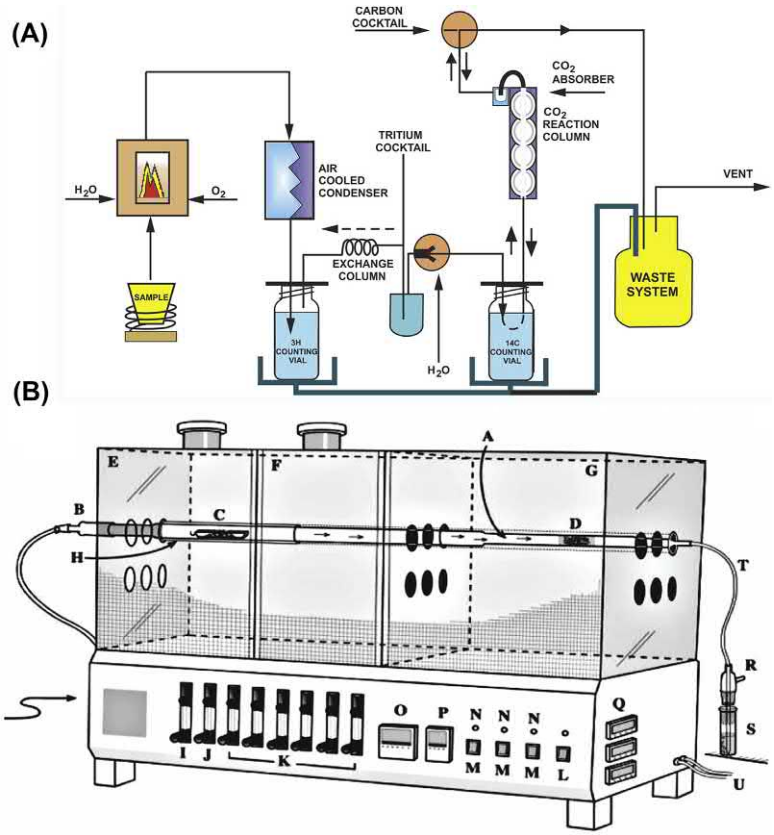

FIGURE 2.17 Diagram of two combustion systems for the separation of ^{14}C and tritium from solid samples.

commonly used form, such as NIST-4222d carbon-14-n-hexadecane standard solution provided by the National Institute of Standards and Technology. This standard solution can be directly mixed with scintillation cocktail for LSC measurement.

c. Quality assurance

There is an inevitable diversity of experimental approaches within radiocarbon dating facilities and in this situation, the issue of comparability of results among laboratories becomes paramount. Over the past 20 years, a number of international intercalibration programs have taken place (ISG, 1982; Scott et al., 1990, 2010; Rozanski et al., 1992; Gulliksen and Scott, 1995). These intercomparisons are of direct benefit to the participating laboratories as an independent check of laboratory performance and provide indirect benefit to the user communities. As a result of these studies, a range of natural samples (e.g., dendrochronologically dated wood, marine sediment, peat, barley, and so on) are available, albeit in limited quantities. These materials have known ages or consensus activities that cover the entire applied radiocarbon timescale. In addition, an annual intercomparison exercises have been organized by National Physical Laboratory, UK, for the determination of ^{14}C and other radionuclides in the spiked solutions and real samples from decommissioning of nuclear facilities.

d. Calculation of results and radiocarbon conventions

Most radiocarbon laboratories, in performing their calculations, use an activity value $A_{ON,}$ which is 74.59% of the measured net Oxalic Acid SRM 4990C activity (A_{OX}), normalized for ^{13}C fractionation according to:

$$A_{ON} = 0.7459A_{OX}\left[1 - \left\{2\left(25 + \delta^{13}C\right) / 1000\right\}\right]$$

(Measurements of $\delta^{13}C$ are made by stable isotope mass spectrometry and are relative to the VPDB (Vienna-Pee Dee Belemnite) standard. The PDB is a Cretaceous belemnite, *Belemnita americana*, from the PeeDee formation in South Carolina).

The term *percent modern* equates to the activity ratio $A_{SN}/A_{ON} \times 100\%$ where A_{SN} is the sample activity (A_S) normalized for sample fractionation to $-25‰$. However, the activity A_{ON} depends on the year of measurement (y) and has to be corrected for decay between 1950 and the year (y) of actual measurement. The *absolute international standard activity* is given by

$$A_{abs} = A_{ON}e^{\lambda(y-1950)}$$

where y is the year of oxalic acid measurement and $\lambda = 1/8267\ a^{-1}$ is based on the 5730 year half-life.

For geochemical and environmental ^{14}C studies, the term *absolute percent modern* (pM) is more commonly used. This is defined as:

$$pM = A_{SN}/A_{abs} \times 100\%$$

When one refers to 100% modern, this is effectively the specific activity that prevailed in 1890, prior to the onset of the Suess Effect; 100% modern is equivalent to 226 Bq/kg C.

For radiocarbon age calculations the equation is:

$$t = \frac{1}{\lambda} \ln \frac{A_{ON}}{A_{SN}}$$

where t = time (age), $\lambda = \ln 2/5568$ (where 5568 years is the Libby half-life of ^{14}C), A_{ON} is 74.59% of the measured net Oxalic Acid SRM 4990C activity (A_{OX}), normalized for ^{13}C fractionation, and A_{SN} is the sample activity (A_S) normalized for sample fractionation to $-25‰$.

A comprehensive discussion of the reporting of ^{14}C data is given in Stuiver and Polach (1977) and updated in Mook and van der Plicht (1999).

3. Analysis of ^{14}C in fuels containing biogenic materials

a. Carbon dioxide emissions and reduction measures

Carbon dioxide is the main greenhouse gas released to the atmosphere as a result of human activities. A 30% rise in CO_2 concentration has been observed since the start of the industrial revolution. Much of the increase came and will come from energy production, industrial emissions (Hämäläinen et al., 2007) and transportation using fossil-based fuels.

World-wide efforts are now pursued in order to slow down the predicted climate warming related to the rising carbon dioxide concentration in the atmosphere. Renewable energies are quickly developed and applied to reduce the utilization of fossil fuel. Among the renewable energies, biogenic energy is an important one. The raw biogenic materials can be converted to liquid fuel (biofuel), which can be added to the conventional fossil liquid fuel in some percentage. The European Parliament Directive, 2003/30/EC promotes the usage of biofuels or other renewable fuels for transport, and the Commission Green Paper 52000DC0769 sets the objective of a 20% substitution of conventional fuels by alternative fuels in the road transport sector by the year 2020. Pressures are mounting in US industry for increased utilization of biomass feedstocks and biotechnology in production (Currie et al., 2000). USDA Federal Biobased Products Preferred Procurement Program (FB4P) of 2002 encourages federal agencies to purchase products made of biobased materials instead of petroleum-based equivalents. The US Energy Policy Act of 2005 further refined the rules to identify and evaluate the bio-based products and issued tax credits for them. Its renewable fuels standard urges the doubling of the use of biorenewable ethanol and biodiesel (to annually $28 \times 10^6\ m^3$) by 2012. The Energy Independence and Security Act of 2007 raised the standard, to $140 \times 10^6\ m^3$ of annual renewable fuel use by 2022. Third party verification is required of a product's biobased content or mass of biobased carbon as a percent of the total organic carbon mass in the product in order to qualify for preferred procurement status and for tax credits.

b. Testing methods for product biocomponent verification

Bio-ethanol is the most common renewable component in gasoline, and it is chemically indistinguishable from synthetic ethanol. The only difference between the two is the isotopic composition of the carbon (Tamers, 2006). Synthetic ethanol comes from fossil raw materials with negligible amount of ^{14}C, and bio-ethanol is made of contemporary materials with environmental level of ^{14}C.

As discussed below, some methods have been reported for the evaluation of fossil CO_2 emission and the level of biogenic fuel applied for energy production:

1). ASTM D6866 Standard Method The ASTM International Radioisotope Standard Method D6866 contains three alternative radiocarbon dating methods to monitor the biobased carbon content in the sample, which may cover almost any type of solid, liquid, or gaseous products (ASTM D6866 - 11, 2011). The method applies to carbon dioxide emissions, waste fuels, biofuels, bioplastics, and other biopolymers.

Method A. The first ASTM Standard D6866 method is based on trapping CO_2 from a combusted sample into a Carbo-Sorb/methanol mixture. ULTIMA Gold is proposed as the scintillation cocktail to be used. The manufacturer of Carbo-Sorb E recommends trapping of up to 4.8 mmol CO_2 per mL, and Permafluor E+ as the cocktail, in a ratio of 1:1 or lower (Thomson and Burns, 1995).

Note that combustion of fuel cannot be done in an ordinary oxidizer due to the risk of explosion (Use a Parr oxygen combustion apparatus instead). The maximum total analytical uncertainty of 15% in the method is associated with sample preparation and actual counting.

Method B. The second method combines accelerator mass spectrometry (AMS) and isotope ratio mass spectrometry (IRMS) with an approach similar to the one used in routine radiocarbon dating. CO_2 is converted to graphite and the ratio of ^{14}C atoms relative to either the ^{12}C or ^{13}C atoms is measured (as opposed to measuring only decaying radiocarbon by radiometric counting). Uncertainties of

measurements in these two technologies are 1%−2% and 0.1%−0.5%, respectively.

Method C. Benzene synthesis is a conventional sample preparation method for ^{14}C dating by LSC, in which sample carbon is converted to benzene via CO_2, lithium carbide, and acetylene (Gupta and Polach, 1985). Primary (and secondary) fluors in solid form can be added directly to the benzene for sample counting in an LS spectrometer. Low background glass (low potassium glass) or Teflon vials are needed to minimize loss of benzene and reduce the background. As no liquid scintillation cocktail is added, the vial can contain the maximum amount of carbonaceous sample. Maximum total analytical uncertainty of 3% is associated with this method in ASTM D6866.

2). Tests according to the ASTM D6866 Standard Method Numerous radiocarbon laboratories have well established dating procedures suitable also for bio-materials testing. Some of them can already provide services related to this new application (Tamers, 2006).

Noakes et al. (2006) compared analytical methods for the certification of biobased products and found an inverse relationship between the analytical precision and the overall cost of the equipment and analysis. Methods A, B, and C allowed 0.2−1 g, 1 mg, and 2−10 g of carbon sample and yielded precisions of 8.80%, 0.88%, and 1.86%, respectively. Culp and Noakes (2009) pointed out that the inorganic carbon compounds, such as calcium carbonate, must be removed prior to the analysis of bio-based materials, and they discuss the removal methods. Norton and Devlin (2006) published results of a comparison study, where AMS and LSC laboratories using benzene synthesis had ± 3% (absolute) variation in results. Norton et al. (2007) reported that benzene synthesis and AMS yielded mean biobased content values that were within 1% content from one another. They interpreted the small difference as strong evidence that all of the carbon was converted to CO_2. Various sample matrices were successfully analyzed within ±3% of the real carbon content. Culp et al. (2011) used benzene synthesis in the analysis of biobased materials.

Oinonen et al. (2010) shortened the liquid sample combustion times to 10 minutes for AMS and analyzed gasoline and diesel fuel samples with better than ± 0.5% accuracy. Reddy et al. (2008) investigated diesel fuels and found that inaccurate blending may occur. Only one out of 10 retail samples met the specification in 2006, when analyzed by AMS with ±1% accuracy.

3). Other standard methods The ASTM D7026-04 provides a framework for collecting and handling samples for the determination of biobased content of materials by means of the carbon isotope method described in Test Methods D6866. ASTM D7459-08 describes sample collection for the speciation of biogenic and fossil-derived carbon dioxide emitted from stationary sources (ASTM D7459 - 08, 2008).

CEN 15747:2008, Solid recovered fuels-^{14}C-based methods for the determination of the biomass content, is only applicable to solid recovered fuels and is developed for the European Union Emission Trading Scheme. The analysis of the ^{14}C content can be applied both on the input (waste) and on the output (exhaust gases) from waste installation. Three methods are included in the technical standard, viz. CO_2 adsorption of up to 1 g carbon and subsequent LSC, gas proportional counting of CO_2 up to 1.4 g C in a 10 L counter at NTP, and AMS of 1 mg C. Special attention is given on the measurement of peat, which has a ^{14}C content well below that of other biobased material.

There is also a measurement standard for stationary combustion emission sources published in March 2011, ISO 13833, Stationary source emissions − determination of the ratio of biomass (biogenic) and fossil-derived carbon dioxide − radiocarbon sampling and determination. This standard combines the concepts of ASTM D6866 and D7459.

4). Direct analysis method, "Method D" Sample preparations in Methods A, B, and C do not pose limitations to sample matrices. However, Method A could not be directly used for oil samples, and Methods B and C are time consuming and more expensive. A more simple and direct method has also been applied in many labs for measuring the component of biogenic fractions in liquid fuel (Dijs et al., 2006; Idoeta et al., 2014; Kristof and Logar, 2013; Bronic et al., 2017; Stojkovic et al., 2017; Muir et al., 2015).

Method D: A wide range of liquid chemicals can be mixed directly with modern scintillation cocktails to make homogeneous and stable samples. Ethanol is a typical example, which has been measured in wines and liquors to detect falsifications by monitoring the ^{14}C content (Schönhofer, 1989a, 1992). This method can be also used to measure ^{14}C in fuel by extraction of ethanol in fuel or directly mixing fuel with scintillation cocktail.

Organic cocktails are also compatible with a wide range of gasoline/ethanol mixtures and diesel oil. The most often used commercial organic scintillation cocktails are Optifluor O, Ultima Gold F and OptiScint HiSafe, whereby ethanol, gasoline, and diesel fuels can be mixed with these cocktails in a suitable volume ratio. The best ratios of volume have been reported to be 14:6 diesel fuel mixing ratios and at 12.5:7.5 in pure ethanol samples. In addition, quench correction, range of channels in the LSC spectrum, and background (varies with vial type, sample type, ratio of sample to cocktail and measurement instrument) have to be considered for the ^{14}C measurement due to the low count

rates of ^{14}C in these types of samples. The spectrum was cut below Ch 150 with high bias setting, which totally eliminates all random noise and chemiluminescence. A stable sample count rate could therefore be achieved (Stojkovic et al., 2017).

Current-day bio-ethanol served as a reference sample and eliminated the need to correct for "bomb carbon." The method has good potential for determining the bio-ethanol content in commercial ethanol/gasoline blends. However, as the levels of pMC (percent modern carbon) of bio-ethanol from various locations are not the same, verification is needed for this variation. Fractionation corrections did not affect the final results, when reported to the nearest 1% of ethanol concentration. The LSC results can be accurate to within about 2% (absolute). It is likely that the accuracy can be improved by selecting a pipette designed for highly volatile, low viscosity liquids. The dependence of sample background on matrix effects should also be examined.

Norton (2009) tested fuel samples for ethanol from gas stations by mixing them with Permafluor E+ in a 1:1 volume ratio and counted them with quench correction. Norton and Woodruff (2011) mixed diesel fuels directly with a fluor and then analyzed samples in an LSC without further processing. Mean results from triplicate analyses were accurate within 0.4% in a 180 minutes counting time. Yunoki and Saito (2009) reported a two-step extraction of ethanol by water from the fuel mix for avoiding sample color. Water and ethanol was mixed with cocktail for LSC. In this method, fuel samples (100 g) containing 3% and 10% wt of bio-ethanol were mixed in glass vessels with 3 and 10 mL water and shaken. The water-ethanol phase was separated by centrifugation and then transferred to a scintillation vial, cocktail was added and ^{14}C was measured using LSC. An additional extraction was applied to the residual fuel and the process repeated to ensure all ethanol is extracted. A direct mix of 3 g fuel (gasoline or diesel) with cocktail for LSC counting of ^{14}C was also reported (Idoeta et al., 2014; Kristof and Logar, 2013; Bronic et al., 2017; Stojkovic et al., 2017; Muir et al., 2015). For the measurement of extracted ethanol, a standard/quench curve can be prepared using difference amounts (e.g., 0.5, 1, 2, 3, 4, 5, 7, and 10 g) of bio-ethanol spiked with a small volume of ($<$0.20 mL) unquenched ^{14}C standard and a certain volume of scintillation cocktail. A quench curve can be prepared using a similar method. Due to the strong color quench of diesel, special attention should be given and a small sample volume ($<$3 mL) is often applied for diesel samples. Background samples must be prepared with the same type and level of quench as the samples to be analyzed, as background count rate depends on sample quench. Much lower background of ^{14}C has been observed for oil compared to water, gasoline, and other samples (Stojkovic et al., 2017). A good fit between theoretical and experimental data was obtained for the two-step method, whereas a large discrepancy was found in the direct method applied for color quenched samples in the low concentration range.

5). Merits of the analysis methods Although Methods A, C, and "D" are less sensitive than AMS/IRMS in Method B, they have two distinct advantages:

1) Lower costs per evaluation and **2)** higher instrument availability worldwide. Sophisticated sample preparation methods are contained in Methods B and C.

The high cost of AMS instruments and sample backlogs at AMS facilities may not make Method B very attractive except for small sample sizes and when a high degree of precision is required (Noakes et al., 2006). LSC methods involve longer analysis time and lower precision, leading to a poorer detection limit compared to the AMS method, but make use of lower-priced equipment and offer a lower cost per analysis (Culp and Noakes 2009; Norton, 2009). The method of benzene preparation followed by LSC measurement also involves a more labor-intensive process, although the detection limit is much better than the Methods D and A.

Direct Method "D", which is not included in ASTM 6866, is clearly less time consuming, less expensive, adequate for practical biocomponent concentrations and a proven, conventional method. No chemical modification of the sample is required (Yunoki and Saito, 2009). No bomb effect correction is needed, when the reference sample is made of modern and known activity material (Norton, 2009; Norton and Woodruff, 2011). The direct method is also applicable for solid samples, if they can be dissolved in a suitable solvent or solubilized and further mixed with cocktail. The solvent should not be a strong quencher, and aromatic solvents are often compatible with scintillation cocktails.

c. Carbon dioxide and particulate analyses

CO_2 emission trading in Europe has been established and it is therefore important to distinguish between biogenic and fossil emissions. The standard methods ISO 13833, ASTM D6866 and D7459 apply in this work. Waste incineration has been widely applied to produce heat and energy, ^{14}C in the released CO_2 and source materials is applied to monitor the fossil CO_2 emission. AMS (Hämäläinen et al., 2007; Oinonen et al., 2010) and CO_2 absorption followed by LSC have been applied for this work (Staber et al., 2008; Silva et al., 2010). A comparison using ^{14}C monitor and the industry material classification methods for this purpose was conducted, and found to be comparable (Muir et al., 2015).

Air particulate analyses to identify their origin via the ^{14}C content has been conducted over a long time (Clayton et al., 1955; Lodge et al., 1960; Currie, 1978; Court et al., 1981, and reviewed by Currie et al. (2000). Recently, apportionment of biogenic and fossil particulates using the

AMS method has been intensively carried out (Gustafsson et al., 2009; Gilardoni et al., 2011; Heal et al., 2011; Szidat et al., 2009; Mouteva et al., 2017).

C. Iron-55 (^{55}Fe)

1. Environmental occurrence

^{55}Fe is produced by neutron activation reactions of two major stable iron isotopes: ^{54}Fe(n,γ)^{55}Fe and ^{56}Fe(n,2n)^{55}Fe. Since iron is the main component of construction materials in nuclear reactors, huge amounts of ^{55}Fe are produced in nuclear reactors and other nuclear facilities/devices with neutron production. ^{55}Fe enters into the environment mainly through the release of radioactive effluents of nuclear reactors, as well as atmospheric nuclear weapons tests in 1945−80. Nuclear accidents, nuclear reprocessing plants, and radiochemical and radiolabeling labs might also release some amount of ^{55}Fe to the environment.

^{59}Fe ($t_{½} = 44.5$ days) is produced through similar process by neutron activation of stable ^{58}Fe (0.28%). However, because of its relative short half-life and delayed discharges from the nuclear facilities, it is often not present in the environment. ^{59}Fe decays by emission of beta particles with high-energy gamma rays (1099.3 keV, 56.5% and 1292.6 keV, 43.2%). Thus, it can be easily measured by gamma spectrometry.

Determination of ^{55}Fe is often required for monitoring the radioactivity in the nuclear facilities and their discharges, as well as characterization and depository of nuclear wastes.

2. Sample preparation and analysis

^{55}Fe ($t_{1/2} = 2.7$ years) decays via electron capture to stable ^{55}Mn with the emission of Auger electrons and low-energy X-rays (5.89 keV, 16.9%). Measurement of ^{55}Fe can be carried out with an X-ray detector or gas flow proportional counter, but their counting efficiencies are very low (<1%). The most common and more sensitive technique is LSC. Due to the very low energy of the Auger electrons, ^{55}Fe has to be first separated from the sample matrix and then completely purified from other radionuclides prior to counting.

The separation of iron from the sample matrix (solution) is often carried out by hydroxide precipitation based on the formation of $Fe(OH)_3$ and $Fe(OH)_2$. However, for some special samples, the matrix component needs to be first removed. For instance, in an acid-dissolved lead sample, lead has to be removed by $PbSO_4$ precipitation to avoid the formation of a large amount of $Pb(OH)_2$ during the $Fe(OH)_3$ precipitation step. For aluminum samples, the bulk $Al(OH)_3$ in the $Fe(OH)_3$ precipitation step can be removed by adding more NaOH to > 0.2 M to convert $Al(OH)_3$ precipitate to soluble $NaAlO_2$ (Hou et al., 2005).

All transition metals can be coprecipitated with $Fe(OH)_3$ in alkali solution, among them the most important radionuclides are ^{60}Co, ^{63}Ni, ^{54}Mn, ^{152}Eu, and ^{154}Eu, and further chemical separation is needed to isolate iron from these interfering elements.

Chelating and anion exchange chromatography combined with solvent extraction have been used to separate iron from other nuclides (Konig et al., 1995; Warwick et al., 2001). The commonly used extraction reagents include ethyl acetate, isobutyl ketone, and isopropyl ether; particularly iron has a high partition coefficient in ethyl acetate (Warwick and Croudace, 2002). However, as solvent extraction is not very specific for iron, the decontamination of Fe from other metals is not satisfactory. To improve the separation efficiency of iron from other radionuclides, an extraction chromatography based on diisobutyl-ketone has been developed (Warwick and Croudace, 2002). A commercial solid phase extraction resin, the TRU resin, has also been applied to separate iron for the determination of ^{55}Fe (Dai and Kramer-Tremblay, 2014; Hou et al., 2015). One of the limitations of this resin is the low capacity of the small extraction chromatographic column (2 mL), which can only allow for the uploading of sample solutions with less than 2 mg iron. For sample with high iron content, such as soil, sediment and steel, anion exchange chromatography using strong basic anion resin (e.g., AG1x-4) has been confirmed to be a reliable method for the separation of iron from other interfering radionuclides with a high recovery (>95%) and a high decontamination factor ($>10^4$). This is mainly due to the high distribution coefficient of $FeCl_4^-$ on the anion resin in high concentration of HCl solution. Fig. 2.18 illustrates a separation procedure of iron from the most important interfering radionuclides using a strong anion exchange chromatography. In this way, ^{55}Fe can be completely separated from

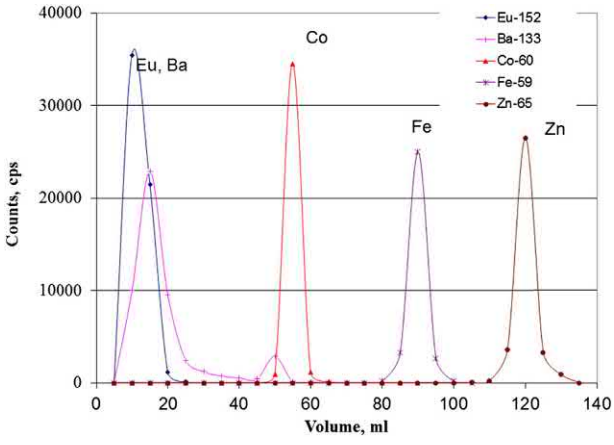

FIGURE 2.18 Separation of Eu, Ba, Co, Cu, Fe, and Zn by anion exchange chromatography (Bio-Rad AG1x-4, ϕ1 × 20 cm), 0−40mL: 9 mol/L HCl, 40−70mL:5 mol/L HCl, 70−105 mL: 0.5 mol/l HCl and 105−135: 0.05 mol/L HCl.

^{60}Co, ^{63}Ni, $^{152/154}$Eu, and ^{65}Zn. Other radionuclides, including all alkali and alkaline earth metals, could not form an anion complex with chloride and would also be removed. In combination with hydroxide precipitation, a chemical separation procedure has been applied for the separation of iron from different environmental and waste samples for ^{55}Fe determination. This method has also been used to investigate the distribution of ^{55}Fe in the environment surrounding a nuclear power plant (Gudelis et al., 2010). For samples with high iron content (>50 mg) and high ^{60}Co radioactivity, a repeated anion exchange chromatographic separation can effectively remove ^{60}Co with a high recovery of iron (Fig. 2.19).

A modified procedure using hydroxide precipitation followed by anion exchange chromatographic separation and LSC measurement has also been applied to the determination of ^{55}Fe in urine samples (Guerin and Dai, 2015). Due to a complicated matrix component in urine, the hydroxide precipitation step needs an adjustment of the concentration of NaOH to 2 M.

Ion chromatography using an HPLC system and a mixed cation/anion exchange column (CS-5, i.d. 9 mm, 25 cm length, Dionex, Idstein, Germany) has also been applied for the separation of ^{55}Fe for LSC measurement (Geckeis et al., 1997). This method is simple and fast, but the decontamination factor is not sufficient for the complete removal of ^{60}Co and other radioisotopes of transition metals; thus, it is not feasible for measuring ^{55}Fe in samples containing a high activity of ^{60}Co.

The distinct yellow color of Fe^{3+} can cause a very strong color quench and significantly reduce the counting efficiency of ^{55}Fe by LSC. Due to the very low energy (5–6 keV) of Auger electrons emitted by ^{55}Fe measured by LSC, the high color quench of iron solutions could reduce the counting efficiency to <10%, causing a high detection limit. A number of approaches have been adopted to reduce the color quenching of Fe, such as solvent extraction to transfer iron to an organic phase and reduction of Fe^{3+} to Fe^{2+} by ascorbic acid. It has not been possible to overcome the color quench of Fe completely. In addition, the Fe^{2+} is not very stable and can be oxidized to Fe^{3+} slowly in air, causing a gradually decreased counting efficiency. An effective method for removing the yellow color of Fe^{3+} using H_3PO_4 has been proposed (Warwick and Croudace, 2002; Hou et al., 2005). By this method, a colorless Fe^{3+} solution is obtained, and the counting efficiency is significantly improved to more than 40%. Since H_3PO_4 has a reduced quench effect and high compatibility with scintillation cocktail compared to other acids, the amount of Fe mixed with cocktail can thus be significantly increased. It

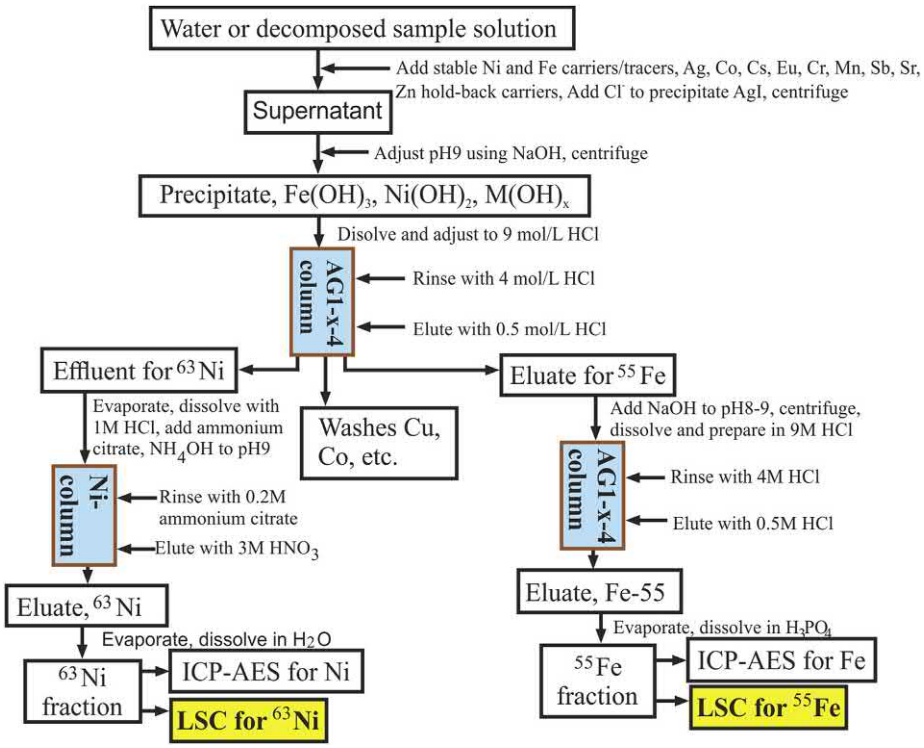

FIGURE 2.19 Analytical procedure for ^{55}Fe and ^{63}Ni in environmental and waste samples.

has been confirmed that for less than 10 mg Fe carrier, 40% counting efficiency is obtained, and for 200 mg Fe, the counting efficiency is 15% (Hou et al., 2005).

The counting efficiency of ^{55}Fe could also be affected by the addition of hydrochloric acid and phosphoric acid to the counting sample (Guerin and Dai, 2015). The counting efficiency as a function of the LSC cocktail/water ratio has been studied, and the results showed an obvious drop in counting efficiency from 62% for pure LS cocktail down to 30% for a 1:1 water/cocktail volume ratio using a Hidex 300 SL counter. An empirical formula of power function between the measured TDCR value and counting efficiency of ^{55}Fe was obtained, which can be used to correct the quench effect without a need to produce an external calibration curve.

D. Nickel-63 (^{63}Ni)

1. Environmental occurrence

^{63}Ni ($E_{max} = 67$ keV, $t_{1/2} = 101.2$ y) is a neutron activation product formed by neutron capture of stable nickel (^{62}Ni), released through corrosion of steel components, associated with the primary coolant system of nuclear power reactors. Another nickel isotope, ^{59}Ni ($t_{1/2} = 7.5 \times 10^4$ y) is similarly formed from stable ^{58}Ni. The initial activity ratio of ^{63}Ni/^{59}Ni is around 100 or more, and ^{59}Ni decays by electron capture with emission of X-rays. Given the low sensitivity of LSC to X-rays, ^{59}Ni has a very minor effect on the low-energy part of the beta spectrum of ^{63}Ni (Hou and Roos, 2008). Consequently, only ^{63}Ni is detected by LSC. ^{63}Ni in the environment originates from radioactive effluents from nuclear facilities and from nuclear weapons tests and accidents.

The principal requirement for the determination of ^{63}Ni is to characterize nuclear waste for decommissioning and radioactive waste disposal.

2. Sample preparation and analysis

Due to its low beta energy, the determination of ^{63}Ni requires chemical separation and purification of nickel from coexisting elements and radionuclides. Methods for determining ^{63}Ni have been reported for many sample matrices including liquid effluent, sludge, ion exchange resin, graphite, heavy concrete, steel, copper, lead, and aluminum from nuclear power plants and environmental samples like soil, sediment, sea water, fish, vegetation, and urine (Harvey and Sutton, 1970; Kojima and Furukawa, 1985; Holm et al., 1990; Lo et al., 1993; Kaye et al., 1994; Numajiri et al., 1994; Kramer, 1981; Russow and Dermietzel, 1990; Radwan et al., 1981; Skwarzec et al., 1994; Lee et al., 1997; Hou et al., 2005, 2015; Warwick and Croudace; 2006; Jordan et al., 2008; and Gudelis et al., 2010; Huang et al., 2017; Gautier et al., 2016). The most common sample matrices to be assayed are liquid effluents, waste from nuclear facilities, the coolant water from nuclear power plants, and environmental soil and sediment.

The sample matrix dictates whether any specific sample collection, preservation, pre-treatment, and pre-concentration processes are required. The pre-treatment of samples containing organic matter is started by wet or dry ashing after adding the carriers, and then continued by leaching the residue with concentrated HCl or HNO_3 to dissolve nickel and other elements. Stable nickel is added as carrier, and other elements as hold-back carriers, to determine chemical yield and to effectively separate nickel from other elements. Yield corrections have also been performed using ^{65}Ni as a tracer (Lee et al., 1997). Sample pre-concentration may be necessary to enable the analysis of low-activity environmental samples like seawater (Lo et al., 1993).

Many chemical separation methods for the ^{63}Ni assays take advantage of following processes:

1. Precipitation of $Fe(OH)_3$ with ammonia, coprecipitates many metals, while nickel remains in the supernatant.
2. Precipitation of nickel using an alcoholic solution of dimethylglyoxime (DMG) is highly selective for nickel in an alkaline medium and produces an insoluble Ni-DMG complex.
3. Anion exchange from HCl solution removes most of the activation products by adsorbing those as chloride complexes onto the column, while nickel passes through and is fully collected in the effluent and washing solutions.

Most of the separation methods for ^{63}Ni are performed using complicated, multistep procedures based on a combination of these processes and possibly completed with additional purification steps like solvent extraction, ion exchange and/or extraction chromatography (Kirby, 1961; Holm et al., 1990; Lo et al., 1993; Kaye et al., 1994; Skwarzec et al., 1994; Numajiri et al., 1994; Scheuerer et al., 1995; Lee et al., 1997; Dewberry et al., 1999; Hou et al., 2005; Warwick and Croudace; 2006; Jordan et al., 2008). Each separation step requires optimization and careful control of the conditions during processing to achieve consistent yields and desired purity of ^{63}Ni. Multistep separations are necessary for sample matrices like nuclear wastes, which include a great number of radionuclides with different chemical properties and with much higher concentrations than that of ^{63}Ni. Many methods referred here have been developed to be applicable to different types of sample matrices such as low- and high-active wastes from nuclear power plants and environmental samples (Kaye et al., 1994; Scheuerer et al., 1995; Lee et al., 1997; Hou et al., 2005; Warwick and Croudace, 2006; Jordan et al., 2008).

Williams et al. (1994) developed a method based on a series of separations using anion, cation exchange, and liquid extraction with tri-n-octylphosphine (TOPO) for the separation of ^{63}Ni from targets irradiated at the high flux

isotope reactor. This method was accomplished using simple fluid operations which are easily adapted for execution in hot cells. Based on the formation of specific complex/precipitation of Ni with DMG, three methods, i.e., Ni-DGA precipitation, Ni-DGA-solvent extraction, and DMG resin (Ni resin), have been applied in the separation of nickel from other radionuclides (Huang et al., 2017). Among other separation methods, extraction chromatography has become the most popular method applied in the ^{63}Ni separation. The extractive resins are based on dimethylglyoxime (DMG) which is coated onto a solid support such as Microethene (Testa et al., 1991) or coated onto an acrylic ester-based resin. This is known as Ni Resin, which is commercially available from Eichrom Industries and applicable with other separation techniques commonly used in assaying ^{63}Ni. Dewberry et al. (1999) used Ni Resin to determine ^{63}Ni in the presence of fission products and α- and β-emitting plutonium isotopes with activities up to 10^3 times the observed ^{63}Ni activity. Hou et al. (2005) developed a chemical separation procedure, which was started by hydroxide precipitation, continued with anion exchange and thereafter with the Ni Resin extraction chromatography. They used the method for determining ^{63}Ni and ^{55}Fe in nuclear waste samples including heavy concrete, aluminum, lead and graphite, and achieved high decontamination factors ($>10^5$) for all interfering radionuclides. Chemical yields were over 90% and the detection limit of 0.014 Bq for ^{63}Ni using a low-background LS spectrometer. This method has also been applied to environmental samples (Gudelis et al., 2010). Warwick and Croudace (2006) developed a method that was based on the same separation steps as those of Hou et al. (2005), but with the difference that the extraction chromatography separation using Ni resin was performed prior to the anion exchange. The residual ^{60}Co was removed during the anion exchange by adding Co-carrier prior to passing the ^{63}Ni solution through the anion exchange column. The same method was validated for separating ^{63}Ni and ^{55}Fe from reactor effluents, and the effect of ^{59}Ni on the ^{63}Ni beta spectrum was studied. It was reported that the separation characteristics and the detection limits for ^{63}Ni and ^{55}Fe were improved by applying extraction chromatography and that the chemical yields were over 90% in all cases, with no evidence of interference from activation products expected in reactor effluents. Also, it has been observed that ^{60}Co and ^{58}Co could not be sufficiently removed by using only Ni resin extraction chromatography, making the method unreliable and a correction has to be implemented to subtract the inference from ^{58}Co and ^{60}Co. Two sequential Ni resin chromatography separation steps can reduce the contribution of radioactive cobalt. Therefore, a separation step using anion exchange chromatography is necessary for samples with high radioactive cobalt isotopes (^{58}Co, ^{60}Co) (Hou et al., 2015). Fig. 2.19 illustrates a combined procedure for the separation of nickel and iron for the determination of ^{63}Ni and ^{55}Fe.

The sample preparation for measuring the ^{63}Ni activity by the LSC counter is quite simple. The eluate containing the sample fraction is collected from the chromatographic column at the end of separation procedure. The eluate is evaporated to near dryness and the residue is dissolved in a few milliliters of dilute HCl or HNO_3 which is placed in a LSC vial for counting. Attention has to be given when evaporating the Ni eluate to dryness, because nickel in the HNO_3 (3−12 M) eluate is present as $Ni(NO_3)_2$, which has a low boiling point (136.7°C) and can be easily lost during evaporation at high temperature (>137°C). Therefore, the eluate of Ni is often evaporated to near dryness (<0.5 mL) on a hotplate with low temperature (<120°C) in the end of the evaporation (<3 mL).

The counting efficiencies of the prepared sample of ^{63}Ni may vary from ~50% to ~80% depending on the sample composition. Quench corrections are applied in most cases. Many authors (Kramer, 1981; Russow and Dermietzel, 1990; Harvey and Sutton, 1970) have reported detection limits, which vary between 0.055 and 0.099 Bq/sample while others (Scheuerer et al., 1995; Hou et al., 2005; Warwick and Croudace, 2006; Jordan et al., 2008) have obtained significantly lower detection limits of 0.005−0.014 Bq/sample. The main reason for this difference is the higher background (20−25 cpm) of the older generation LSC counters compared to the low backgrounds (0.5−1.0 cpm) of modern instruments equipped with low-level count options. Modern instrumentation is equipped with background reduction features, as discussed in Section II.

Mellado et al. (2005) have evaluated the ability to rapidly determine individual radionuclide activities from the mixture of beta-emitters (^{55}Fe, ^{63}Ni, ^{99}Tc, ^{137}Cs, and ^{90}Sr/^{90}Y) present in radioactive wastes using multivariate calibration combined with limited chemical separations. The authors conclude that the combined data treatment procedure they applied was able to quantify all of the five tested radionuclides, in a single measurement. However, special care has to be taken with extremely quenched samples due to the increased uncertainty of the model with such samples. This technique could reduce the chemical separation steps required, which may simplify and reduce analysis costs, which is important in routine operations of nuclear reactors and in decommissioning.

Besides the radiometric techniques, ^{63}Ni can be also determined using accelerator mass spectrometry (AMS) (Wang et al., 2015). The comparison by Hou and Roos (2008) demonstrated that the detection limits (0.12−45 mBq) achieved by the AMS methods can be significantly lower than detection limits obtained by LSC. For both methods chemical separation is necessary. Nevertheless, the ^{63}Ni assays are mostly performed using

LSC, because of the accessibility of the LSC counters in radiochemical laboratories.

In summary, the current separation methods are suitable for assaying ^{63}Ni in nuclear waste and environmental samples. Very low ^{63}Ni activities in environmental samples can be analyzed using modern LSC spectrometers. The chemical yields have been over 90% for most sample matrices and the decontamination factors have been between 10^3 and 10^{11} for most of interfering radionuclides presenting in nuclear waste samples (Scheuerer et al., 1995; Hou et al., 2005; Warwick and Croudace; 2006).

E. Strontium-89 and strontium-90/yttrium-90 (^{89}Sr and ^{90}Sr/^{90}Y)

1. Environmental occurrence

^{90}Sr ($E_{max} = 546$ keV, $t_{1/2} = 28.8$ y) is a fission product and ^{89}Sr ($E_{max} = 1495$ keV, $t_{1/2} = 50.57$ d) is part of the mass 89 fission chain, so their main sources in the environment are atmospheric nuclear weapons testing, nuclear accidents, and discharges from nuclear facilities. Fallout from nuclear weapons testing is primarily responsible for the ^{90}Sr/^{90}Y concentrations found globally in the environment. ^{90}Sr is normally in equilibrium with its ^{90}Y daughter ($E_{max} = 2280$ keV and $t_{1/2} = 64.05$ hours) in the environment (Kossert and Schrader, 2004). ^{90}Sr is important for environmental monitoring because of its relatively high fission yield (5.7% for ^{235}U), its long physical and biological half-lives, and its transfer to food chains. It is highly toxic, because it accumulates in bone tissues which are exposed by high-energy betas of ^{90}Sr/^{90}Y. ^{89}Sr shares the same biological significance but is less hazardous. It has a much shorter physical half-life and thus will not have a long-term environmental impact. The term "radiostrontium" is used for two strontium isotopes of ^{90}Sr and ^{89}Sr. In nuclear explosions or reactor accidents, other short-lived strontium radioisotopes, e.g., ^{91}Sr ($t_{1/2} = 10$ hours), ^{92}Sr ($t_{1/2} = 3$ hours), and ^{91}Y ($t_{1/2} = 59$ d), are also released (Vajda and Kim, 2010c). Milk, meat, vegetation, water, soil, urine, and bone are the typical sample matrices that have been analyzed in environmental monitoring.

2. Sample preparation

The quantitative analysis of radiostrontium is based on four major considerations: sample pre-treatment, preconcentration, chemical separation, and beta counting (Vajda and Kim, 2010c). As strontium belongs to the alkaline earth elements, it mimics calcium in its behavior, but its amount is less abundant in most environmental samples. The assay of radiostrontium is difficult because three beta-emitting nuclides with overlapping beta spectra must be distinguished from each other and strontium must be separated from large amounts of calcium and from inactive and radioactive elements without significant losses. The pretreatments like drying, pre-concentration, ashing, digestion, and dissolution are tedious for many environmental samples, and furthermore, samples like soil, milk, and bone contain relatively large amounts of stable strontium, which is the most commonly used yield tracer for radiostrontium and requires additional Sr analysis for the yield corrections. Much of the emphasis on the assay of radiostrontium has been focused on the separation chemistry and the methods have developed over decades (Sunderman and Townley, 1960; L'Annunziata, 1967, 1971; Wilken and Joshi, 1991; Chen et al., 2002b; Vajda and Kim, 2010c). They are based on several principles: precipitation/coprecipitation, solvent extraction, ion chromatography or ion exchange, extraction chromatography, or combination of these techniques. In extraction chromatography, extractant is sorbed on an inert solid support material.

The oldest method for radiostrontium determination is based on precipitations and on using fumic nitric acid, it is hence referred to as classical or nitric acid method (Sunderman and Townley, 1960). In this method, strontium is separated from calcium and alkali metals by two successive nitric acid precipitations, from yttrium and fission products by the hydroxide precipitation and from barium, radium and lead by chromate precipitation. The strontium fraction is further purified by carbonate and nitrate precipitations. The strontium is finally precipitated as carbonate and measured with a low-background gas flow counter. The first counting result consists of the total strontium (^{89}Sr, ^{90}Sr) activity and of a small amount of ^{90}Y grown in the separated strontium sample. ^{90}Y is permitted to reach near secular equilibrium with ^{90}Sr. Thereafter, the strontium sample is dissolved and ^{90}Y is separated by precipitation as the hydroxide that is converted to the oxalate for the measurement of the ^{90}Y activity. The ^{90}Sr content is recalculated from the ^{90}Y activity and thereafter the ^{89}Sr content is calculated from the first counting of the sum activity of ^{89}Sr, ^{90}Sr, and ^{90}Y. This method is still used and some standard procedures are based on it (Wilken and Diehl, 1987; Bojanowski et al., 1990; IAEA, 1989; EPA, 1991; HASL and Chieco, 1997; ISO, 2010). The method is efficient but not selective for strontium. It nevertheless ensures the purification of the strontium and yttrium samples from the major interfering elements and radionuclides like alkali and alkaline earth metals, ^{91}Y, ^{140}Ba, ^{140}La, ^{226,228}Ra, ^{210}Pb, and fission products, because each precipitation can be repeated once or more if necessary. Consequently, the analysis of large samples and sample matrices with high mineral salt contents are also possible. Similar precipitations are often used for pre-concentration or they are combined with ion exchange or extraction chromatographic methods for removing or reducing other

element contents to lower level. Hence, the total column capacity will not be exceeded.

Currently, the most popular methods for radiostrontium analysis are based on the extraction chromatography using the Sr•Spec resin that was developed by Horwitz et al. (1991). In this resin, a crown ether [bis-4,4′(5′)-*tert*-butylcyclohexano-18-crown-6] in 1-octanol is grafted on an inert polymeric resin (Amberlite XAD-7 or Amberchrom CG-71 ms) and packed into a chromatographic column. Strontium is efficiently retained by the Sr•Spec resin from nitric acid solutions and that the resin is selective for strontium ions over calcium, magnesium, most other metals and fission products present in the synthetic nuclear waste solution. A procedure based on Sr resin was reported for the determination of ^{89}Sr and ^{90}Sr in urine (Dietz et al.,1991). It involved wet ashing, pre-concentration using calcium phosphate precipitation, dissolving the precipitate using HNO_3 and prepared in a 2M HNO_3−0.5M $Al(NO_3)_3$ solution and loading it onto the Sr Spec column. After rinsing the column with 8M HNO_3, strontium was eluted with 0.05M HNO_3 solution. Strontium was strongly adsorbed on the column, whereas most interfering elements, including yttrium, were removed with the feed and rinse solutions. Yields from the pre-concentration step and from column separation were reported to be around 95% ± 5% overall. Barium, lead, and tetravalent neptunium and plutonium are also retained by the column, and attention should be given to avoid these elements entering into the eluate of Sr. The Sr•Spec resin is commercially available, as well as pre-packed columns, from Eichrom Industries and TRISKEM. It is often referred as a Sr resin.

A very rapid bioassay method for emergency preparedness, based on direct separation of ^{90}Sr in acidified urine samples (to 8M HNO_3) using stacked TRU and Sr resin, was also developed with good decontamination factors of Ba, Pb, Pu, Th, and U (Dai et al., 2013). Today, there is a number of appropriate modifications from the Sr resin method for various matrices including a lot of experience and results on comparison and validation tests (Vajda et al., 1992; Altzitzoglou et al., 1998; Tait et al., 1997, 1998; Chu et al., 1998; Fliss et al., 1998; Scarpitta et al., 1999; Brun et al., 2002; Saxen, 2002; Günther et al., 2003; Grahek and Măcefat, 2005; Landstetter and Wallner, 2006; Eikenberg et al., 2006; Heckel and Vogl, 2009; Kim et al., 2009; Maxwell III and Culligan, 2009a; Maxwell et al., 2013, 2016; Surman et al., 2014; Olfert et al., 2014; Tayeb et al., 2016; Miura and Minai, 2017; Guerin et al., 2017a; Hou, 2017; Grahek et al., 2018). Some standard procedures are also based on using the Sr resin (ASTM D5811 - 08, 2008; ISO, 2009). In general, the separations using Sr resin are considered simple, rapid, economic, and safe. Moreover, the yields are mostly good (over 80%), the separation times are only some hours and the resin can be regenerated and reused. All these aspects are important in selecting a routine method for laboratories. The Sr resin can be combined with other extractive resins, such as TRU, TEVA, U/TEVA from Eichrom Industries or with ion exchangers to perform sequential separation of radiostrontium, actinides, thorium, ^{99}Tc or ^{55}Fe from a single sample aliquot (Alvarez and Navarro, 1996; Moreno et al., 1998; Altzitzoglou et al., 1998; Pilviö et al., 1999; Mellado et al., 2002; Wang et al., 2004; Harrison et al., 2011; Lee et al., 2002a; Grahek and Măcefat, 2004; Lee et al., 2011; Dai and Kramer-Tremblay, 2011, 2014).

The main advantages of these procedures are that only one pre-treatment is necessary, the whole sample can be used for analyses, if it is small or of low activity, and the amount of wastes will be decreased. Otherwise, a simple and rapid assay of radiostrontium in environmental water samples can be performed using the Empore Strontium Rad Disk from 3M Company, US (Scarpitta et al., 1999; Smith et al., 1996). In this method the pre-filtered water sample (1 L) is simply passed through the disk which had previously been conditioned with methanol and 2M HNO_3. Strontium is retained on the disk which can be used directly for counting of the radiostrontium activity with a gas proportional counter. The disk is selective for strontium and can retain up to 3 mg of Sr.

In addition to the Sr Spec resin provided by Triskem and Eichrom, other similar resins for the separation of strontium have been developed. AnaLigSr01 (or SuperLig 620) resin is prepared by covalently bonding of ligand, most likely a variation of an 18-crown-6 (18C6) structure on silica gel (Grahek et al., 2018). Another one was prepared by grafting two extractants, 4,40(50)-bis-t-butylcyclohexano-18-crown-6 and di(2-ethyl-hexyl) phosphoric acid onto Amber chrom CG-71 (Surman et al., 2014). These resins showed similar features in the separation of radiostrontium for the determination of ^{89}Sr and ^{90}Sr using LSC. However, they are not well commercialized and not easy to obtain. The most popular Sr resin is still the Sr Spec resin from Triskem and Eichrom.

To meet the requirement of emergency analysis, a number of rapid analytical methods have been reported for the determination of radiostronium. A rapid method applying the Sr Spec column was reported for the determination of radiostrontium in milk samples (Guerin et al., 2017a). In this method, after the addition of stable Sr as tracer and carrier, HCl and trichloroacetic acid were added to the sample to flocculate the suspended fat and proteins in milk. The sample was centrifuged and the strontium in the supernatant was precipitated as carbonate. Afterward, $SrCO_3$ was dissolved and prepared in 8M HNO_3 and purified using a Sr Spec column, the eluate of Sr in water was measured using LSC for ^{89}Sr and ^{90}Sr. For the determination of radiostronium in steel and iron samples, a procedure was reported by using SrF_2/CaF_2 precipitation for the separation of Sr from a large amount of iron, followed by the Sr Spec

column to purify strontium (Maxwell et al., 2017). It should be mentioned that the main limitation on the application of Sr Spec resin in the determination of radiostronium is its low capacity for Sr and the interferences of high calcium and salt content in a sample on the strontium separation. For a 1.5 g Sr Spec resin column, loading of no more than 5 mg Sr should be followed. For analysis of high Sr and Ca containing samples (e.g., bone ash), a large column or splitting sample into aliquots and loading to more Sr Spec columns is needed (Miura and Minai, 2017). For low-level environmental samples, large sample size is needed for the determination of ultra-low level ^{90}Sr, which often contains a large amount of stable Sr, Ca, Ba, other interferring elements and radionuclides, the simple extraction chromatography separation using Sr resin may not be suitable. Chen et al. (2002b) reported a simple method for the determination of ^{90}Sr in a large volume of seawater samples (45 L). In this method, strontium is first separated from seawater by coprecipitation of $CaCO_3$−$SrCO_3$ with the addition of stable strontium carrier of 0.3−0.5 g Sr and Na_2CO_3, the sample was heated to 90−95°C and kept for 2 hours. The precipitation is separated by settling overnight to remove the supernantant followed by centrifuging the remaining sludge. After dissolution of the $CaCO_3$−$SrCO_3$ using HCl, calcium is separated by hydroxide precipitation with the addition of NaOH to a final concentration of 0.5 M NaOH. In this condition, $Ca(OH)_2$ precipitate is formed, but strontium remains in the solution and separated from a large amount of calcium. Strontium in the supernatant is then separated as $SrCO_3$ precipitate by the addition of Na_2CO_3. The $SrCO_3$ precipitate is dissolved in HNO_3 solution and kept for 2−3 weeks for ingrowth of ^{90}Y with ^{90}Sr. To this solution, yttrium carrier is added, and then strontium is separated by adding H_2SO_4 to form $SrSO_4$ precipitate, and in this case, Ba and Ra remaining in the sample are also precipitated and removed from yttrium. ^{90}Y is then separated by adding oxalic acid to form yttrium oxalate precipitate, and ^{90}Sr in the precipitate is measured using low-background gas flow proportional counting. The main feature of this method is its capacity to handle high calcium samples. This method has also been applied to the analysis of milk, bone, and large size soil samples for ^{90}Sr (Popov et al., 2006).

In addition, solvent extraction and ion exchange chromatography are frequently used for separating radiostrontium from various environmental matrices (Vajda and Kim, 2010c). Tributyl phosphate (TBP) and bis-2-etytlhexylphosphoric acid (HDEHP) have been the most commonly used organic extractants to separate ^{90}Y from liquid samples, which is assumed to be in equilibrium with ^{90}Sr. Consequently, rapid assays of ^{90}Sr via its daughter nuclide are possible, e.g., in environmental water, liquid milk, or nuclear waste samples using Cerenkov counting or LSC (Martin, 1987; Suomela et al., 1993; Jabbar et al., 2009; ISO, 2010; Tayeb et al., 2015; Yang et al., 2017). The tedious pre-treatments of milk samples are as well avoided when strontium is first separated from fat and proteins using cation exchange resins and subsequently separated from interfering elements by other methods (Kim et al., 2009; Maxwell III and Culligan, 2009a).

Regardless of the separation method, the sample can be prepared for LSC or Cerenkov counting. At the end of the separation procedure, strontium is precipitated as the carbonate or the oxalate, then dissolved in dilute HCl or HNO_3 acid and mixed with the LS cocktail. The aqueous or organic eluates from the chromatographic columns can be used as such, or after processing further, for the sample preparation. They are mixed with the scintillation cocktail or measured directly by Cerenkov counting. Chemical yields of strontium and yttrium can be determined by gravimetric methods or atomic absorption spectrophotometry, flame photometry or using ^{85}Sr as a yield tracer.

3. LSC measurements

The simultaneous determination of ^{90}Sr and ^{89}Sr by LSC is possible using several approaches. The pure strontium sample can be measured merely by LSC after mixing with scintillation cocktail or directly by Cerenkov counting or by measuring the sample first by Cerenkov counting followed by adding scintillation cocktail for LSC. Because there are two unknowns, ^{90}Sr and ^{89}Sr, the strontium sample should be measured twice at various times during the ^{90}Y ingrowth or once in two counting windows. Thereafter ^{90}Sr and ^{89}Sr activities will be calculated from the two independent counts by two equations where the contribution of ^{90}Sr, ^{90}Y and ^{89}Sr on the counts in different counting windows are taken into account. These counts are corrected for efficiency and for the ^{90}Y ingrowth and the ^{89}Sr decay using the time, which has transpired from the separation of strontium from yttrium to the midpoint of the measurement. Because LS spectra of ^{90}Sr, ^{89}Sr, and ^{90}Y have different end-point energies, spectrum deconvolution or unfolding methods can be applied, and consequently only one measurement or one counting window is needed. For the same reason, the chemical separation of yttrium from strontium is unnecessary for the simultaneous assay of ^{90}Sr from ^{89}Sr unlike methods that utilize gas proportional counters. When ^{90}Y is separated, its activity is often measured by Cerenkov counting immediately after the separation. If only ^{90}Sr is to be determined, this measurement is sufficient, but in the occurrence of ^{89}Sr, the combined ^{89}Sr and ^{90}Sr activity should be measured in advance from the previously separated strontium sample.

a. Early LSC methods

Several methods of measuring radiostrontium have been reported (Uyesgi and Greenberg, 1965; Piltingsrud and Stencel, 1972; Randolph, 1975; Regan and Tyler, 1976;

Salonen, 1978; and Carmon, 1979). These are categorized as liquid scintillation and/or Cerenkov counting methods. Some early methods for the assay of ^{90}Sr and ^{89}Sr were based on Cerenkov counting immediately after the separation of strontium and yttrium and on the subsequent LSC after adding the scintillation cocktail and allowing some ingrowth of ^{90}Y (Randolph, 1975; Salonen, 1978). Other methods were based on two Cerenkov measurements (Regan and Tyler, 1976; Carmon, 1979). The measurements were usually performed in nonequilibrium conditions between ^{90}Sr and ^{90}Y and using optimized windows for both measurements. In the initial Cerenkov counting almost all counts are due to ^{89}Sr, because of the low beta-energy of ^{90}Sr (end point at 546 keV) resulting in a very low counting efficiency (less than 1.4%). Therefore, the ^{90}Sr counts are neglected in some methods in the calculations although these counts, as wells as those from ^{90}Y ingrowth, can easily been considered by determining the efficiencies of ^{90}Sr, ^{89}Sr and ^{90}Y separately in each counting window in LS and Cerenkov counting (Salonen, 1978). The inherent errors of the results will then be avoided especially when the first counting is more or less delayed. The uncertainties of the ^{90}Sr and ^{89}Sr concentrations depended mainly on the activity ratio of ^{90}Sr/^{89}Sr, on the degree of the ^{90}Y ingrowth and on the optimization of the energy windows (Randolph, 1975; Salonen, 1978; Carmon, 1979). No quench correction was required for routine samples prepared from well-purified strontium carbonate precipitate which was dissolved in dilute HCl and mixed with Insta-Gel (Randolph, 1975; Salonen, 1978). Constant quench conditions were obtained regardless of the sample composition variation in the range typical for routine analysis. Some early attempts at radiostrontium assay involved the suspension of the insoluble strontium precipitates into a suitable cocktail containing a gelling agent. One such method employed a suspension technique for the strontium carbonate containing ^{90}Sr, ^{90}Y, and ^{89}Sr and a spectrum unfolding computer program to determine the quantity of each of the three isotopes (Piltingsrud and Stencel, 1972). Another method involved dissolution of the ^{90}Sr carbonate into glacial acetic acid and adding of 2-ethylhexanoic acid to form strontium and yttrium 2-hexanoates which are then soluble in a toluene-based cocktail (Uyesgi and Greenberg, 1965).

b. Recent LSC methods

Current LS spectrometers can be applied in several ways to the simultaneous measurements of ^{89}Sr and ^{90}Sr. Some rapid assays are based on measuring the samples in the LS cocktail using the two- or three-window method (Amano and Yanase, 1990; Dietz et al., 1991; Tait and Wiechen, 1993; Fliss et al., 1998; Heilgeist, 2000; Günther et al., 2003; Eikenberg et al., 2006; Kim et al., 2009). Another method was based on using one open window for LS and Cerenkov counting and on employing a spectrum deconvolution method to calculate the ^{89}Sr and ^{90}Sr activities separately (Heckel and Vogl, 2009). Walter et al. (1993) performed a comparison study using three different methods to evaluate their applicability for low activity samples with high ^{89}Sr/^{90}Sr activity ratios, which usually occur in emergency situations. These methods were: 1) LS counting with two pulse height windows, 2) the combination of Cerenkov and LS counting with open windows, and 3) the combination of the Cerenkov and LS counting with two counting windows during LS counting. The methods were tested with variably quenched samples, at variable ^{89}Sr/^{90}Sr activity ratios and by applying automatic quench corrections. According to this study, the best method for the fresh fallout samples was the third method, which was accurate for the ^{89}Sr/^{90}Sr activity ratios from 0.2 up to 15. Reliable results were obtained using the second method, which is almost similar as referred to in the previous paragraph (Salonen, 1978). This approach simplifies quench corrections. Another alternative approach was recommended by Eikenberg et al. (2006), whereby the ingrown ^{90}Y would be separated from the Sr resin column and then measured by Cerenkov counting. In this method, strontium in the sample solution is first adsorbed onto the Sr Spec column, then waiting for 1−2 days to allow ingrowth of ^{90}Y on the column. The ingrown ^{90}Y is then eluted from the column using 8M HNO_3 and measured by Cerenkov counting. ^{89}Sr and ^{90}Sr are eluted afterward in the normal way using water or diluted HNO_3 (i.e., 0.05 M HNO_3) and measured by LS counting. In accord with all of these methods, the strontium sample can be measured immediately after separating strontium from yttrium. However, recounting at various times during the ^{90}Y ingrowth will confirm the results obtained, and also indicate whether interfering radionuclides have been eliminated during the chemical separation. The recounting also improves the separation of ^{89}Sr and ^{90}Sr when there is a large excess of ^{89}Sr. Fig. 2.20 illustrates the spectra of ^{89}Sr, ^{90}Sr, and ^{90}Y in the application where the measurement is based using two LSC windows (Kim et al., 2009).

The spectrum unfolding methods have been applied to radiostrontium determinations in aqueous solution (Hong et al., 2001; Lee et al., 2002b) and for the simultaneous separation of ^{90}Sr and ^{99}Tc (Lee et al.,2002a). This technique has been utilized successfully for the analysis of ^{90}Sr in bone samples in combination with the CIEMAT/NIST method for quench corrections (Altzitzoglou et al., 1998; Pilviö et al., 1999).

Using rapid separation methods, the total analysis time of radiostrontium in different sample matrices is 1−2 days or only some hours for samples such as water, aerosol, milk, and urine when the Sr resin is used for chemical separation (Heckel and Vogl, 2009; Kim et al., 2009; Maxwell III and Culligan, 2009a; Dai et al., 2013; Tayeb et al., 2016;

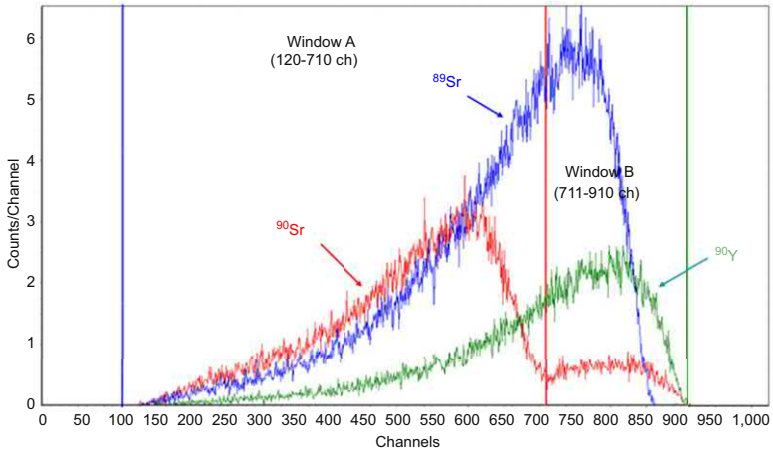

FIGURE 2.20 LSC spectra of ^{89}Sr, ^{90}Sr, and ^{90}Y (Kim et al., 2009). *Reprinted by permission of Elsevier © 2009.*

Guerin et al., 2017a). The detection limits by the current low-background LS spectrometers are typically less than 0.1 Bq (1−2 hours count time).

c. Cerenkov counting methods

Several attempts have been made to determine ^{89}Sr and ^{90}Sr simultaneously by Cerenkov counting (Randolph, 1975; Buchtela and Tschurlovits, 1975; Regan and Tyler, 1976; Carmon, 1979; Martin, 1987; Rucker, 1992; Chu et al., 1998; Vaca et al., 2001; Grahek and Măcefat, 2005; Günther et al., 2009). The determination is based on the fact that both ^{89}Sr and ^{90}Y can be detected by measurement of the Cerenkov radiation (photons) in colorless aqueous solutions with about 40% and 60% counting efficiency, respectively, while the counting efficiency of ^{90}Sr is less than 1.4% because of the low energy of its beta particles. The ^{89}Sr activity is determined almost exclusively from the freshly separated strontium sample when the first counting is performed immediately after the separation. Recounting is performed after some ingrowth of ^{90}Y from ^{90}Sr, and the calculation of the concentrations of ^{89}Sr and ^{90}Sr is possible from these two counts. Alternatively, ^{90}Y can be separated from the purified strontium sample after its ingrowth and counted separately (Carmon, 1979). When the ^{90}Sr activity alone is to be quantified, the calibrations and the calculations of the results are much simpler particularly after a complete ingrowth of ^{90}Y (Martin, 1987; Suomela et al., 1993; Friberg, 1997; Vaca et al., 2001; Torres et al., 2002; Wang et al., 2004; Jabbar et al., 2009; Harrison et al., 2011). In the methods mentioned previously, separation techniques like precipitation, ion exchange, solvent extraction, and extraction chromatography were used to isolate radiostrontium. In another method, the separation of ^{89}Sr and ^{90}Sr from water and milk samples was tested using a chelating resin, Chelite P (from Serva Company), and alginate spherules in batch form followed by the Cerenkov count (Günther et al., 2009). The milk samples were prepared without ashing and the results were obtained in 4 days by using 3 days for the ^{90}Y ingrowth. Because the Cerenkov counting is sensitive to color quenching, the effect of color quenching has been studied (Fujii and Takiue, 1988; Mosqueda et al., 2007), especially for samples in organic solutions (Suomela et al., 1993; Vaca et al., 2001). The Cerenkov counting techniques allow the use of ^{85}Sr as a yield tracer. The ^{85}Sr carrier decays via electron capture. It cannot produce Cerenkov radiation, and therefore, it is not detected by this counting. This makes radiostrontium assay simpler than determining the yield with a gravimetric method. For additional information on Cerenkov counting techniques, please refer to Chapter 6, Volume 2.

In summary, chemical separation of strontium has developed greatly, and the methods based on extraction chromatography have gained wide popularity. Rapid assays of radiostrontium are possible by combining such methods with low-background LS counting, which offer the ability to measure ^{89}Sr, ^{90}Sr, and ^{90}Y at very high counting efficiency immediately after the separation. The detection limits are less than 0.1 Bq with a 1−2 hours count time. A number of methods have been developed based on the extraction chromatography for emergency analysis, which requires analytical results in hours. Significant advances have also been made in analyzing radiostrontium simultaneously with other nuclides and in off-line or on-line monitoring models. These techniques are important in the future monitoring of nuclear wastes and in decommissioning of nuclear facilities.

F. Technetium-99 (^{99}Tc)

1. Environmental occurrence

^{99}Tc ($E_{max} = 293.5$ keV and $t_{1/2} = 2.11 \cdot 10^5$ y) is a pure beta-emitter which decays to stable ^{99}Ru (Laureano-Perez et al., 2010). It is a fission product of ^{235}U and ^{239}Pu and is mainly produced by thermal neutrons in nuclear reactors

with relatively high fission yields (6.1% from ^{235}U). Its presence in the environment is due to nuclear weapon tests and nuclear fuel cycle operations. The global inventory of ^{99}Tc from weapons testing is currently small. The main sources are nuclear reactors, although releases to the environment occur primarily from fuel reprocessing plants (Till, 1986). The principal reasons for the high level of interest in the analysis of ^{99}Tc in environmental samples are its very long half-life, high mobility and solubility as the pertechnetate ion (TcO_4^-) in oxidative conditions, and consequently its high transfer rate from soil to edible vegetation and from seawater to seaweeds. Under reducing conditions, it can be reduced to Tc^{4+} and strongly bound to sediments (Burke et al., 2010). ^{99}Tc is considered a long-term risk, because it is taken up readily by aquatic and terrestrial organisms (Degenkolb et al., 1994). Because Tc has no stable isotope, ^{99}Tc is the dominating isotope and used to study the behavior of this element in the environment. Studies have focused on marine and coastal environments owing to discharges from nuclear reprocessing plants (Ikäheimonen et al., 2002; Oliver et al., 2006; Begg et al., 2007; Keogh et al., 2007; Shi et al., 2012a, 2012b; 2013, 2016; Kolacinska et al., 2018; Barrera et al., 2016; Rodriguez et al., 2015; Jenkinson et al., 2014; Marshall et al., 2014). ^{99}Tc is one of the most significant components in the long-term storage and disposal of nuclear wastes (Zhang et al., 2010). In nuclear medicine, ^{99m}Tc ($t_{1/2} = 6$ hours) is used in high-activity amounts, which decay to ^{99}Tc, and becomes another source of ^{99}Tc in the environment.

2. Sample preparation and analysis

Chemical separation techniques including anion exchange, solvent extraction, selective precipitation, extraction chromatography, and even a combustion technique have been used to assay ^{99}Tc in various environmental samples, nuclear effluent and waste samples (Golchert and Sedlet, 1969; Holm et al., 1984; Cattarin et al., 1985; Silva et al., 1988; Jordan et al., 1995; Wigley et al., 1999; Tagami and Uchida, 1999; Gómez et al., 2001; Ikäheimonen et al., 2002; Lee et al., 2002a; Shi et al., 2012a, 2012b; 2013, 2016; Kolacinska et al., 2018; Guerin et al., 2017b, 2017c; Barrera et al., 2016; Rodriguez et al., 2015; Jenkinson et al., 2014; Marshall et al., 2014; Kabai et al., 2013). Because ^{99}Tc concentrations are generally very low, it is necessary to preconcentrate technetium from large sample sizes before the chemical separation. Direct evaporation of water samples is time consuming and not suitable for high salt containing samples (e.g., seawater); it also presents a risk in loss of Tc as the volatile heptoxide, if the temperature is increased sufficiently high. Loss of technetium might also occur during dry ashing of organic matter, unless some precautions are taken during evaporation or ashing (Wigley et al., 1999). Shi et al. (2012) investigated the stability of technetium in various chemical treatments including ashing of solid materials and evaporation of aqueous solution. It was reported that no significant loss of technetium was observed in ashing of seaweed under 800°C for less than 6 hours and under 500°C for soil and sediment samples. Evaporation of a solution to dryness in different concentrations of HNO_3 at less than 100°C does not cause obvious loss of technetium, while significant loss of technetium happens in HCl media, especially in high concentrations of HCl. However, if a small volume of solution (more than 0.5 mL) remained after evaporation, the loss of technetium can be highly reduced. Salt present in the solution can reduce the loss of technetium during evaporation.

^{99}Tc has no stable isotope to use as a carrier or for chemical yield monitoring. Although the analytical behavior of rhenium is quite similar to that of Tc, these elements can behave quite differently under certain conditions. Hence some precautions need to be taken if rhenium is used as a tracer (Anders, 1960; Mas et al., 2004). An advantage of using rhenium is that it is inexpensive and easier to handle than radioactive tracers (Gómez et al., 2001). ^{99m}Tc, obtained from a ^{99}Mo-^{99m}Tc generator has been used widely as a yield tracer in the radiochemical separation of ^{99}Tc for environmental samples, because it is readily available, and its emission of gamma rays (Hou and Roos, 2008). The disadvantage of the ^{99m}Tc tracer is that it may contain ^{99}Tc, ^{99}Mo, and ^{103}Ru as impurities, which may cause serious interference in the measurement of ^{99}Tc at low levels, requiring correction for each tracer solution used (Dowdall et al., 2004). Hou et al. (2007a) developed a simple method to produce the ^{99m}Tc tracer solution that is pure enough to be utilized in the analysis of low-level environmental samples. The ^{99m}Tc-^{99}Mo generator was first eluted using saline water (0.9% NaCl) for 3−5 times to remove the accumulated ^{99}Tc in the generator through decay of ^{99m}Tc and ^{99}Mo, the new ingrown ^{99m}Tc is then eluted after a suitable ingrowth time (1 minute−3 hours). The newly obtained ^{99m}Tc solution is then purified by passing it through an activated alumina cartridge to remove any ^{99}Mo and ^{103}Ru leaked from the column. The ^{99m}Tc activity is measured with a gamma spectrometer before preparing the sample for the LS counting. Thereafter, the sample is stored for a week to allow ^{99m}Tc to decay completely before measuring the ^{99}Tc activity by LSC. Another possibility for a yield tracer would be to use ^{95m}Tc (half-life = 61 d). ^{95m}Tc decays through electron capture with emission of gamma rays, and can be measured by counting the low-energy Auger electrons using LSC. Therefore, ^{99}Tc and ^{95m}Tc can be discriminated and measured by LS spectrum (Silva et al., 1988).

Chemical separation methods are mainly based on a combination of selective precipitations, ion exchange and solvent extraction using different extractants like DB18-C6

crown ether (dibenzo-18-crown-6), *tri-n*-octylamine (TnOA), and *tri-n*-butyl phosphate (TBP) (Holm et al., 1984; Wigley et al., 1999; Jordan et al., 1995). Separation of technetium using anion exchange chromatography is based on the very high affinity of TcO_4^- on the strong anion exchange resin in either diluted acid, alkaline, or neutral media. Chen et al. (1994) has reported a method for the determination of ^{99}Tc in seawater and other environment samples. ^{99}Tc is first pre-concentrated from a large volume of seawater samples (up to 200 L) using anion exchange chromatography. The filtered seawater is spiked with ^{99m}Tc tracer, and then loaded onto a big anion exchange column (2.5 cm in diameter and 40 cm in length, AG1x-4 resin, Cl^- form), after washing with diluted NaOH and diluted HNO_3 solution, ^{99}Tc is eluted from the column using 8−10 M HNO_3. The eluate is evaporated to a small volume (<10 mL), and treated with H_2O_2 and NaClO with heating to remove Ru. Afterward, the solution is converted to 1M H_2SO_4 medium, ^{99}Tc in the solution is further purified by solvent extraction using 5% triisooctylamine in xylene. The overall recovery of ^{99}Tc is more than 75% and the most interference can be completely removed to be able to measure background level ^{99}Tc in seawater samples (0.003mBq/L) using up to 500 L seawater.

Wigley et al. (1999) investigated all different steps of the analytical procedure including grinding, dry and wet ashing, dissolution, chemical separation, and measurement to find optimum conditions for separating ^{99}Tc from environmental samples. ^{95m}Tc was used as the chemical yield tracer. The first step of chemical separation was $Fe(OH)_3$ precipitation, which removed transition metals, actinides and lanthanides while Tc remained in the supernatant. The separation continued with an anion exchange chromatography in alkaline solution where Tc was retained in the column but alkali and alkaline earth ions and doubly charged transition metals passed through the column, and consequently interfering radionuclides such as ^{60}Co, ^{63}Ni, ^{90}Sr, and ^{137}Cs were removed. Tc was eluted from the column with concentrated HNO_3, which was then evaporated, and the residue was dissolved in 2 M H_2SO_4. The final purification of Tc from Ru, in H_2SO_4 solution, is accomplished by extraction using 5% tri-n-octylamine (TnOA) in xylene, the ^{106}Ru remains in aqueous phase. Recovery of the ^{99}Tc was determined immediately by gamma spectrometry measurement of ^{99m}Tc tracer and the sample left for 1 week to allow the ^{99m}Tc to decay completely. The extracted ^{99}Tc in TnOA-xylene was mixed with the scintillation cocktail and subsequently counted by LSC. Typical yields varied between 70 and 95%, and decontamination factors were between $10^3$and 10^6 for ^{137}Cs and ^{241}Am but only 3−5 for ^{106}Ru/^{106}Rh.

Jordan et al. (1995) obtained very high (10^5−10^8) decontamination factors for all important fission products, activation products and naturally occurring radionuclides, with chemical yields from 50% to 80%. The separation procedure is based on anion, cation exchange, and solvent extraction with TBP in H_2SO_4. Golchert and Sedlet (1969) reported a contamination factor of 1.3×10^4 for ^{106}Ru/^{106}Rh in environmental water samples. Their method was based on selective precipitations followed by solvent extraction using TnOA in xylene. They found that the Ru contamination factor was improved when it was removed initially by precipitation. This was accomplished by converting the Ru to a single species, Ru(VII), with NaOCl as oxidizer and then reducing it to the insoluble Ru(IV) oxide by the alcohol. The decontamination factor was improved by several hundred times and can be repeated if Ru activity is high. The overall chemical yield was 79.6%.

Selective extraction chromatographic methods using TEVA●Spec resin (Eichrom Industries, Darien, Illinois) and LSC or inductively coupled plasma mass spectrometry (ICP-MS) have become the most popular method for the determination of ^{99}Tc in environmental samples (Beals, 1992; Scarpitta, 1993; Gómez et al., 2001; Ikäheimonen et al., 2002; Lee et al., 2002a; Shi et al., 2012a, 2012b; Rodriguez et al., 2015; Jenkinson et al., 2014). Quantitative measurement of ^{99}Tc by LSC is viewed as a practical but also as the main approach, because of the more widespread accessibility of the LS counters, meanwhile it is also tolerant of isobaric ions (^{99}Ru and ^{98}Mo^{1}H) which is the major challenge in the ICP-MS measurement of ^{99}Tc (DOE, 1993; Hou and Roos, 2008). In environmental assays, the TEVA resin is used in combination with selective precipitations and anion exchange similarly to solvent extraction. The main purpose of the TEVA is to purify the Tc in the presence of Ru, which works very efficiently (Lee et al., 2002a). When the sample is loaded in a neutral solution or in 0.1M HNO_3 solution to a TEVA column, Tc is retained, while the Ru passes through the column. ^{99}Tc can be eluted with 4−8 M HNO_3 and an aliquot submitted for LSC. The overall yields by extraction methods are reported to be from 73% to 94%. Shi et al. (2012a) has reported a method for removing Ru from ^{99}Tc by pretreatment of the loading solution with 30% H_2O_2 in alkaline media, and found a significantly improvement in the removal of ruthenium in chromatographic separation using TEVA column. This might be attributed to the reduction of ruthenium in this process.

The LS counting efficiencies of ^{99}Tc are typically in the range of 70%−80% depending on sample composition and quenching. The backgrounds using low-background LS spectrometers are between 1.6 and 3.3 cpm, and the detection limits vary over a large range (0.16 mBq/L −1.7 Bq/kg) depending mainly on the count time and background level and sample size (Ikäheimonen et al., 2002; Jordan et al., 1995; Gómez et al., 2001; Wigley et al., 1999). The comparison study by Hou and Roos (2008) demonstrated that the detection limit by LSC is

approximately 17 mBq (2 hours count), which is about two orders of magnitude higher than those achieved by ICP-MS. Chemical separation is necessary for both methods.

Tarancon et al. (2017) have proposed the concept of combining the chromatographic separation with scintillation for the determination of radionuclides using LSC. In this method, a plastic scintillation resin is synthesized, in which the extraction reagent and scintillator are grafted on plastic beads. The plastic scintillation resin behaves as both extraction chromatographic resin and scintillator. The resin is prepared in a column, the sample solution is loaded to the column, the analyte radionuclide is adsorbed on the resin, and the matrix and interferring radionuclides are removed by rinsing. The scintillation resin with the analyte radionuclides in the column is directly measured by normal LSC. This research group has reported a method for the determination of ^{99}Tc in environmental and waste samples (Barrera et al., 2016). A specific plastic scintillation resin was synthesized by binding Aliquat 336 (trioctylmethylammonium chloride) as extractant to plastic scintillation microspheres. Here, the plastic scintillation microspheres (PSm) behaves like liquid scintillation cocktail but in a solid phase. PSm consists of a polymeric solvent and both primary and secondary scintillators, such as the classical PPO, POPOP, PTP, or bis-MSB. Fluor molecules remain encapsulated inside the PS solid. Fig. 2.21 illustrates a schematic diagram of the determination of ^{99}Tc using the plastic scintillation resin.

In summary, very low ^{99}Tc activities in environmental samples can be analyzed using several separation methods with current LS counters. The ^{99}Tc assay requires special attention to address the volatility of Tc and the separation difficulties encountered when trying to separate it from Ru, as well as from other elements depending on chemical conditions. Attention should also be paid to the ^{99m}Tc tracer, which may contain significant amounts of ^{99}Tc as an impurity.

G. Plutonium-241 (^{241}Pu)

1. Environmental occurrence

Plutonium (Pu) was released to the environment from nuclear weapons tests and nuclear fuel cycle operations particularly from reprocessing plants (Pimpl, 1992; Hou and Roos, 2008; Qiao et al., 2009). There are four isotopes of plutonium present in the environment, namely, ^{238}Pu ($t_{1/2} = 87.74$ y), ^{239}Pu ($t_{1/2} = 2.41 \times 10^4$ y), ^{240}Pu ($t_{1/2} = 6563$ y), and ^{241}Pu ($t_{1/2} = 14.4$ y). Among all isotopes of plutonium, only ^{241}Pu is a beta-emitter with emission of low-energy β-particles ($E_{max} = 21$ keV); thus, it is less radiotoxic than other alpha-emitting plutonium isotopes. However, ^{241}Pu decays to α-emitting ^{241}Am, which is more radiotoxic than ^{241}Pu. The differences in the Pu isotopic ratios are used to trace the origin of the environmental contamination (Kershaw et al., 1995; Turner et al., 2003; Carbol et al., 2003; Ketterer et al., 2004; Kwong et al., 2004; Alamelu and Aggarwal, 2007; Hou and Roos, 2008; Varga et al., 2008, 2018; Alamalu and Aggarwal, 2016). For instance, the activity ratio of ^{241}Pu/$^{239+240}$Pu differs depending on whether the contaminations originate from releases of nuclear fuel reprocessing plants (25), nuclear tests (15), weapon grade uranium (3), or the Chernobyl accident of 1986 (Holm et al., 1992). Environmental monitoring of ^{241}Pu around nuclear facilities is needed, and its determination in high-activity waste in nuclear fuel reprocessing cycles is important, as it will influence the method of final disposal (Prosser et al., 1994; Feng and He, 2009). In fact, ^{241}Pu is the only significant beta-emitting transuranium nuclide in low-level radioactive waste from nuclear power plants (Martin, 1986). Liquid scintillation is the major method for its measurement, although mass spectrometry has also been widely applied for its determination (Oh et al., 2013; Jaggi et al., 2012; Alvardo et al., 2011; Dai et al., 2012b). ^{241}Am is the direct decay daughter of ^{241}Pu, therefore measurement of the ingrown ^{241}Am from ^{241}Pu using alpha spectrometry has also been used for the determination of ^{241}Pu. In addition, the decay of ^{241}Pu causes continuous formation of ^{241}Am, and the ^{241}Am concentration in the environment would gradually increase to a maximum concentration in the middle of the 21st century (Hou and Roos, 2008). ^{241}Am is a unique tracer in oceanographic and sedimentation studies.

2. Sample preparation and analysis

Many methods have been developed for the determination of plutonium in environmental and nuclear samples, as summerized in four comprehensive reviews by Hou and Roos (2008), Qiao et al. (2009), and Vajda and Kim (2010a; 2010b). The chemical separation schemes of ^{241}Pu are normally complicated, because the concentrations of ^{241}Pu are normally very low. Its oxidation states have to be considered during the

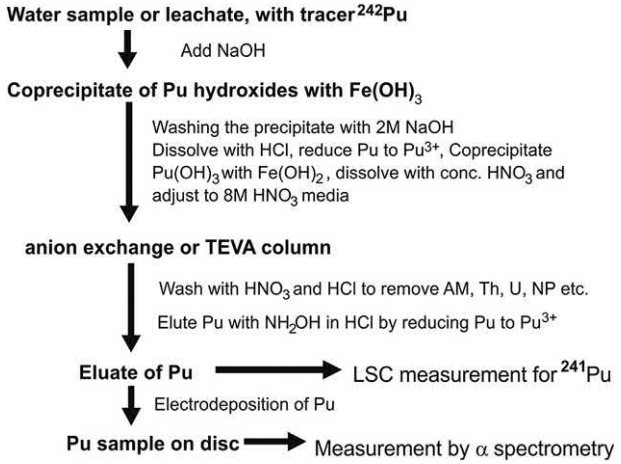

FIGURE 2.22 Diagram of chemical separation procedure for determination of plutonium isotopes.

separation, and plutonium has to be purified completely from other radionuclides in advance to avoid interference. Fig. 2.22 illustrates an often-applied analytical procedure for the determination of plutonium isotopes. In general, plutonium is first released from the solid sample matrix by acid leaching or alkaline fusion followed by acid dissolution. The released plutonium in the sample solution or in liquid samples (water sample) is then pre-concentrated by coprecipitation of hydroxide, fluoride, or phosphate. The precipitate is dissolved and plutonium is converted to Pu^{4+} valence state, which can be implemented by first reducing all plutonium to Pu^{3+} using strong reductant such as $KHSO_3$, and then oxidize Pu^{3+} to Pu^{4+} using $NaNO_2$, concentrated HNO_3 containing HNO_2 can be also used for this purpose. The prepared sample solution is loaded to an anion exchange column (e.g., AG 1x-4, or Dowex 1x-4) or TEVA extraction chromatographic column, followed by rinsing with HNO_3 to remove uranium and all transition elements, and finally HCl for Th removal. Plutonium absorbed on the column is then eluted by reducing it to Pu^{3+} using $NH_2.OH{-}HCl$ or using diluted HCl or diluted HF. The plutonium eluate is evaporated to dryness and dissolved in a small volume of diluted HCl for LSC measurement of ^{241}Pu.

^{241}Pu is a low-energy β-emitter, and LSC is the ideal measurement technique for determining its activity. While, other plutonium isotopes are alpha-emitters, and often measured using alpha spectrometry, especially ^{238}Pu which has to be measured by alpha spectrometry, because of the serious interference of ^{238}U for its measurement by mass spectrometry. Therefore, ^{241}Pu and other alpha-emitting plutonium isotopes are usually measured separately. This is often implemented that the separated plutonium is first electro-deposited on metal disc or micro-precipitated as NdF_3 coprecipitate on membrane filter and measured for alpha-emitting plutonium isotopes (^{238}Pu, ^{239,240}Pu and ^{242}Pu as chemical yield tracer) (Vajda and Kim, 2010a). Afterward, the Pu sample on the disk or filter paper is dissolved and measured using LSC for determining the ^{241}Pu activity. The initial α-spectroscopic measurement is required, if the measurement of all plutonium isotopes is necessary, and it provides the chemical yield for the ^{241}Pu analysis and reveals possible impurities in the purified Pu fraction. The Pu on stainless steel is dissolved in concentrated HNO_3 and then purified by solvent extraction or ion exchange, which is necessary if some interfering elements like Fe and Pt are present in the solution with Pu (Mietelski et al., 1999; Oh et al., 2009). They cause quenching which decrease the counting efficiency of ^{241}Pu and also increase misclassification (Condren et al., 1996; Kwong et al., 2004). The Pu coprecipitated with NdF_3 is prepared for LSC by placing the filter in the LS vial, dissolving Pu in a solution of H_3BO_3/HNO_3 and ethanol and adding the LS cocktail. The sample needs no quench corrections, because the membrane becomes translucent and the dissolver solution has no effect on the counting efficiency (Moreno et al., 1998; Kwong et al., 2004; Varga and Tarján, 2008). A constant counting efficiency of 37% could be applied for all samples (Moreno et al., 1998). The counting efficiency of ^{241}Pu was improved (48.8%) when it was separated with an extractive cocktail composed of HDEPH and scintillants in toluene (Yu-Fu et al., 1992). The application of the α/β discrimination feature in the LSC can reduce interferences and background in the low-energy β-region of the ^{241}Pu (Lee and Lee, 1999). A typical β-spectrum of ^{241}Pu with α-peak of other Pu-isotopes is shown in Fig. 2.23. The detection limits for ^{241}Pu are of the order of 30−100 mBq per sample based on a 100- to 600-minute count time (Pimpl, 1992; Moreno et al., 1998; Mietelski et al., 1999; Varga and Tarján, 2008). Paatero et al. (1994) reported a ^{241}Pu lower detection limit of 7 mBq for a lichen sample using the Quantulus and a 600-minute count time.

H. Other radionuclides (^{36}Cl, ^{41}Ca, ^{129}I)

The radionuclides discussed previously are the most important radionuclides in the environment in view of radiation protection and environmental monitoring. Meanwhile, many other anthropogenic radionuclides have also been released to the environment by human nuclear activity. Due to the long half-life and relative small amount of radioactivity compared to the above mentioned radionuclides, they are less important in the view of radiation risk, but they are more important in view of waste depository and are very useful for investigation of environmental processes. Among them, ^{36}Cl, ^{129}I, and ^{41}Ca are presented here.

1. Chloride-36 (^{36}Cl)

^{36}Cl is a long-lived ($t_{1/2} = 301$ ky) pure beta-emitter ($E_{max} = 709$ keV), formed by neutron activation reaction of stable chlorine ^{35}Cl(n,γ)^{36}Cl in a nuclear reactor. Less

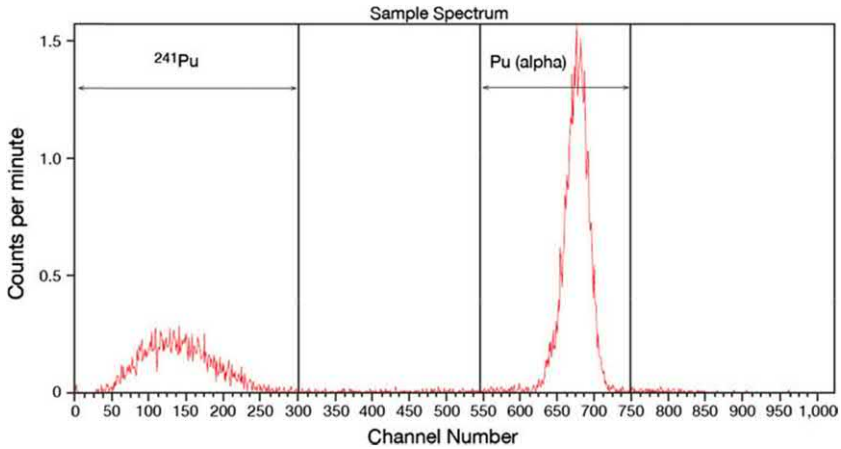

FIGURE 2.23 LSC spectra of a plutonium sample measured by the Quantulus LSC (Oh et al., 2013). *Reprinted by permission of Springer Nature © 2013.*

important sources are nuclear reactions induced by cosmic radiation in the atmosphere, water, and bedrock. Because of its low specific activity, ^{36}Cl is not considered a substantial danger to humans at present environmental levels. However, due to the high mobility of chlorine and its long half-live, ^{36}Cl is a useful tracer in interpreting environmental processes (Shaw et al., 2014; Muensterer et al., 2012; Fehn, 2012).

Many methods have been reported for the determination of ^{36}Cl in environmental and waste samples (Hammer-Rotzler et al., 2015; Hou et al., 2007b; Fréchou and Degros, 2005; Itoh et al., 2002a; Tolmachyov et al., 2001; Ashton et al., 1999; Szántó et al., 1998; Moir et al., 1995). For soil, concrete, and other solid materials, chlorine is separated from the sample in one of the following ways: vaporizing the chlorine to Cl_2 gas by subjecting the sample to high temperature or by boiling the sample in strong oxidizing acids. The released chlorine gas from the samples is captured in a NaOH solution. The sample can also be dissolved so that the chlorine remains in solution as chloride ions. In all three cases, a known amount of chlorine carrier, in the form of NaCl, for example, is added to the sample. Chlorine gas trapped in the NaOH solution is reduced with $NaNO_2$ to chloride, and the chloride is precipitated as silver chloride (AgCl) by adding $AgNO_3$ after acidifying the solution to a weakly acidic medium. Iodide precipitates along with the silver chloride, which means that the long-lived radionuclide ^{129}I, might also be present in the precipitate. Iodine can be removed by extracting the precipitate with NH_4OH, in which AgCl dissolves, but AgI does not. The AgI precipitate is discarded and the chloride in the NH_4OH solution is again precipitated by acidification to $pH < 2$. At the end of the analysis, the chemical yield of the separation is determined by measuring the amount of chlorine by ICP-MS or ion chromatography. Finally, ^{36}Cl in the purified AgCl precipitate is counted by LSC after dissolving the precipitate with ammonium and adding scintillation cocktail. Because of the relative high beta energy of ^{36}Cl, the counting efficiency of ^{36}Cl is normally higher than 85% depending on the quench level, and the need to be corrected using a quench curve or internal standard method. For nuclear waste samples, ^{36}Cl levels are sufficiently high to be measured by LSC. But for most environmental samples, especially samples with natural originated ^{36}Cl, the most sensitive method of accelerator mass spectrometry is needed, which can measure ^{36}Cl in the sample target with a $^{36}Cl/^{35}Cl$ atomic ratio of 10^{-15}.

Hou et al. (2007b) reported a method for the determination of ^{36}Cl in nuclear waste samples, including graphite, concrete, and metals. Fig. 2.24 illustrates an analytical procedure for the determination of ^{36}Cl in waste samples. In this method, the sample is first decomposed. A graphite sample is decomposed by acid digestion with a mixture of acid (H_2SO_4:HNO_3:$HClO_4$ = 15:4:1); metals such as lead, aluminum, and stainless steel are dissolved with 5M HNO_3, 5M H_2SO_4, and H_2SO_4−H_3PO_4, respectively. During the decomposition by heating, the solution is bubbled with nitrogen gas, and the released gas is trapped in three series if interconnected trapping solutions: one H_2O, and two with 0.4M NaOH. A concrete sample is decomposed by alkaline fusion by mixing the sample with NaOH−Na_2CO_3 and fused at 500°C for 3−4 hours, the fused cake is dissolved with H_2O, and the leachate is used for the determination of ^{36}Cl. Before sample decomposition, stable chloride as carrier and other stable element as hold back carriers are added. The decomposed sample solution is then transferred to a separation funnel. $NaHSO_3$ solution is added to convert all iodine to iodide, HNO_3 is then added to adjust $pH < 2$. After the addition of CCl_4, $NaNO_2$ solution is added to oxidize iodine to I_2, and chlorine is reduced to Cl^-, I_2 is then extracted to CCl_4 phase by shaking. $AgNO_3$ solution is added to the aqueous phase after extraction of iodine, and the solution is stirred to aggregate the AgCl precipitate. The

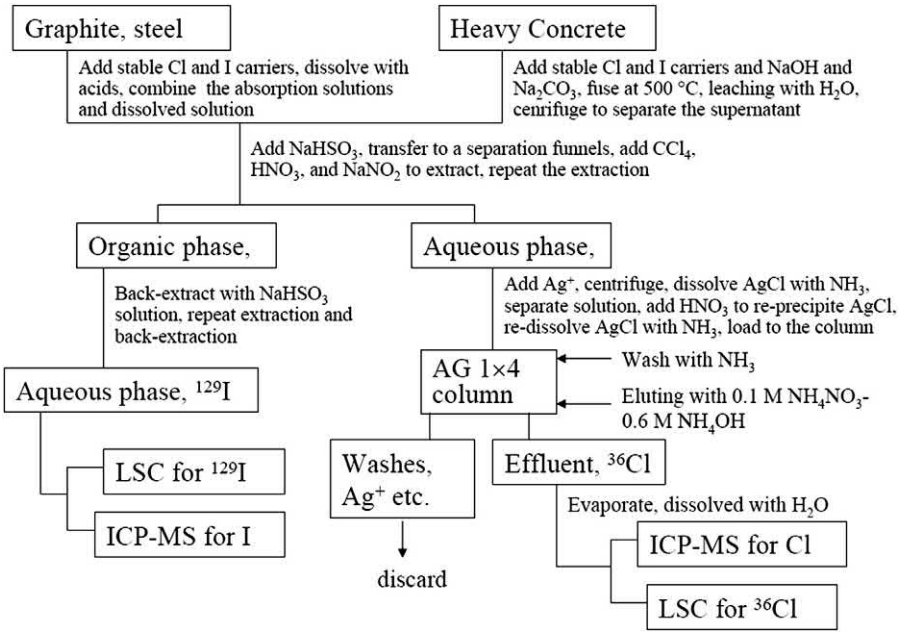

FIGURE 2.24 Analytical procedure for the determination of ^{36}Cl in nuclear waste samples (Hou et al., 2007a, 2007b).

AgCl precipitate is separated by centrifugation, and washed with 1 M HNO_3 to remove the interfering metal radionculides. The precipitate is dissolved with 25% NH_3, and HNO_3 is then added to the solution to pH < 2. The AgCl precipitate formed is separated by centrifugation and the supernatant (metal radionculides) is discarded. The AgCl precipitate is dissolved in 25% NH_3 solution, and the solution is loaded to an anion exchange column which is converted to OH^- form and conditioned with 25% NH_4OH. The column is washed with 25% NH_3 until there is no Ag^+ in the wash effluent. Chloride on the column is then eluted with 0.2 mol/L NH_4NO_3-0.6 mol/L NH_4OH. The eluate is evaporated to dryness on a hotplate. The residue is dissolved with 2 mL water, and transferred to an LSC vial. A small fraction of the solution (0.1 mL) is taken to measure stable chlorine by ICP-MS for chemical yield monitor. Scintillation cocktail (15 mL) is added to the remaining solution, and ^{36}Cl in the solution is measured by LSC. The decontamination factors for all interfering radionculides are higher than 10^6, and the recovery of Cl is higher than 90%. Since the final solution of ^{36}Cl is prepared in 2 mL of water, the quench level is very low and the counting efficiency is high (>98%). In addition, compared to the other methods of preparing the final ^{36}Cl sample in ammonium solution or suspending AgCl precipitate in scintillation cocktail, the measurement solution is stable and the measurement results are more precise and accurate.

2. Iodine-129 (^{129}I)

^{129}I decays by beta emission to the excited state of xenon isotope ^{129m}Xe with a beta-particle $E_{max} = 150$ keV. The decay of the excited state ^{129m}Xe takes place mostly by internal conversion with the emission of a low intensity (7.5%) of 39.6 keV gamma ray and some X-rays including 29.46 keV (20.4%) and 29.78 keV (37.7%). Therefore, ^{129}I can be measured by LSC and γ spectrometry, and LSC is more sensitive compared to γ spectrometry.

^{129}I is naturally present in the environment, generated in the atmosphere from xenon by nuclear reactions induced by cosmic radiation, and in the soil from uranium through spontaneous fission and fission due to thermal neutrons. The concentration of natural ^{129}I in the environment is so low that it is not usually expressed in terms of activity concentration, but in proportion to the only stable isotope of iodine, ^{127}I. Before the nuclear age, the $^{129}I/^{127}I$ atomic ratio was about 10^{-12} in the sea and somewhat higher in the terrestrial environment. Now, as a result of nuclear weapons tests, nuclear accidents, and emissions from nuclear facilities, the level of ^{129}I in the environment has risen, and the $^{129}I/^{127}I$ ratio has increased by several orders of magnitude, up to as much as 10^{-4} in the surrounding location of nuclear fuel reprocessing plants. The most extensive releases of ^{129}I to the environment occurred at the spent nuclear fuel reprocessing facilities at Sellafield (UK) and La Hague (France) since the early 1990s (Hou et al., 2009, 2001; 2002).

The very long half-life of ^{129}I (1.6×10^7 y) means that its specific activity is very low (6.5×10^6 Bq/g). Thus, radiometric methods including LSC are suitable only for samples in which the activity of the isotope is fairly high. Such samples are found in nuclear power plants and fuel reprocessing facilities, or environmental samples around

the reprocessing plants. Radiometric methods are not sensitive enough for measuring the very low activity concentrations of ^{129}I in the environment. More sensitive methods are neutron activation analysis and especially accelerator mass spectrometry (Hou et al., 1999).

When the activity is high enough, ^{129}I can be measured by LSC (Zulauf et al., 2010; Osman et al., 2016). In determining ^{129}I in the ion exchange resin used in the purification of the primary circuit of nuclear power plants, the iodine in the resin is eluted with NaOCl. In this case, iodide adsorbed on the exchange resin is oxidized to iodate, which has a low affinity to the resin, and it is eluted from the resin. Subsequently, KIO_3 is added to the solution as carrier, and the iodate is reduced to I_2 with hydroxylamine hydrochloride. The I_2 is then extracted into CCl_4 phase. Afterward, iodine is back extracted into water with $NaHSO_3$, which reduces I_2 to I^-. The iodide is then oxidized to I_2 with $NaNO_2$ in acidic medium, which is extracted with toluene. The iodine in the toluene is back extracted into aqueous solution with 0.01 M $NaHSO_3$. Scintillation cocktail is added to the aqueous solution and the activity of ^{129}I is measured by LSC. The detection limit of 0.6 Bq/L can be achieved (Puukko and Jaakkola, 1992).

For solid samples, such as soil, sediment, vegetation, and air particles, ^{129}I must be separated from the sample matrix and then purified for its measurement using LSC or other techniques. Based on its volatility, iodine is often separated from solid samples by combustion to release iodine in gaseous form (Muramatsu et al., 1995; Hou and Wang, 2016, 2018). The released iodine is trapped in NaOH solution, which is then used to separate iodine by extraction with CCl_4, as described above, for its measurement. In addition, alkali fusion can be also used to separate iodine from environmental samples, such as soil, sediment, air particles, vegetation, and animal tissues (Hou et al., 1999; Zhang et al., 2015). In this case, ^{125}I tracer is first added to the sample, NaOH is then mixed with the sample. After drying, the mixture is ashed/fused at 500−550°C for 3−4 hours. The ashed/fused sample is leached with hot water, and the leachate is separated from residue by filtration. Iodine in the leachate is finally separated by CCl_4 extraction, as described previously (Fig. 2.24) (Hou et al., 1999; Zhang et al., 2015). Fig. 2.24 illustrates a combined procedure for the determination of ^{129}I and ^{36}Cl in soil samples, in which alkaline fusion and acid digestion were applied for decomposition of samples and solvent extraction was applied for separation of ^{129}I from sample matrices and interference radionuclides. For the separation of iodine from water, milk, and urine samples, especially large volumes of seawater (30−50 L), an anion exchange chromatographic method has been reported by Hou et al. (2001, 2002). In this method, iodine in the water or other liquid samples is first reduced to iodide using $KHSO_3$ at pH < 2, the sample is loaded to an anion exchange column (AG1×-4, NO_3^- form), the adsorbed iodine is then eluted with 2 M $NaNO_3$ solution. The iodine in the eluate is separated by CCl_4 extraction. Iodine is finally obtained in a small volume of back extraction solution, which is used for LSC measurement or prepared in suitable target for neutron activation analysis or accelerator mass spectrometry measurement for ^{129}I.

3. Calcium-41 (^{41}Ca)

^{41}Ca, with a very long half-life (1.03×10^5 years), is mainly produced by neutron activation reaction of $^{40}Ca(n, \gamma)^{41}Ca$. It is also a naturally occurring radionuclide produced by the reaction of stable calcium (^{40}Ca) of the earth with neutrons from cosmic rays and fission of uranium (Fink et al., 1990). Human nuclear activities, including atmospheric nuclear weapons testing and operation of nuclear facilities have also released some ^{41}Ca to the environment. In the nuclear reactor, ^{41}Ca is mainly produced in the concrete shielding, because of its high calcium content and its exposure to the neutrons from the reactor. ^{41}Ca is an important radionuclide in the disposal of radioactive waste, because it can exist for a very long time with a high mobility in the environment and high bioavailability.

^{41}Ca decays to the ground state of ^{41}K by pure electron capture, emitting X-rays and Auger electrons of very low energy (0.3−3.6 keV), it can thus be measured by X-ray spectrometry and LSC. LSC is much more sensitive (Suárez et al., 2000; Itoh et al., 2002b; Hou, 2005a, 2005b; Warwick et al., 2009; Hampe et al., 2013), because of its low counting efficiency (<0.08%) by X-ray spectrometry and the low abundance of X-rays of ^{41}Ca (11.4% for 3.31 keV X-ray). Mass spectrometry techniques such as accelerator mass spectrometry (AMS) (Fink et al., 1990; Zerle et al., 1997) and resonance ionization mass spectrometry (RIMS) (Müller et al., 2000) are more sensitive techniques for its measurement and have also been used for its determination. A $^{41}Ca/^{40}Ca$ atomic ratio as low as 10^{-15} can be measured by AMS.

Due to the pure electron-capture decay of ^{41}Ca, chemical separation from the sample matrices and purification from all other radionuclides are necessary prior to the measurement of ^{41}Ca using LSC or other techniques. Suárez et al. (2000) reported a radiochemical separation procedure for the separation of calcium from other radionuclides, which is based on hydroxide precipitation of transition metals and chromate precipitation of Ba, Sr, and Ra with a chemical recovery of 40%. In this procedure, the separation of Ba, Sr, and Ra by chromate precipitation is very critical, because of very strict control of pH value. Ion exchange and extraction chromatography have also been used for the separation of calcium (Itoh et al., 2002b; Hampe et al., 2013). Anion exchange chromatography was used to remove all radionuclides presenting as anion in high concentration HCl media, and extraction chromatography

using TRU resin was applied to remove actinides and lanthanides. However, this procedure is not well suitable for the removal of alkaline earth radionuclides such as radioisotopes of strontium, radium and barium. A tertbutylmethylether/ethanol extraction step was proposed to extract calcium and to remove Sr, Ba, and Ra (Hampe et al., 2013). With all of these steps, a recovery of more than 65% and decontamination factor for most of interfering radionuclides are higher than 10^3. Hou (2005b) reported a simple and effective method for the determination of ^{41}Ca in ordinary and heavy concrete (containing more than 75% of $BaSO_4$) based on the relative low solubility production of $Ca(OH)_2$, compared to Sr, Ba, and Ra in NaOH solution. Calcium (mainly as calcium carbonate) is first leached using aqua regia, and the experiment shows that more than 95% of Ca can be leached out from the concrete sample in this step. There are three main steps for the separation of Ca from the interfering radionuclides, namely,

(1) Ca is first separated from the transition metals, such as Co, Eu, Fe, Ni, and tranuranics by precipitation at pH 9 using NaOH. In this step, the interfering radioisotopes of these elements are precipitated, while Ca remains in the solution with Sr, as well as Ba, Ra, Cs, etc.
(2) Ca and Sr in the supernatant are then precipitated as carbonates with Ba and Ra by adding Na_2CO_3 and separated from alkali metals and nonmetal elements.
(3) Ca is finally separated from Sr, Ba and Ra by precipitation of Ca as $Ca(OH)_2$ in 0.5 mol/L NaOH solution after dissolution of the carbonate precipitates. This is based on the low solubility of $Ca(OH)_2$ in high concentration of NaOH (higher than 0.5 mol/L) compared with Sr, Ba, and Ra. This step is repeated and the separated $Ca(OH)_2$ is dissolved with HCl for measurement using LSC after neutralizing to pH 6-8.

The chemical yield of ^{41}Ca of 80%−90% was obtained by the measurement of Ca before and after chemical separation using ICP-OES. The decontamination factor for the interfering radionuclides such as ^{60}Co, ^{152}Eu, ^{133}Ba, ^{85}Sr, ^{137}Cs, ^{55}Fe, and ^{63}Ni are higher than 10^5. The detection limit of the analytical method for ^{41}Ca is 0.020 Bq.

This method could not separate ^{45}Ca from ^{41}Ca. If both isotopes exist in the sample, interference of ^{45}Ca to the measurement of ^{41}Ca has to be corrected, which can be carried out by measurement of the contribution of ^{45}Ca to the counting window of ^{41}Ca in the lower channel. Due to the low energy of Auger electrons (0.3−3.6 keV) detected in the measurement of ^{41}Ca by LSC, the counting efficiency is relatively low (<25%), and highly influenced by quench. The separated calcium sample is normally prepared in a neutral solution of $CaCl_2$, and all other interfering elements (especially iron) have to be removed completely. The major quench effect is the amount of calcium in the samples. In addition, luminescence is also an interference for the measurement of ^{41}Ca, which has to be considered in the measurement of ^{41}Ca using LSC.

VII. Analysis of radionuclides from natural decay series

A. Uranium

1. Environmental occurrence and importance

Natural uranium has three isotopes ^{238}U ($t_{1/2} = 4.5 \cdot 10^9$ y), ^{235}U ($t_{1/2} = 7.0 \cdot 10^8$ y) and ^{234}U ($t_{1/2} = 2.5 \cdot 10^5$ y) which belong to two decay series. ^{238}U is the parent of the uranium series where ^{234}U belongs as a member, and ^{235}U is the parent of the actinium series. The atom abundances of ^{238}U, ^{235}U and ^{234}U are 99.2745%, 0.7200% and 0.0055%, respectively. ^{232}Th ($t_{1/2} = 1.4 \cdot 10^{10}$ y) starts the third natural decay series. The decay scheme of the uranium series is presented in Fig. 2.25. Uranium and thorium are widely distributed throughout the earth's crust, in surface and ground waters. The current worldwide average value of 33 Bq/kg for ^{238}U in soil is low, but the reported concentrations vary largely up to 1000 Bq/kg (UNSCEAR, 2008). Practically, almost all of the natural environmental radiation of terrestrial origin is due to radionuclides of the uranium and thorium series and to ^{40}K. The actinium series is of lesser importance due to its low abundance of natural uranium.

Because members of the natural series have different chemical and physical properties, they are separated from their parents and from each other in the course of normal geological processes, and the members of the series are rarely in radioactive equilibrium with each other. The disequilibrium ratios

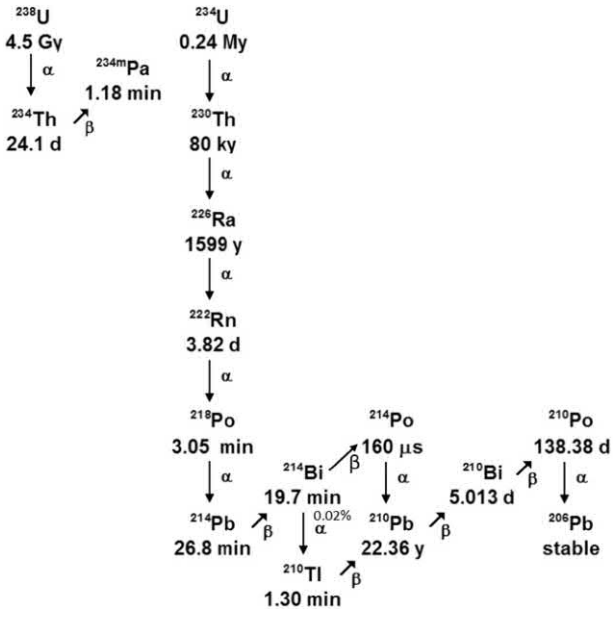

FIGURE 2.25 Decay scheme of uranium series (^{238}U).

between the members of uranium series are utilized widely in many studies in hydrology, age dating, marine chemistry, and exploration of uranium (Ivanovich et al., 1992). The disequilibrium state between ^{238}U and ^{234}U is rather common in nature, especially in waters. Depending on the origin of the water, the $^{234}U/^{238}U$ activity ratios can vary greatly; values ranging up to 30 have been reported in the groundwater. The main intake of uranium occurs through food. The contribution of drinking water is normally very low; but it can exceed the intake through food by several orders of magnitude, if uranium is present in drinking water sources (UNSCEAR, 2000, 2008). Uranium is retained in the body primarily in the skeleton. The major health effect from uranium is due to its chemical toxicity rather than to the radiotoxicity. Continuous uranium intakes may affect the human kidney, in particular, proximal tubular function (Zamora et al., 1998; Kurttio et al., 2002, 2006; Health Canada, 2010; WHO, 2011).

The limit of uranium in drinking water is set on the basis of its chemical toxicity. WHO has set a provisional guideline of 30 μg/L (WHO, 2011), and the limits in USA and Canada are 30 μg/L and 20 μg/L, respectively (EPA, 2009; Health Canada, 2010). The 30 μg/L natural uranium ($^{234}U/^{238}U$ activity ratio = 1) corresponds to 0.37 Bq/L of ^{238}U. Environmental monitoring of uranium and other natural radionuclides is of great concern due to the operation of nuclear fuel cycle installations and due to other industries where uranium containing minerals are processed (UNSCEAR, 2008).

2. Sample preparation and analysis

Today, the most common methods for uranium analysis are mass spectrometric, alpha-spectrometric, and LSC methods. Mass spectrometric methods are more than six orders of magnitude sensitive than the radiometric methods for ^{238}U and ^{232}Th due to their long half-lives, whereas their short-lived isotopes are best determined by radiometric methods (Hou and Roos, 2008). The sample preparation for the mass spectrometric analysis is often much easier and very small samples are needed for the analysis compared to the alpha spectrometric methods. Today, the multicollector systems both in TIMS and ICP-MS instruments have significantly contributed to making mass spectrometry a main tool for the high-precision assay of long-lived uranium and thorium isotopes (Bou-Rabee et al., 1995; Werner et al., 1997; Forte et al., 2001; Tagami and Uchida, 2004; Rathore, 2008; Andersen et al., 2009). The measurement time for one sample is only about 1 minute, and a great number of samples can be measured accurately in a short time. Also, ^{234}U can be determined using the MC-ICPMS and ICP-QMS instruments even though its isotopic abundance is extremely low ($^{234}U/^{238}U = 5.49 \cdot 10^{-5}$) compared to that of ^{238}U (Karpas et al., 2005). Alpha spectrometric methods have been used widely to determine uranium activities and $^{234}U/^{238}U$ activity ratios in environmental samples over several decades (Lieberman and Moghissi, 1968; Sill and Williams, 1969; Holm and Fukai, 1977; Singh and Wrenn, 1983; Anderson, 1984; Godoy et al., 1994; Hrnecec and Irlweck, 1995; Carter et al., 1999; Forte et al., 2001; Wang et al., 2004; Kovács et al., 2004; Bojanowski et al., 2005; Kozłowska et al., 2007; Wallner et al., 2008; Eikenberg et al., 2009; Jia et al., 2009; Kiliari and Pashalidis, 2010; Dircan and Sahin, 2016; Sonali et al., 2016; Jia, 2017; Kallithrakes-Kontos et al., 2018). The chemical separation methods are well established and the $^{234}U/^{238}U$ activity ratios are determined accurately, because the silicon surface-barrier or PIPS detectors provide a good resolution for α-particles from isotopes of uranium. These methods, however, assume that uranium is separated from the sample matrix as a pure fraction and that it is deposited on a metal disc as a thin layer to reduce self-absorption of alpha particles in the sample itself. Uranium can be separated either alone, or together with other actinides and radium, using several methods like precipitation, anion or cation exchange, liquid-liquid extraction or extraction chromatography or a combination of these. Uranium is finally electrodeposited onto a stainless-steel disk or it is coprecipitated as fluoride with CeF_3, LaF_3, or NdF_3, which is collected on a filter for the measurement with an alpha spectrometer. ^{232}U, ^{233}U, or ^{236}U is used as a yield tracer. The drawback of the method is that the alpha resolution will be impaired, if the uranium mass on the disk or the filter is too high. Hence, the uranium concentration should be assessed in advance to use the appropriate amount of sample and yield tracer for analysis. Because the sample size is limited, it usually means long counting times, probably several days.

Although ICP-MS and semiconductor alpha spectrometry are most common techniques for low-level uranium measurement, LS methods have been used to monitor for uranium in a variety of matrices including water, urine, phosphate containing materials, air, and fallout (Horrocks, 1974b; Miller, 1991; Prichard and Cox, 1991; Venso et al., 1993; Salonen, 1993a; Zelensky et al., 1993; Füeg et al., 1997; Sanchez-Cabeza and Pujol, 1998; Eikenberg et al., 1999; Forte et al., 2001; Bem and Wieczorkowski, 2002; Navarro et al., 2004; Aupiais, 2004a, 2004b; Antoniou et al., 2008). The LS methods are often used to screen uranium in drinking water for which purpose they are practical and cost-effective. The sample preparation is easy, and the LS spectrometers with α/β discrimination provide much information on the radionuclide composition in water as well. In some methods, water is concentrated directly in the LS vial by freeze-drying or evaporation, the residue is dissolved in dilute HCl, the cocktail is added and the sample is measured with LSC using α/β discrimination (Salonen, 1993a; Sanchez-Cabeza and Pujol, 1998; Zelensky et al., 1993). Uranium can also be extracted from a larger water sample. Prichard and Cox (1991) extracted it from a 1L water sample (acidified to pH 1.5 with HNO_3) into 20 mL of toluene containing the scintillants and bis(2-ethylhexyl)phosphoric acid (HDEHP) as an extractant and measured it with the PERALS spectrometer. Venso et al.

(1993) used the same extractant, HDEHP, but mixed it with a DIN-based cocktail. Bem and Wieczorkowski (2002) separated uranium and thorium from fallout samples by extracting them into 10 mL of 5% (w/w) tri-n-octylphosphine oxide (TOPO) in toluene from 10 mL of 3M HNO_3 where fallout residue had been dissolved by microwave digestion. The toluene was mixed with 10 mL of Ultima Gold LLT and measured with LSC using α/β discrimination. The only significant interfering radionuclide in the fallout samples was ^{210}Po which was removed by washing the toluene phase with 10 mL HNO_3.

Miller (1991) developed a rapid and economic method for the separation of uranium from urine. In this method, a 200 mL urine sample and an equal amount of concentrated HCl were mixed, the mixture was passed through an anion exchange column, impurities were first eluted from the column with HCl/HI acid mixture and thereafter uranium with 10 mL of 0.1M HCl. The destruction of the organic matter was not applied in this method, and therefore the analysis time was shortened. Eikenberg et al. (1999) developed a quite simple and fast procedure for the separation of actinides from urine. They used an extraction chromatography (Actinide Resin), which is based on the extractant with trade name DIPEX. Uranium and other actinides can be absorbed effectively on the resin and separated from the matrix. The separated actinides were evaporated and finally dissolved in 2 mL of 0.5 M HCl, then mixed with 12 mL of Ultima Gold AB and measured with a low-background LS spectrometer using α/β discrimination. The counting efficiency was 95%, the recoveries were between 90 and 100% and the detection limit was 1.5 mBq/L for a 0.5 L urine sample and for a 500 minutes counting time.

Antoniou et al. (2008) proposed an ion exchange method for the separation followed by LSC counting. Uranium was pre-concentrated from 1 L of ground water sample using a cation exchange resin, Chelex 100. The uranium was eluted from the resin with 30 mL of HNO_3 which was evaporated to incipient dryness. The residue was dissolved into 4 mL of 0.5M HCl and mixed with 16 mL of OptiPhase HiSafe three cocktail and measured with the Triathler. The detection limit was 30 mBq/L.

Leyba et al. (1995) tested an extractive scintillation cocktail, URAEX, to separate uranium from water and to measure the samples with the PERALS spectrometer. The results were comparable with those obtained by an alpha spectrometric method. The extraction efficiency for uranium decreased when nitrate and chloride concentrations were high and these samples have to be pre-treated. The whole separation time by this extraction method was short (30 minutes) compared to that by alpha spectrometry (6 hours). Extraction chromatography is becoming a popular technique for the separation of radionuclides. UTEVA resin has been widely used for the separation of uranium from various sample types. Uranium is first released from samples using acid dissolution or alkaline fusion followed by pre-concentration using coprecipitation with $Fe(OH)_3$, then prepared in 3M HNO_3 media, the sample solution is loaded to a UTEVA column. The uranium is strongly adsorbed on the column, all matrices and interfering radionuclides are removed by rinsing with 3M HNO_3 and 6M HCl, and the uranium is finally eluted from the UTEVA column with diluted HCl (0.02 M). After the eluate is reduced to a small volume, the solution can be mixed with scintillation cocktail for the LSC measurement of uranium (Qiao et al., 2015). Füeg et al. (1997) also used extractive chromatographic resin, UTEVA and extractive scintillation cocktails, URAEX, THOREX and RADEX, to separate ^{234}U, ^{238}U, Th isotopes and radium from soil samples and measured the samples with the PERALS spectrometer. U/Th-disequilibrium in soil was determined easily without using U- and Th-tracers. Aupiais (2004) developed a rapid and simple method to measure uranium in all types of water samples. Uranium separation was performed using an extractive scintillation cocktail, Alphaex, which contains HDEHP as extractant. The co-extraction of the interfering radionuclides such as ^{210}Po, Th-, and Pu-isotopes was prevented by complexing them with DTPA (final conc. 0.1M) and by adjusting the pH to 3.5 with 10M NH_3 before the extraction. The sample was measured with the PERALS spectrometer. However, some ^{210}Po was found to be extracted, because the yield with the ^{232}U tracer was over 100%. This was caused by ^{210}Po having an α-energy equal to that of ^{232}U. Hence, an additional step was included into the separation procedure for removing ^{210}Po using a silver powder. The separation time was 2 hours and the detection limit is 0.003 Bq/L for a 100 mL water sample and for a 4000 minutes count time. However, because of the low resolution of LSC to alpha-emitting radionuclides, the measured activity is the sum of total alpha activity or total activity of uranium when uranium was separated from other alpha-emitters.

In summary, the rapid LS methods are sensitive enough to determine the uranium concentration in drinking waters to achieve the regulations. The application of the α/β discrimination provides accurate results of uranium, and valuable information on additional radionuclides in water. The main disadvantage of the conventional LS counters is their poor resolution, which does not allow the determination of the concentration of individual uranium isotopes. Among them, the activity concentration of ^{234}U often exceeds that of ^{238}U in ground waters, and the radiation dose will be underestimated if only ^{238}U is determined and these isotopes are supposed to be in the equilibrium.

B. Gross alpha and beta measurements

Gross alpha and beta activity screening analyses are used for many purposes such as the monitoring of environmental and bioassay samples, low-level liquid effluents, workplace

surveys, characterization of low-level radioactive wastes and for assessing environmental contamination after accidental release (Salonen, 1993a; Sanchez-Cabeza and Pujol, 1995; Eikenberg et al., 1996; Cooper et al., 1998; Burnett et al., 2000; Warwick and Croudace, 2002a, 2002b; Verzilov et al., 2002; Kleinschmidt, 2004; Forte et al., 2006; Ruberu et al., 2008; Mizutani et al., 2009; Piraner and Jones, 2009; Zapata-García et al., 2009). Particularly drinking water supplies are screened by the gross alpha and beta analysis method, which is a highly useful control measure for the radiological characterization of water and as a factor in the decision as to whether further analyses by radionuclide-specific methods will be required. Urine samples from workers who potentially are exposed to radioactive contamination is also often screened by gross alpha and gross beta measurements to obtain an overview on internal exposure of radiation. The national and international regulations assume the radiological quality of drinking water to be controlled. The maximum contaminant level in public water supplies in the USA is 0.56 Bq/L (= 15 pCi/L) for gross alpha including radium but excluding uranium (EPA, 2009). The guideline activity concentrations of WHO (2011) are for gross alpha and gross beta to be 0.5 Bq/L and 1 Bq/L, respectively; whereas the European Union (1998) has set the screening values of 0.1 Bq/L for gross alpha and 1 Bq/L for gross beta. No further analyses are recommended under these screening levels, but if these levels are exceeded, radionuclides should be identified and their concentrations must be determined. Because the gross alpha and beta screening is a simple and rapid procedure, it often results in remarkable time and cost savings if the tedious radiochemical analyses are found unnecessary. The regular gross alpha and beta measurements are also a practical means for immediate detection of radioactive contamination in drinking water supplies, and it is possible that some radionuclides would remain unidentified if only radionuclide specific methods are applied. Some radionuclides which are in volatile compounds or in gaseous form are lost during the sample preparation. These are ^{3}H, ^{14}C, and radon which have to be determined by specific methods. These nuclides, as well as short-lived daughters of radon, are excluded from the gross alpha and gross beta screening analyses. In the normal situation, most important radionuclides to be screened by gross alpha and beta analyses in drinking water sources are the long-lived radionuclides, ^{234}U, ^{238}U, ^{226}Ra, ^{228}Ra and ^{210}Pb and ^{210}Po, from uranium and thorium decay series. The alpha and beta spectra of natural uranium, ^{226}Ra and ^{210}Pb in equilibrium with their short-lived daughters are illustrated in Fig. 2.26. ^{40}K occurs in variable amounts in all

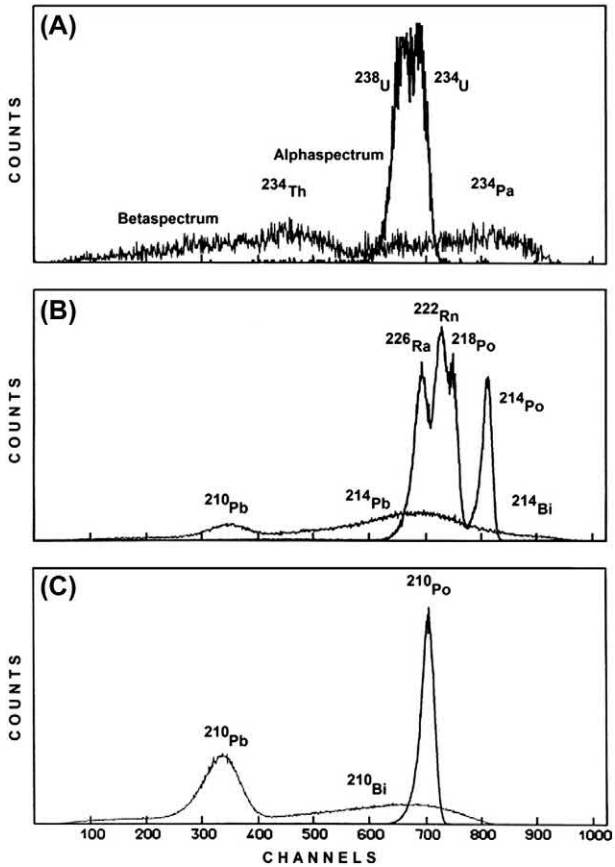

FIGURE 2.26 Alpha and beta spectra of (A) $^{234,238}U$ (natural uranium), (B) ^{226}Ra (in equilibrium with ^{222}Rn and its short-lived daughters), and (C) ^{210}Pb (in equilibrium with its daughters) from standard samples (Salonen, 1993a). *Reprinted by permission of Elsevier © 1993.*

natural waters, and its contribution to the gross beta counts can be significant. However, its determination is not important, because potassium is under homeostatic control in the body and its amount remains constant in healthy people. Gross alpha measurements are also used to screen transuranic elements in nuclear wastes and gross beta for fission products in reactor wastes and in accidental releases.

The methods commonly used for gross alpha and beta analysis in drinking water are based either on gas proportional counting (GPC) or on LSC techniques. Bonotto et al. (2009a) presented another method, which is based on a combination of a well-type NaI(Tl) scintillation detector and alpha spectrometry with surface barrier detectors. They tested the method and applied it successfully to the analyses of ground water samples. The conventional/standard method is based on GPC techniques. It involves the evaporation of a water sample to near dryness, quantitative transfer of the residue on a planchet and its subsequent counting (APHA/AWWA/WEF, 1998; ISO 9696, 2007; ISO 9697, 2008). Zikovsky (2002) used a faster sample preparation method whereby they precipitated alpha-emitters from ground water as sulfates (Ra) and hydroxides (Po, Th, and U) using Ba^{2+} and Fe^{2+} as carriers and obtained overall a yield higher than 80% for all nuclides and a better sensitivity than that obtained by the evaporation method. The disadvantages of the GPC method are: 1) sample preparation is tedious and labor-intensive, 2) there is a lack of high precision primarily owing to the inherent variability of the sample preparation technique and water composition, 3) sample size is strongly limited due to the total dissolved solids (TDS) which cause self-absorption of α-and β-particles, and 4) the counting efficiency is affected by TDS and the chemical composition of water (Ruberu et al., 2008; Martín Sánchez et al., 2009; Jobbágy et al., 2010). The small sample size combined with the relatively low counting efficiency of the GPC makes it difficult to attain low detection limits except by applying very long counting times. The reported detection limits of the GPC methods are 0.8 Bq/L for the gross alpha and 3 Bq/L for gross beta using a 22 hours counting time (Jobbágy et al., 2011), which could not meet the requirement of the regulation for screening of the gross alpha in drinking water (0.1−0.5 Bq/L).The LSC methods with α/β-discrimination avoids most of the difficulties typical of the GPC methods, although dissolved minerals or organics in water may cause variable quenching which must be considered in the calibrations (Sanchez-Cabeza and Pujol, 1995; Pates et al., 1996a; Pujol and Sanchez-Cabeza, 1997; Warwick and Croudace, 2002a, 2002b; Kleinschmidt, 2004; Ruberu et al., 2008; Zapata-García et al., 2009; Jobbágy et al., 2010). The LSC method involves the mixing of a water sample directly or after some concentration with the LS cocktail followed by LS counting using α/β-discrimination. If the sample is concentrated, the residue is dissolved into a few mL of dilute HCl, HNO_3, or H_3PO_4 prior to the addition of the LS cocktail. Water can be concentrated directly in the LS vials once or several times after successive evaporations using a freeze-dryer (Salonen, 1993a; Salonen and Hukkanen, 1997) or block heater (Kleinschmidt, 2004), or by the evaporation of the water sample in another vessel from which concentrated water or the residue is transferred to the LS vial (Sanchez-Cabeza and Pujol, 1995; Wisser et al., 2006; Forte et al., 2006; Ruberu et al., 2008; ASTM D7283-06, 2006; ISO 11704). Happel et al. (2004) used an extraction chromatographic resin to separate alpha-emitters from drinking water. The resin showed a strong affinity for actinides in tri-, tetra-, and hexavalent oxidation states and for Ra even in presence of large amounts of Ca. Radionuclide uptakes by the resin were greater than 80% even at very high Ca, K, Fe, carbonate, and sulfate contents. The sample preparation was fast, because it consists of the extraction of radionuclides from water to resin, the separation of the resin from water by filtration, the mixing of the dried resin with the scintillation cocktail followed by LS counting using α/β discrimination. The detection limits reported for the low-background LS spectrometers and the portable Triathler are between 0.01 and 0.08 Bq/L for gross alpha and 0.1−0.2 Bq/L for gross beta using 40−150 mL water samples and 3−8 hours counting times.

The calibrations of gross alpha and beta analyses include the optimization of the α/β discrimination performance and the determination of α- and β-counting efficiencies and spillovers in the selected α- and β-windows as presented previously in this chapter and elsewhere (ASTM D7283-06, 2006; ISO/DIS 11704). The α- and β-activities are calculated by the formulas where all these parameters are included. The results would be rather accurate for the real samples, if their composition and the quench levels agree to that of standard samples used for calibrations. This is not, however, the actual situation, and the calibrations become more complicated if variable quenching is corrected, because the optimum pulse decay (PD) setting (optimal PSA value), as well as efficiencies, backgrounds and spillovers, depend on quenching (Pates et al., 1996a, 1998; Bakir and Bem, 1996; DeVol et al., 1996, 2007; Pujol and Sanchez-Cabeza, 1997; Burnett et al., 2000; Bhade et al., 2010). Hence, each sample should be measured at its optimum PD setting, which is not a practical approach in routine measurements. The approaches to solve this problem are discussed previously in this chapter and elsewhere (Warwick and Croudace, 2002a, 2002b; Ruberu et al., 2008). Another drawback for performing precise calibrations is due to the fact that the optimum PD setting and alpha and beta spillovers depend on particle energies. The real samples may contain several α- and β-emitters with largely variable particle energies compared to those used for calibrations including the setting of the optimum PDD. The dependence of β-spillover on particle energy was recognized earlier than that of α-particles (Salonen, 2006;

DeVol et al., 2007). Salonen (2006) established the dependence of α-spillover on α-particle energy using ^{218}Po and ^{214}Po, which have a large difference in particle energies (1.69 MeV). DeVol et al. (2007) observed this effect using ^{241}Am and ^{239}Pu, which have particle energies differing only by 0.33 MeV. The optimum PDD setting is highly affected for higher-energy α- and β-emitters than for lower-energy emitters. The β-spillover increases with β-particle energy while α-spillover decreases with α-particle energy. With increasing quench, the higher energy β-particle produces a higher spillover compared to the lower-energy particles while the higher-energy α-particle produces a lower spillover compared to the low-energy particles at the same PSA level. In summary, the calibrations with appropriate quench corrections are necessary, although they would not provide accurate results for variably quenched samples with variable radionuclide composition. The calibrations would be simplest if the samples were unquenched and as similar as possible to the nuclides used for the PDD instrument calibration. It is preferable to perform the calibrations with α- and β-emitters with the energies equal to the averages of the nuclides expected to be in actual samples to be analyzed.

Fig. 2.27 illustrates the gross alpha and gross beta spectra of four ground water samples, which have been measured at the same PSA level set according to an unquenched sample. The measurements of these samples have been made 1 month after the sample preparation to establish the equilibrium between ^{222}Rn with its parent ^{226}Ra in order to enable the subtraction of the counts owing to ^{222}Rn and its short-lived daughter from the gross alpha and beta counts. The counts due to the β-emitting daughters (^{234}Th and ^{234}Pa) of ^{238}U are also subtracted after making appropriate ingrowth corrections. ^{234}U, ^{238}U, ^{226}Ra, ^{210}Pb, and ^{210}Po have been analyzed in these samples using radiochemical methods except ^{226}Ra that was determined directly from the gross alpha spectrum using the ^{214}Po peak (Salonen, 1993a). The increased quenching in the samples (Fig. 2.27) is indicated by the SQP(E) values, i.e., the magnitude of the SQP(E) decreases as quench increases). The spectra shifts to the left to different degrees and the alpha spillover increases on the smooth beta spectrum are visible in the region of ^{238}U which has lowest alpha energy. Thus, the difference between results obtained from gross alpha and radiochemical analyses is the greatest for the most quenched sample (Fig. 2.27B). The spillover corrections and setting of the PSA level at a lower value would improve the result of uranium-rich ground waters. The comparison of the spectra in Figs. 2.26 and 2.27 indicate quite clearly whether U, ^{226}Ra, and ^{210}Pb should be

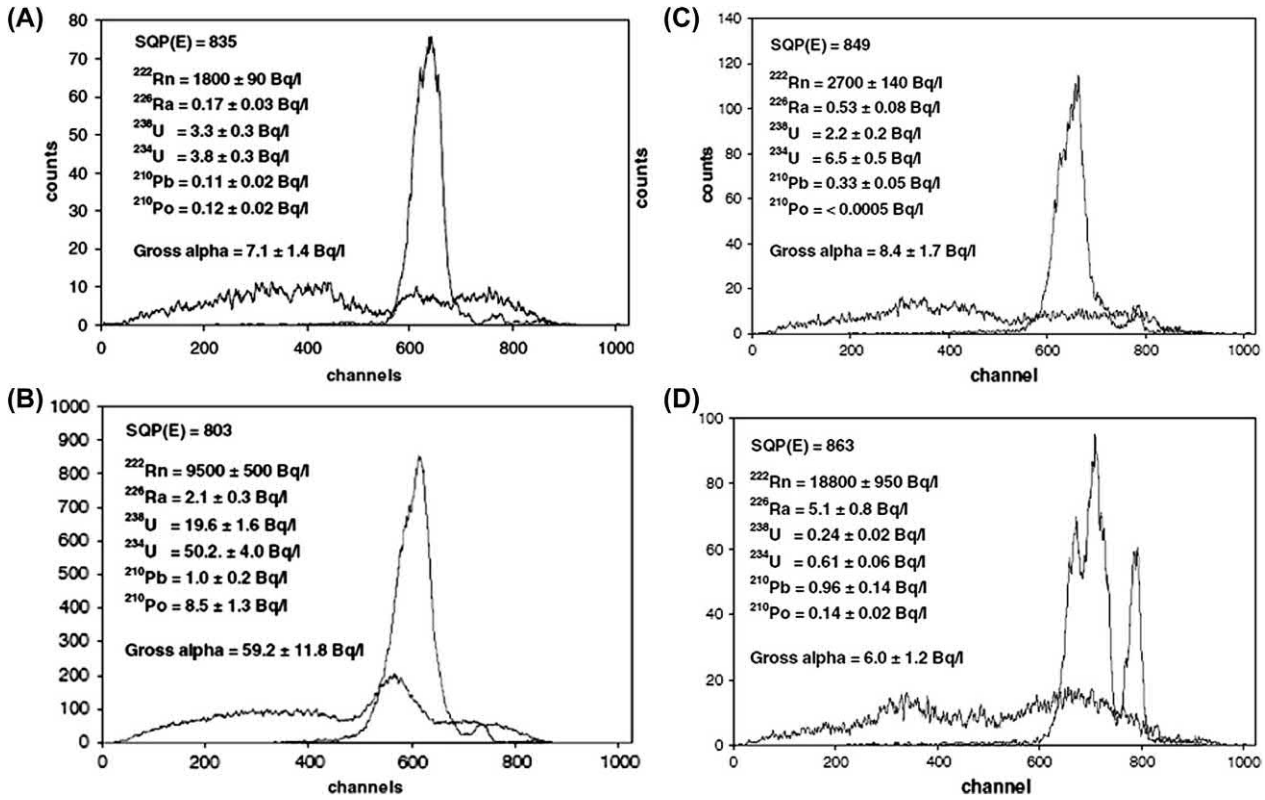

FIGURE 2.27 The gross alpha and beta spectra of the Quantulus from 4 drinking water samples originating from drilled wells (Salonen, 2006). *Reprinted by permission of* Radiocarbon, *University of Arizona, Tucson.*

analyzed by specific methods which is a big advantage compared to the GPC methods. ^{210}Po cannot be observed easily unless it exists almost alone in water.

In a similar manner, gross alpha and gross beta activities may be determined for a range of other environmental matrices. A filter sample is simply placed in the scintillation vial with the scintillation cocktail (Cooper et al., 1998). Urine samples have been prepared by mixing urine directly with the cocktail (Piraner and Jones, 2009) or after some processing which involve oxidation of organic substances with HNO_3, coprecipitation of actinides as phosphate, wet ashing using HNO_3 and H_2O_2, transfer of the nitrates to the chlorides, dissolution of the white residue in 0.2 M HCl followed by the addition of the cocktail (Eikenberg et al., 1996).

C. Radon

1. Environmental occurrence and importance

^{222}Rn ($t_{1/2} = 3.82$ d) is an inert radioactive gas and the immediate daughter product of ^{226}Ra in the uranium decay series (Fig. 2.25). ^{222}Rn is commonly known as radon. Other natural radon isotopes are ^{220}Rn ($t_{1/2} = 55.6$ seconds) and ^{219}Rn ($t_{1/2} = 3.96$ seconds), which are known as thoron and actinon, respectively. They arise in the decay series of ^{232}Th and ^{235}U, respectively. Uranium and thorium occur in all rocks and soils at varying concentrations. They produce ^{222}Rn and ^{220}Rn, which can diffuse from mineral grains into pore spaces and thereafter escape to air and dissolve in water. Because ^{220}Rn has a much shorter half-life than ^{222}Rn, it moves much shorter distances before decaying. Therefore, ^{220}Rn is of concern only where the concentration of ^{232}Th is high (UNSCEAR, 2006). Actinon (^{219}Rn) is not of significant concern for radiation exposure owing to its short half-life and to the low abundance of ^{235}U in natural uranium. Radon-222 is the most significant, and it is present in air and in ground and surface waters. Exposure to radon occurs by inhaling radon and by ingesting radon with water. The most important mechanism of exposure is the inhalation of radon and its short-lived decay products with indoor air. It accounts for the majority of the human exposure to radiation and presents the largest risk to human health from all natural sources of radiation by increasing the risk of lung cancer (UNSCEAR, 2006). The worldwide average annual dose from inhaled radon (1.26 mSv) is about half of the average dose from all natural sources of radiation (2.4 mSv) and about twice of the dose from all artificial sources (0.6 mSv) (UNSCEAR, 2008). Radon was first identified as a carcinogen by epidemiological studies of underground miners, and later by numerous epidemiological studies of the general population. An extensive overview on these studies is presented in the UNSCEAR 2006 report which summarizes all epidemiological studies performed in different countries and assesses lung cancer risks from occupational and residential radon exposures. It also summarizes the worldwide indoor radon concentrations based on national studies. The countrywide averages of radon indoor concentrations vary from 7 Bq m^{-3} to about 200 Bq m^{-3}, but much higher (up to 2745 Bq m^{-3}) values were observed at high-background areas. For single residences, indoor radon concentrations of 10,000−84,000 Bq m^{-3} have been reported from many countries. When radon-rich water is used as a household water, people are exposed both by radon ingested in water and by radon being released from tap water to indoor air during water use. Radon in drinking water also presents a risk of the development of internal organ cancers by radiation exposure of cells in the gastrointestinal tract and in other organs once radon is absorbed into the blood stream (NRC, 1999). In fact, the lung cancer risk from radon in drinking water is higher than that of stomach cancer, which is the most probable compared to other cancers. Usually radon from tap water is a smaller source in indoor air, because the major part of radon in indoor air arises from soil under the house and construction materials in some cases. Radon concentrations in surface waters are typically less than 4 Bq/L, while in ground waters the concentrations vary over a wide range up to 10,000 Bq/L or even higher.

As an inert gas, radon is an excellent tracer either alone or together with radium for studying geochemical, hydrogeological and oceanic processes like groundwater discharge rates, groundwater seepage, vertical turbulent mixing, gas exchange across the air-water interface, mixing processes between ground- and seawater and submarine groundwater discharges (Horiuchi et al., 1993; Cook et al., 2003, 2008; Purkl and Eisenhauer, 2004; Lamontagne et al., 2008; Murad et al., 2014). Radon is also a useful natural tracer in geophysical investigations, as in predicting earthquakes (King, 1985; Theodórsson, 1996; Yalım et al., 2007). In these studies, the radon concentration is determined in the field using an extraction method and a portable LS spectrometer or by bringing the sample into the laboratory for measurement with a low-background LS spectrometer.

2. Sample preparation and analysis

a. ^{222}Rn measurements in air

There exist numerous methods for monitoring radon and its daughters in air at homes and at workplaces. These include alpha track detection (filtered), unfiltered track detection, charcoal adsorption, liquid scintillation charcoal, continuous monitoring using an ionization chamber or scintillation cell, evacuated scintillation cell methods, electric ion chamber methods, grab radon methods, and several radon decay product measurement methods (WHO, 2009). The indoor radon concentrations both at homes and at workplaces are monitored most often using an integrated method with alpha track detectors, which consists of a small piece of special plastic or film

in a small container. Radon diffuses through a filter covering the holes inside the container, and the alpha particles of radon and its decay products strike the film and cause damage tracks. The tracks become visible by electrochemical etching and can be counted. Long exposure times (2–6 months) are necessary, because of less sensitivity of this method and the temporal and seasonal variation of indoor radon concentrations. Charcoal adsorption methods are appropriate mostly for screening because charcoal allows continual adsorption and desorption of radon, the method does not give a true integrated measurement over the exposure time. It gives radon concentration during the specific time, but does necessarily represent average concentration measured during longer periods of time. In this method, radon is adsorbed on activated charcoal granules packed in an airtight circular canister which is opened in the area to be sampled. Typical exposure times are between 2 and 7 days, thereafter the canister is closed and radon is determined via its daughters, ^{210}Pb and ^{210}Bi, by gamma spectrometry (George, 1984). The method is inexpensive and easy to use and therefore popular for screening at workplaces and mines. The liquid scintillation charcoal method is an attractive alternative to the gamma spectrometric method, because of its much higher sensitivity, simplicity and the ability to automate the counting of large numbers of samples. There are several modifications to this method for measuring radon in indoor air and radon emanation rates from soil (Prichard and Marlën, 1983; Buzinny, 1996; Schönhofer et al., 1995; Iimoto et al., 2008). In all of these methods, radon is adsorbed on activated charcoal in a small vial during a few days. Afterward, radon is extracted from the charcoal into toluene or into an LS cocktail to be measured. Radon emanation rates from soil can be determined in the laboratory or in situ (Wadach and Hess, 1985; Turtiainen, 2009). In the laboratory, a few grams of dried soil are weighed into a glass vial, soil is wetted with distilled water and an organic scintillation cocktail is added. The vial is closed tightly and stored for a month to attain the constant radon level emanated from soil before the measurement. Alternatively, radon can be trapped from the dried soil sample directly into the LS cocktail in a glass vial. This is performed in a tightly closed glass bottle where the soil is located at the bottom and the LS vial is hanging from a hook fixed into the stopper of the glass bottle (Turtiainen, 2009). The in-situ measurement is performed by hanging an open LS vial containing the cocktail inside a test hole or tube sunk into the soil (Horiuchi and Murakami, 1983).

b. ^{222}Rn measurements in water

Radon in water originates from the decay of ^{226}Ra, which is either dissolved in water or localized in rock or soil minerals in contact with water. Most of the radon in water originates from ^{226}Ra in minerals from where radon gas diffuses into pore spaces and dissolves in soil or ground water. Hence most of radon in water is unsupported and therefore its concentration in water is often orders of magnitude higher than that of ^{226}Ra dissolved in the same water. However, radon will not be transported far from its place of birth owing to its short half-life. Special attention should be paid to sample collection and its transport when undertaking radon measurements. Radon can easily escape from water during the sampling as well during the sample transport and storage, if the sampling vials are not gas-tight. Samples should also be collected into glass bottles or containers, because some radon will be lost by adsorption onto the surface of polyethylene bottles (Saito, 1983). The caps should be equipped with rubber or Teflon septum to prevent radon leakage from the bottle. Sampling instructions depend on the sampling situation and purpose. For drinking water samples appropriate sampling instructions are available, e.g., in the ASTM and ISO standards. The most widely used methods for determining radon in water are radon emanation, gamma counting and LSC, the last of which has become the most popular technique during the recent decade. These methods are based on the detection of radon gas and its short-lived α- and β-emitting daughters, the decay properties of which are shown in Table 2.6.

c. Emanation and gamma spectrometric methods

The earliest and still often used methods are those based on radon emanation (Lucas, 1957; EPA, 1987; Mathieu et al., 1988; Kitto et al., 1996; Belloni et al., 1995; Stringer and Burnett, 2004; Bonotto and Mello, 2006; de Oliveira Lucas et al., 2009). In these methods radon gas is transferred from water into an alpha scintillation cell called the Lucas cell, which is coated with solid scintillator, ZnS(Ag). The sample is usually collected into a glass bottle, transported to the laboratory where radon is stripped from water using a carrier gas (e.g., helium) and transferred into an evacuated Lucas cell. The stripping of radon from water (emanation) is performed using a special glass-ware bubbler, which is connected to the Lucas cell. Several improvements to the sampling bottle and radon emanation system design have been presented over the years, and the fragile glassware bubbler has been replaced with more practical radon degassing or vacuum extraction units for field sampling (Smethie and Schell, 1980; Mathieu et al., 1988; Kitto et al., 1996; Stringer and Burnett, 2004; de Oliveira Lucas et al., 2009). The emanation method requires extensive sample handling, but it is very specific and sensitive. Very low detection limits (0.04–1.0 mBq/L) have been achieved using improved sampling and bubbler devices and large (5–19 L) sample volumes (Mathieu et al., 1988; Kitto et al., 1996; Stringer and Burnett, 2004). The main advantage of the emanation method is its high sensitivity making it appropriate for determining very low radon activities. See also Chapter 9, Volume 1 for a description of the Lucas cell.

TABLE 2.6 Members of ^{226}Ra subseries and their most significant decay properties. Values obtained from NuDat (2016).

Radio-nuclide	Half-life	α-decay energy (MeV) and intensity (%)	β-decay energy (MeV) and intensity (%)	γ-emission energy (keV) and intensity (%)
^{226}Ra	1600 y	4.784(93.8), 4.601(6.2)	–	186.2 (3.64)
^{222}Rn	3.82 d	5.489 (99.9), 4.986 (0.1)	–	510 (0.076)
^{218}Po	3.10 minutes	6.002 (100)	–	–
^{214}Pb	27.1 minutes	–	0.667 (45.9), 0.724 (40.2), 1.019 (11.0)	351.9 (35.6), 295.2 (18.4), 242.0 (7.3)
^{214}Bi	19.9 minutes	–	3.270 (19.1),1.540 (17.6), 1.505 (17.0), 1.423 (8.1), 1.892 (7.4), 1.151 (4.4), 1.066 (5.6)	609.3 (45.5), 1764.5 (15.3), 1120.3 (14.9), 1238.1 (5.8), 2204.1 (4.9), 768.4 (4.9)
^{214}Po	163.6 μs	7.687 (100)	–	–

Gamma spectrometers equipped with NaI(Tl) or HPGe(Li) detectors are often used for measuring radon in water (Belloni et al., 1995; Al-Azmi et al., 2004; Bonotto and Mello, 2006; Talha et al., 2008). The determination is based on measuring the gamma photons of radon daughters, ^{214}Bi or ^{214}Pb, which are in equilibrium with the parent (Table 2.6). The water sample can be measured directly in gas-tight Marinelli beakers or radon is stripped with gas from a larger amount of water and then trapped into activated charcoal in a canister. The detection limits are quite high (1−9 Bq/L); however, the simplicity of sample preparation and the wide availability of gamma spectrometers renders it a potential alternative for measuring radon in water.

d. Liquid scintillation methods

The LS methods are based on the high solubility of radon in organic solvents such as toluene and xylene. Water samples can be prepared by introducing a small amount of water directly into the LS vial containing the cocktail either in the field or in the laboratory. If higher sensitivities are required, radon can be extracted from a larger water volume directly into the LS cocktail or into toluene to be mixed with the cocktail. The main advantages of the LS methods are their simple methodology, high sensitivity, and automatic sample counting.

Determination of the radon concentration in drinking water belongs to the routine analysis in environmental laboratories. The analysis is most often performed using the direct LS methods without any sample pre-concentration. The detection limits using the direct LS methods are mostly less than 1 Bq/L with a 20−60 minutes count, but lower (0.04−0.2 Bq/L) by applying longer count times and α/β discrimination (Prichard and Gesell, 1977; Schönhofer, 1989b; Spaulding and Noakes, 1993; Salonen, 1993b; Belloni et al., 1995; Gómez Escobar et al., 1996; Salonen and Hukkanen, 1997; Kozłowska et al., 1999; Maragheh et al., 2002; Cho et al., 2004; Galán López and Martín Sánchez, 2008). The detection limits by LS counting are low enough to meet the regulatory requirements as strict as in the USA where the limit is 11 Bq/L (EPA, 2009). The low detection limits are due to the high counting efficiency of radon and its daughters (^{218}Po, ^{214}Po) and to very low α backgrounds using α/β discrimination. The good efficiency is due to the fact that ^{222}Rn is measured when it is in equilibrium with its short-lived daughters (^{218}Po, ^{214}Pb, ^{214}Bi, and ^{214}Po), and consequently 3α- and 2β-particles are measured with nearly 100% efficiency in a wide-open counting window.

The most widely used direct method for ^{222}Rn in drinking water is the standard ASTM method (ASTM D5072_98, 1998). This method was originally developed by Prichard and Gesell (1977) and later modified by the U.S. EPA (Horton, 1983). The samples are prepared by injecting 10 mL of water with a syringe into a low potassium glass vial below an organic, water immiscible scintillation cocktail (10 mL). The vial is tightly capped and vigorously shaken for 1 minute. During the shaking, ^{222}Rn is extracted almost entirely from water into the cocktail, while other radionuclides, elements or minerals remain in the water. The samples are measured 3−4 hours later when the equilibrium between ^{222}Rn and its short-lived daughters has been established in the cocktail and ^{222}Rn has partitioned between the three phases: water, scintillation cocktail and air. The performance and reliability of this method has been demonstrated in numerous studies (Horton, 1983; Whittaker et al., 1987; Parsa and Horton, 1990; Vitz, 1991; Kinner et al., 1991; Kitto, 1994).

In another direct LS method, water is mixed with an emulsifying cocktail to have a homogeneous sample (Asikainen, 1981; Salonen, 1993b). In this method, the samples are prepared without using syringes or pipette fillers to avoid suction and ^{222}Rn release. The pipette tip is simply placed near to the bottom of the sampling bottle, from where water is allowed to enter the pipette up to the 10 mL level. Thereafter, the water is transferred onto the cocktail (12 mL) in a glass counting vial. The vial is tightly closed and vigorously shaken. Because this method involves direct mixing of water with cocktail, other radionuclides occurring in surface and ground waters are all observed and their effect on the results must be considered. The glass vials equipped with urea screw caps and Al foil liners have found to be radon gastight (Vitz, 1991; Salonen, 1993b; Kitto, 1994).

Salonen (2010a) compared two methods in the following two ways: (1) by preparing two phase and homogeneous samples similarly from the same ^{222}Rn-bearing ground water (35,000 Bq/L) according the method of homogeneous samples, and (2) by calibrating both methods with the ^{226}Ra standard solution according to their own calibration procedures (ASTM D5072_98, 1998; Salonen, 1993b). Three PerkinElmer organic cocktails: Betaplate Scint, Ultima Gold F and High Efficiency Mineral Oil Scintillator and one emulsifying cocktail, Ultima Gold XR (PerkinElmer, Inc.) were used. The measurements were implemented with the Wallac Quantulus using α/β discrimination to separately measure α- and β-emitting nuclides. The results from ^{222}Rn-bearing water samples were excellent. The results of ^{222}Rn in all parallel samples prepared in different cocktails were very consistent and remained very stable for 3 weeks during which the measurements were repeated (Salonen, 2009). The count rates of various two-phase samples were 3.6%−4.4% lower than those of the homogeneous samples, whereby the difference is due to the partition of ^{222}Rn into the water and air phases. All the results of the ^{226}Ra standard samples were not as good as expected on the basis of radon bearing water samples; the counting efficiencies of the two phase ^{226}Ra samples were partly too low and variable, the counts slowly decreased over time and 1-min shaking time was not sufficient to transfer radon to the organic phase although this

had been sufficient for the ^{222}Rn-bearing water samples. The ^{222}Rn-counting efficiencies derived from the homogeneous ^{226}Ra samples were equal and the samples remained very stable. An additional study was performed to examine whether ^{210}Pb, ^{210}Bi, and ^{210}Po, which were present in an old ^{226}Ra standard, could cause the instability of the two phase ^{226}Ra samples (Salonen, 2010b). It showed that these nuclides contributed to the instability and to the calibrations mostly through ^{210}Po, which had affinity to organic cocktails while ^{210}Pb and ^{210}Bi were hydrophilic and thus tended to remain in the water phase. The above studies demonstrated that the distribution of ^{222}Rn and its short-lived daughters between the two phases obviously depends on the existing chemical conditions such as the presence of acids and carriers in the ^{226}Ra standard solution, temperature, and vial material as assessed in the earlier studies (Vitz, 1991; Kinner et al., 1991; Kitto, 1994). Figs. 2.28 and 2.29 show the α- and β-spectra of ^{222}Rn-bearing water and ^{226}Ra samples prepared in Ultima Gold F and Ultima Gold XR. Fig. 2.28 indicates that no ^{226}Ra has been extracted into the organic cocktail, because the α-spectra of the two samples are quite identical while the α-peak broadening by ^{226}Ra and ^{210}Po is clearly visible for the homogeneous samples in Fig. 2.29. The effect of ^{226}Ra and other radionuclides can principally be eliminated by separately preparing the background sample for each water sample from the same water as the actual sample and by measuring it rapidly before the ingrowth of ^{222}Rn from ^{226}Ra (Salonen, 1993b). This involves a considerable amount of extra work. For most samples, the effect is insignificant because ^{222}Rn concentrations are often orders of magnitude higher than any of other radionuclides (Asikainen, 1981; Longtin, 1990; Salonen, 1994; Isam Salih et al., 2002; Vesterbacka et al., 2005).

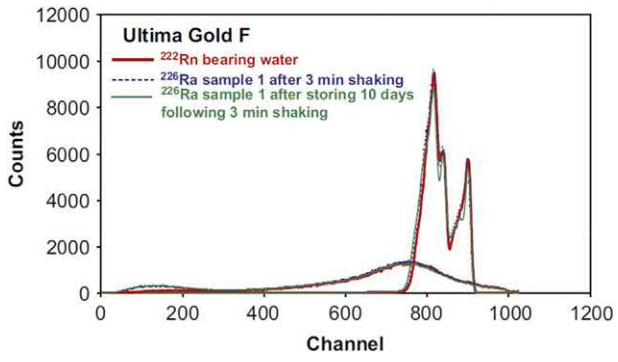

FIGURE 2.28 The α and β spectra of two-phase samples prepared from ^{222}Rn-bearing water and ^{226}Ra standard solution. The vertical scales of the ^{222}Rn and ^{226}Ra samples have been adjusted to correspond to the same ^{222}Rn activity. The two α spectra of the ^{226}Ra sample show that the counts decreased a little under both α peaks during the 10 days that the sample was stored and then measured without shaking. The ^{226}Ra standard has a low peak (chs 1−200) in the β spectra, which is due to the Cerenkov photons of ^{210}Bi accumulated with its parent (^{210}Pb) in the old ^{226}Ra standard. Similar Cerenkov peaks are not visible for ^{222}Rn-bearing water samples (Salonen, 2010a). *Reprinted by permission of Elsevier © 2010.*

The theoretical 500% counting efficiency of ^{222}Rn cannot be attained by LS counters such as the Quantulus or the Wallac Guardian due to their external guard counters and to the short-lived daughters of ^{222}Rn which occur in series with each other. Hence, the external guard counter observes the gamma photons of ^{214}Bi simultaneously with the α-particle of ^{214}Po in the detector (Salonen, 2006), and it eliminates about 19% of the β-counts of ^{214}Bi. ^{214}Po has a very short half-life (164 μs) and, therefore, part of its counts are lost because of the dead time (Salonen, 2006; Cassette et al., 2006), causing a decreased counting efficiency of ^{214}Po of 86% (Salonen, 1993b). The radon efficiencies ($3\alpha + 2\beta$) for the Ultima Gold XR and Ultima Gold F samples in fully open counting windows (1−1024 ch) were 446.0% and 429.5%, respectively, but higher, 480.8% and 465.2%, when the guard counter of the Quantulus was switched off (Salonen, 2009). According to these results, the overall counting efficiency of radon in Ultima Gold F cocktail is 3.7% lower than that in the Ultima Gold XR cocktail. This difference is a little smaller than that obtained with radon bearing water (4.2%). This is due to the interference of ^{210}Bi and ^{210}Po being present in an old ^{226}Ra standard solution. They increased the counting efficiency of radon in Ultima Gold F cocktail, because some ^{210}Po migrated from water to the cocktail and ^{210}Bi in water increased the counting efficiency of Cerenkov photon fraction (Salonen, 2010b). The best detection limits (0.02−0.05 Bq/L) were obtained by calculating the results from the counts in the α-window, which has a very low background (0.006−0.03 cpm). Because α- or β-spillovers depend on sample quench level, this should be considered in measuring variably quenched samples.

The comparison study (Salonen, 2010a) shows that the calibration is critical for obtaining accurate results. This assumption is supported by the observation that the counting coefficients of radon reported in the literature vary considerably although these could be assured quite easily using fully open counting windows for which the α+β efficiencies vary in rather narrow limits (450−490%) for different cocktails and sample volumes. Several intercomparison studies also demonstrate large variability between the results (Wiegand et al., 2000; Möbius and Salonen, 2002; Guiseppe et al., 2006; Vesterbacka et al., 2010). The validity of the calibrations can be checked with a ^{222}Rn standard, which does not contain ^{226}Ra at all (Hutchinson et al., 1986; Dean and Kolkowski, 2004; Havelka, 2009; Kitto et al., 2010). Such a ^{222}Rn standard is produced in a generator which consists of an encapsulated ^{226}Ra source placed in a small accumulation chamber filled with water and equipped with the connections for inlet and outlet waters. ^{222}Rn diffuses into the water through the polyethylene capsule where the ^{226}Ra standard solution is

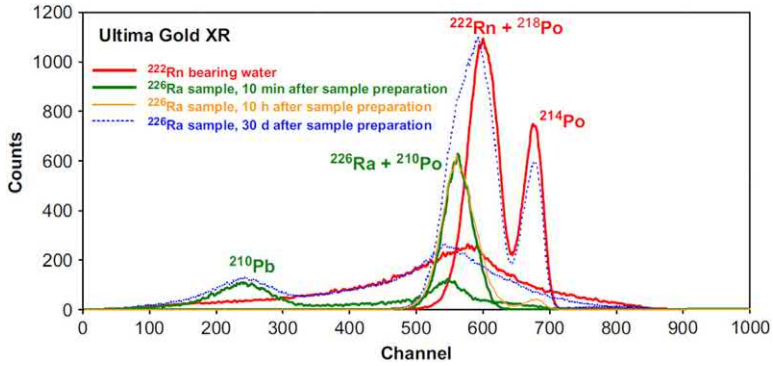

FIGURE 2.29 The α and β spectra of homogeneous samples prepared from ^{222}Rn-bearing water and ^{226}Ra standard solution. The vertical scales of these samples have been adjusted to correspond to the same ^{222}Rn activity. The spectra of the ^{226}Ra standard originate from the measurements performed at various times after sample preparation. The ^{214}Po peak is not visible in the α spectrum measured 10 minutes after sample preparation, while it is visible in the later (10 hours) spectrum as an indication of the rapid in-growth of ^{222}Rn and its daughters. The β spectrum reveals that a significant amount of ^{210}Pb had accumulated in the old ^{226}Ra standard (Salonen, 2010a). enclosed. Yasuoka et al. (2005) have presented another alternative for the calibrations. It is based on a direct dpm method and on an internal counting.

e. Extraction of radon from a large water sample

Because ^{222}Rn concentrations in surface waters are generally very low, it has to be extracted from large water samples to ensure the sensitivity and precision of the analyses required in hydrological studies. This complicates the analysis, because the extraction efficiency must be determined and ^{222}Rn losses during the sample preparation must be assessed. The extraction of ^{222}Rn can be performed with toluene, toluene-based scintillation cocktail or other water-immiscible cocktail as extractant (Murakami and Horiuchi, 1979; Horiuchi et al., 1993; Bem et al., 1994; Hoehn and von Gunten, 1989; Purkl and Eisenhauer, 2004; Pates and Mullinger, 2007; Cook et al., 2008). ^{222}Rn is usually extracted from 0.5 to 1 L water sample with 20−40 mL of extractant. After shaking and allowing the layers to separate, a known proportion of the extractant is transferred into the scintillation vial for the measurement. The detection limits obtained by these methods are between 0.0015 and 0.02 Bq/L depending mainly on the count time and the sample volume. Pates and Mullinger (2007) studied thoroughly various factors which may have an effect on the extraction efficiency, ^{222}Rn losses, and the sensitivity and the accuracy of the measurement method. They used α/β-discrimination and obtained the detection limits of 0.020 and 0.015 Bq/L with the use of 20 mL of toluene and 30 mL of Ultima Gold F extractants, respectively, when the sample volume was 580 mL and the count time 60 minutes. They recommend only a single extraction, rather than two, and to use smaller sample volumes for practical reasons. The volume difference is partly compensated by using scintillation cocktail as extractant, because a greater proportion of it can be taken for the measurement. They concluded that the method is fast, simple, reproducible, and more sensitive than the ASTM method. Purkl and Eisenhauer (2004) extracted radon from 1 L of seawater with 22 mL of MaxiLight cocktail (Hidex, Finland) and measured the samples with a portable LS spectrometer, Triathler (Hidex, Finland), directly on board a research vessel. They re-extracted ^{222}Rn from the same water sample a month later when ^{222}Rn was in equilibrium with radium. The supported ^{222}Rn (equal to ^{226}Ra) was obtained from the latter extraction and the proportion of the unsupported ^{222}Rn from the difference of the two extractions. Submarine water samples could be analyzed directly using a two-phase sample (3.5 mL water and 3.5 mL organic cocktail) and α/β discrimination. The detection limit for this sample was 0.15 Bq/L using 3.5 hour count.

D. Radium

1. Environmental occurrence and importance

Radium has four naturally occurring isotopes, ^{226}Ra ($t_{1/2} = 1600$ y), which belongs to the ^{238}U decay series (Fig. 2.25), ^{228}Ra ($t_{1/2} = 5.75$ y), and ^{224}Ra ($t_{1/2} = 3.66$ d), which belong to the ^{232} Th day series (Fig. 2.31), and ^{223}Ra ($t_{1/2} = 11.43$ d), which belongs to the ^{235}U decay series. The term "radium" is commonly used in reference to ^{226}Ra. Radium is widespread in the environment. It is present in soil, minerals, foodstuffs, surface and ground waters, and many common materials. The worldwide average concentration of ^{226}Ra in soil is 32 Bq/kg (UNSCEAR, 2008). Radium is one of the most hazardous long-lived α-emitters in the environment, with respect to internal radiation exposure. As an alkaline earth element, radium is accumulated in the skeleton through a process similar to calcium. Food consumption is the main source of ^{226}Ra to

man. The contribution of water to total intake is usually small, if the drinking water supply originates from surface water (UNSCEAR, 2000). However, the radiation exposure through drinking water can be an important source, or even be extremely high, if the drinking water originates from ground water sources in contact with uranium rich minerals like granites or phosphates.

^{226}Ra concentrations over 40 Bq/L in drinking water has been reported (UNSCEAR, 2000). Due to the possible health hazard, regulations limit the maximum contaminant level in public water supplies for combined ^{226}Ra and ^{228}Ra to 0.19 Bq/L in the USA (EPA, 2009). The primary health concerns of radium have been directed to ^{226}Ra and ^{228}Ra and little attention has been given to the short-lived ^{224}Ra. The study of public water supplies in the USA has shown that ^{224}Ra can make a significant contribution to elevated measurements of gross α-activities (Parsa, 1998). ^{224}Ra has remained largely undetected in the past, due to its short half-life allowing the activity to decay during the delays in routine gross α-activity or radium measurements, which are not processed rapidly after sampling (EPA2009Parsa et al., 1999; Moon et al., 2003; EPA 2009). Earth, marine, and environmental scientists often determine ^{226}Ra, ^{228}Ra, ^{224}Ra, and ^{223}Ra in ground and surface waters, because these nuclides have proven useful as natural tracers to study geochemical processes, particularly in the marine environment (Burnett and Tai, 1992; Lamontagne et al., 2008). Radium assays are frequently carried out when environmental contamination around uranium mine and mills, phosphoric acid factories and coal mines is investigated (Moreno et al., 2000; Absi et al., 2004; Chalupnik et al., 2001; Vera Tomé et al., 2002a, 2002b; Carvalho et al., 2007). The ^{226}Ra concentrations in tissue, soil, sediment, and rock samples have also been determined by liquid scintillation methods (Gregory, 1972; Higuchi, 1981; Blackburn and Al-Masri, 1993; Juntunen et al., 2002).

2. Sample preparation and measurement of ^{226}Ra, ^{228}Ra, ^{224}Ra, and ^{223}Ra

There are a variety of methods for determining one or more radium isotopes in environmental samples using different chemical separation and measurement methods (Goldin, 1961; Horiuchi and Murakami, 1981; Sedlaček et al., 1980; Smith et al., 1988; Alvarado et al., 1995; Al-Masri and Blackburn, 1995; Baeza et al., 1998; Kim et al., 1999, 2017; Lawrie et al., 2000; Sato et al., 2000; Blanco et al., 2002; Aupiais, 2005; Purkl and Eisenhauer, 2003a; Bojanowski et al., 2005; Zoriy et al., 2005; Wallner et al., 2008; Dimova et al., 2007; Antovic and Svrkota, 2009; Tsai et al., 2010; Dinh et al., 2017; Fons-Castells et al., 2017).

The most common measurement methods are based on liquid scintillation, radon emanation, or alpha or gamma spectrometry. The chemical separation methods are mainly based on precipitation, cation exchange, extraction, adsorption, or a combination of these techniques. Several comparison studies have been made on the commonly used methods for the determination of ^{226}Ra and ^{228}Ra. Chałupnik et al. (2002) compared alpha spectrometric and LS spectrometric methods, Köhler et al. (2002) compared the radiometric methods; and Hou and Roos (2008) did the same but also included a mass spectrometric method in their comparison. Decaillon et al. (2004) validated a few chemical separation methods, and Vasile et al. (2010) performed a comparison using different chemical separation methods and measurement techniques for determining ^{226}Ra and ^{228}Ra in mineral waters.

a. Alpha and gamma spectrometric methods

Comparisons among the measurement methods for radium demonstrate that alpha spectrometry is the most sensitive radiometric method, because of its low background. To avoid impairing the resolution and chemical yield, radium must be separated carefully from the sample matrix and from other elements, including barium, and thereafter electrodeposited as a thin layer on a stainless steel disk or coprecipitated with $BaSO_4$ and/or $PbSO_4$ which is collected on a membrane filter (Hancock and Martin, 1991; Alvarado et al., 1995; Vargas et al., 1995; Crespo, 2000; Lawrie et al., 2000; Blanco et al., 2002; Chałupnik et al., 2002; Purkl and Eisenhauer, 2003b; Bojanowski et al., 2005; Dai et al., 2012a, 2012b, 2012c; Song et al., 2017). The high resolution of alpha spectroscopy for low mass samples permits the direct measurement of the concentrations of ^{226}Ra, ^{224}Ra, and ^{223}Ra, and analytical determinations of ^{226}Ra can be obtained in a much shorter time than by other methods based on the indirect determination through the ^{222}Rn daughter.

^{133}Ba (β/γ-emitter) is the most commonly used chemical yield tracer, but ^{225}Ra (via its α-emitting daughter ^{225}Ac) is also used (Hancock and Martin, 1991). ^{228}Ra can be measured directly from the same disk either by gamma spectrometry via the γ-emitting daughter, ^{228}Ac, after 2 days of ingrowth (Hughes et al., 2004) or by alpha spectrometry via its α-emitting grand-daughter, ^{228}Th, after 6−12 months of ingrowth (Eikenberg et al., 2001).

Radium is often separated using an efficient and simple method where radium isotopes are adsorbed on a MnO_2-coated polyamide disk or thin film which is measured directly with an alpha spectrometer (Surbeck, 1995, 2000; Eikenberg et al., 2001; Kovács et al., 2004; Karamanis et al., 2006).

The detection limits of ^{226}Ra and ^{228}Ra in environmental samples by alpha spectrometric methods are between 0.1 and 0.5 mBq and 0.2−0.3 mBq, respectively, and 0.1−1 Bq and 0.1−0.3 Bq, respectively, by gamma spectrometry (Hou and Roos, 2008; Eikenberg et al., 2001; Hughes et al., 2004; van Beek et al., 2010). Lower detection limits of 7.4−81 mBq by gamma spectrometry can be obtained when low-level gamma spectrometry is employed (shielded underground laboratory), and radium is separated

from the sample matrix or β−γ-coincidence techniques are used (Köhler et al., 2002).

The main advantage of the gamma spectrometric method is that ^{226}Ra, ^{228}Ra, and ^{224}Ra can be determined simultaneously using simple sample processing (Smith et al., 1997; Bonotto, 2004; Vasile et al., 2010).

b. Emanation methods

Emanation methods can be the best choice when low detection limits (0.02−0.002 Bq/L) are required (EPA, 2009; Sedlaček et al., 1980; Smith et al., 1988). Dimova et al. (2007) reported an automated analysis method for determining ^{223}Ra, ^{224}Ra, and ^{226}Ra in water samples, based on the pre-concentration of radium isotopes on MnO_2 Resin, followed by the emanation of their radon daughters (^{219}Rn, ^{220}Rn, ^{222}Rn) and analyses using a commercial radon-in-air analyzer.

The emanation method permits the determination of ^{226}Ra activity from the pre-concentrated sample after setting the sample aside for approximately 3 weeks and allowing radon ingrowth from ^{226}Ra. Sample analysis by the emanation method is simpler and the results can be obtained much faster than by alpha spectrometry.

c. Liquid scintillation counting methods

Low background LS spectrometry with α/β discrimination is the most popular technique for determining ^{226}Ra activity. This is due to the high counting efficiency, easy sample preparation and automatic sample counting. The typical detection limits are between 0.3 and 1.4 mBq for a 6 hour count time (Hou and Roos, 2008).

In practice, any measurement method for ^{222}Rn will also be relevant to ^{226}Ra (see Section C. Radon). There are many alternative methods for ^{226}Ra. In most of these methods ^{226}Ra is determined indirectly through ^{222}Rn and its short-lived daughters or together with them. In the latter case, a water sample containing ^{226}Ra is simply mixed with the cocktail either directly in the LS vial or after some pre-concentration, or ^{226}Ra can be separated chemically and mixed with the cocktail, followed by the measurement 3−4 weeks later when the equilibrium between ^{226}Ra and ^{222}Rn with its short-lived daughters is established (Schönhofer and Weitz, 1987; Salonen, 1993a; Chałupnik and Lebecka, 1993; Sanchez-Cabeza and Pujol, 1998). The counting efficiency of ^{226}Ra will then be high, close to 600%, in which case each of the 4α- and 2 β-particles (Table 2.6) are detected in fully open α- and β-windows with nearly 100% efficiency. In other methods using two-phase samples, the water containing ^{226}Ra is lying under the organic cocktail and ^{222}Rn produced by ^{226}Ra will transfer to the organic phase by shaking (Horiuchi and Murakami, 1981; Parsa and Horton, 1990) based on the high solubility of radon in organic solvent (scintillation cocktail). The counting efficiency of ^{226}Ra will now be near 500%, if full open windows are used. The pre-concentration is often performed using toluene, where ^{222}Rn is extracted from water into solvent and then mixed with the LS cocktail (Schönhofer, 1989b; Chalupnik et al., 1996; Bem et al., 1998; Möbius and Zeisberg, 2002; Forte et al., 2006; Desideri et al., 2007; Mosqueda et al., 2009; ISO/NP standard 13165-1). These methods are appropriate for monitoring ^{226}Ra in drinking and mineral waters, because the detection limits (5−60 mBq) attained by the low-background LS spectrometers and by the mobile Tri-athler are well below the detection limits set in the regulations.

The conventional method of separating ^{226}Ra from a sample matrix is the so-called barium sulfate method (Goldin, 1961; EPA, 2009). The method is still used for separating ^{226}Ra from water, and a number of new applications based on this separation have been reported after the low-background LS spectrometer with α/β separation became common in environmental laboratories (Suomela, 1993; Manjón et al., 1997; Bem et al., 1998; Kim et al., 2001; Chau et al., 2001; Wallner, 2002; Chałupnik et al., 2002; Repinc and Benedik, 2002; Villa et al., 2005; Kozłowska et al., 2007; Lasheen et al., 2007; Godoy et al., 2016). The analysis generally follows the basic steps. The Pb- and Ba-carriers are added into the water sample to coprecipitate radium with $BaSO_4$ and $PbSO_4$ at pH 1 with H_2SO_4. The precipitate is washed a few times with HNO_3 and then dissolved in alkaline EDTA. For further purification and separating radium from lead, radium is precipitated again as sulfate using an acetic acid solution at pH 4.5 and lead remains in solution. ^{210}Pb can be determined from this solution by precipitating it as the sulfate (Chałupnik and Lebecka, 1993; Kim et al., 2001; Chau et al., 2001; Wallner, 2002). Hence, this method enables the simultaneous analysis of ^{226}Ra, ^{228}Ra, and ^{210}Pb from the same water sample. The nitric acid wash and the re-precipitation of $RaSO_4$ in EDTA solution by adjusting to pH 4.5 to ensure high purification of radium from most interfering radionuclides, especially those belonging to natural series, ^{137}Cs and ^{90}Sr. The chemical yield can be determined gravimetrically or by using ^{133}Ba as a yield tracer. The Ra-$BaSO_4$ precipitates are prepared for the LS measurement by suspending fine crystal precipitates into a scintillation gel or by dissolving the precipitates in warm alkaline EDTA solution. $BaSO_4$ precipitate can be converted also to the more soluble $BaCO_3$, which is dissolved in HNO_3 and then mixed with the LS cocktail (Wallner, 2002; Repinc and Benedik, 2002). They also measured the samples shortly after the separation and calculated the ^{226}Ra concentration from its own alpha peak and thus obtained the results rapidly after the sampling. In that case, the ^{228}Ra activity can be calculated from the β-counts with the least amount of corrections owing to minor ingrowth of

^{214}Pb and ^{214}Bi. The detection limits reported for ^{226}Ra, ^{228}Ra and ^{210}Pb are 0.5−2 mBq, 4 mBq, and 2−5.2 mBq, respectively.

Selective extractants are also used for radium separation. One of these is the Empore Radium Rad Disk, which selectively extracts radium from water (Alvarado et al., 1995; Smith et al., 1997; Schönhofer and Wallner, 2001; Möbius et al., 2002; Decaillon et al., 2004; Wallner et al., 2008; Eikenberg et al., 2014). The Empore Radium Rad Disk exhibits a large capacity for radium, with recoveries ranging from 90 to 100% for the 1−3 L sample volumes. Water samples are acidified with HNO_3 to a 2M concentration and then passed through the disk. After washing the disk with 2M HNO_3, radium is eluted from the disk with 0.25M EDTA solution, which can be concentrated prior to mixing with the LS cocktail. Lead, strontium and barium are co-extracted with radium. High Ba concentrations reduce the Ra-recovery considerably, and the interfering ^{210}Pb should be separated from radium either before or after the elution (Smith et al., 1997; Möbius et al., 2002; Wallner et al., 2008). This method is not suitable for waters with a high content of salts (Decaillon et al., 2004). The detection limits reported for the Empore Radium Rad Disk extraction method vary between 1 and 2 mBq, 4−8 mBq and 2−6 mBq for ^{226}Ra, ^{228}Ra and ^{210}Pb, respectively.

Other possible extractants are sym-Di[4(5)-tert-butylbenzo]-16-crown-5-oxyacetic acid (DTBDB16C5-OAcH) (Chu and Lin, 2001), tricaprylmethylammonium chloride (Aliquat-336), triphenylphosphine sulfide (TPPS), or tri-n-octylphosphine (TOPO) dissolved in toluene with PPO and POPOP in order to obtain an extractive scintillation cocktail (Borai et al., 2008). A commercial extractive scintillation cocktail RADAEX is available, which was developed specifically for LSC measurement of radium (Case and McDowell, 1990), this cocktail has been successfully applied for the determination of radium in water (Aupiais et al., 1998; Gómez Escobar et al., 1999; Blanco Rodríguez et al., 2000; Möbius, 2002; Wallner, 2002; Aupiais, 2005). RADAEX can be combined also with other extractive scintillators to determine radium simultaneously with other nuclides. Blanco Rodríguez et al. (2000) presented a procedure where they applied RADAEX, URAEX, and THOREX for the sequential analysis of radium, uranium, and thorium. RADAEX also extracts lead that must be complexed before extraction in order to obtain a pure radium sample (Wallner, 2002).

The extraction of radium with RADAEX needs to be carried out in alkaline media (pH 10−12); however, large amount of metals in high salt content water will be precipitated in this condition. Therefore, this method cannot be directly applied for the analysis of high saline water samples. Aupiais (2005) presented an improvement on the RADAEX procedure for samples of high salinity, whereby α-hydroxyisobutyric acid (HIBA) solution is first added into the sample to form a complex with most of metals in the sample solution to prevent precipitation. However, HIBA could not prevent the extraction of uranium into the organic scintillation phase, causing a co-extraction of uranium into scintillation phase with radium. If uranium is assumed to be present, it should be removed by extraction with ALPAEX prior to the extraction of radium. The detection limits of ^{226}Ra using RADAEX vary between 19 and 26 mBq for the Quantulus LS spectrometer (Gómez Escobar et al., 1999; Blanco Rodríguez et al., 2000).

d. Determination of ^{228}Ra in natural waters

Nour et al. (2004) developed a rather simple procedure for separating ^{228}Ra from natural waters. This method is based on the indirect determination of ^{228}Ra through the ^{228}Ac daughter and on measuring its β-activity by LSC. The method includes a preconcentration step based on the coprecipitation of radium with MnO_2 and two extraction chromatographic column separations using Diphonix resin, which effectively retains actinides and lantanides while divalent cations like Ra and Ba pass through. In the first Diphonix column separation, U-, Th-isotopes and ^{90}Y as well as ^{228}Ac are retained in the column. Radium isotopes remain in the effluent and wash solutions, which are set aside for 30 hours to permit the ^{228}Ac ingrowth to attain secular equilibrium with ^{228}Ra. Thereafter ^{228}Ra and ^{228}Ac are separated from each other by the second Diphonix resin separation. The ^{228}Ac retained on the Diphonic column is eluted using 5 mL of 1 M HEDPA (1-hydroxyethane-1,1 diphosphonic acid) directly into a plastic LS vial and mixed with LS cocktail. The overall yield of this procedure is typically over 95% as determined by the ^{133}Ba-tracer, and the detection limit of 23.2 mBq/L was reported based on 1 L sample volume and 60 minutes counting time. L'Annunziata and coworkers (See Aleissa et al., 2008) used the same procedure with the only difference that the ^{228}Ac activity was measured by Cerenkov counting. The detection limit, for 1 L water volume and a 100 minutes count, was 53.8 mBq/L (3.24 dpm/L). Utilizing sodium salicylate as a wavelength shifter, at a concentration of 0.1 g/mL in the counting vial, yielded an increase in the Cerenkov counting efficiency of more than 3-fold for ^{228}Ac (38%). The increase in Cerenkov counting efficiency in this case was explained to be due to an increase in the refractive index produced by the high concentration of sodium salicylate. A recent study by Wang et al. (2018) showed that such a sharp increase in counting efficiency would be mainly attributed to the scintillation effect of the high concentration of sodium salicylate, with a small contribution to Cerenkov counting efficiency from the increase in the refractive index produced by sodium salicylate.

e. Preconcentration of radium isotopes from large water volumes

Preconcentration of radium isotopes from large water volumes (up to 1000 L) is often necessary when low-activity environmental waters are analyzed. Preconcentration methods are often based on the coprecipitation of radium with MnO_2 or on MnO_2-impregnated acrylic fiber followed by the dissolution of the radium for further purification by other methods (Michel et al., 1981; Baeza et al., 1998; La Rosa et al., 2001; Sidle et al., 2001; Saito et al., 2003; Nour et al., 2004; Aleissa et al., 2008; Lamontagne et al., 2008; van Beek et al., 2010; Bhangare et al., 2017; Schubert et al., 2018). A commercial MnO_2 resin (impregnated MnO_2 on a modified polyacrylonitrile (PAN) supporting material) is available from Triskem International (or Eichrom) for the separation of radium from water samples.

The investigation of the sorption characteristics of radium onto MnO_2 Resin with a goal to simplify the preconcentration of radium isotopes from natural waters shows that the MnO_2 Resin is appropriate for that purpose over a range of salinities. The sorption of Ra was especially favorable for low-salinity waters, like typical drinking waters, but it was highly dependent on pH with the most useful range from pH 4 to 8. At higher salinities, other alkaline earth elements (Mg, Ca, and Sr) compete with Ra for the free sorption sites in the MnO_2 Resin, and Ra is more effectively adsorbed onto MnO_2 Resin than Ba in seawater. This means that ^{133}Ba is not an appropriate yield tracer for saline waters (Moon et al., 2003).

f. Other methods

Sato et al. (2000) have used LSC combined with α/β coincidence for low-level measurements of radium. This method is based on the coincidence counting of the β-particle from ^{214}Bi and the α-particle from ^{214}Po (half-life = 164 μs). These paired pulses can be separated electronically from background events and single pulses from other radionuclides, giving significant reductions in background. Antovic and Svrkota (2009) used a γ-ray coincidence spectrometer with multidetector to determine ^{226}Ra in soil and sand samples and obtained a detection limit of 0.68 Bq/kg. A compact, single PMT LSC with automatic sample changer dedicated to analysis of the paired pulses has been developed by Gudjonsson and Theodorsson (2000). Low detection limits have been achieved using mass spectrometric methods following the preconcentration and chemical separation of radium from matrix (Zoriy et al., 2005; Tsai et al., 2010; Van Es et al., 2017; Lagace et al., 2017; Dalencourt et al., 2018).

In summary, the current LS instruments with sophisticated pulse shape analysis permit the determination of low concentrations of ^{226}Ra and ^{228}Ra in environmental samples using chemical separation and preconcentration methods. Regardless of that, for most methods that have been demonstrated to be accurate, the results for radium analysis are not necessarily satisfactory. Intercomparison studies have indicated that a substantial number of radium results are erroneous. In a world-wide intercomparison organized by the International Atomic Energy Agency (IAEA) the percentage of "not acceptable" results was 43% and 31% for two spiked water samples having the ^{226}Ra activity concentrations of 0.69 Bq/L and 1.93 Bq/L, respectively (IAEA/AQ/15, 2010). Another intercomparison exercise organized among 45 European laboratories also showed many discrepant results for radium isotopes in mineral waters (Wätjen et al., 2010). The results showed 19% of the results off by a factor of two or more, whereas the proportion of such results for uranium was only 6%. The participating laboratories of these two studies used very different methods for radium analyses, almost all of the methods described here.

An intercomparison also showed deviating results but with fewer outliers (Möbius and Salonen, 2002), and the best results were obtained using the $BaSO_4$ coprecipitation method and many of the deviating ^{226}Ra results had been determined using different extraction methods. It is obvious that chemical separation methods work for radium, as well as for uranium, with most of the problems involved in radium assays due to the presence of gaseous ^{222}Rn and its daughters which are chemically different elements, occurring in the same series. ^{222}Rn can be lost easily during the extraction, and its daughters can behave differently during the sample processing and measurement depending on the chemical conditions. Hence, attention should be paid to the various stages of analysis including an evaluation of the extraction and detection efficiencies, which are often assumed to be constant or close to 100%.

E. Lead-210 (^{210}Pb) [Bismuth-210 (^{210}Bi) and Polonium-210 (^{210}Po)]

1. Environmental occurrence and importance

^{210}Pb ($t_{1/2}$ = 22.2 y), ^{210}Bi ($t_{1/2}$ = 5.01 d) and ^{210}Po ($t_{1/2}$ = 138.4 d) constitute their own subseries in the ^{238}U decay series (Fig. 2.25). ^{210}Pb decays by emitting β particles (E_{max} = 63.5 keV), with γ emission (E_γ = 46.5 keV) and internal conversion to the β-emitting ^{210}Bi (E_{max} = 1161.5 keV) which decays to the α-emitting ^{210}Po (E_α = 5.3 MeV). The decay scheme of the ^{210}Pb subseries is shown in Fig. 2.30 (Laureano-Pérez et al., 2007). ^{210}Pb, ^{210}Bi, and ^{210}Po exist everywhere, in rock, soil, atmosphere, and natural waters, as a result of the ^{222}Rn decay and subsequent deposition. ^{210}Pb and ^{210}Po belong to the most toxic radionuclides, and 79% of the internal dose following ingestion of uranium and thorium series radionuclides is caused by ^{210}Pb and ^{210}Po (UNSCEAR, 2000).

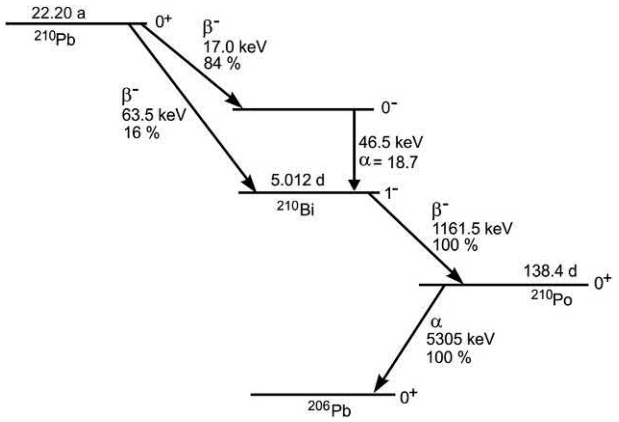

FIGURE 2.30 Decay scheme for the ^{210}Pb subseries (Laureano-Pérez et al., 2007). *Reprinted by permission of Elsevier © 2007.*

^{210}Pb accumulates in bone while ^{210}Po is distributed mainly to soft tissues. The main intake of ^{210}Pb and ^{210}Po is derived from the food, with the exception of smokers whose intake can significantly increase by inhalation because ^{210}Pb and ^{210}Po exist in tobacco (UNSCEAR, 2000). Although the origin of most of the ^{210}Po in the body is normally through ingestion of ^{210}Pb, some diets high in certain foodstuffs with enriched ^{210}Po are able to increase the normal intake of ^{210}Po considerably (NCRP, 1984; Matthews et al., 2007; Fowler, 2011; Persson and Holm, 2011). The ^{210}Po concentrations are high in seafood like fish, mollusks, and crabs, and high ^{210}Pb and ^{210}Po concentrations were found in reindeer and caribou meat (Hassona et al., 2008; Persson and Holm, 2011; Fowler, 2011; Carvalho, 2011). Drinking water usually constitutes a minor contribution to the normal intake of ^{210}Pb and ^{210}Po, but it can be significant for some population groups consuming ground water, particularly well or mineral waters of which very variable concentrations up to 21 Bq/L have been reported (UNSCEAR, 2000; Persson and Holm, 2011). The guideline value of WHO for ^{210}Pb and ^{210}Po in drinking water is 0.1 Bq/L (WHO, 2011). According to the recommendations of the European Commission (EURATOM, 2001), the maximum concentration of ^{210}Pb and ^{210}Po in drinking waters are 0.2 Bq/L and 0.1 Bq/L, respectively. Owing to the low permissible concentrations, much attention is paid to the analyses of ^{210}Pb and ^{210}Po in drinking waters.

^{210}Pb, ^{210}Bi and ^{210}Po have been widely used as tracers in studies on environmental processes (Peck and Smith, 2000; Papastefanou, 2006; Matthews et al., 2007; Zaborska et al., 2007; Persson and Holm, 2011; Baskaran, 2011; Fowler, 2011). All these elements are particle reactive species; this property has been used in the study of particle scavenging processes in aquatic and atmospheric environments. For example, ^{210}Pb is widely used to date sediments in seas, lakes and estuaries (Goldberg, 1963; Monna et al., 1996; Zaborska et al., 2007), to study bioturbation in slowly accumulating sediment systems, e.g., deep ocean sediments (Thomson et al., 1993) and accumulation rates in rapidly accumulating sediment systems, e.g., some peat profiles and lake sediments (MacKenzie et al., 1998). ^{226}Ra, ^{210}Pb, and ^{210}Po are used to estimate the rates at which reactive elements are removed from seawater by adsorption onto particles, to determine residence times of lead, other pollutants and materials in the oceans, and to assess redistribution of pollutants from the atmosphere in estuarine systems (Wu and Boyle, 1997; Zaborska et al., 2007; Matthews et al., 2007; Fowler, 2011; Mikalauskiene et al., 2018). ^{210}Po/^{210}Pb activity ratio measurements have been used to study biological productivity and boundary scavenging (Nozaki et al., 1976, 1997; 1998; Smith and Ellis, 1995). ^{222}Rn and its progenies, ^{210}Pb, ^{210}Bi, and ^{210}Po, are very useful tracers in quantifying several atmospheric processes such as circulation, mixing, stability, transport, and vertical movement of air masses, removal rate constants, and the residence time of aerosols, chemical behavior of analog species and washout ratios, and deposition velocities of aerosols (Peck and Smith, 2000; Papastefanou, 2006; Yamamoto et al., 2006; Baskaran, 2011; Persson and Holm, 2011).

2. Sample preparation and analysis

Traditional analysis methods of ^{210}Pb, ^{210}Bi, and ^{210}Po are based on three measurement techniques:

1) Direct counting by γ-spectrometry,
2) α-spectrometry,
3) β-counting using liquid scintillation (LS) or gas-proportional counters

The methods based on α and β counting require ^{210}Pb, ^{210}Bi, and ^{210}Po to be separated from the matrix and from other radionuclides. Because ^{210}Pb and ^{210}Po are found in disequilibrium in biological and most environmental samples, they have to be analyzed individually. Methods based on ICP-MS have also been investigated for the measurement of ^{210}Pb in water samples (Larivière et al., 2005). Owing to a very low mass concentration of ^{210}Pb in samples, it is necessary to pre-concentrate the sample and to separate ^{210}Pb from the matrix. The detection limit was about 90 mBq/L. The usability of the method is limited because of the stable lead, which cannot be removed from the sample by conventional methods and interferes in the measurement of ^{210}Pb.

a. Direct counting of ^{210}Pb by gamma spectrometry

The gamma spectrometric measurement of ^{210}Pb is implemented by counting the 46.5 keV gamma photon emissions of ^{210}Pb using an N-type HPGe gamma detector with a

beryllium or carbon epoxy thin window or planary HPGe detector. The difficulty in this method is the relative low counting efficiency of HPGe detectors combined with the low absolute intensity (4.25%) of 46.5 keV gamma photon. Consequently, the direct gamma spectrometric method requires the analysis of large sample sizes, long counting times, corrections for self-absorption and interferences from other γ- and X-rays (Cannizzaro et al., 1999; San Miguel et al., 2002; Ebaid and Khater, 2006; Lauria et al., 2006; Villa et al., 2007; Hou and Roos, 2008). The method is feasible but the measurement uncertainties is normally high (Cannizzaro et al., 1999; Zaborska et al., 2007). Samples commonly analyzed are peat, soils, and sediments (Thomson et al., 1993; MacKenzie et al., 1998; San Miguel et al., 2002; Lauria et al., 2006; Zaborska et al., 2007) and atmospheric aerosol particles which have been collected using high-volume air samplers (Cannizzaro et al., 1999; Papastefanou, 2006). The detection limit of this method for ^{210}Pb has been reported to be 440 mBq/sample for a 1000 minutes counting time (Ebaid and Khater, 2006). Grahek et al. (2006) developed a rapid procedure to separate ^{210}Pb and ^{90}Sr from sea and drinking water samples by chromatography using Sr resin and anion exchange resin, ^{210}Pb and ^{90}Sr were separated efficiently from large volumes of sample (10 L). The detection limit was 6 mBq/L for ^{210}Pb with the counting time of 100,000−200,000 seconds.

b. Measurement of ^{210}Pb and ^{210}Po by alpha spectrometry

The alpha spectrometric measurement of ^{210}Pb and ^{210}Po is a classical method for determining ^{210}Pb and ^{210}Po in various matrices. It is based on two spontaneous depositions of ^{210}Po onto a silver disc and on measuring the ^{210}Po activity with an alpha spectrometer (Flynn, 1968; Peck and Smith, 2000; Vesterbacka and Ikäheimonen, 2005; Ebaid and Khater, 2006; Matthews et al., 2007; Ruberu et al., 2007; Wallner et al., 2008; Benedik et al., 2009; Bonotto et al., 2009b; Jia et al., 2009; Hou and Roos, 2008; Henricsson et al., 2011; Carvalho, 2011; Idoeta et al., 2011). Following the first deposition of ^{210}Po, the sample solution is stored for several months to allow sufficient ingrowth of ^{210}Po from ^{210}Pb and then perform the second deposition of the newly generated ^{210}Po from ^{210}Pb. Besides silver, Ni and Cu are also used as spontaneous deposition materials. Environmental water samples are usually pre-concentrated either by evaporation or by coprecipitation with $Fe(OH)_3$ or MnO_2, and organic material is decomposed by wet digestion before dissolving the residue for the deposition. ^{208}Po or ^{209}Po are used as chemical yield tracers. The detection limits by this method are very low, down to 0.1−0.3 mBq, and the α-spectrometric methods are especially suited to the analysis of low-activity samples (Matthews et al., 2007). However, there are several potential problems associated with this method, not least of which is the length of time required for ^{210}Po ingrowth when ^{210}Pb is determined indirectly via its granddaughter, ^{210}Po. Some ^{210}Po compounds are volatile even at 100°C and can be lost during the evaporation and wet digestion (Vreček et al., 2004; Matthews et al., 2007; Henricsson et al., 2011). ^{210}Po can also be adsorbed onto the walls of the storage container during the storage between the two depositions (Vesterbacka and Ikäheimonen, 2005), all these issues have to be considered and well treated to obtain accurate results.

c. Measurement of ^{210}Pb, ^{210}Bi, and ^{210}Po by liquid scintillation counting

^{210}Pb is a beta-emitter, and can be measured by LSC. However, due to its low-energy beta particles (17.0 keV (84%) and 63.5 keV (16%)), it is often measured via its high beta-energy daughter, ^{210}Bi (1161.5 keV). The low-energy beta emission of ^{210}Pb is hardly detected by GPC, and it is sensitive to sample quenching in LSC (Lebecka et al., 1993; Kim et al., 2001; Villa et al., 2003, 2007; Blanco et al., 2004; Ebaid and Khater, 2006; Idoeta et al., 2011). The LS measurement is performed often after some ingrowth of ^{210}Bi, If the ^{210}Pb itself is measured, the interference from the ^{210}Bi low-energy tail into the ^{210}Pb counting window has to be considered (Lebecka et al., 1993; Kim et al., 2001; Blanco et al., 2004; Villa et al., 2007). Similarly using the GPC, it is unnecessary to wait for secular equilibrium between ^{210}Pb and ^{210}Bi, because the effect of ^{210}Pb on the ^{210}Bi counts is eliminated by covering the sample with a Mylar or aluminum foil (Ebaid and Khater, 2006; Ruberu et al., 2007; Jia et al., 2009).

The most common separation methods are: (i) precipitation of Pb as the sulfate, (ii) extraction chromatography, and (iii) solvent extraction. The separation of ^{210}Pb by coprecipitation as $Ba(Ra,Pb)SO_4$ is a traditional method by which radium isotopes and ^{210}Pb can be separated simultaneous from ground waters, soils and sediments (Lebecka et al., 1993; Chau et al., 2001; Kim et al., 2001; Blanco et al., 2004; Villa et al., 2007). After sample pretreatments, the chemical separation is started by adding stable Pb and Ba carriers as the yield tracers, followed by precipitation as the sulfate, the formed sulfate is then dissolved in alkaline EDTA. The separation of Pb from Ra is achieved by adjusting the pH to 4.2−4.5 of the EDTA solution of the sample with acetic acid. The Ra precipitates with $BaSO_4$, and the Pb remains in the solution. Afterward, the solution is further acidified to precipitate Pb as $PbSO_4$ and separate ^{210}Pb from the solution. The precipitate is washed with distilled water to remove other interfering radionuclides. The $^{210}PbSO_4$ can be prepared for LS counting by suspending it in a scintillation gel or dissolving it in

alkaline EDTA solution and then mixing with the LS cocktail. The sample is counted using LSC with α/β-discrimination, and the ^{210}Pb is determined from the spectrum of ^{210}Pb or the ingrown ^{210}Bi. ^{210}Pb can be also measured by Cerenkov counting of the ingrown ^{210}Bi after separation of ^{210}Pb (Al-Masri et al. 1997). The potential interferences from alpha and soft beta-emitters can be avoided in this method, but the counting efficiency of Cerenkov counting is comparatively low (20%). A 14%−16% counting efficiency of Cerenkov counting for ^{210}Bi was reported in the analysis of air filters (Dale et al. (2002). An increased Cerenkov counting efficiency form 17%−75% was achieved through the use of Triton X-100 and sodium salicylate as enhancers (Peck et al. 1998). Under these conditions, ^{210}Po caused some interference, which was not present in the absence of the enhancers. When Cerenkov counting was used for measurement of ^{210}Pb through ^{210}Bi, no scintillation cocktail is needed, the EDTA dissolution of $PbSO_4$ is directly applied for the measurement.

Extraction chromatography using Sr Spec resin have been applied to the separation of ^{210}Pb and ^{210}Po for their determination in various environmental and biological samples (Vajda et al. 1997; Vreček et al., 2004; Ruberu et al., 2007; Hassona et al., 2008; Sirelkhatim et al., 2008; Outola et al., 2008). This is based on the high adsorption of Pb and Po on this resin in dilute HCl solution, while ^{210}Bi does not. The sample is first decomposed and prepared in 2M HCl medium and loaded to a Sr Spec column, ^{210}Po and ^{210}Pb absorbed on the column were eluted from the column sequentially using 6M HNO_3 and 6M HCl, respectively. The HCl eluate was evaporated to dryness followed by converting lead from chloride to nitrate and by precipitating it as the oxalate for the yield determination. ^{210}Po was determined by alpha spectrometry using ^{208}Po as the yield tracer after spontaneous deposition on a metal disc. The separated ^{210}Pb was determined by LSC after dissolving PbC_2O_4 into 1 mL of 6M HNO_3 and mixing it with scintillation cocktail. In this method, ^{210}Po and ^{210}Pb were efficiently separated from other elements and interfering radionuclides (Vajda et al. 1997). Biggin et al. (2002) modified the Sr•Spec resin method for determining ^{210}Pb, ^{210}Bi and ^{210}Po in seawater using ^{212}Pb, ^{207}Bi, and ^{208}Po, respectively, as yield tracers. This method offers the opportunity to investigate the geochemical cycling of the ^{210}Pb/^{210}Bi/^{210}Po system in the marine environment and to use them as tracers of scavenging processes operating on time-scales ranging from a few days to tens of years.

Solvent extraction methods using a variety of extractants are also applied for the separation of ^{210}Po and ^{210}Pb in environmental samples (Véronneau et al., 2000; Matthews et al., 2007). POLEX is an extractive scintillation cocktail by which ^{210}Bi and ^{210}Po can be extracted into the cocktail from phosphoric acid solutions and subsequently measured by LSC using α/β discrimination (Monna et al., 1996; Wallner, 1997; Katzlberger et al., 2001; Aleissa et al., 2006; Landstetter and Katzlberger, 2006). ^{210}Pb, which remains in the aqueous phase, can be determined by two methods: (i) carrying out a second POLEX extraction on the same aqueous phase as the first one after allowing for ^{210}Bi ingrowth for 2 weeks, and (ii) taking a sample from the aqueous phase and mixing it with the cocktail for direct measurement of ^{210}Pb using LS measurement. Forte et al. (2009) recommended a toluene-based cocktail, which includes TOPO, naphthalene, and PBBO. Peck and Smith (2000) proposed a method using 0.2% DDTC (diethyldithiocarbamate) in chloroform to extract ^{210}Bi from rainwater samples, and Chen et al. (2001) used 5% TIOA (triisooctylamine) in xylene to extract ^{210}Po quantitatively from 10M HCl solution, while ^{210}Pb was not extracted.

F. Thorium

1. Environmental occurrence and importance

Thorium (Th) has three principal isotopes, ^{232}Th ($t_{1/2} = 1.41 \cdot 10^{10}$ y), ^{230}Th ($t_{1/2} = 7.54 \cdot 10^{4}$ y) and ^{228}Th ($t_{1/2} = 1.91$ y), all of which are alpha-emitters. ^{232}Th is the parent of the thorium series (Fig. 2.31) where ^{228}Th belongs as a member. ^{230}Th and the β-emitting ^{234}Th ($t_{1/2} = 24.1$ d), belong to the uranium series (Fig. 2.25). ^{234}Th is a very useful tracer in marine studies. Other natural Th isotopes are ^{231}Th ($t_{1/2} = 25.5$ hours) and ^{227}Th ($t_{1/2} = 18.7$ d) from the actinium series. Th is widely distributed over the earth's crust at different levels similarly as U. The worldwide average value of ^{232}Th in soil is about 45 Bq/kg, but the concentrations reported vary largely up to 360 Bq/kg (UNSCEAR, 2008). Th and U concentrations are high in igneous rocks of granite composition, some

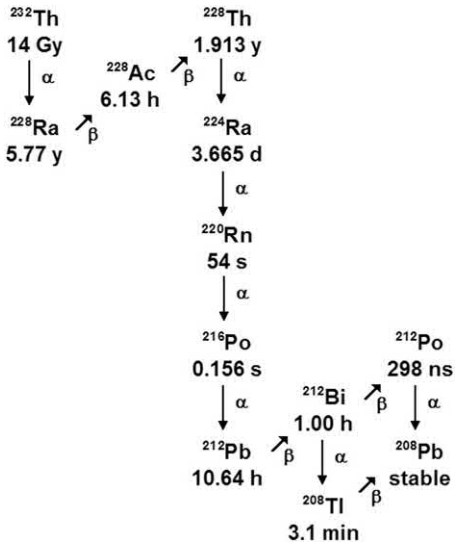

FIGURE 2.31 Decay scheme of thorium (^{232}Th).

shales and phosphate rocks, while high concentrations of Th are associated with minerals such as monazites and zirkons (UNSCEAR, 2000). In seawater, ^{232}Th concentration is very low, because Th has only one stable oxidation state, 4+, under all redox conditions in natural waters, and thorium ions (4+) are extremely particle reactive (Santschi et al., 2006). Consequently, Th is highly insoluble and of low environmental mobility in contrast to U, which occurs under oxidizing conditions in the 6+ oxidation state as the soluble uranyl ion (UO_2^{2+}, or carbonate complex). These contrasting geochemical behaviors have enabled any disequilibrium between the ^{234}Th/^{238}U daughter/parent pair to be used to study the temporal and spatial dynamics of particle and particle reactive species and other short-term processes occurring in the oceans (Geibert and Usbeck, 2004; Smith et al., 2004; Waples et al., 2006; Santschi et al., 2006; Buesseler et al., 2006; Anand et al. 2017, 2018). In the water column, the major applications for ^{234}Th/^{238}U disequilibrium have focused on either elucidating oceanic carbon fluxes or modeling reactive pollutant behaviors in coastal environments. In the sediment, this disequilibrium is typically used to study reworking processes (Martin and Sayles, 1987; Foster and Schimmield, 2002). Thorium is a radiotoxic element, but the exposure from thorium is generally very low, because of its less volatility and enrichment in foodstuff, accounting for only 0.8% of the internal dose from ingestion of natural series radionuclides (UNSCEAR, 2000). The main goal in the determination of thorium is environmental monitoring for mining, milling, and mineral processing industries and for occupational exposures of workers (Poole et al., 1995; Clulow et al., 1998; Chen et al., 2005; Saueia and Mazzilli, 2006; Carvalho et al., 2007; Arogunjo et al., 2009; Sartandel et al., 2009; Lipsztein et al., 2001; Al-Jundi et al., 2004; Ting et al., 1999; UNSCEAR, 2008).

2. Sample preparation and analysis

a. ^{232}Th, ^{230}Th, and ^{228}Th

The alpha-emitting thorium isotopes, ^{232}Th, ^{230}Th, and ^{228}Th, are determined mostly by α- and γ-spectrometry and mass spectrometric methods and rarely by LSC methods. For the long-lived ^{232}Th, the mass spectrometric methods (e.g., ICP-MS) are six orders of magnitude more sensitive than the α-spectrometric methods, while the short-lived ^{228}Th is preferably determined by α-spectrometry (Hou and Roos, 2008). Consequently, the mass spectrometric methods have become the main techniques for determining ^{232}Th and ^{230}Th in geochemical, environmental and bioassay studies (Clulow et al., 1998; Ting et al., 1999; Fujino et al., 2000; Unsworth et al., 2001; Lipsztein et al., 2001; Al-Jundi et al., 2004; Arogunjo et al., 2009; Harrison et al., 2011; Zoriy et al., 2010). For the α-spectrometric methods, Th is separated using ion exchange or extraction chromatography and thereafter electrodeposited onto a stainless-steel disk for α-counting (Poole et al., 1995; Clulow et al., 1998; Purkl and Eisenhauer, 2003a, 2003b; Wang et al., 2004; Hirose et al., 2004; Carvalho et al., 2007; Saueia and Mazzilli, 2006; Jia et al., 2009). Soil, sediment, and mineral samples are often determined by γ-spectrometric methods, which entail analysis based on measuring Th isotopes by their decay products in equilibrium with the parent nuclides. The measurements are performed using HPGe detectors (Vuković et al., 1996; Tzortzis and Tsertos, 2004; Shetty et al., 2006; Arogunjo et al., 2009; Sartandel et al., 2009). Wallner (1996) determined thorium in excretion samples of persons occupationally exposed to thorium, which was based on the combination of precipitation and extraction techniques and α-counting with the Quantulus. Fig. 2.32 illustrates the alpha spectra of ^{232}Th and ^{228}Th (in secular equilibrium) and the beta spectra of ^{234}Th and its daughter, ^{234m}Pa measured immediately after the thorium separation.

b. ^{234}Th

The radionuclide ^{234}Th ($t_{1/2} = 24.1$ d) is the immediate daughter of ^{238}U ($t_{1/2} = 4.47 \cdot 10^9$ y), emitting low-energy betas ($E_{max} = 199$ keV) with low-energy gamma photons at low probabilities (63.3 keV (4.8%) and 92.4–92.8 keV (5.6%)). Its daughter, ^{234}Pa ($t_{1/2} = 6.75$ hours), decays by the emission of a high-energy beta particle ($E_{max} = 2.29$ MeV), which can be used to determine the ^{234}Th activity of a sample. ^{234}Th activities in seawater are traditionally determined by gamma spectroscopy via the low probability gamma emissions, which consequently requires large sample volumes (>200 L) (Buesseler et al.,

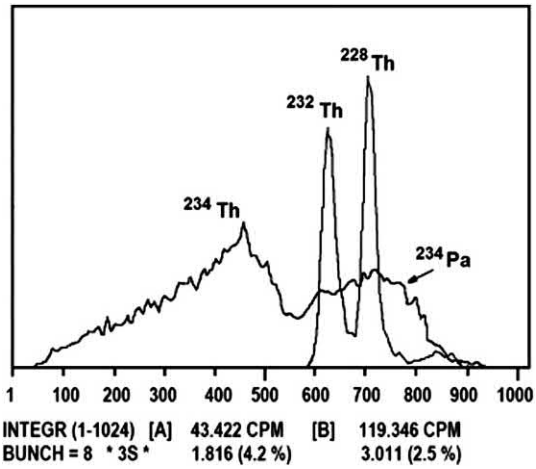

FIGURE 2.32 Spectra of a thorium sample measured immediately after the thorium extraction, containing 0.33 ± 0.02 Bq ^{232}Th (channel 580–675), 0.35 ± 0.02 Bq ^{228}Th (channel 675–760), ^{234}Th and ^{234}Pa in the β-spectrum between channel 550 and 900). Note that the two spectra have different energy scales (Wallner, 1996). *Reprinted by permission of Elsevier © 1996.*

1992, 2001; Schmidt and Reyss, 2000) and by the determination of the beta emissions from ^{234}Th and ^{234m}Pa by gas proportional counting (Coale and Bruland, 1987; Moran and Buesseler, 1993; Buesseler et al., 2001) or by liquid scintillation spectrometry (LSC) (Anderson et al., 1991; Pates et al., 1996b; Smith et al., 2004). The beta counting methods require sample volumes in the range of 2−100 L. The LSC method is briefly described below (Pates et al., 1996b). After the addition of Fe-carrier and the ^{230}Th yield tracer into a filtered seawater sample, thorium is coprecipitated with $Fe(OH)_3$ by addition of ammonium to pH 8−9, the coprecipitate is then dissolved in HCl. Following the removal of U and Fe from the HCl solution by anion exchange, Th is converted from chloride to nitrate, prepared in high concentration HNO_3 solution and further purified by anion exchange using a nitrate-form resin. After loading the sample solution and rinsing the column with HNO_3, thorium is finally eluted with diluted HCl, which is evaporated to prepare a sample for LS counting using α/β discrimination. A detection limit of 0.4 mBq/L for a 20 L sample and a counting time of 400 minutes has been achieved using this method. Preparation of the ^{230}Th yield tracer from uranite ore requires a complex procedure, the full details of which are given in Pates et al. (1996b). Smith et al. (2004) determined the chemical yield using a ^{229}Th tracer after electroplating the separated thorium onto a stainless-steel disk and counting it by α-spectrometry. Thereafter, thorium on the disc was removed using HNO_3, and the solution was evaporated to dryness. The residue was dissolved into 1 mL of 0.1 M HCl and transferred into an LS vial and mixed with 10 mL of Ultima Gold AB to achieve a good α/β discrimination with a low-background LS spectrometer. Nour et al. (2002) developed a similar method for the determination of ^{234}Th in sediments using ^{230}Th as yield tracer. An extraction chromatography using TEVA resin rather than ion exchange was used to separate and purify the thorium. ^{234}Th was measured via the ^{234m}Pa by Cerenkov counting with a counting efficiency of 27.6%. By adding LS cocktail and measurement by LSC using α/β discrimination, an efficiency of 156% was achieved, because both ^{234}Th and ^{234m}Pa are measured. An extensive review on the methodology for the ^{234}Th analysis in aquatic systems has been presented by Rutgers van der Loeff et al. (2006). It covers the sampling and analysis methods, recommendations on calibration procedures and production of standard reference materials.

VIII. Spectrum deconvolution methods in environmental analysis

A. Spectrum deconvolution, unfolding, stripping, peak fitting

Separation of multinuclide liquid scintillation spectra into components from individual radionuclides has been referred to, in the LSC literature, as spectrum deconvolution, unfolding, stripping and peak fitting. Deconvolution in this context is not the recovery of the pure spectrum from the composite one that has been blurred by the instrument (point or slit spread function in optical spectrometries, signal, image processing), but rather separation of merged emission peaks from each other. There are numerous factors in each sample that affect the LS spectrum and therefore removal of the instrument function automatically would be a formidable task.

Actually, isolation by mathematical deconvolution of instrument, temperature, vial, cocktail fluor and quench effects from composite spectra have not been applied in LSC at all. Usually the sum of squared differences of measured and model spectrum points is minimized and the best fit then found.

B. Approaches in LS beta spectrometry

Shapes and positions of liquid scintillation spectra depend on the sample matrix, as the sample itself mixed with scintillating cocktail is a part of the detector system. It is not an invariant light-emitting detector component, as NaI crystal in gamma spectrometers for instance. Quench is one reason for the difficulty in the development of automatic spectrum separation software for liquid scintillation spectrometry. Some tests in late 1980s at Wallac with MINUIT minimization software indicated that alpha spectrum shape is difficult to handle automatically. Later, a spectrum analysis software package, EASY View for Quantulus and 1400 series LSAs, included a nonautomatic, interactive spectrum stripping routine, where a set of quenched reference spectra are required to reduce multiple components from the beta and alpha spectra.

The latter instrument series analyzes up to three beta labels automatically using digital spectrum libraries. The method is called the Digital Overlay Technique (DOT) (Rundt, 1989, 1992; Kouru and Rundt, 1991). A library of six beta-emitters is stored in a reduced form as a function of chemical and color quench indices measured in conventional and safe cocktails and in plastic and glass vials leading to 4 combinations. The spectrum form is saved as recorded in up to 32 windows over the spectrum. A composite sample spectrum fit is achieved by taking up to three reference spectra at the measured quench index values and adjusting their activity ratios so that minimum error is achieved in the fit. The method contains background and chemiluminescence corrections and correction for the sample size. Sample quality count rate monitoring is also included (Wallac 1414 WinSpectral, 2001).

New radionuclide spectrum libraries can be created, and existing libraries fine-tuned to better fit the sample matrix (Kouru, 1991). The method can be applied to resolve ^{14}C and ^{35}S activities from a mixed sample.

Deterioration of PMT efficiency is automatically taken care of in the method, as the shift of the spectra means higher quench and spectrum libraries do have matching

spectra to correct for the PMT aging. The instrument versions, which have a pulse shape analyzer, can separate the alpha signal into its own spectrum.

Beta spectrum deconvolution is discussed in more detail in Chapter 6, Volume 1 and some references are given in the Sr section of this chapter.

C. Alpha spectrum unfolding

1. Energy resolution

Alpha spectra are monochromatic. Monochromatic emissions in LS beta spectra are seen only from conversion electrons, for instance in the ^{137}Cs spectrum.

The larger number of photons per decay is recorded, the smaller is the variation of their number, which relates to the observed width of the emission peak. Light yield is thus one factor affecting the energy resolution (Nähle et al., 2009). Poor alpha peak resolution in LSC, due to the modest number of detected photoelectrons by PMTs per decay event, poses a great difficulty.

If samples are not preconcentrated, water samples mixed with cocktail including most of the sample would usually give the best LLD. However, the alpha energy resolution deteriorates under quench close to 1 MeV FWHM and heavy peak overlay of multiple emissions makes it impossible to resolve them. In gross alpha counting, separation into components from different alpha-emitting radionuclides is not necessary.

Extractive cocktails could lead to low quench samples and thus much improved energy resolution. The PERALS alpha spectrometer is constructed to optimize light collection with optical coupling using immersion fluid between the PMT and sample tube and offers good resolution, which can be achieved in double PMT instruments only with equivalent sample and vial optimization.

Solutions to improve energy resolution are focusing on instrumentation and light yield from cocktails as has been done with the PERALS alpha spectrometer (McDowell, 1992) or the use of numerical methods to resolve poor resolution spectra.

Aupiais (2005) points out that the energy resolution is also a function of count rate. In the case of very low count rates, there is a strong probability for an α event to appear near the center of the related α peak because energy distribution follows a Poisson law. A practical consequence is a narrower peak at a lower count rate than that observed at higher count rate. If the full width at half maximum (FWHM) is fixed, an over-estimation of 30%–40% is observed.

2. High energy tailing

Aupiais and Dacheux (2000) have studied peak asymmetry in PERALS spectra produced with extractive cocktails and found that the main reason for the high-energy tail is internal conversion involving L and M shells. Peak asymmetry was studied for ^{210}Po, ^{214}Po, ^{218}Po, ^{228}Th, ^{230}Th, ^{232}Th, ^{232}U, ^{233}U, ^{234}U, ^{235}U, ^{238}U, ^{236}Pu, ^{238}Pu, ^{239}Pu, ^{242}Pu, ^{241}Am, ^{243}Am, and ^{244}Cm. The asymmetry is not observable with other LSCs, where water miscible cocktails are often used resulting in a poor energy resolution.

An electron is quickly ejected in internal conversion from the shell of the daughter nuclide, whose excited level has a life-time of less than a nanosecond. The instrument does not recognize these successive events as separate ones. The result is a sum of monoenergetic beta and alpha particle energies piling up as a separate peak on the higher energy side of the main alpha peak as illustrated in Fig. 2.33 (Aupiais, 2004a, 2004b; 2005). The distance of the conversion peak is enhanced, as about 8 times more light per electron is produced than per alpha-particle.

No asymmetry due to conversion electrons is present in major α emissions from ^{226}Ra, ^{224}Ra, ^{220}Rn, ^{222}Rn, ^{210}Po, ^{214}Po, and ^{218}Po, which are even-even nuclides (Aupiais, 2004b). Approximate 5% α emissions from for ^{224}Ra and ^{226}Ra produce internal conversion peaks at higher energies overlaying α peaks of their respective daughter nuclides and cannot be separated in LS spectra. The total contribution is about 2%.

All isolated alpha and internal conversion peaks (close to each other) are Gaussian in this analysis and have equal FWHM (Aupiais, 2005). The error due to the deconvolution is equal or within the statistical fluctuations and therefore neglected. Extra caution is necessary in the case of very low count rates, which require free adjustment of the peak width to avoid large errors.

Aupiais et al. (2003) enhanced the resolution obtained with a Tri-Carb liquid scintillation counter by reducing the

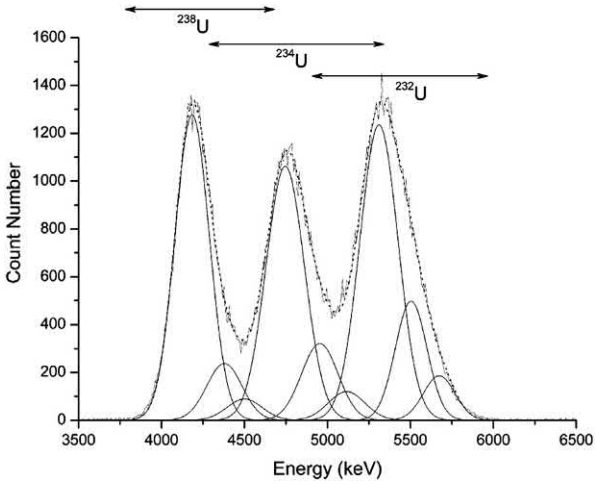

FIGURE 2.33 Energy spectrum of natural uranium doped with ^{232}U. Each isotope is fitted by three peaks – a main peak and two peaks of internal conversion (Aupiais, 2004a). *Reprinted by permission of Elsevier © 2004.*

optical path and by using extractive cocktails rather than water accepting cocktails for aqueous samples. The detection limits of the Tri-Carb were improved by 300%, but remained 40% lower than in PERALS. Tri-Carb energy resolution is improved by a factor of 2.

3. Software

Rusconi et al. (2004) and Forte et al. (2003) used aqueous samples and the Quantulus liquid scintillation counter to evaluate ^{238}U and ^{234}U content by applying spectral deconvolution with Canberra Genie 2k Interactive Peak Fit software. The ^{235}U contribution to total uranium was estimated to be lower than 2.5%, and it was neglected in the alpha spectra deconvolution. The method was compared with good results against two independent methods on some bottled water samples, viz. high-resolution alpha spectrometry on electrodeposited samples and ICP-MS (inductively coupled plasma mass spectrometry) on ^{238}U alone. Each sample was counted for 1000 minutes; the MDA for total uranium content was 0.4 mBq/L. Leyba et al. (1995) analyzed U isotope spectra from the PERALS spectrometer using three Gaussian functions in PeakFit software (Jandel Scientific Software, later acquired by Systat Software Inc.).

Bianchi et al. (2005) used Physics Analysis Workstation (PAW) from CERN in determining the ^{234}U/^{238}U ratio in environmental samples. Several free parameters are contained in the process: two activities, background spectrum shape, spectrum offset, peak width, and peak position of the first peak. The width and position of the second peak is based on a linear response, constant energy resolution and detection efficiency. The values of the fit parameters are obtained performing a Chi-squared minimization using MINUIT software from CERN. With ^{235}U contents greater than 0.26%, the average discrepancy with the reference values is 3.5% (with a maximum of 6.4%).

Nebelung and Baraniak (2007) examined ^{226}Ra and progeny, ^{233}U and ^{237}Np by liquid scintillation spectrometry using the Wallac 1414 WinSpectral Low-Level α/β LSA and low quenched aqueous samples. The detection limits are 0.02 Bq for α-emitting nuclides, and 0.09 Bq for β-emitting nuclides during 20 minutes of measurement.

^{226}Ra, ^{233}U and ^{237}Np can be determined in mutual activity ratios of 1:50 with a relative standard deviation of less than 4% for the major activity and 9% for the minor activity. If each nuclide is only present to 0.5 Bq, the spectrum of a 20 minutes counting time can also be exactly evaluated.

The authors used Origin Peak Fitting software (MicroCal Software Inc., now OriginLab Corporation) and asymmetric double sigmoidal function, a function that considers beside the peak center three peak widths. The errors were below 3%. The methods overestimate the first peak and gives 26% of total activity for ^{226}Ra instead of 25%.

Aupiais (2004a; 2004b) used Origin 7.0 peak fitting (OriginLab Corporation) software to resolve U spectra (Fig. 2.25).

Vera Tomé et al. (2002a) studied alpha peak shapes in extracted ^{226}Ra and progeny samples in High Efficiency Mineral Oil Scintillator using the Quantulus LSA and low-diffusion polyethylene (PE) vials. Peak shape was measured for radon and progeny in low diffusion PE and copper-teflon vials using mineral oil scintillator. Weak low-energy tailing was observed. This curve shape has been described by the mathematical functions formed by the convolution of a Gaussian with one or two left-handed exponential curves. The effect of sample shaking on peak asymmetry was tested. Less low-end asymmetry was observed with homogeneous samples. Also, a small shoulder on the high energy side of the peak disappeared. A Teflon-copper vial produces a peak shape closer to Gaussian than a plastic vial.

The best-fit curve can be calculated by using the nonlinear minimization method of Levenberg−Marquardt. The fit is independent on the logarithmic scale as the peaks lie in a very high-energy range. The same peak form was used by Verzilov et al. (2002) in the analysis of ^{234,238}U, ^{238,239,240}Pu, ^{241}Am and ^{244}Cm.

Stamoulis et al. (2010) analyzed ^{226}Ra and progeny, and ^{234}U and ^{238}U in preconcentrated water samples with the Tri-Carb 3170TR/SL LSA and Ultima Gold AB as scintillant. The alpha spectrum and the background were approximated with sums of exponential terms including the dependence of peak positions and half-widths on quench levels. Deconvolution of alpha spectra was carried out with Origin software. The detection limit was 8.2 mBq/kg for a 0.4 kg water sample for a 1000 minutes counting time, and the alpha detection efficiency was 97.4%.

RadSpectraDec software was developed by Ermakov et al. (2006) to analyze liquid waste, drill water, liquid leakages, potable water, etc. The deconvolution is a recursive minimization of the difference between a weighted multilabel model and experimental spectra. A premeasured spectrum library contains at least 10 model spectra for each radionuclide at different quench levels with CCl_4 as a chemical quench agent. Intermediate spectra are fitted to the required quenching parameters via an interpolation of two of the neighboring reference spectra. The developed approach can be applied to most scintillation cocktails and all modern LS counters with linear and logarithmic amplification, including the Tri-Carb, Quantulus, 1414 Guardian and Triathler. Export of the spectrum libraries to other LSCs is discussed by Ermakov et al. (2006).

The Tri-Carb 3100 LSA achieves an MDA of ~10−20 mBq for beta and 5 mBq for alpha-emitters in a 10 hours counting time. Its energy resolution is ~10% for alpha-emitters, and the PERALS spectrometer has 5% resolution at 150−300 keV.

Sixty alpha and beta labels are now in the spectrum library for the linear energy scale of the Tri-Carb 2550 TR/AB (Ermakov et al., 2006). For example, for the determination of natural decay chains, the following sets of convolved spectra were generated: ^{238}U, ^{234}Th+^{234m}Pa (in equilibrium), ^{232}Th, ^{228}Th, ^{210}Pb, ^{210}Bi, ^{210}Po, ^{235}U, ^{231}Th + ^{231}Pa(equ), ^{228}Ra + ^{228}Ac(equ), ^{234}U, ^{230}Th, ^{226}Ra, ^{226}Ra + ^{222}Rn + ^{218}Po + ^{214}Pb + ^{214}Bi + ^{214}Po (in equil.), ^{224}Ra + ^{220}Rn + ^{216}Po + ^{212}Pb + ^{212}Bi + ^{212}Po + ^{208}Tl (in equil.).

A rapid, 3 hours analysis of a technological sample (wash-out from the disk, "U-1", IRM, Zarechnyi) using the Tri-Carb 3170 TR/SL, ALPHAEX-extraction and Rad-SpectraDec software has been described by Ermakov et al. (2011).

Matzke (2002) investigated the propagation of uncertainties in several unfolding codes.

D. Better energy resolution enables more complete separation

1. Cocktail and sample quench

Resolution can be improved by reducing the aqueous sample to a cocktail mixing ratio which lowers the quench (i.e., increasing number of recorded photons per decay). The sample volume will be reduced in this case and lead to a higher LLD. Purge with oxygen-free, toluene-saturated (when toluene is compatible) argon (McDowell and McDowell, 1994). Extractive cocktails give the best energy resolutions.

The effect of quench is nicely demonstrated by Aupiais et al. (2003) by removing detergent from Ultima Gold AB in comparison with ALPHAEX extractive cocktail. Kossert et al. (2009) used mixtures of nonaqueous cocktails Ultima Gold F with water-miscible Ultima Gold AB, and the ratio 13 mL:2 mL gave the best resolution. Emulsifier in Ultima Gold AB, which does not produce light, was then adequate to accept 1 mL water.

Resolution of alpha spectra from solid samples is severely deteriorated by self-absorption.

2. Vial selection

Order of vial excellence in improving energy resolution: glass, plastic and Teflon vial. Glass vials show strong low-energy tailing due to the multiple reflections, which lead to loss of photons received by the PMTs.

Small vials, 16 mm in diameter and 5 mm in length have produced the best resolutions in PERALS spectrometer (Dacheux et al., 2000; Reboli et al., 2005). This choice does not apply to routine counters, which use 20 and 7 mL vials.

Etching, sandblasting and taping the outside surface of the glass vial improves energy resolution and so does a careful optics design (Verzilov et al., 2002; Kossert et al., 2009; Nähle et al., 2009). Bianchi et al. (2005) tested several vial types (made of glass, standard polyethylene, and high-density polyethylene) for energy resolution. The best results were obtained with teflon-coated, low-diffusion, high-density polyethylene vials from PerkinElmer, which exhibit a low background, high efficiency, good spectral resolution and slow solvent permeability.

3. Lower sample temperature

The counting efficiency is improved at a lower temperature of the sample and cocktail (Homma and Murase, 1987). This method is usually limited to stabilization of sample temperature to a few degrees below ambient using the instrument cooling unit, which also helps in reducing PMT dark current noise.

4. New detector designs

Cassette and Monnard (1999) show a hybrid PMT or HPMT which is composed of a planar silicon diode in a vacuum tube facing a photocathode. This detector is able to resolve multi-photoelectron peaks up to the 11th photoelectron in a scintillation spectrum and the peak resolution is approximately constant. A 15 keV photoelectron produces more than 4000 electron-hole pairs – relative standard deviation of the number of photoelectron pairs is 2%. Even a high gain PMT would reach only a 15% standard deviation.

Large area avalanche photodiodes have been tested (16 mm diameter) by Reboli et al. (2005). Energy resolutions are much improved in the higher energy range, 260 keV (3.9%) energy resolution for ^{216}Po versus PERALS′ 448 keV (6.6%) and ^{232}Th 200 keV (5.0%) versus PERALS′ 210 keV (5.3%). The improved resolution is not due to the higher quantum efficiency of photodiodes compared to PMTs, but to the uniformity of the spatial photo response. Reboli et al. (2005) suggest that even better results would be reached by using green scintillators with larger Stokes shift and blue-enhanced photodiodes.

According to Ivan et al. (2008), the HPMT is complex to operate. Solid-state photo detectors like avalanche photodiode arrays resolve single-photon events, but their actual dark counting rate prohibits their use in LS counters. Ivan et al. (2008) also tested channel photomultipliers (CPMs), which have low and stable dark counting rate and high gain allowing a good peak-to-valley ratio of the photoelectron peak. Contrary to the PMT, the pulse amplitude in a channel photomultiplier is not a function of the number of photons reaching the photocathode. This feature prohibits the use of channel photomultipliers for spectroscopy, which is a useful but not mandatory feature of an LS counter. They also do not reach the PMT performance with the current windows sizes of CPMs.

Xiaolin Hou

Xiaolin Hou is a Full Professor of the Technical University of Denmark (DTU) and Lanzhou University. His primary research interests include radioanalytical chemistry, characterization of decommissioning waste, speciation analysis of radionuclides and its application in environmental and geological sciences, environmental radioactivity and radioecology, measurement techniques of radionuclides including LSC, alpha and gamma spectrometry, ICP-MS, and AMS. Prof. Hou has led and actively participated in more than 30 research projects funded by EU, Nordic, Denmark, China, Norway, and Sweden. He is the author and coauthor of more than 220 papers in peer-reviewed scientific journals with an SCI total citation of more than 3200 times and *h*-index of 32. He has also published one monograph, written six chapters for books. He is now a nominated committee member of the Division of Nuclear and Radiochemistry of the EUChemS, associated editor of the *Journal of Environmental Radioactivity*, and editor board member of Scientific Reports, *Journal of Radioanalytical and Nuclear Chemistry*, and other three journals (e-mail: xiho@dtu.dk).

Xiongxin Dai

Xiongxin Dai earned his B.Sc. and M.Sc. degrees in Radiochemistry from Lanzhou University, China, and obtained a Ph.D. degree from the Institute of High Energy Physics, Chinese Academy of Sciences. He is presently a Principal Radiochemist and Director of the Nuclear and Radiation Frontier Technology Research Center at the China Institute for Radiation Protection. He worked as a postdoctoral fellow at the University of Vienna (Austria) and Oxford University (UK). He was also a senior research associate at Carleton University and Queen's University in Canada. Lately, he was the head of the Radiochemistry Section of Radiological Protection Research Branch at Chalk River Laboratories, Atomic Energy of Canada Limited. His research activities have included radioanalytical chemistry and related applications in the areas of radiological protection, environmental monitoring, environmental sciences, neutrino physics, geochemistry, etc. He has developed numerous radioanalytical methods for rapid and sensitive determination of difficult-to-detect radionuclides in various environmental and biological samples.

I. Introduction

All nuclides that are nowadays present in the environment are either stable or unstable. The stability of any nucleus is determined by the number of neutrons and protons in its structure. A radioactive nuclide, or in short, radionuclide, is an unstable nuclide composed of the nucleus with the out of balance number of neutrons. Such nuclides have excess energy, which they sooner or later loose by decay processes, leading to the emission of gamma rays or subatomic particles, i.e., radiation. Depending on a particular radionuclide, it can either decay to a stable nuclide or another radioactive one, however, the ultimate fate of every radionuclide ever made is to become stable. If we do not count rare processes such as internal transition, a daughter nuclide is always a different element than its parent.

Although more than 100 years have passed since the discovery of radioactivity, many people still believe that radioactivity and exposure to radiation are problems, which emerged with the dawn of the nuclear era in the previous century, first of all due to nuclear weapon explosions and nuclear reactor accidents. Radionuclides are a natural part of the environment; they are continuously produced in the atmosphere, Earth's crust, or brought to our planet from the outer space, e.g., as a part of meteorites. From the place of their production, they can be distributed to other spheres of the environment by different transfer paths. It is not audacious to say that there is no material on Earth that does not contain any radionuclides. Furthermore, all living organisms, including humans take up millions of unstable nuclides by breathing, eating, and drinking every day without even noticing it, though amounts of inhaled/ingested radionuclides can significantly vary, as their concentration is dependent on location and time.

More than 340 nuclides were discovered on Earth, from which more than 90 nuclides are radioactive. Additionally, more than a 1000 nuclides have been synthesized in laboratories, although most of them are unstable. Elements with the atomic number greater than 83 do not form stable isotopes at all, which also applies to technetium ($Z = 43$).

Investigations of radionuclides in the environment have had a long tradition. Actually, we may say that papers published by Maria Curie after the discovery of radioactivity (e.g., on radium, polonium, etc.) were the first dealing with environmental radionuclides. Similarly, the first papers by George de Hevesy discussed environmental radionuclides, which later led to the discovery of natural radionuclides as tracers of environmental processes.

We shall cover in this chapter the analysis of radionuclides in the terrestrial environment as the marine environment is covered in Chapter 5, Volume 2.

II. Environmental radionuclides

All radioactive nuclides found in the environment can be divided into four main categories:

- Primordial—created during the formation of Earth
- Radiogenic—daughter radionuclides of primordial ones
- Cosmogenic—produced by interactions of cosmic ray particles with elements on Earth or in extraterrestrial materials
- Anthropogenic—produced during human nuclear activities

The first three groups could also be called as natural radionuclides, as they all were either formed during the nucleosynthesis (primordial radionuclides) and, because of their long half-lives, they can be still found in the environment or they have been permanently produced in the environment due to decay chains of primordial radionuclides (therefore, we call them radiogenic radionuclides), or they have been permanently produced on Earth by interactions of cosmic ray particles (cosmogenic radionuclides). Anthropogenic radionuclides form a special group produced from time to time by human activities, and not all of them can be found in the environment because of their short half-lives, production mechanisms, or ways of their possible releases to the environment.

An essential condition for the analysis of anything is to comprehensively understand the subject to be analyzed. In the following sections, we shall briefly characterize specificity and relevance of each group of radionuclides mentioned above. While focusing on the most important ones, we shall also describe basic properties, origin, abundance, and general distribution of selected environmental radionuclides, which are routinely analyzed by techniques discussed later in this chapter.

A. Primordial radionuclides

Primordial radionuclides were created about 4.5 billion years ago when the Sun and all planets of our solar system were formed. During the first stage of nucleosynthesis, which consisted of nuclear reactions initiated mainly by protons and alpha particles, the light stable and radioactive nuclides with mass numbers less than 60 were created. Heavier elements, i.e., those with mass numbers between 60 and 90, were primarily produced by capturing neutrons and subsequent emissions of beta particles. Neutron capture reactions also resulted in the formation of the heaviest nuclei ($Z \geq 92$), which could decay by emission of alpha particles or undergo nuclear fission because of high-repulsive Coulomb force. However, only

dozens of primordial radionuclides have survived until now, as most of them having half-lives much shorter than the time that passed since the nucleosynthesis simply decayed. These naturally occurring radionuclides either decay directly to stable nuclides or initiate decay chains (uranium, thorium, and actinium series). Summary of known primordial radionuclides with half-lives less than 1×10^{18} y is presented in Table 3.1. With the exception of ^{40}K, ^{87}Rb, uranium, and thorium, they are insignificant in terms of environmental concentrations and delivered radiation doses.

Due to the high abundance and ubiquity of potassium and due to the relatively high specific activity of ^{40}K (and a relatively short half-life of 1.25×10^9 y), its total activity in the Earth's crust and surface ocean substantially exceeds the cumulative activity of all other natural radionuclides (Table 3.1). The mean concentration of potassium in the lithosphere and surface seawater is roughly 2.09% and 3.99×10^2 mg L^{-1}, respectively, though its concentration in soils can vary substantially (UNSCEAR, 2000). ^{40}K is also present in living organisms with a content of about 0.2% of total potassium, which means that average humans, animals, and plants have approximately 60 Bq kg^{-1} of ^{40}K in their bodies (Yamagata, 1962). The biological half-life of ^{40}K, which is equal to the time of eliminating 50% of the radionuclide activity from the body, is about 30 days. From the chemical point of view, potassium is present in the environment almost exclusively in the form of monopositive cation (K^+), primarily because of its tendency to be easily oxidized. Primordial ^{40}K decays to stable ^{40}Ca while emitting beta particles with the maximum energy of 1.311 MeV or, with a much lower probability, to the excited state of the inert gas ^{40}Ar after capture of a K electron, followed by gamma ray emission with the energy of 1.461 MeV. The latter process is exploited in the K-Ar radiochronometric method, commonly used for dating in geochronology (Dalrymple and Lanphere, 1969; Turner et al., 1994; Schaeffer and Zähringer, 2012).

Natural rubidium consists of one stable, ^{85}Rb, and one radioactive primordial isotope, ^{87}Rb ($T_{1/2} = 4.97 \times 10^{10}$ y), which decays to ^{87}Sr purely by emission of beta particles with the maximum energy of 0.274 MeV. As rubidium is, same as potassium, part of the alkali metals group, they have similar physicochemical properties, leading to a fact that potassium is often replaced by rubidium in various chemical compounds. Moreover, both elements naturally accompany each other in different spheres of the environment. After ^{238}U, ^{232}Th and ^{187}Re, radioactive ^{87}Rb has the third highest specific activity among all primordial radionuclides, and this is the reason why its activity in the Earth's crust and surface seawaters is only one to two orders lower than the ^{40}K activity, even though potassium is much more abundant than rubidium in the respective compartments (Table 3.1). Total activity of ^{87}Rb in a human body (mass of 70 kg), in which it is assumed to behave comparable to potassium, is estimated to be roughly 300 Bq (Yamagata, 1962).

Two primordial uranium isotopes, ^{235}U ($T_{1/2} = 7.04 \times 10^8$ y) and ^{238}U ($T_{1/2} = 4.47 \times 10^9$ y) together with ^{232}Th ($T_{1/2} = 1.40 \times 10^{10}$ y), create three distinctive decay series (Figs. 3.1–3.3), comprising altogether 42 daughter radionuclides and 3 different stable isotopes of lead. The neptunium radioactive decay series is now extinct due to the short half-life (2.14×10^6 y) of the mother nuclide ^{237}Np, leaving only the very last nuclide, ^{209}Bi ($T_{1/2} = \sim 2 \times 10^{19}$ y), as a reminiscence of the existence of the series. The ^{235}U/^{238}U ratio in nature is considered to be stable, meaning that ^{235}U and ^{238}U make 0.72% and 99.27% of all naturally occurring uranium in the environment, respectively. The mean concentration of uranium in the lithosphere is 2.7 mg kg^{-1}. From about 200 of recognized uranium minerals, only several can be found in the form of ore, e.g., uraninite (UO_2), pitchblende (mixture of UO_2 and UO_3) or carnotite ($K_2(UO_2)_2(VO_4)_2 \cdot 3H_2O$). While the amount of uranium in terrestrial waters varies from less than 1 μg L^{-1} to a few mg L^{-1} (Lehto and Hou, 2011), it is quite homogenously distributed in the oceans ($\sim$3 μg L^{-1}). Because of this and the enormous volume of seawater present on Earth (some 1.3×10^9 km^3), oceans have been suggested as a potential future source of uranium for the nuclear industry (Kim et al., 2013; Kuo et al., 2015). Uranium can also undergo spontaneous fission, which leads to the production of fission productions of natural origin, such as ^{90}Sr or ^{99}Tc (Curtis et al., 1999; Tykva and Berg, 2004), though the probability for the process to occur is very low (5.5×10^{-5}% for ^{238}U).

Although an average thorium content in the bedrock (9.6 mg kg^{-1}) is about four times higher than that of uranium, their contribution to the natural radioactivity background is very similar due to much lower specific activity of ^{232}Th (Table 3.1), which represents approximately 99.9995% of the overall mass of thorium. Minerals containing exclusively thorium are very rare and are often found mixed with uranium. Monazite, in which thorium can comprise up to 12%, is considered as the main source of this element (Lehto and Hou, 2011). Unlike the case of uranium, the concentration of thorium in seawater is only $\sim$1 ng L^{-1}, which is roughly three orders of magnitude lower than the typical value for oxic groundwater bodies. In general, thorium is poorly soluble. In seawater, thorium is mostly in particulate form; therefore, it can be found in biological systems mostly in very low amounts. On top of that, removal of thorium from bones was observed to be

TABLE 3.1 Primordial radionuclides and their characteristics.

Nuclide	Half-life (years)	Decay mode	Relative abundance (%)	Specific activity (Bq g^{-1} of element)	Activity in Earth's crust (Bq kg^{-1})	Activity in surface seawater (Bq L^{-1})

After Haynes (2017).

quite slow, leading to its accumulation with increasing age (Eisenbud and Gessel, 1997).

B. Radiogenic radionuclides

As already stated earlier, radiogenic radionuclides are part of three decay series, which all start with decay of primordial isotopes of uranium (^{235}U, ^{238}U) and thorium (^{232}Th). Interestingly, each series contains a radioactive isotope of radon, namely, actinon (^{219}Rn), thoron (^{220}Rn), and radon (^{222}Rn) and ends with a stable isotope of lead. Radiogenic radionuclides are produced by alpha- and beta transformations, though many of these radionuclides are also gamma emitters. Their half-lives cover a wide range, from several hundreds of microseconds (^{212}Po) to hundreds of thousands of years (^{234}U). More than 68% of the world annual average dose can be attributed to products of the radioactive natural decay series (UNSCEAR, 1988); however, only a few of them are really important from the radiological point of view.

In a closed system, activities of mother and daughter radionuclides of natural decay series, which are directly linked through subsequent decay, can reach equilibrium. The difference between the production from decay of its parent radionuclide and its respective decay into a next nuclide is equivalent to the activity of a progeny radionuclide. However, the ultimate condition for such a steady state to occur is that no radionuclides are delivered in or released from the system, which is rarely met in the environment (Ivanovich and Harmon, 1992; Ivanovich, 1994). If the half-life of the parent radionuclide (e.g., ^{210}Pb, $T_{1/2} = 22.6$ y) is substantially longer than the half-life of its daughter (^{210}Bi, $T_{1/2} = 5.01$ d), a so-called secular equilibrium can be achieved, which can be exploited for the

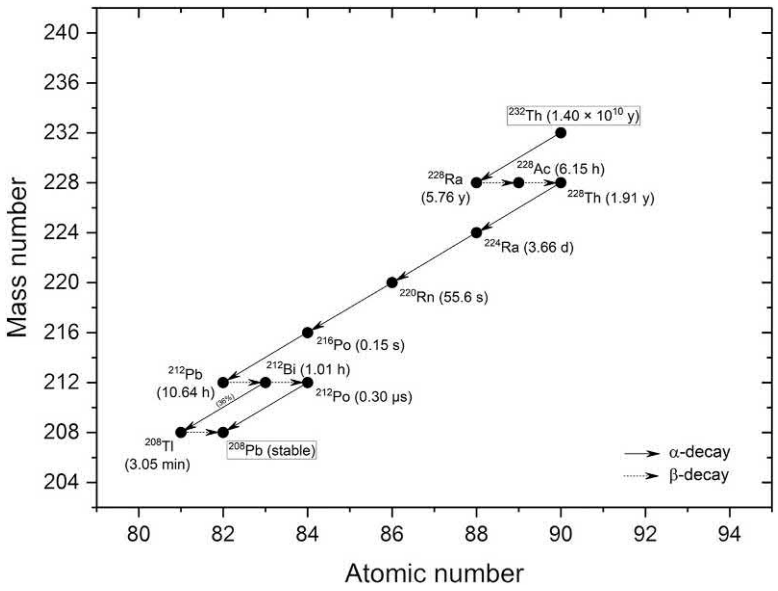

FIGURE 3.1 Thorium (^{232}Th) decay chain.

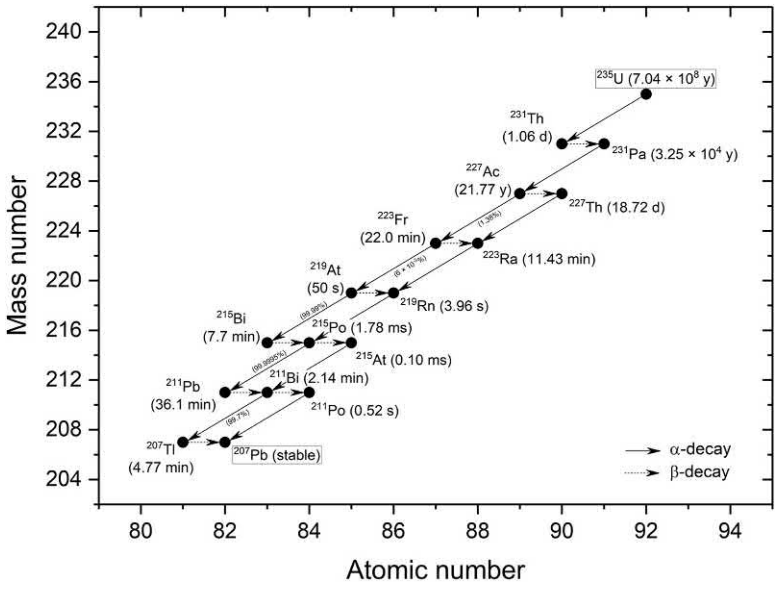

FIGURE 3.2 Uranium (^{235}U) decay chain.

determination of the activity of some hard-to-analyze radionuclides (Larivière and Guérin, 2010). Transient equilibrium is achievable when the half-lives of the mother and its daughter are quite comparable, e.g., in the case of ^{214}Bi ($T_{1/2} = 19.7$ minutes) and ^{210}Tl ($T_{1/2} = 1.30$ minutes), leading to a scenario in which both radionuclides would decay completely during their measurement. On the other hand, if the half-life of the parent radionuclide is shorter than that of the progeny, equilibrium cannot be accomplished under any circumstances.

The first crucial radiogenic radionuclide to discuss is ^{226}Ra ($T_{1/2} = 1.60 \times 10^3$ y), a decay product of long-lived ^{230}Th ($T_{1/2} = 7.56 \times 10^4$ y), which is part of the uranium decay series (Fig. 3.3), and while it is an almost pure alpha emitter, its contribution to the natural radiation exposure is insignificant, the opposite can be said for its beta- and gamma-emitting daughter nuclides. Various amounts of radium can be found in all types of rocks and soils, its mean lithospheric content is ~33 Bq kg^{-1} (Fukai and Yokoyama, 1982). Sandstones and limestones have generally by a factor of 2–3 lower activity concentration of ^{226}Ra than igneous rocks (Rankama and Sahama, 1950). Despite the earlier assumptions, it was shown that the content of ^{226}Ra in waters may be in near

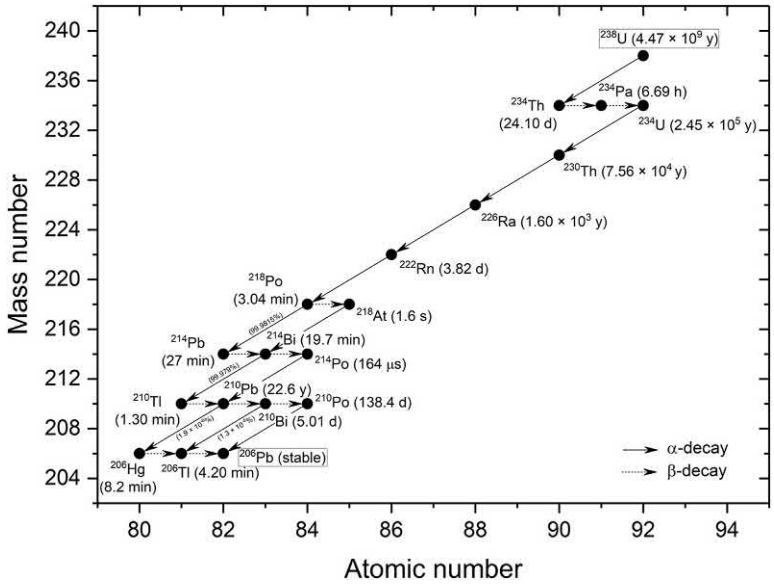

FIGURE 3.3 Uranium (^{238}U) decay chain.

equilibrium with ^{228}Ra ($T_{1/2} = 5.76$ y) originating from the thorium decay series. The mean surface water concentration of ^{226}Ra is much lower if compared to groundwater where it can be as high as around 900 Bq m^{-3} (Hess et al., 1985). The oceans contain even less radium (8.9×10^{-11} mg L^{-1} in average), which means that it is the third least abundant element determined in this particular reservoir. From the chemical point of view, radium is very close to calcium and barium; it is therefore transferred from soil and through the food chain in a similar way. However, due to the considerable variability of radium concentration in soil, its content in foods differs as well.

Even though there are three distinctive isotopes of radon produced in natural decay series, the most important one is ^{222}Rn ($T_{1/2} = 3.82$ d), which is a progeny of ^{226}Ra, discussed above. Radon decays by alpha particle emission, while also generating gamma rays with very low probability (<0.08%). Together with its mainly short-lived daughters (Fig. 3.3), radon's contribution to the world annual dose from background radiation is on the level of 1.2 mSv, representing roughly 50% of the overall dose (UNSCEAR, 1988). After smoking of tobacco products, radon has been recognized as the main source of lung cancer, responsible for tens of thousands of diseases worldwide (Tracy, 2010). Because of this, many countries have established national programs for the reduction of population exposure to radon. Such a nonnegligible effort usually requires conducting an extensive survey to determine radon levels at different places, e.g., at residential areas, like houses, schools, or kindergartens (Müllerová et al., 2016). As an example of results from this type of scrutiny, the mean indoor radon activity concentration of various buildings measured in Central European countries is depicted in Fig. 3.4.

Being a noble (inert) gas and having a relatively long half-life give radon some unique properties. First, it is extremely mobile and can be easily transported through the all spheres of the environment. After radon is generated by decay of solid radium in soil or rocks, it enters the porous system of the geologic body. While a part of the ^{222}Rn decays, the other fraction is either dissolved in water present in the capillary spaces or is released into the atmosphere together with soil gas. Radon can diffuse from soil gas to the air in the atmosphere, though this mechanism is much less relevant. Long-distant transport of radon is also

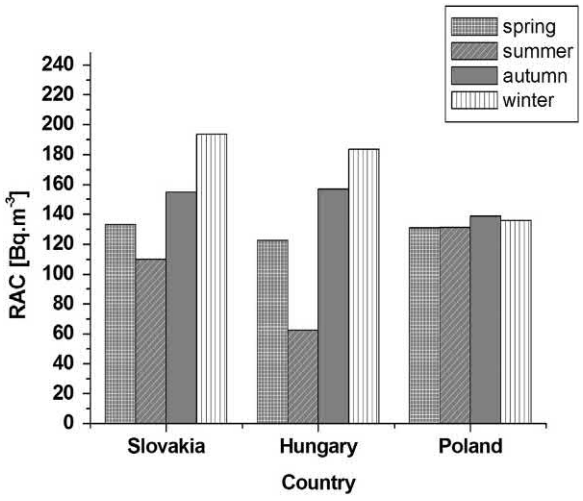

FIGURE 3.4 Mean indoor radon activity concentration (RAC) measured in various buildings in Slovakia, Hungary, and Poland for the whole year. *From Müllerová et al. (2016).* Printed with permission © Elsevier 2018.

possible due to convection or tectonic breaks in rocks. Groundwater content of ^{222}Rn, which depends on the intensity of emanation (release of gaseous decay products) and diffusion, can be quite high because of its good solubility in water, principally controlled by temperature and level of mineralization (Wilhem et al., 1977). It is important to note that spreading of radon through the environment leads to spreading of its more radiologically dangerous daughters as well.

Concentration of ^{222}Rn in the pedosphere, atmosphere, and waters is affected by several different factors. In soil, radon content typically ranges from 4 to 40 kBq m^{-3} (Eisenbud and Gessel, 1997), depending on the content of ^{226}Ra, emanation rate, porosity, and humidity and showing a positive asymptotic correlation with the increasing depth. Great variability, resulting in diurnal and seasonal variations, can be also observed in the case of outdoor radon whose average activity concentration is 3−18 Bq m^{-3} (Masarik, 2009), which is mostly influenced by geographic location, meteorological conditions, and rate of radon exhalation from the soil surface. Increased ^{222}Rn content in groundwater, where a wide spectrum of its activity concentration was found (1−1000 kBq m^{-3}; Hess et al., 1980), is dominantly connected with elevated levels of radium in rock.

Among other progenies of radon, ^{210}Pb with its fairly long half-life (22.6 y) is one of more interesting ones. It is produced via decays of six short-lived alpha and beta emitters, being the mother of ^{210}Po ($T_{1/2} = 138.4$ d). The average content of ^{210}Pb in the atmosphere, where it is readily attached to aerosols and can be transported over long distances before decaying, is about 5×10^{-4} Bq m^{-3} (UNSCEAR, 2000). Furthermore, airborne lead can be effectively washed out by processes of dry and wet deposition, consequently reaching soil, freshwater, and marine reservoirs. Typical rainwater concentration of ^{210}Pb ranges from 37 to 370 Bq m^{-3}, with the mean value of ∼74 Bq m^{-3} (Sýkora et al., 2017). Due to the tendency of toxic lead to accumulate in the human body, absorbed ^{210}Pb is eliminated only slowly, resulting in its deposition in bones (Demayo et al., 1982). Moreover, both ^{210}Pb and ^{210}Po are especially hazardous for tobacco smokers, where their rib content was observed to be by a factor of 2 higher than for nonsmokers (Holtzman and Ilcewicz, 1966).

C. Cosmogenic radionuclides

Cosmogenic radionuclides are continuously produced by interaction of energetic cosmic ray particles with atomic nuclei present in the stratosphere and on the Earth's surface or even beneath it (Lal and Peters, 1967; Gosse and Phillips, 2001). They also include radionuclides induced in situ on extraterrestrial material (meteorites, interstellar dust, moon, planets), which is then driven by the force of Earth's gravity. Cosmic ray particle fluxes consist of primary particles and secondary particles, generated by reactions of the primary ones with the atmospheric nuclei (Fig. 3.5). At ground altitude levels (<3 km), the flux of primary particles is almost negligible, and production of cosmogenic radionuclides is almost exclusively caused by secondary particles (Masarik, 2009). The composition of the cosmic radiation at the Earth's orbit vastly depends on its origin. While galactic cosmic rays (GCRs) are mostly created outside the boundaries of our solar system, solar cosmic rays (SCRs) are emitted from the Sun itself.

Typical GCR flux is composed of protons (∼87%), ^{4}He nuclei (∼12%), high-energy electrons (<1%), and some heavier nuclei with the atomic number between 4 and 26, although the occurrence of even heavier elements was also observed (Simpson, 1983). The average energy of highly penetrating cosmic ray particles is around tens GeV, with

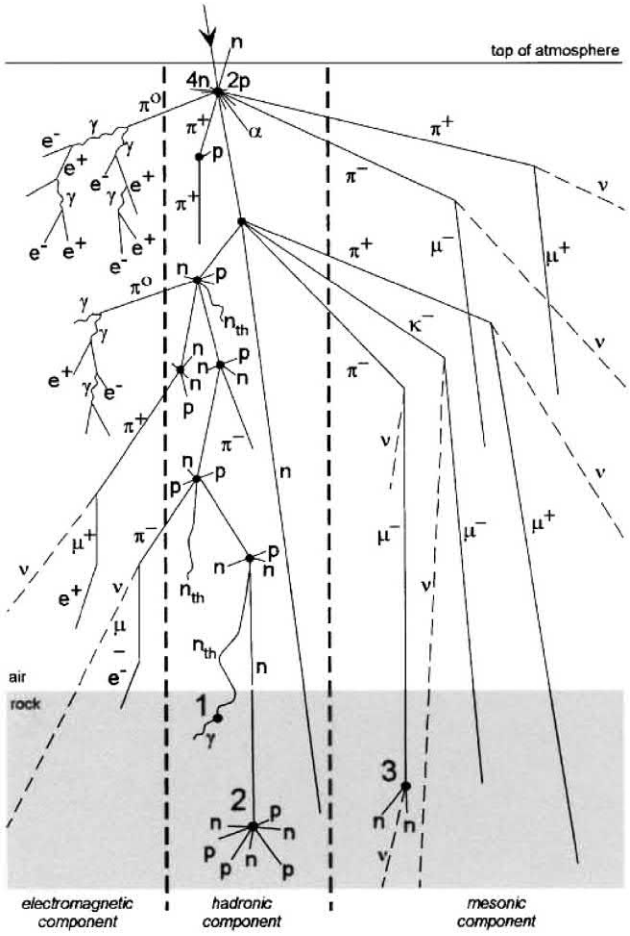

FIGURE 3.5 Production of secondary particles in the atmosphere and rock from cosmic ray extensive air shower. n, neutron; e, electron; p, proton; μ, muon; ν, neutrino; π, pion; γ, photon. Examples of in situ−produced cosmogenic radionuclides: (1) ^{35}Cl(n,γ)^{36}Cl; (2) ^{16}O(n,4p3n)^{10}Be; (3) ^{28}Si(n,p2n)^{26}Al. *From Gosse and Phillips (2001).* Printed with permission © Elsevier 2018.

the maximum energies of as much as 10^{11} GeV, though their spectral distribution is rather similar when compared with units of energy per nucleon. During the past several millions of years, the GCR flux intensity was constant within a factor of 2. On the contrary, the low-energy part of the GCR flux ($E < 1$ GeV nucleon^{-1}) varies significantly due to solar modulation, which is a result of interactions of approaching GCR particles with magnetic fields connected with the solar wind. The modulation becomes less effective with increasing energy of the particles.

In comparison with GCR, the SCR particles produced during solar particle events (e.g., solar eruptions) have substantially lower energy, i.e., on the level of 1−100 MeV. Because of this, they can interact with target nuclei only in the upper part of the atmosphere and at the northern or southern latitudes above 60 degrees where the shielding effect of the Earth's geomagnetic field is much weaker. The SCR particles are primarily composed of protons (~98%) and ^{4}He nuclei (~2%), whereas heavier nuclei or energetic electrons are not part of this type of extraterrestrial flux (Goswami et al., 1988). Strong temporal variations are observed in the case of the total SCR flux, with a mean value determined to be 75−100 nucleons cm^{-2} s^{-1} (Masarik, 2009). Overall, the long-term contribution of SCR to the production of cosmogenic radionuclides is quite small, with an exception when huge solar particle events happen, having a potential to locally enhance the generation of some radionuclides.

As indicated in the previous paragraph, primary and secondary particle fluxes depend on the latitude. The Earth's geomagnetic field and the atmosphere decrease the amount of incoming galactic or solar particles arriving at the surface of our planet. The efficiency of the magnetic fields to shield cosmic ray particles is a function of their energy, angle of incidence, and electric charge. If the particle energy is below the critical value, which is determined by angle of incidence and latitude, it is deflected by the geomagnetic field without reaching the surface. As a consequence, the production of cosmogenic radionuclides is more intensive around the magnetic poles and less intensive in the equatorial area (Lal and Peters, 1967; Masarik and Beer, 2009). Moreover, the altitudinal dependency of cosmic ray fluxes and subsequently the rate, at which radionuclides are produced, was observed as well. Secondary particles, generated by interaction of primary particles with atmospheric nuclei, have usually enough energy to propagate a hadronic cascade, resulting in the production of several generations of secondary particles. In this manner, the production intensity of induced cosmogenic radionuclides is maximal at the altitude of approximately 12−16 km, while steadily decreasing down to the sea level.

While there are tens of different cosmogenic radionuclides constantly produced, only part of them are truly interesting (Table 3.2). Their half-lives are of a wide range, from minutes (e.g., ^{34m}Cl) to more than 1 million years (^{10}Be). Cosmogenic radionuclides generated in the atmosphere act according to their physicochemical properties. In the gaseous form or as attached to aerosol, they are distributed by motion of air masses, and due to stratosphere−troposphere transport, they get to the lower parts of the atmosphere, and finally, they can be absorbed

TABLE 3.2 Characteristics of cosmogenic radionuclides.

Nuclide	Half-life	Decay mode	Production rate (10^{-3} atoms cm^{-2} s^{-1})[a]	Global inventory (PBq)[b]	Average concentration (10^{-3} Bq kg^{-1})[c]	
					Troposphere	Seawater
^{3}H	12.32 years	β^-	320	1300	1.2	7×10^{-1}
^{7}Be	53.28 days	EC	40	410	10	660

by precipitation droplets and deposited on the Earth's surface. Therefore, the amount of precipitation can have significant influence on the concentration of these radionuclides at a particular site. On the other hand, some cosmogenic radionuclides have such short half-lives that they decay soon after their production; thus, they are irrelevant for scientific studies. The most salient cosmogenic radionuclides present in the environment are ^{3}H, ^{7}Be, and ^{14}C.

The heaviest naturally occurring isotope of hydrogen, tritium (^{3}H or T), is produced mainly in the lower parts of the stratosphere by the interaction of neutrons or protons with nitrogen and oxygen, i.e., dominantly in ^{14}N(n,T)^{12}C or ^{16}O(p,T)^{14}C reactions. Tritium is a pure beta emitter ($E_{max} = 18.6$ keV) with the relatively long half-life of 12.31 y, which enables its distribution through all spheres of the environment. Atmospheric tritium can be found in the form of gaseous water vapors (mostly as HTO or T_2O), molecular hydrogen (HT or T_2), and methane (e.g., CH_3T), all of which are easily incorporated into living organisms (Vichot et al., 2008). However, because tritiated methane is created in very low amounts and molecular hydrogen is rapidly oxidized into water, the only important form of ^{3}H in the atmosphere are water vapors (HTO), which participate in the hydrological cycle. As a part of water vapors, tritium is transferred onto the Earth's surface by precipitation and exchange between the atmospheric moisture and hydrosphere. Since diffusion characteristics of H_2O and HTO are almost the same, tritium is also found in groundwater. Activity concentration of tritium in waters is often expressed in tritium units (TU), where 1 TU is equivalent to the activity of 0.119 Bq L^{-1} or ^{3}H/^{1}H isotopic ratio of 10^{-18}. This roughly corresponds to the level of ^{3}H in large lakes and precipitation above oceans before the nuclear weapon testing era.

Generation of fairly short-lived ^{7}Be ($T_{1/2} = 53.28$ d) in the atmosphere is achieved by several spallation reactions on nitrogen and oxygen nuclei, e.g., ^{14}N(p,2α)^{7}Be, ^{14}N(n,^{8}Li)^{7}Be, or ^{16}O(n,^{10}Be)^{7}Be. Since these spallation reactions need high-energy incident particles, the majority (70%) of beryllium is created in the stratosphere by GCRs, whereas the rest in the troposphere by secondary particles or SCRs. After its production, ^{7}Be is converted to oxide or hydroxide form and adsorbed on aerosol in the accumulation mode, usually with the size of 0.04–2.0 μm and activity median aerodynamic diameter of 0.09 μm (Papastefanou and Ioannidou, 1995). Due to vertical mixing of stratospheric and tropospheric air masses, cosmogenic beryllium is transported to the lower parts of the atmosphere. Activity concentration of ^{7}Be near the surface shows typical seasonal variations with distinctive minima in winter and maxima in summer, for the most part caused by wet deposition (precipitation), vertical transport in the troposphere, seasonal shift of the tropopause, and horizontal movement of air masses. Furthermore, a strong correlation between the 11-year solar cycle and ^{7}Be concentration was also documented (Azahra et al., 2003). Radionuclide ^{7}Be decays via electron capture (EC) to ^{7}Li, emitting gamma rays ($E_\gamma = 477.6$ keV) with the 10.3% probability.

Radiocarbon ^{14}C ($T_{1/2} = 5730$ y) is by far the most studied cosmogenic radionuclide, which decays to stable nitrogen by emission of beta electrons ($E_{max} = 156$ keV). The most likely production route for radiocarbon is the interaction of neutrons with stratospheric nitrogen, that is ^{14}N(n,p)^{14}C. Other types of reactions, e.g., ^{16}O(n,^{3}He)^{14}C, ^{15}N(n,d)^{14}C, or ^{13}C(n,β)^{14}C, are also possible; however, their production rates are by at least three orders of magnitude lower (Schopper et al., 1967). The overall average production rate of natural ^{14}C in the atmosphere was calculated to be 2.05 atoms m^{-2} s^{-1} (Masarik and Beer, 2009), peaking at the geomagnetic pole areas. Due to rapid and thorough mixing of the atmospheric masses, radiocarbon concentration is very similar in all regions, regardless the latitude. Similarly to other cosmogenic radionuclides, the production of ^{14}C varies with the solar activity. Results of tree ring analyses clearly showed increased radiocarbon concentrations during the solar minima (Damon et al., 1989). Additionally, a correlation between ^{14}C content and 11-year solar cycle was observed in wines as well (Burchuladze et al., 1980).

Once produced, radiocarbon is quickly oxidized to $^{14}CO_2$, transported into the atmospheric boundary layer, hydrosphere, and, by photosynthesis, into the biosphere. As the long-term production of cosmogenic ^{14}C is practically steady, all living organisms contain about the same amount of ^{14}C (0.225 Bq g^{-1} C), which is exponentially depleted after their death, following the decay of radiocarbon, thus making it exploitable in radiocarbon dating (Libby, 1961). The ratio of cosmogenic radiocarbon to stable isotopes of carbon in the atmosphere is equal to

$$\frac{[^{14}CO_2]}{[^{12}CO_2] + [^{13}CO_2]} = 1 \times 10^{-12} \qquad (3.1)$$

where $[^{12}CO_2]$, $[^{13}CO_2]$ and $[^{14}CO_2]$ are equilibrium concentrations of the respective carbon dioxides present in the air. From the total global inventory of cosmogenic radiocarbon, the vast majority (~90%) is deposited in oceans, where its mean content is around 1.2×10^{9} atom L^{-1}. The rest of the radiocarbon is mainly distributed in the biosphere and atmosphere (Broecker and Peng, 1982).

The equilibrium concentration of radiocarbon in the environment, expressed by Eq. (3.1), was severely disturbed by different anthropogenic activities, whose effects were especially notable in the previous century. Massive combustion of fossil fuels, which started with the dawn of the industrial era, has been introducing large

amounts of ^{14}C-free carbon dioxide. As a result, the radiocarbon activity concentration in the atmosphere and consequently in the whole environment has been diluted. The observed Suess effect (Suess, 1955) has both impacts on a local/regional and on global scales. It is also one of the main reasons of seasonal variations of atmospheric radiocarbon. Opposite to the Suess effect, nuclear weapon testing and nuclear industry, whose influence is discussed in the next subchapter, have produced significant amounts of radiocarbon, overwhelming its activity from natural sources.

D. Anthropogenic radionuclides

Since the discovery of artificial radioactivity some 80 years ago, plentiful human activities have led to production of hundreds of different radionuclides of various half-lives, part of which has been eventually released to the environment. Therefore, anthropogenic radionuclides can be defined as all radionuclides that originate from anthropogenic sources. This not only includes artificially prepared radionuclides, which have not been detected in nature by present analytical techniques, but also those whose natural levels have been substantially increased as a consequence of intended human actions (e.g., nuclear weapon tests in the atmosphere, nuclear accidents) (Livingston and Povinec, 2000, 2002). The latter group mainly consists of long-lived radionuclides from uranium fission. Conveniently, anthropogenic radioactivity also includes so-called technologically enhanced naturally occurring radioactive materials (TENORMs), produced when dealing with naturally occurring radioactive materials (NORMs).

A lot of human activities can result in the modification of NORMs into TENORMs, which may lead to elevated concentrations of NORMs in by-products, end products, or even waste. Consumers and workers can be thus exposed to higher radiation doses. During extreme environmental situations, such as working in space or high-altitude flights, cosmic radiation can cause increased radiation exposure as well. Materials with increased concentration of natural radionuclides, namely uranium, thorium, and radium isotopes, and their respective progenies, are generally created due to change in environmental conditions, which result from the application of different processes. For example, groundwater extraction from aquifers may induce precipitation of salts containing increased amounts of ^{226}Ra, or sedimentation of NORMs can enhance their content of natural radionuclides. Similarly, NORM activities in slime and fines can be further increased by some fractionation processes (Paschoa and Steinhäusler, 2010). The issues of TENORMs are common in several types of industries, such as oil and gas industry, metal (uranium) and mineral mining, fertilizer and building material production, or water treatment.

Although many nuclear activities have caused the addition of anthropogenic radionuclides into the environment, only some of the activities have contributed in significant amounts. The largest contribution by far can be attributed to atmospheric nuclear weapon testing (mainly during the 1950s and early 1960s of the previous century), which resulted in production of huge amounts of radionuclides and their dispersion all over the globe due to air transport processes in the atmosphere. Continuous development in the field of nuclear energy has increased the number of nuclear reactors worldwide. Despite the fact that they can generate and possibly release a wide spectrum of radionuclides (fission products, transuranics, and activation products), the local impact of a normally operating nuclear power plant (NPP) on the environmental radioactivity level is barely measurable, which unfortunately does not apply in the case of nuclear accidents. While nuclear fuel reprocessing facilities represent another important source of anthropogenic radionuclides, the influence of various applications of radiation sources in industry, medicine, and science is negligible.

1. Nuclear weapons testing

Depending on which type of nuclear reaction occurs during their detonation, nuclear weapons can be classified into fission and fusion weapons, commonly referred as atomic and thermonuclear weapons. The former exploit uncontrolled chain fission of heavy nuclei (^{235}U, ^{239}Pu) into the lighter ones, the principle of the latter is based on fusion of light nuclei (deuterium, tritium, lithium), usually triggered by fission. Nuclear weapon explosion yield is generally expressed in equivalent mass of trinitrotoluene (TNT), i.e., the explosion of a 1 kt nuclear weapon would have the same destructive effect as if we would detonate 1 million of kilograms of TNT at once. The power of nuclear weapons seems even more enormous when one realizes that only tens grams of plutonium or uranium are needed to achieve the effect mentioned in the previous sentence.

Explosions of nuclear weapons are extremely fast processes. Almost all energy stored in nuclei to undergo fission or fusion is released within less than 1 μs and transformed into the form of blast (50%), thermal radiation (35%), and ionizing radiation (15%). While one-third of the ionizing radiation is emitted as gamma rays and neutrons in a few seconds after the explosion, the remaining part, representing 10% of the total released energy, can be attributed to the decay of induced radionuclides from the surrounding atmospheric or terrestrial material and fission products. At any given time t, the radioactivity in the location of nuclear weapon detonation A can be approximately calculated as

$$A = A_0 t^{-1.2} \tag{3.2}$$

where A_0 is the initial activity (Eisenbud and Gessel, 1997). Eq. (3.2) is a reasonable estimate for months after the explosion occurred ($t \leq 180$ d). It is worth to note that this calculation strongly depends on the yields of the radionuclides, generated during the nuclear burst.

More than 200 radionuclides of 35 elements are part of the initial fission product mixture, originated from a nuclear weapon detonation, though most of them are short-lived and decay soon after the explosion. The produced radioactive material comprises three distinctive fractions, depending on the explosive yield and height of the burst. The first group is primarily composed of large particles, which are highly radioactive and tend to fall out within several hours. Smaller particles dispersed in the troposphere usually contribute to fallout only after some time, as they behave in a similar way as aerosols, which are subject to specific laws of deposition. The last fraction of particles enter the stratosphere with the residence time of several years, meaning that they can be distributed all over the globe, and thus creating global radioactive fallout (Livingston and Povinec, 2002; Hirose and Povinec, 2015).

In the case of underground nuclear weapon tests, the contribution to global fallout is much smaller; however, gaseous products, such as ^{133}Xe and ^{85}Kr, can still vent through the ground, and eventually reach the atmosphere. The most salient long-lived global fallout radionuclides are summarized in Table 3.3.

The very first nuclear weapon was detonated on a desert of New Mexico in the United States in July 1945. Since then, more than 400 atmospheric tests were conducted by the United States, Soviet Union, United Kingdom, France, and China (Table 3.4). Additionally, hundreds of nuclear devices were detonated underground after 1963, when the United States, the United Kingdom, and Soviet Union signed a nuclear weapon test-ban agreement for atmospheric testing, though France, China, nor India did join the treaty and later conducted several detonations in the atmosphere. The number of underground tests vastly exceeded those made in open air, e.g., the United States alone made more than 800 tests in Nevada (Eisenbud and Gessel, 1997). With the exception of the abovementioned countries, Pakistan and North Korea declared to successfully test nuclear weapons. As the majority of the tests were performed in the Northern Hemisphere, radionuclides from global fallout were distributed mainly in the northern latitudes.

TABLE 3.3 Anthropogenic radionuclides in global fallout.

Radionuclide	Half-life (year)	Decay mode/energy (MeV)	Global fallout (PBq)[a]

2. Nuclear reactors

The main principle of the peaceful use of atomic energy in NPPs is controlled chain fission reaction of nuclei of specific elements, such as uranium, plutonium, and thorium (Fig. 3.6). The most common type of nuclear fuel contains enriched uranium, i.e., uranium oxide (U_3O_8) with the content of ^{235}U up to 3%–4%. It is produced in the form of ceramic pellets, which are sealed in resistant metal (e.g., zirconium alloy) tubes, bundled together into a nuclear fuel assembly. An assembly lasts usually for 3–4 years when it is necessary to replace it with the fresh one.

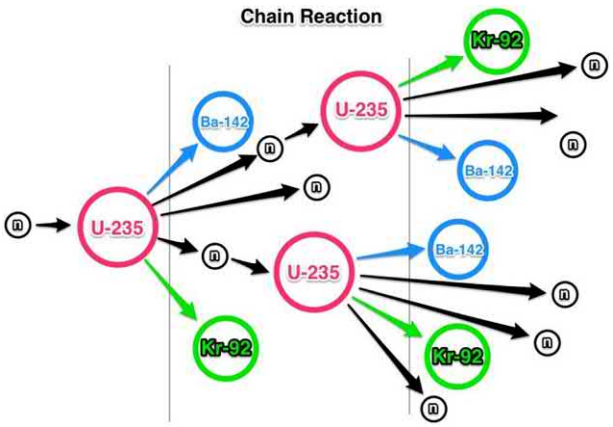

FIGURE 3.6 Fission chain reaction. For the color version of the figure, the reader is referred to the online version of the book. *From Costa et al. (2017).* Printed with permission © Elsevier 2018.

In the case of ^{235}U or ^{239}Pu, the fission yield is the highest when induced by thermal neutrons (<0.1 eV). Therefore, neutrons, which are generated as a result of fission and can have energies above 10 MeV, are needed to be slowed down. This is achieved with the use of a so-called moderator, present in-between the fuel assemblies or as a part of the nuclear fuel.

Moderation is based on elastic collisions of fission neutrons with nuclei of light elements, e.g., hydrogen, deuterium, or carbon. Light water, heavy water (D_2O), and graphite are nowadays the most frequently exploited moderators, depending on a reactor type. The criticality of the chain reaction is sustained by movement of controlled rods, composed of material able to absorb fission neutrons. The heat is generated by decay of fission products, their collision with nearby nuclei, and absorption of gamma rays, which is transferred from the reactor by a coolant. Numerous types of coolants have been developed, which can be in the form of gas (CO_2, N_2, He), liquids (H_2O, D_2O, hydrocarbons), or even molten salts (fluorides) and molten metals (Na, K, Hg) for advanced nuclear reactors (Breeze, 2016). The large majority (65%; IAEA, 2018) of world's NPPs are constituted by pressurized water reactors (PWRs), which use light water for both moderation and cooling.

Hundreds of radionuclides produced during normal operation of a nuclear reactor, which are mostly short-lived and decay within minutes or hours, comprise fission products (and their daughters), activation products, and transuranics. Because primary fission products have an excess of neutrons, they decay via consequent beta transmutations to stable nuclides, while often emitting gamma radiation. Tens of these decay chains occur simultaneously during operation, increasing the activity of fuel assemblies and determining the composition of the spent nuclear fuel (SNF). Plutonium ^{239}Pu is formed by parasitic capture of a neutron on ^{238}U, which is inherently present in the nuclear fuel based on (enriched or natural) uranium and has very low fission yield, followed by two subsequent beta decays of ^{239}U and ^{239}Np. Other heavier transuranics (e.g., ^{240}Pu, ^{241}Am, ^{242}Cm) are generated by additional neutron capture or beta decays. The average content of fission radionuclides and transuranics in a typical nuclear fuel assembly is given in Table 3.5.

The last group of radionuclides created in a running nuclear reactor is represented by activation products that are generated by nuclear reactions on stable nuclei of coolant, moderator, and construction materials of the reactor in (n,p), (n,α), (n,2n), or (n,γ) reactions. Unlike fission products, activation products are not part of decay chains and usually decay to stable daughters by a single beta emission. The variety of these radionuclides is affected by the presence of miscellaneous trace impurities in the structural components, which have a high cross section for neutron interactions. The most abundant activation product

TABLE 3.5 Content of selected radionuclides in a typical thermal reactor after two-thirds of the fuel campaign.

Radionuclide	Half-life	Specific fuel activity (MBq g^{-1})

After Clarke and MacDonald (1978).

is ^{60}Co ($T_{1/2} = 5.27$ y), created principally by the reaction ^{59}Co(n,γ)^{60}Co, and—to much lesser extent—in the reaction ^{60}Ni(n,p)^{60}Co, as well as captures of thermal neutrons on other isotopes of nickel, which is contained in the stainless steel, used for nuclear reactors. This strong gamma emitter can also be found in the coolant, in which it may be dispersed due to corrosion of construction materials. Other noticeable long-lived activation products are ^{3}H, ^{14}C, ^{55}Fe ($T_{1/2} = 2.74$ y), and ^{94}Nb ($T_{1/2} = 2.03 \times 10^{4}$ y), some of which are reviewed below.

If the nuclear reactor is operating under standard conditions, amounts of radioactive substances discharged into the environment are very low and may impact it only locally. Gaseous and liquids releases from NPPs contain direct fission products or radionuclides produced by activation. Even though the former should be hermetically sealed in the fuel assemblies, they may diffuse or leak into the coolant because of microscopic ruptures in the casing. Ubiquitous uranium on the surface of fuel rods or some other reactor elements may contribute to the unwanted presence of fission radionuclides as well. For PWRs, this means that the contamination can be spread through the whole primary loop; however, cleaning systems are used to remove these radionuclides for disposal, effectively reducing potential releases in the case of accident.

Since the successful launch of Fermi's reactor in Chicago in 1942, hundreds of nuclear reactors have been commissioned, either for commercial purposes of electricity generation, production of plutonium for nuclear weapons, and research or to power ships and submarines. Currently, there are 448 land-based nuclear power reactors in operation, with the cumulative installed electric capacity of about 390 GW_e, and with 59 new reactors under construction (IAEA, 2018). Approximately 25−30 t of highly radioactive SNF is produced per 1 GW_e (Macfarlane and Miller, 2007), meaning that some 11,000 t of SNF has been already created worldwide.

3. Nuclear fuel reprocessing plants

Commercial facilities for nuclear fuel reprocessing are nowadays the most significant prevailing sources of anthropogenic radionuclides (fission products of uranium and plutonium, activation products) in the global atmosphere. Reprocessing itself is conducted in several general steps. After removal of the fuel assembly from the nuclear reactor, it requires storage for months or more, so that its activity is lowered enough (by decay of short-lived radionuclides) that it can be transported to the facility and consequently reprocessed. First, the cladding of a fuel assembly, which acts as an ultimate barrier for radionuclide releases from nuclear fuel, is removed. By doing this, radionuclides (mainly isotopes of krypton, iodine, and tritium) in the gaseous form are released into the air. SNF is then divided into smaller parts and chemically dissolved. Residual uranium, plutonium, and other transuranics, together with fission products, are sequentially extracted with the use of radiochemical separation techniques and reagents. All worthless radionuclides end in the radioactive waste, which is further processed before being finally disposed.

Although low- and intermediate-level radioactive wastes are generated during reprocessing of SNF as well, high-level wastes, which may contain up to 99% of all fission products and transuranics, are much more problematic from the environmental point of view. Precise composition of these wastes depends on the reactor, from which the SNF was taken, and on the type of reprocessing. Besides radioactive substances (fission products, uranium, transuranics, activation products), they can also contain nonactive components, such as chemical reagents, corrosion products, or products of radiolysis.

Due to economic and technological constrains and potential environmental risk, there are only a small number of running nuclear fuel reprocessing plants. In Europe, the largest commercial facility is located in Sellafield (Great Britain) that is capable of reprocessing 2400 tHM y^{-1} (metric tons of heavy metal per year). The second plant is situated in La Hague (France), which is in operation since 1976 and has the capacity to process 1650 tHM y^{-1}. Additional plants are running in Mayak (Russia) and Kalpakkam (India), with the annual capacity of 400 tHM and 275 tHM of SNF, respectively. More facilities are in test periods, under construction, or planned in Japan and China (Hu et al., 2010). Atmospheric and liquid discharges from nuclear reprocessing plants in Europe are regularly monitored, especially the content of long-lived radionuclides (mainly ^{99}Tc, ^{129}I, ^{137}Cs, and plutonium isotopes).

4. Nuclear accidents

High requirements on the radiation safety of the NPP operation have been constantly increasing, mainly as a consequence of the accidents, which happened in the past. Despite the previous statement, NPP accidents have occurred again in recent times. Therefore, it is evident that further development and advancement in safety protocols and technologies will be necessary to avoid such catastrophic events and their outcomes, as in the case of the Chernobyl and Fukushima NPP accidents.

a. Three Mile Island (United States)

One of three most serious NPP accidents happened on March 28, 1979, at the Three Mile Island (TMI) site in the United States, when it was proven that even a relatively small mishap can cause severe consequences. Malfunction of a relief valve of a pressure vessel led to a series of unfortunate events (misjudgments of the reactor operator,

inappropriate manipulation with some devices and malfunction of others), which culminated in a loss-of-coolant accident and ultimately in melting of about 50% of the PWR reactor core. Large amounts of highly radioactive steam and water were released from the pressure vessel of the reactor into the containment. It was estimated that at maximum 480 PBq of radioactive gases (mostly ^{133}Xe) together with ~0.5 TBq of ^{131}I was vented to the atmosphere (Livingston and Povinec, 2000). The immediate determination of the environmental contamination was difficult, as the measuring range of the outer monitoring systems was surpassed.

Fortunately, the radiological impact of the TMI accident on the human population was insignificant. The highest doses, which were received by less than 300 people within ~3 km from the NPP, were estimated between 0.2 and 0.7 mSv (Gerusky, 1981). Such values would have a probability to cause one or two fatal cancer diseases for the whole exposed population (about 2 million of individuals in the distance of ~80 km). The exposure from ingestion or inhalation was much lower, and the highest dose from ^{131}I, which entered the body, was calculated to be around 0.05 mSv.

b. Chernobyl (Ukraine) nuclear power plant accident

The accident at the Chernobyl NPP in Ukraine (formerly Soviet Union), which occurred on April 25, 1986, was caused by several factors, though the main contribution can definitely be attributed to the human one. As a result of several thoughtless actions (extraction of manual control rods and violation of the rule about their minimal number, lowering the coolant inflow, disconnection of the automatic regulation for criticality adjustment, etc.) during the experimental test whether the reactor system would be able to continue operation in case the steam supply to turbines would be interrupted, the RBMK reactor reached the supercriticality state with the immediate evaporation of water coolant. The enormous pressure caused fuel channels to rupture. Hydrogen-oxygen mixture, produced from the exothermical reaction of the steam and zirconium, induced the second explosion. As a consequence, the graphite, which was used as moderator in the reactor, got ignited and the top of the reactor vessel was destroyed (Fig. 3.7). Radioactive emissions from the damaged reactor persisted for some 2 weeks after the accident. The damaged nuclear reactor was later enclosed in the concrete-iron sarcophagus (Fig. 3.8), which has recently been covered with a metallic cover (a dome, Fig. 3.9) to prevent further leakage of radionuclides to the environment.

The releases of radioactive substances to the atmosphere were indeed immense. For example, the ^{137}Cs aerosol activity in Bratislava (Slovakia, Central Europe) was increased by five orders of magnitude when in comparison

TABLE 3.6 Reactor core inventory of the Chernobyl nuclear power plant on April 26, 1986, and amounts of radionuclides released after the accident (OECD, 2002).

Radionuclide	$T_{1/2}$	Activity (PBq)	Total released activity (PBq)
^{90}Sr	28.8 years	200	10
^{131}I	8.0 days	3200	1760
^{133}Xe	5.3 days	6500	6500
^{137}Cs	30.05 years	280	85
^{239}Pu	2.41×10^4 years	0.85	0.03
^{240}Pu	6560 years	1.2	0.042

with the pre-Chernobyl data (Povinec et al., 1988). Radionuclides from the Chernobyl NPP accident could be detected all over the Northern Hemisphere. On the other hand, because the releases contaminated only the troposphere, no signal was detected in the Southern Hemisphere. It was estimated that the whole inventory of noble gases (radioisotopes of Xe and Kr) was emitted from the melted reactor core, together with 10%–20% of the inventory of tellurium, iodine, and cesium radioisotopes. The overall activity released to the air was estimated to be more than 12,000 PBq (Table 3.6).

To correctly evaluate the radiological effect of the Chernobyl NPP accident, it was necessary to consider the area of the affected land. Four separate areas were assessed: the NPP site and its near vicinity, the zone within 30 km from the site, the European part of the Soviet Union beyond the 30 km zone, and the European states outside of the Soviet Union. The mean whole-body dose for individuals from the 30 km zone was estimated to be 15 mSv. In-between 1986 and 1989, the population living in the Soviet Union beyond the 30 km zone was exposed to the dose of about 40 mSv. From more than 200 patients, who were professionally engaged in works during the accident and who were diagnosed to suffer acute radiation sickness, about 100 died. The obtained doses for the rest of Europe were relatively low (tens of μSv) and strongly dependent on the geographic location and rate of precipitation at the time of the accident (OECD, 2002).

The difficulties also arose for the land areas, contaminated by deposited radionuclides from the Chernobyl fallout, mainly ^{137}Cs, and in a minor way ^{90}Sr and plutonium isotopes (Fig. 3.10). The most affected countries were the Ukraine and Belarus, where the area of roughly 10,000 km^2 (mostly in Belarus) was contaminated with radiocesium at the level of more than 550 kBq m^{-2}, whereas for 3000 km^2, this value was greater than 1480 kBq m^{-2} (IAEA, 1996). A large part of the area

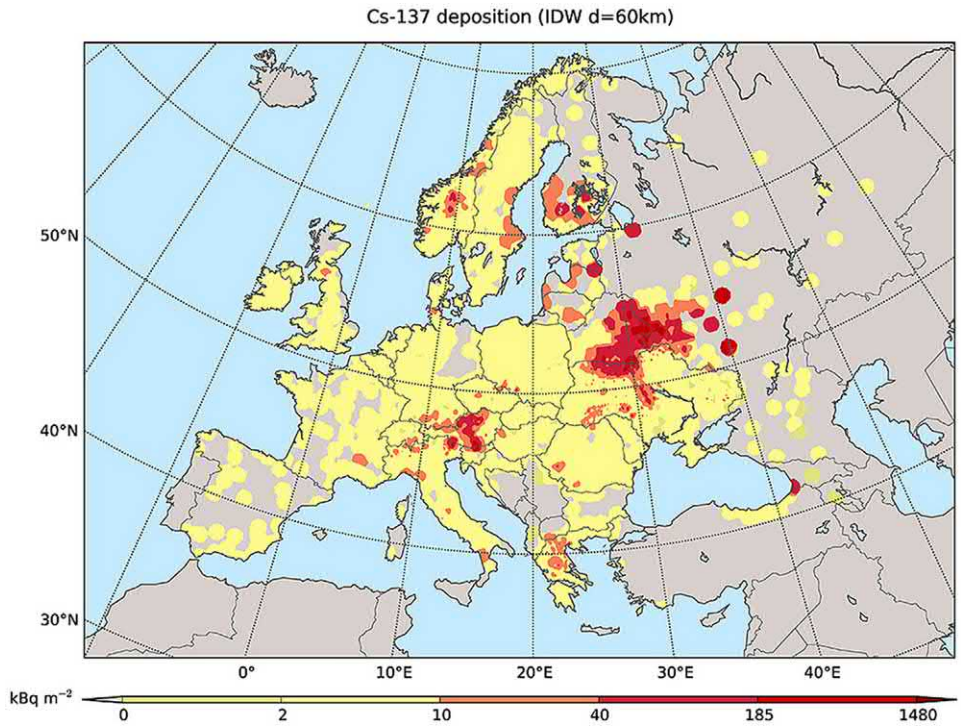

FIGURE 3.10 Total deposition of ^{137}Cs over Europe, irrespective to the source. Orange and red areas (>10 kBq m^{-2}) can be attributed to the Chernobyl nuclear power plant (NPP) accident origin. contaminated by radiocesium was used for agricultural purposes; thus, effective measures had to be implemented to lower the dose rate. This included adding potassium, liming soils, removal of livestock from affected pastures, decontamination in food production, and deep plowing.

c. Fukushima (Japan) nuclear power plant accident

On March 11, 2011, the Tōhoku earthquake (the magnitude of 9.0) with the epicenter located some 130 km offshore of the eastern coast of Japanese islands caused large tsunami waves, which among others struck the Fukushima Dai-ichi NPP, approximately 40 minutes after the most powerful tremor. The Fukushima NPP site was flooded with seawater, reaching the height of 15 m. Because the earthquake damaged transmission facilities, the NPP lost connection to electricity from the outer grid. On top of that, almost all backup power generators were completely destroyed, mainly because of the fact that they were situated below the sea level. Consequently, the cooling systems of the shutdown boiling water reactors (BWRs) in units 1−3 had to be connected to batteries; however, after a relatively short time, the batteries got depleted and the cooling systems were once again without power. Because the reactor cores continued to generate heat, which was critical to transfer, water was pumped into the reactor vessels. Several hours later, the first explosion occurred in unit 1, which was caused by accumulated hydrogen, created in the reaction of steam and zirconium. The situation in unit 2 was similar; however, the explosion at the top of the reactor building was averted by early measures. Unit 3 followed exactly the fate of unit 1, while part of the hydrogen generated here leaked even into unit 4, where another explosion occurred a bit later. The Fukushima accident thus represents the largest accident of NPP observed till now (Fig. 3.11), although total radionuclide releases were smaller when compared with the Chernobyl accident.

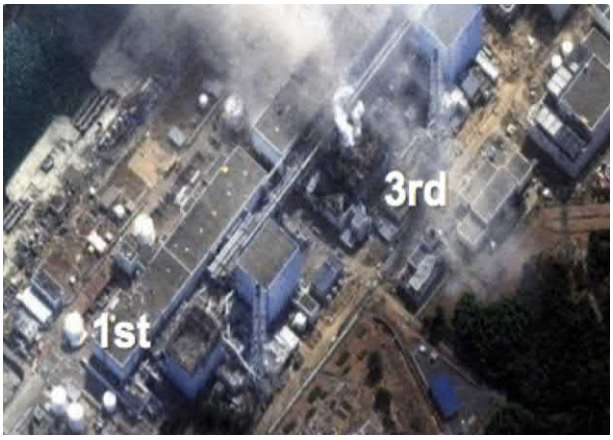

FIGURE 3.11 Damaged Fukushima nuclear power plant (NPP) after the reactor accidents. For the color version of the figure, the reader is referred to the online version of the book. *From Povinec et al. (2013a).*

As a result of the events described above, significant amounts of radioactive substances were released to the environment during the Fukushima NPP accident. The reactor core inventories contained a wide spectrum of radionuclides, though early monitoring was focused primarily on noble gases, ^{131}I, and radiocesium (^{137,134}Cs). First reasonable estimates showed that 160 PBq of ^{131}I and 15 PBq of ^{137}Cs were discharged to the atmosphere (Povinec et al., 2013a). Fig. 3.12 shows the estimated surface ^{137}Cs contamination in the Fukushima region. Atmospheric releases from the Fukushima NPP, recently reviewed by Hirose (2016), are given in Table 3.7.

Regarding the radiological effect of the Fukushima accident, received doses to NPP workers and population living in the vicinity of the site were low, except for a few cases. No individual suffering from acute radiation sickness was diagnosed. Six employees at the NPP were exposed to the dose greater than 250 mSv. Almost 200,000 people, who were screened until May 2011, showed no symptoms, which could be connected to radiation exposure (Povinec et al., 2013a).

The releases of radionuclides from the Fukushima NPP were detected all over the world (Masson et al., 2011; Nakano and Povinec, 2012; Povinec et al., 2012a,b,c, 2013a,b,c,d,e, 2017; Nakanishi and Tanoi, 2013; Povinec and Hirose, 2015; Hirose and Povinec, 2018). Determinations of activities of ^{131}I and radiocesium in atmospheric aerosol collected in Bratislava, which were conducted in the period shortly after the accident, suggested that at least three radioactive plumes arrived in Bratislava. Moreover, it was concluded that both horizontal and vertical transport caused negligible increases of activity concentrations in the ground-level air, and the impact on the atmosphere was by five orders of magnitude lower than in the case of the Chernobyl accident (Fig. 3.13; Povinec et al., 2012a). The influence on the radionuclide inventories of the oceans was studied as well (e.g., Povinec et al., 2013c; Aoyama et al., 2016; Povinec et al., 2017; Kaizer et al., 2018a), and this is covered partially in Chapter 5, Volume 2 of this book.

d. Other nuclear accidents

There were several other nuclear accidents, which caused regional or worldwide contamination of the environment by radionuclides, e.g., Windscale (former Sellafield) nuclear reprocessing facility in 1957 (UK), several accidents at the Mayak nuclear facility in the former Soviet Union (the largest one in 1957), a burn-up of US SNAP-19a satellite generator (containing ^{238}Pu) in the upper atmosphere of the Southern Hemisphere in 1964, accidents with US planes carrying plutonium bombs (in 1966 in Palomares, Spain, and in 1968 in Tula, Greenland), an accident at the Tokaimura (Japan) nuclear facility in 1997, and several

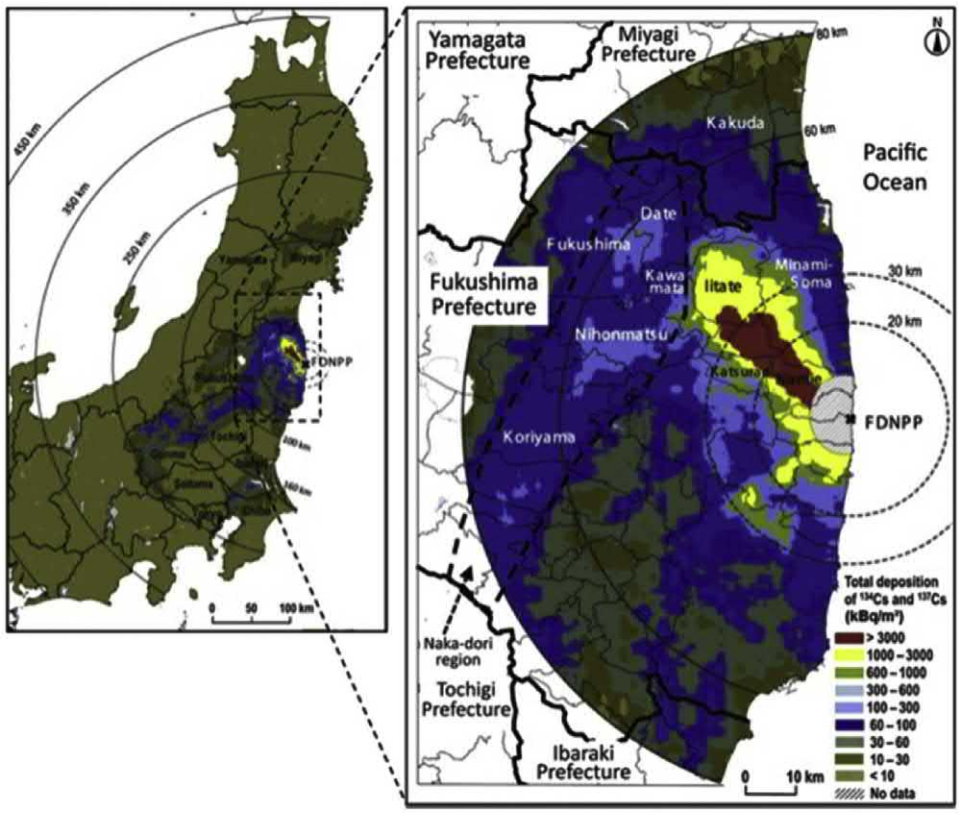

FIGURE 3.12 Surface contamination of ^{137}Cs around Fukushima nuclear power plant (NPP) (Hirose, 2016). For the color version of the figure, the reader is referred to the online version of the book. *Printed with permission © Elsevier 2018.*

TABLE 3.7 Estimations of atmospheric releases of gaseous and volatile radionuclides from the Fukushima NPP.

Radionuclide	$T_{1/2}$	Atmospheric releases (PBq)
^{85}Kr	10.73 years	44
^{133}Xe	5.3 days	11,400–20,000
^{131}I	8.0 days	65.2–380
^{134}Cs	2.07 years	11.8–18
^{137}Cs	30.05 years	6.1–35.9

After Hirose (2016).

small-scale accidents (Livingston and Povinec, 2002; Povinec, 2004).

5. Specific anthropogenic radionuclides

a. Tritium

The natural level of cosmogenic ^{3}H ($T_{1/2} = 12.31$ years) was severely disturbed by nuclear weapon testing and partially by operation of nuclear fuel reprocessing plants and nuclear reactors. While nuclear fuel reprocessing plants have released some 410 PBq of ^{3}H, the contribution from nuclear weapon testing was much more significant. Until the ratification of the test-ban treaty in 1963, around 186 EBq of anthropogenic tritium accumulated in the environment, from which 113 EBq was deposited in the oceans (IAEA, 2005). The main source of global fallout tritium was identified in explosions of thermonuclear weapons, where it was estimated that 1 Mt TNT could generate 0.26–1.8 EBq of ^{3}H, while for atomic weapons, the values are about two to three orders of magnitude lower.

In the case of light-water nuclear reactors, tritium is produced by ternary fission of uranium and activation of light nuclides, e.g., by the nuclear reaction ^{10}Be(n,2α)^{3}H. If the tritium yield for fission of ^{235}U by thermal neutrons is ~0.01%, then 555–740 TBq of ^{3}H per GW_e is annually produced in a light-water reactor by this route (IAEA, 1981). This amount is slightly increased by interactions of fission neutrons with impurities, such as ^{2}H, ^{3}He, ^{6,7}Li, ^{10,11}B, and ^{12}C, present in the construction material, coolant, and moderator of the reactor. According to Kahn et al. (1974), an earlier PWR could overall release tritium activity of 330 TBq GW_e y^{-1}; however, with the improvement of reactor design, as well as better maintenance and management of the reactor component systems,

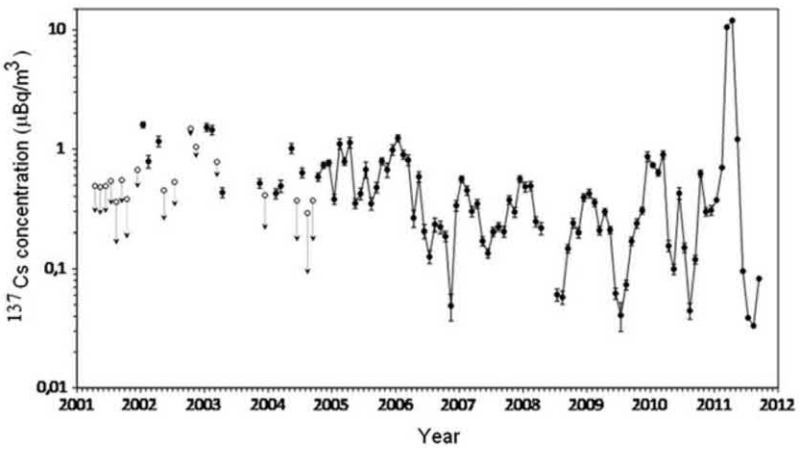

FIGURE 3.13 Time series of ^{137}Cs concentration in aerosols of Bratislava. The Fukushima signal is clearly distinguished. *Modified Povinec et al. (2012a).* Printed with permission © Elsevier 2018.

this value was reduced to around 30 TBq GW_e y^{-1} (IAEA, 2004). In general, PWRs generate and thus discharge more tritium than BWRs, but much less than heavy water reactors. When compared with the aforementioned sources, the impacts from nuclear reactor accidents have been almost negligible, influencing mostly only the local environment (e.g., Povinec et al., 2013a, 2013c; 2017; Kaizer et al., 2018a).

b. Carbon-14

The source terms for anthropogenic ^{14}C ($T_{1/2} = 5730$ years) are quite similar to those of tritium. During numerous explosions of nuclear weapons in the era of atmospheric testing, radiocarbon nuclei were produced by the same types of neutron interactions as the cosmogenic ones. One detonation could produce as much as 1.6 PBq per Mt TNT or more, leading to the estimation of ^{14}C global fallout inventory of 213 PBq (IAEA, 2005). Such huge amounts caused the increase of the atmospheric radiocarbon concentration in the Northern Hemisphere by 100% (Hua et al., 2013). As mixing between two hemispheres is limited and takes some time, the concentration in the Southern Hemisphere was elevated only by the factor of 1.7 (Grammer et al., 2015). Because of the natural carbon cycle, the change in the ^{14}C level was observable in other parts of the environment as well (Fig. 3.14).

Besides nuclear weapon explosions, radiocarbon is produced in nuclear reactors, and during nuclear fuel reprocessing, though on a much lower scale. Activation of nitrogen and the reactions $^{17}O(n,\alpha)^{14}C$ and $^{13}C(n,\gamma)^{14}C$ represent the main source of this nuclide in fuel, coolant, and moderator of the nuclear reactor. The last reaction is especially important for reactors using graphite as the moderator, like the one in the Chernobyl NPP. It was

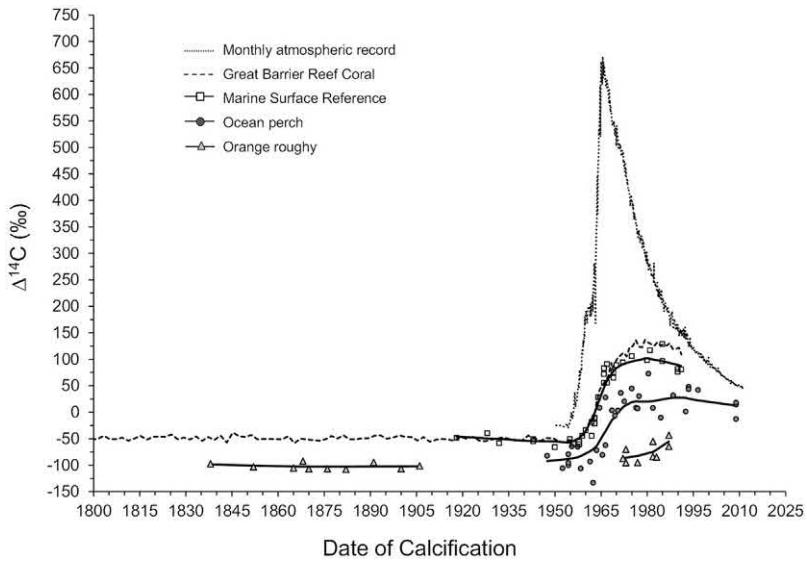

FIGURE 3.14 Time series of Δ^{14}C, representing excess/depletion of radiocarbon above its natural level (0.225 Bq g^{-1} C), in different reservoirs. *From Grammer et al. (2015).* Printed with permission © Elsevier 2018.

estimated that an average PWR can discharge to the air about 0.2 TBq y^{-1}, dominantly in the form of hydrocarbons (~85%), whereas airborne releases for heavy water reactors (mainly as CO_2) are expected to be on the level of 2–2.6 TBq y^{-1} (IAEA, 2004). For a reactor cooled by the mixture of carbon dioxide and nitrogen, amounts of ^{14}C discharges might be significant as well (Chudý and Povinec, 1982). The overall contribution of nuclear fuel reprocessing facilities to the radiocarbon inventory in the oceans was estimated to be 2 PBq (IAEA, 2005).

c. Strontium-90

The longest-lived isotope of strontium, ^{90}Sr ($T_{1/2} = 28.8$ y), decays by beta electron emission to another radionuclide, ^{90}Y ($T_{1/2} = 64$ hours), ingrowth of which is usually exploited for the determination of its mother. Radiostrontium (^{90}Sr and ^{89}Sr with $T_{1/2} = 56$ d) is highly radiotoxic, as it is intensively accumulated in human bones. This dangerous characteristic of ^{90}Sr was especially concerning at the end of the period of nuclear weapon testing when its deposition in the Northern Hemisphere was the highest and could reach up to 3 GBq km^{-2}. Due to the lower number of tests conducted and limited mixing of the hemispheres, the deposition of global fallout radiostrontium in the Southern Hemisphere was less than one-third that in the Northern Hemisphere (Eisenbud and Gessel, 1997). Local differences in deposition were also caused by the precipitation rate. In total, around 600 PBq of global fallout ^{90}Sr was spread all over the Earth's atmosphere, reaching the surface by 1970 (UNSCEAR, 2008).

Radiostrontium together with radiocesium are the main fission radionuclides in nuclear fuel that provide the majority of the activity of SNF in the first several hundred years. Since the construction barriers prevent ^{90}Sr to be released from the fuel matrix, it does not represent a radiation hazard in the final disposal of SNF. However, the barriers are removed during its reprocessing, resulting in transferring of radiostrontium into liquid wastes. About 7 PBq of ^{90}Sr has been introduced into the European seas as a consequence of authorized releases from the La Hague and Sellafield nuclear fuel reprocessing plants (IAEA, 2005). A similar amount was also accidentally discharged from the Chernobyl nuclear reactor (10 PBq; OECD, 2002) whose impact on the nearby water reservoir territory, which could be observable especially during winter months (Fig. 3.15). In the case of the Fukushima NPP, cumulative releases into the environment were much smaller and estimated to be around 2 PBq (Povinec et al., 2012b).

d. Technetium-99

With the atomic number of 43, technetium is surprisingly one of those elements that does not form stable isotopes.

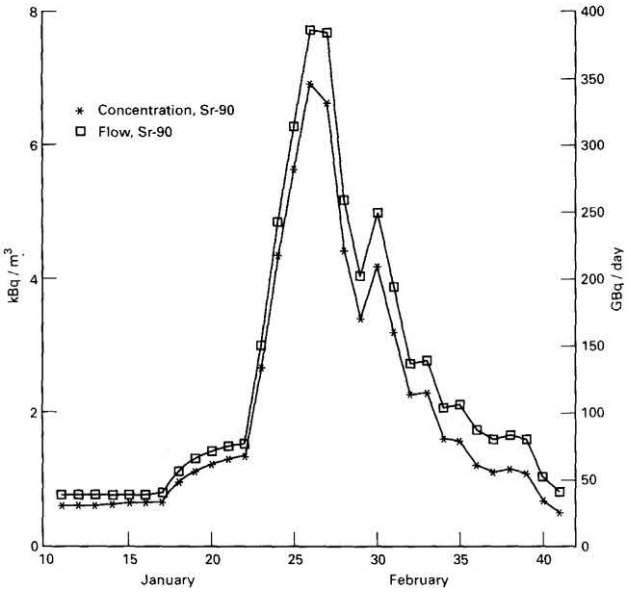

FIGURE 3.15 Temporal variations of the ^{90}Sr activity concentration in water (kBq m^{-3}), and radionuclide run-off (GBq day^{-1}) in January–February 1991 in the Pripyat River, near Chernobyl. *From Vakulovsky et al. (1994).* Printed with permission © Elsevier 2018.

For the long-lived beta emitter ^{99}Tc ($T_{1/2} = 2.1 \times 10^5$ years), this deficiency has caused nonnegligible problems in its determination by mass spectrometric techniques. Even though it can be produced naturally by fission of uranium or activation of Ru, Mo, and Nb isotopes in the Earth's crust, it was suggested that the amount of technetium (60 PBq) generated in this fashion has never entered other parts of the environment (Shi et al., 2012). Therefore, ^{99}Tc can be considered as strictly an anthropogenic nuclide, originating primarily from nuclear fuel reprocessing and nuclear weapon testing.

The largest producers of environmental ^{99}Tc are by far nuclear fuel reprocessing plants, which is well illustrated by the fact that the Sellafield facility has discharged liquid wastes containing roughly 1.7 PBq of this radionuclide into the sea (CEFAS, 2009). Global fallout inventory of technetium was calculated to be around 140 TBq (Aarkrog et al., 1986), whereas about 23.5 TBq was produced during underground nuclear weapon testing in Nevada (United States) and French Polynesia; however, most of this activity remained presumably beneath the surface of the testing sites (IAEA, 1998; Smith et al., 2003). A comparable amount was cumulatively generated in nuclear power reactors between 1971 and 2001, though it is expected that less than 10 GBq was unintentionally released into the environment during their operation (Shi et al., 2012). A small contribution (~1 TBq) could also be attributed to NPP accidents and applications of ^{99m}Tc in medicine (Aarkrog et al., 1988; Shi et al., 2012).

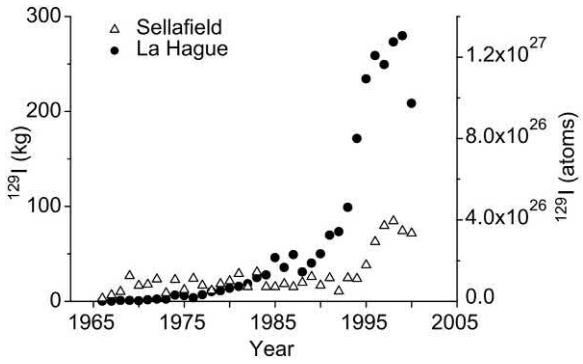

FIGURE 3.16 Annual liquid discharges of ^{129}I to the sea from the La Hague and Sellafield nuclear fuel reprocessing plants. *From Alfimov et al. (2004).* Printed with permission © Elsevier 2018.

e. Iodine-129

A relatively small natural inventory of beta decaying ^{129}I ($T_{1/2} = 1.57 \times 10^7$ y), generated by stratospheric interactions of cosmic rays with xenon, neutron reactions with tellurium, and spontaneous fission of uranium, is determined to be 650 GBq. Most of the activity has been deposited in the oceans, giving the prenuclear era isotopic ^{129}I/^{127}I ratio of 10^{-12} (Raisbeck and Yiou, 1999). Anthropogenic activities from nuclear weapon testing, accidents in NPP, and reprocessing facilities have increased this ratio up to 10^{-5}, while it was estimated that approximately 0.4 TBq of global fallout ^{129}I was transported into the oceans (IAEA, 2005). During the nuclear weapon testing period, around 370 GBq of long-lived iodine was deposited into the lithosphere (Eisenbud and Gessel, 1997).

Nuclear fuel reprocessing plants, namely the two in Europe, have produced more ^{129}I than natural production combined with all other anthropogenic sources. The annual liquid discharges from the La Hague and Sellafield plants, which have released altogether the ^{129}I activity of about 2.9 TBq into the atmosphere and 34.8 TBq into the sea (Hou et al., 2009a,b), are depicted in Fig. 3.16. The accidents in Chernobyl and Fukushima have also impacted the ^{129}I inventory, though the actual releases were calculated to be only 13 and 8.06 GBq, respectively (IAEA, 2003; Hou et al., 2013).

f. Cesium-137

Excluding a very rare probability of spontaneous fission of uranium, ^{137}Cs ($T_{1/2} = 30.05$ y) was produced and introduced into the environment exclusively by humans. Nuclear weapon testing, NPP accidents, and nuclear fuel reprocessing plants were identified as the prime sources of ^{137}Cs. Before its deposition, global fallout contained approximately 950 PBq of ^{137}Cs (UNSCEAR, 2008). Such immense activity, in fact the highest from all long-lived radionuclides, was generated due to very high fission yield for ^{137}Cs, induced by thermal neutrons (~6.3%). As can be seen in Fig. 3.17, where temporal changes in the ^{137}Cs deposition are shown, global fallout ^{137}Cs severely affected the Northern Hemisphere, whereas the Southern Hemisphere was barely contaminated. This can be explained by the fact that ^{137}Cs produced in the Northern Hemisphere was unable to reach southern parts of the atmosphere because of its quite short residence time, as opposed to, e.g., radiocarbon, in which case the difference between two spheres was less dramatic.

For the very same reason, mentioned in the case of nuclear weapons in the previous paragraph, nuclear fuel in the running nuclear reactor contains relatively large quantities of ^{137}Cs and ^{134}Cs ($T_{1/2} = 2.07$ years), which is also

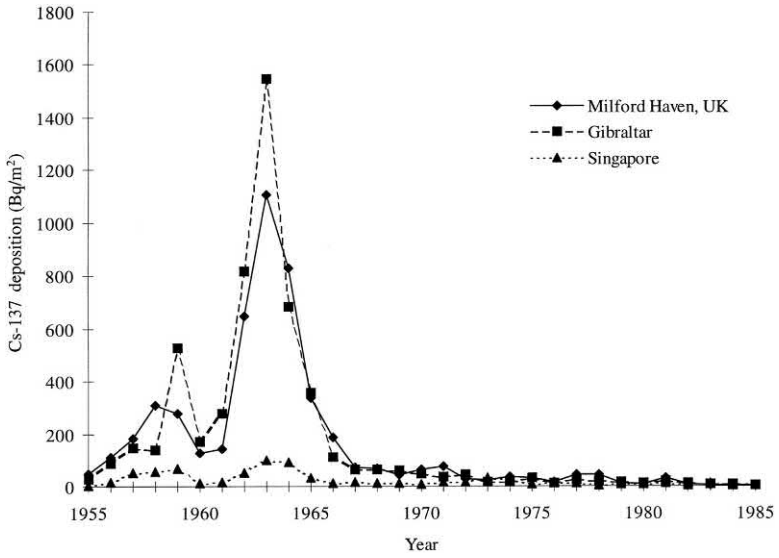

FIGURE 3.17 History of ^{137}Cs deposition for Milford Haven (UK), Gibraltar, and Singapore. *From Wright et al. (1999).* Printed with permission © Elsevier 2018.

produced by neutron capture on ^{133}Cs, the only stable isotope of cesium. The specific content of ^{137}Cs and ^{134}Cs in a fuel assembly of a typical thermal reactor after two-thirds of the fuel campaign was calculated to be roughly 2330 and 3700 MBq g^{-1}, respectively (Table 3.5) (Clarke and Macdonald, 1978). For a standard PWR, the concentration of ^{137}Cs of the primary was found to be by four orders of magnitude higher than the concentration of ^{90}Sr, which is caused by lower diffusivity of strontium isotopes (Eisenbud and Gessel, 1997). Nevertheless, releases of radiocesium from NPP are small in comparison with the global fallout inventory or accidental discharges, and it is hard to distinguish these releases from soil resuspension or burning of biomass effects (Sýkora et al., 2017; Ješkovský et al., 2018).

The ^{137}Cs/^{134}Cs activity ratio can be exploited to track origin of radioactive contamination as they both emit signature and reliably detectable gamma rays. For example, the ^{137}Cs/^{134}Cs activity ratio for liquid and airborne releases from the Fukushima accident was determined to be ~1, in agreement with the calculations of the core inventories for the damaged reactors (Povinec et al., 2013a). Because most of the atmospheric release from the Fukushima was deposited into the ocean, it has been recently estimated that the combined input of radiocesium to the North Pacific was in the range of 15–18 PBq (Aoyama et al., 2016), where it can potentially be used as a tracer for different oceanographic studies due to its unique properties (good solubility in seawater, long half-life, measurable on the mBq scale). According to the OECD (2002) report, the overall atmospheric discharges of ^{137}Cs from the Chernobyl NPP were much higher (85 PBq). On the other hand, nuclear fuel reprocessing facilities have produced in total some 40 PBq of radiocesium in their liquid effluents (IAEA, 2005).

g. Uranium-236

Potential of ^{236}U ($T_{1/2} = 2.3 \times 10^7$ years) for various environmental and geochemical studies was discovered only after the development of mass spectrometry techniques sensitive enough to determine its very low concentration in samples of interest. The most prevailing natural production routes of this uranium isotope are the thermal neutron capture ^{235}U(n,γ)^{236}U and reaction ^{238}U(n,3n)^{236}U. However, the total amount of naturally generated ^{236}U (0.07 GBq) is extremely low when compared with production from anthropogenic source terms (~10^3 GBq), mostly stored as a part of SNF. The ^{236}U/U ratio in uranium ores and deeper rock formations, undisturbed by human activities, was measured to be 10^{-11}–10^{-9} and 10^{-14}, respectively (Steier et al., 2008).

In the vicinity of nuclear fuel reprocessing plants, damaged nuclear reactors, or in the areas contaminated by depleted uranium, the ^{236}U/^{238}U isotopic ratio was found to be between 10^{-7} and 10^{-3}. The global fallout ^{236}U deposited on the Earth's surface was estimated to be around 2.2 GBq, comprised by directly generated ^{236}U during nuclear weapon explosions via the reactions mentioned above and by uranium originated from alpha decays of the deposited ^{240}Pu, produced also during the nuclear weapon testing. The latter production path resulted in the ^{236}U/^{238}U atomic ratio of (2.6–53) × 10^{-12} (Sakaguchi et al., 2009). Some examples of ^{236}U concentration measurements in the environment are shown in Fig. 3.18.

h. Plutonium isotopes

Other than negligible generation of ^{239}Pu ($T_{1/2} = 2.41 \times 10^4$ years) in uranium ores, where the mean atomic U/Pu ratio of 3.1×10^{12} was determined (Curtis et al., 1999), and its accumulation of around one tone in the natural Oklo uranium reactors in Gabon in Africa (Neu et al., 2010), all plutonium currently present in the environment originate from nuclear weapon testing and nuclear industry. Heavier plutonium isotopes are created by consequent neutron captures on ^{239}Pu, whose production route was discussed earlier in this chapter. Plutonium has high radiotoxicity, and with the exception of ^{241}Pu ($T_{1/2} = 14.33$ years), which decay by beta emission, all of its isotopes are alpha emitters.

Plutonium from global fallout has already been deposited onto the Earth's surface, where it has become part of soils, and into the ocean or terrestrial water sediments (Hirose and Povinec, 2015; Livingston et al., 2001). In total, about 15 PBq of plutonium was produced in the atmosphere as result of nuclear weapon testing, from which ^{239}Pu and ^{240}Pu ($T_{1/2} = 6560$ years) comprise 7.4 and 5.2 PBq, respectively (Lehto and Hou, 2011), corresponding to the ^{240}Pu/^{239}Pu isotopic ratio of ~0.18 (Lee et al., 2001). These activities vastly exceed the amounts released due to NPP accidents,

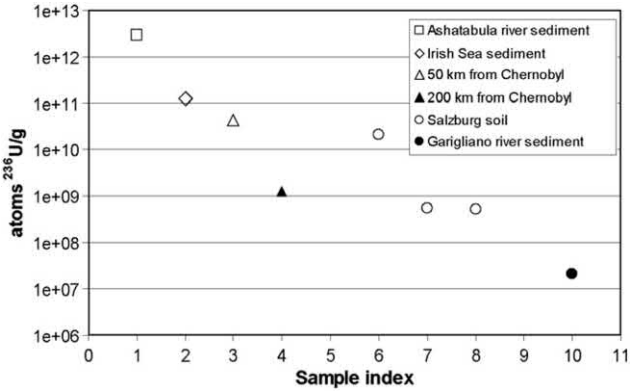

FIGURE 3.18 Concentration of ^{236}U in soil and sediment sample of various origins. *From Steier et al. (2008).* Printed with permission © Elsevier 2018.

accidental events with the aircrafts carrying nuclear weapons in the 1960s, and operation of nuclear fuel reprocessing plants at Sellafield and La Hague. Global fallout contained also other isotopes of plutonium (e.g., ^{238}Pu), their amounts were smaller but useful, as the ^{238}Pu/^{239,240}Pu activity ratio of 0.028 has been a good indicator of global fallout origin of plutonium when compared with other Pu source terms, generally showing higher ratios (Hirose and Povinec, 2015; Povinec et al., 2013a).

Although nuclear weapon testing in the open atmosphere was prohibited several decades ago, small amounts of anthropogenic plutonium have been still entering the environment as a consequence of dealing with uranium-based SNF. The ratio of plutonium isotopes in typical nuclear fuel changes with the duration of nuclear reactor operation. While the ^{240}Pu/^{239}Pu ratio reaches the value of around 0.16 after 1 year, it is increased to ~0.42 after two more years of nuclear reactor operation. After some 30 years, the ratio can be as high as 1.6, which is much higher than for weapon grade plutonium (WNA, 2018). Thus, analysis of the ^{240}Pu/^{239}Pu ratio could be used for identification of the source, from which plutonium was released into the environment.

TABLE 3.8 Concentrations of different constituents in particulate-free dry air near sea level.

Component	Volume (ppm)
N_2	780,840
O_2	209,480
Ar	9340
CO_2	350
Ne	18.2
CH_4	1.7

III. Radionuclide compartments

A. Atmosphere

The atmosphere as the gaseous cover isolates Earth from space and represents the reservoir of the gases, needed by the life forms. It shields Earth from shortwave radiation and cosmic radiation and provides temperature balance from rapid heat exchange. Due to its small mass, great mobility, and chemical composition, it significantly differs from other spheres on Earth. The border of the Earth's magnetic field is considered as the upper border of the atmosphere, called magnetopause (the lowest altitude at 65,000 km), but usually for meteorological purposes, the stratopause (~50 km) is defined as the upper border. Compared with the Earth's radius (6378 km), the atmosphere is only a thin layer. There is about 50% of the atmosphere within 5 km above sea level and 90% within 12 km. The mass of the atmosphere is roughly 5.1×10^{18} kg, which is distributed over the 5.1×10^{14} m^2 of the Earth's surface, and represents pressure of about 10^4 kg m^{-2} at sea level (Bailey et al., 2002). The atmosphere usually contains water vapor, dust particles, and various gases (Table 3.8). However, concentrations of some trace constituents, like methane or carbon dioxide, have been increasing in last decades. The building block of the molecules is seldom replaced by radioactive nuclides such as ^{3}H, ^{14}C, and other. The concentrations of constituents may vary in different parts of the atmosphere. Table 3.8 does not include particulate matter (radius 10^{-7}–10^{-2} cm), which covers particles from molecular dimensions to large dust particles. Particulate matter in the atmosphere can be the result of human activities, impact of meteorites, volcanic activity, dust storms, forest fires, and ocean spray. The smallest particles, with radii of 0.1–1.0 μm, have a maximum concentration at about 18 km above the Earth's surface. Large particles can settle out of the atmosphere by gravitational settlement; furthermore, it is estimated that approximately 70% of the particles that enter the atmosphere are washed out back to surface as condensation nuclei of the water droplets that form rain clouds. Water droplets with radii from 1 to 50 μm are usually present in clouds; however, droplets with radii of 100 μm generally fall as a drizzle and larger droplets as rain.

The mixing characteristics of the atmosphere are influenced by its vertical temperature gradient. With increasing altitude, the properties of the atmosphere are changing rapidly; density and pressure are decreasing by exponential order. Similar behavior can be observed with temperature changes depending on day/night cycle, seasons, or as a result of vertical mixing of air masses. Exact changes of temperature and pressure with altitude can be described by an atmospheric model called the US Standard Atmosphere

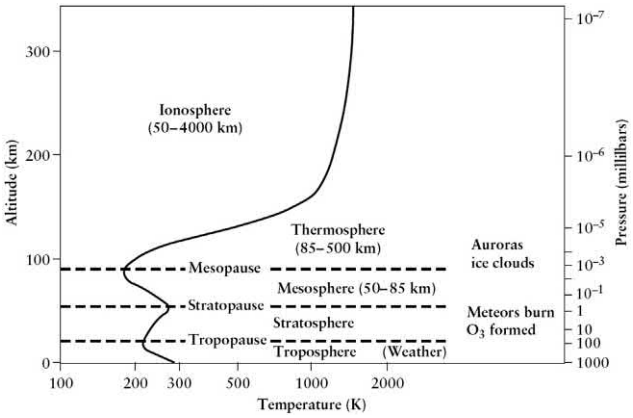

FIGURE 3.19 Temperature and pressure distribution in the atmosphere for different altitudes in US Standard Atmosphere model. *From Bailey et al. (2002).* Printed with permission © Elsevier 2018.

(Sissenwine et al., 1962). Several layers of atmosphere with different properties can be recognized from the model in Fig. 3.19. The closest layer to the Earth's surface is the troposphere with a height ranging from 8 km at polar latitudes to 18 km at the equator. Atmospheric water is mostly concentrated in the troposphere, and most of the physical processes forming weather occur in the troposphere. The temperature decrease with increasing altitude allows vertical mixing within the troposphere with vertical exchange of masses, momentum, and temperature, including water vapor transportation and dispersion of anthropogenic emissions. The boundary layer between the troposphere and the stratosphere is the tropopause. The height of the tropopause varies with latitude and with the season of the year, which is responsible for transport of air masses during spring and early summer from the stratosphere to the troposphere.

The stratosphere reaches up to 50 km with the maximum temperature of 0°C at its higher edge. Inversion conditions (the increase of the temperature with the altitude) are the reason for slow vertical mixing, and therefore, the pollution that reaches the stratosphere remains here even for several years.

In the range from 50 to 80 km, in the mesosphere, the temperature is again decreasing down to the lowest temperatures (−90°C) in the atmosphere. The course of temperature in the stratosphere and mesosphere is related with absorption of ultraviolet radiation by ozone. In higher altitudes (thermosphere), the temperature is rising. The velocity and mean free path of particles at high altitudes allow gases to escape to space.

To understand the global movements of the pollutants in the atmosphere, a simplified circulation in the atmosphere will be described. In general, there are two major reasons for circulation in the atmosphere. The first one is the difference in heating of the air masses by solar energy in equatorial and polar regions. In comparison with the atmosphere, the Earth's surface absorbs much more solar radiation, and by conduction, convection, and radiation from the ground, it heats the air in lower levels of atmosphere. The hot air is less dense and therefore tends to rise above it. In the equatorial region, the hot air rises to some height and flows toward the poles; however, in polar regions, the cold air travels near the surface toward the equator.

The second reason is the rotation of Earth; while the air near the equator rotates with the same velocity as Earth, the poles do not rotate and the air in these regions is static as well. The Coriolis effect describes the air movement between latitudes in which the speed of rotation is different, and this results in an unexpected component of wind speed with respect to the earth. A three-cell model describes the tree main prevailing wind directions in each hemisphere, as can be seen in Fig. 3.20. This model does not assume, however, the movement of the cells and the air exchange between them, but in comparison with Hadley's one-cell model (Hadley, 1735), it is a great improvement. Taking into consideration the global transport of air masses, the mean resident time of particulate matter in the lower atmosphere is between 3 and 22 days. When the aerosols reach the stratosphere, the mean resident time is 6 months to 5 years, and 5−10 years in the mesosphere.

Although radionuclides can be produced in the atmosphere, the pollutants are frequently released to the atmosphere from the surface. Once a gas, vapor, or aerosol has been introduced into the atmosphere, it is diluted by molecular and turbulent diffusion. While the diffusion coefficient for molecular diffusion is orders of magnitude lower than for turbulent, one can neglect it during the dilution

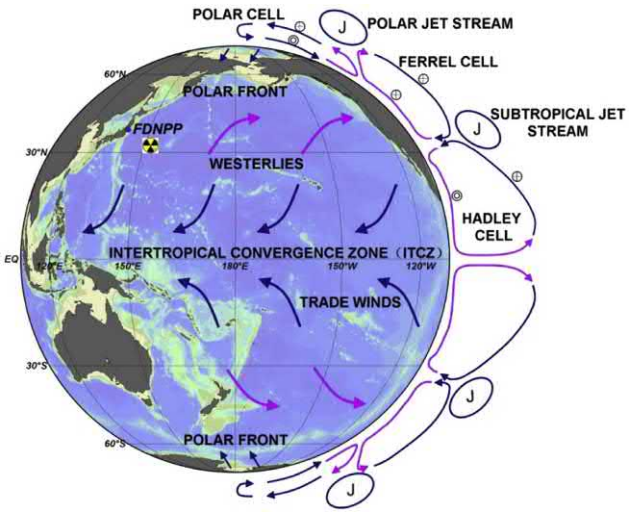

FIGURE 3.20 Three-cell model for motion of air masses around the globe. For the color version of the figure, the reader is referred to the online version of the book. *From Lin et al. (2015). Printed with permission © Elsevier 2018.*

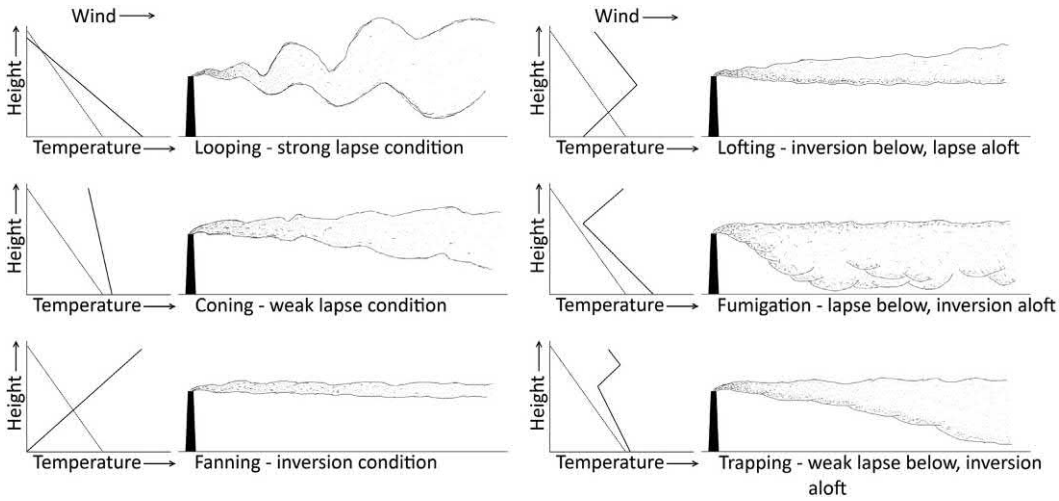

FIGURE 3.21 Stack-gas behavior of released pollutants under various stability conditions of atmosphere. Vertical stability is represented by temperature (black line) and dry adiabatic lapse rate (gray line).

processes (Eisenbud and Gessel, 1997). The vertical profile of the temperature greatly affects the stability of the atmosphere and therefore also the characteristics of dispersion, as can be seen in Fig. 3.21. When air temperature increases with altitude at some elevation, inversion conditions are formed. These temperature inversions trap rising air below effective stack height and result in accumulation of the pollutants.

B. Hydrosphere

The hydrosphere can be defined as the combined mass of all water present on Earth, either on its surface (oceans, river, lakes, glaciers) or under the ground (groundwater). Atmospheric moisture, mainly found in the form of vapor, snow, and rain, is also part of the hydrosphere. The overall mass of water in the hydrosphere is approximately 1.6×10^{21} kg. Only some 2.5% of the Earth's water is so-called freshwater, the rest is composed by seawater reservoirs. Water in the oceans covers about 71% of the planet's surface, whereas about 5% of the water mass is contained in the lithosphere. The largest reservoir of freshwater is incorporated in ice caps, glaciers, and permanent snow (68.7%), followed by groundwater (30.1%) (Gleick, 1996). Freshwater bodies support rather complex systems for living organisms. It has been estimated that about 12% of all animal species live in such ecosystems (Desonie, 2007). On top of that, millions of eukaryotic species can be found in the oceans (Mora et al., 2011).

Even though the total amount of water in respective reservoirs is more or less constant, water molecules are in permanent movement, which enables continuous exchange of water between the atmospheric, surface water, groundwater, and even living organisms. There are several transport processes of water (Fig. 3.22). Water is transferred to

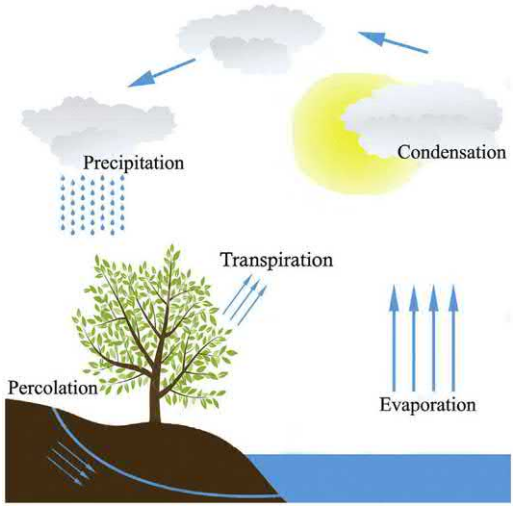

FIGURE 3.22 Schematic view of hydrological cycle. For the color version of the figure, the reader is referred to the online version of the book. *From Sadollah et al. (2015).* Printed with permission © Elsevier 2018.

the atmosphere from vegetation by transpiration, from surface of water bodies by evaporation, and from snow and ice by sublimation. In the air, if its temperature is lowered enough, it may be formed into clouds by condensation. Under the right conditions, water is transported back to the surface in the form of precipitates. Streams (rivers) assure flowing of liquid water from landscape areas to surface sources (lakes, ponds, seas), while part of it may be seeped into the ground by infiltration or may get even deeper where it can refill groundwater reservoirs (aquifers). The residence time of water in a particular reservoir depends on its type and may vary from days to hundreds of years (Table 3.9).

TABLE 3.9 Mean residence time of water in different reservoirs.

Reservoir	Mean residence time of water
Oceans	3100 years
Polar ice, glaciers	16,000 years
Groundwater	300 years
Freshwater lakes	1–100 years
Saline lakes	10–1000 years
Soil and subsoil moisture	280 days
Rivers	12–20 days
Atmospheric water vapor	9 days

After Wetzel (2001).

According to Lvovitch (1973), more water is evaporated from the surface of the oceans than is returned back by precipitation, while the opposite is true for continental areas where more water is transported onto lands than is transformed into vapors. Evaporation of oceans is the main source of continental water, which is unevenly distributed over the continents. For example, South America has the greatest total and groundwater runoff from all continents.

Recently, local fluctuations in the steady global water balance have been caused by anthropogenic activities, such as land clearing, exploitation of groundwater, and changes in drainage patterns. Before the end of the 21st century, the human-induced fraction of continental evaporation is expected to increase to about 50% by raising demand of water for agricultural and industrial uses. Therefore, freshwater will become a strategic material of the present century. This will further accelerate the rate of land freshwater turnover, which will be insufficient; thus large-scale desalinization of seawater will be necessary. Massive manipulations of surface waters at immense energy costs will eventually lead to changes of climate. As a result of huge modifications of large river systems, alterations of regional climate conditions have already been documented (Wetzel, 2001).

With the average depth of about 3700 m and the total volume of $\sim 1.35 \times 10^9$ km^3, oceans contain almost all Earth's water. While three-fourths of the oceans have a temperature in the range of 1–4°C, their overall average salinity and temperature is 3.47% and 3.51°C, respectively (Kennish, 2001). Because of wind action, a region with rapid mixing occurs near the surface of the oceans (the depth of 10–200 m). As a result of this mechanical mixing, the salinity, density, and temperature vertical gradients are fairly uniform. The surface and deeper water layers are generally separated by an intermediate zone, which can be as much as 1000 m deep and where density and salinity increases while temperature decreases with depth. Due to the fact that lighter (less dense) water overlies the heavier, vertical motions of water are restricted. Thus, the intermediate zone may limit exchange between the surface and deep layers, which can be important for the spreading of contaminants. The same might be said for surface currents that can transport large quantities of substances with the speed of tens kilometers per day.

Groundwater is an important source of water for agriculture, industry, and households, which might be reasoned by the fact that the world's volume of groundwater is by a factor of about 30 greater than the cumulative volume of water in lakes and rivers. Other aspect is that the quality of groundwater is usually better than the quality of water from surface sources. Groundwater only rarely occurs in underground pools or lakes but rather in saturated geological formations (aquifers), with the depth up to hundreds of meters. The amount of water potentially contained in the aquifer depends on porosity (percentage of pores) of its material where average porosities are between 30% and 40%, and for example, sediments have typical porosity of 10%–60% (Fetter, 2001). Permeability and the hydraulic gradient affecting the pressure determine the flow rate of the water in the geological formations. In general, groundwater is much less prone to contamination than surface water, because possible contaminating substances are often filtrated out during the infiltration. On the other hand, once the groundwater source gets contaminated, dissolved harmful substances are naturally removed from the source at a slow rate, about 4 cm d^{-1} (Desonie, 2007).

The atmosphere, soils, surface waters, and groundwater aquifers are connected via various transport pathways (Eisenbud and Gessel, 1997). Pollutants, which somehow occur in the deep underground aquifers, may reach surface waters and get distributed into the biosphere. Contaminants released to the atmosphere are deposited on surface waters or soils. From soils, polluting substances are removed by leaching into soil water or surface runoff. The fate of contaminants in the aquatic environment depends on several biological and physical processes. A suspended solid can be filtered by organisms, settle to bottom sediments, or become attached to plants. Dissolved contaminants can be adsorbed on inorganic and organic particulate matter or incorporated into the animals and plants. When the suspended solids settle at the bottom, they become part of the organic-rich substrate, useable by miscellaneous microorganisms. The sediments can act either as a sink for pollution or as a source when they are resuspended and redeposited at another place. If desorption occurs, the sediments may also act a secondary source.

Water has many unique properties connected with its molecular structure and unusual bonding, which makes it essential for life. A polar molecule of water forms in equilibrium an isosceles triangle, having a bond angle of 104.5° at oxygen and molecular electric dipole moment of

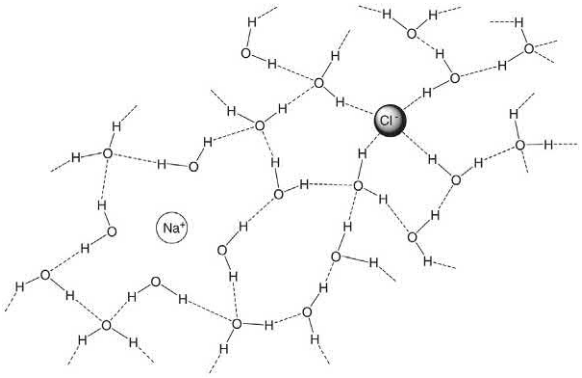

FIGURE 3.23 Illustration of hydrogen bonds in liquid water containing Na^+ and Cl^- ions. *From Maréchal (2007).* Printed with permission © Elsevier 2018.

1.85 D. The length of the O−H bond is 0.96×10^{-10} m. Probably the most characteristic feature of water is that it can create weak electrostatic interactions called hydrogen bonds between the oxygen atom of one molecule and hydrogen atoms of other molecules (Fig. 3.23). This means that each and every water molecule can be attracted by hydrogen bonds to four other ones. As a consequence of the existence of hydrogen bonds, water has many anomalous properties (e.g., unusually high melting and boiling point, highest density at 3.98°C, high specific heat capacity, lower density of the solid phase than the liquid phase, high viscosity and surface tension, etc.). Altogether, more than 70 water anomalies have been identified so far (Chaplin, 2018). A typical molecule of water in nature may be composed of three different oxygen ($^{16,17,18}O$) and hydrogen ($^{1,2,3}H$) isotopes, the molecule $^{1}H_2^{16}O$ being the most abundant. Because of its exceptional properties, water is the only substance naturally present in all phases. Another important feature of water is its relatively high capability to dissolve ions of inorganic and organic salts, which is crucial for continual transport of substances in the environment.

C. Biosphere

The biosphere is defined as a sum of all living organisms and their ecosystems on the planet. Another way of looking at the biosphere is as a layer of the planet where life forms live, evolve, and propagate. This definition allows one to define the boundaries of the biosphere where environmental conditions such as temperature, pressure, and chemical composition can no longer support any life forms. In the atmosphere, macroorganisms can be found in heights up to 11.2 km above sea level, as shown by a collision of an aircraft with a vulture at this altitude (Laybourne, 1974). However, microbial life forms can exist at even higher altitudes after being ejected high into the stratosphere during massive volcanic events. As an example, microorganisms were extracted and cultured from air at 41 km above sea level (Wainwright et al., 2003). In the oceans, both macroscopic and microscopic life forms are present even in the deepest parts of the Mariana Trench 10.9 km beneath the Pacific Ocean (Horikoshi, 2016). Single-cell and multicellular life has also been discovered in subsurface regions of Earth up to 3.6 km deep (Borgonie et al., 2011).

From a chemical point of view, living organisms in the biosphere are based on carbon−water chemistry, and carbon, oxygen, and hydrogen together with nitrogen and phosphorus are present in all organisms and make up more than 95% of living matter. In addition to these five elements, the most important biogenic elements are S, Na, K, Ca, Mg, and Cl, and they add up to 99% of living matter.

The biosphere permeates all of the environmental layers and closely interacts with them because they contain chemical elements and compounds necessary for life and procreation of living organisms—nutrients from the pedosphere, water from the hydrosphere, and gases from the atmosphere. These interactions together with reprocessing of organic material from dead organisms create material fluxes and cycles. This cyclic nature prevents depletion of material reservoirs essential to the biosphere. The most important cycles relating to the biosphere are water cycle and cycles of biogenic elements. These cycles are not independent; they are interconnected and often influence each other. Carbon, nitrogen, and sulfur (unlike other major biogenic elements) can take part in these interactions both in the form of gases and dissolved or undissolved in water (Smil, 2002). This makes them highly mobile, and their cycles are crucial for the biosphere. Other mineral biogenic elements can be transported only in water and are imported into the biosphere mainly by weathering processes from the lithosphere.

The water cycle (described in Section III.B) is essential for the biosphere as well, as water acts as a solvent, metabolite, and temperature buffer in the chemistry of living organisms and also as a living environment for many life forms. In terms of reservoir size, the biosphere is only a small part of the water cycle, but plant transpiration is a significant source of water input into the atmosphere.

Carbon is the most important biogenic element, and its cycle is therefore central to the entire biosphere. The carbon cycle consists of chemical and physical processes that exchange and accumulate carbon in different ecosystems, which represent carbon reservoirs. Major reservoirs of carbon are the atmosphere, terrestrial biosphere, oceans, and lithosphere. Atmospheric carbon is mainly in the form of CO_2, and it is biologically transported into the terrestrial biosphere by photosynthesis and becomes part of land organic matter. Autotrophic organisms store the assimilated carbon in their bodies, and heterotrophic organisms gain carbon by consuming other living organisms. A significant

part of the CO_2 converted to organic matter is emitted back into the atmosphere in the process of aerobic respiration and also by combustion of organic matter (either in wildfires or in the controlled burning of biomass).

Human civilization is also a part of the biosphere, and human activities can influence many of the aforementioned processes, including global water cycle and biogenic element cycling. A good example is the anthropogenic influence on the global carbon cycle. Human use of fossil fuels for energy generation added a new flux into the carbon cycle—removal of organic matter from sedimentary rocks and release of this fossil carbon into the atmosphere. Nitrogen and phosphorus cycles are heavily influenced by the production and use of synthetic fertilizers. The nuclear industry represents an input of radionuclides into the biosphere, some of which do not occur naturally in the environment. These anthropogenic interferences are usually faster than unperturbed processes in the biosphere and, therefore, it is hard to determine what the consequences of human activities in the biosphere will be on different time scales ranging from civilizational to geological.

The intensive cycling of materials within the biosphere itself and the interconnection of the biosphere with other environmental compartments is very important for environmental radioactivity studies, as these interactions determine which radionuclides migrate into the biosphere from other compartments and vice versa.

D. Pedosphere

The pedosphere is a layer of Earth formed mostly by soil, which originated from the lithosphere by rock erosion, actions of organisms, solar radiation, water, and air impacts, all during long geological times. The thickness of the soil layer is from a few cm to about 3 m. It is an interface between the lithosphere, atmosphere, hydrosphere, and biosphere. Soil comprises a multielement composition with some crucial elements such as carbon, oxygen, nitrogen, and phosphorus.

A fraction of organic carbon is stored in soil. Carbon from soil organic matter can be released as carbon dioxide by soil respiration (Raich and Schlesinger, 1992) or as a result of microbial decomposition. Exchange of carbon between the atmosphere and oceans is caused by a dynamic equilibrium of CO_2 dissolution in surface waters. Different solubilities in warmer water and colder water drive the so-called solubility pump that cycles carbon between surface and deep ocean waters. A similar biological pump is driven by photosynthesizing marine organisms (mainly phytoplankton) that fix carbon in their bodies, and after dying, they sink to the bottom of the ocean. Certain organisms can also combine calcium with carbonates dissolved in the water to create calcium carbonate in their shells. Carbon from these shells and dead phytoplankton is eventually sequestered in sediments on the ocean floor. Over geological time scales, these sediments create limestone and sedimentary rocks, and they become part of the lithosphere.

Although the lithosphere is the largest reservoir of carbon on Earth, its carbon is, however, relatively inert compared with other reservoirs, and therefore, it is cycled with the rest of the environment on very large time scales. Lithospheric carbon is bound in carbonate rocks and as organic matter in sedimentary rocks. Subduction of these carbon-containing rocks can produce carbon dioxide that is released into the atmosphere from volcanoes and volcanic vents.

Natural radioactivity in the Earth's environment depends primarily on geological and geographical conditions, appearing thus at different levels in soils of each region of the world (UNSCEAR, 2000). A number of natural radionuclides are observed as inherent soil contents, mainly ^{40}K and the isotopes of uranium and thorium with their daughter nuclides. With the use of nuclear technologies, anthropogenic radionuclides enter the soil environment as well, of which ^{137}Cs and ^{90}Sr are the most abundant ones. These radionuclides contribute to the radiation exposure, externally through gamma radiation and also internally through inhalation and the food chain.

Uranium and thorium isotopes are sources of radium isotopes (^{226}Ra, ^{228}Ra, ^{224}Ra), which are found in soil in trace concentrations. They are important sources of radon gas in the soil. The radon isotopes (^{222}Rn—uranium decay series, and ^{220}Rn—thorium decay series) are formed in soil by alpha decays of radium in the soil grains. After alpha decay of radium, radon atoms get kinetic energy as a consequence of their recoil. This energy is several times higher than the typical energy of a chemical bond, and therefore, radon atoms do not stay as a component of initial chemical structure, but they can migrate to the surface. The radon concentration in the soil air is thus created by radon atoms that reach the pores. The radon concentration in soil air varies depending on locality and time. It is mostly influenced by radium concentration in mother rock and by emanation processes, moisture, and permeability of soil layers. In common soils, the radon concentration decreases toward the surface very markedly, as radon is released into the outdoor atmosphere. In the long term, perspective ^{40}K, uranium and thorium isotopes, and their decay products, mainly radon, have been delivering the largest radiation doses to the public (EPA, 2007). In the soil air, the radon activity concentration reaches the value of several kBq m^{-3}, and it is not stable.

The interest in radon in the soil air is connected with a possibility of its use in the forecast of earthquake and volcanism (Igarashi et al., 1995; Weinlich et al., 2006), and also as a tracer of the transport of the other gases in the soil (CO_2, CH_4) (Dörr and Münnich, 1990).

IV. Analytical techniques

A. Radiometric techniques

Radioactive nuclides undergo radioactive decay and deexcite to the stable state with a characteristic half-life. The energy of the excited states can be released in several nuclear processes, i.e., by alpha decay, beta decay, EC, internal conversion, gamma ray emission, and spontaneous fission. By the detection of emitted particles and/or radiation, the radionuclides can be identified, and their activity concentration can be estimated. Several radiometric techniques have been developed, which meet the requirements for low-level analysis of radionuclides in the environment (e.g., Povinec, 2004, 2005, 2008a,b; Povinec et al., 2008).

1. Alpha spectrometry

During alpha decay, alpha particles with specific energy are emitted from the decaying radionuclide. Known radionuclides emit alpha particles in the energy range from 4 to 9 MeV. Alpha spectrometry uses a detector to record registered energy of the alpha particle in the form of a pulse height distribution. Several types of detectors, such as ionization chambers, proportional counters, and scintillation detectors, can be used for the determination of emitted alpha particle energy; however, semiconductor detectors are most frequently used. Statistical variations in interactions between alpha particle and the detector cause the emergence of energy broadening in the registered spectra. Ionization chambers have normally a high counting efficiency, but the energy resolution is very poor, unless equipped with a Frisch grid, which enables fast collection of the electrons by shielding the induction from the positive ions. Poor energy resolution of the proportional counters and liquid scintillation counters (about 20%) disadvantage the spectrometric use of these detectors, despite their 4π counting geometry. For some applications, solid scintillators such as CsI(Tl) and ZnS(Ag) are used as thin cover of the inner surface of the detector, i.e., Lucas cell. Because of the good counting efficiency and excellent energy resolution (0.5−1%), surface barrier and ion-implanted silicon semiconductor detectors are widely used in alpha spectrometry. Although the superior energy resolution, the small difference in the energy of alpha particles from a few radionuclides (^{239}Pu and ^{240}Pu, ^{214}Am and ^{238}Pu, ^{237}Np, ^{233}U, ^{234}U and ^{230}Th) makes the spectrometric separation of the peaks difficult.

Because of the significant energy losses of the alpha particles in the matter, measurements with solid detectors are carried out in a vacuum, to avoid energy losses in the air and additional energy straggling. The emitted alpha particles are registered within a thin surface layer of the detector, and the number of produced electron−hole pairs is proportional to the energy of the alpha particles. To avoid losses due to self-absorption and resulting reduction of counting efficiency and worsened energy resolution, the source containing the sample matrix should be as thin as possible. To remove the major matrix elements to minimize self-absorption and minor radionuclides with interfering energy of alpha particles, chemical separation is required. The thin layer of sample is prepared by electrodeposition on stainless steel disks; however, evaporation, coprecipitation, electrospraying, electrostatic precipitation, spontaneous deposition, molecular plating, and vacuum sublimation are also used (Lally and Glover, 1984). Sorption of some radionuclides on a thin manganese oxide film has been recently developed and used for alpha source preparation (Karamanis et al., 2007). To estimate the contribution of a technique to the sample counts, a procedure blank is often prepared. Concentrations of radionuclides in environmental samples are very low, and to obtain acceptable counting uncertainty, a long counting time is needed (i.e., 1−10 days for activities of about 10 mBq and below). For the absolute activity determination of an unknown radionuclide, a standard with known activity is determined in relation to the analyzed sample. A standard should be prepared from the same radionuclide to determine the detector efficiency, prepared, and measured under the same conditions. An alternative is to use an internal tracer, another isotope that is added to the sample during the radiochemical separation. The main advantage of alpha spectrometry is the relatively low cost of the equipment, a reasonable sensitivity because of the low background and the selectivity of alpha particles against other types of radiation (Povinec, 2004, 2010, 2011, 2013). The main disadvantages are the complicated chemical separations and long counting times (Miura et al., 1999). Radionuclides commonly determined by alpha spectrometry are listed in Table 3.10.

2. Beta counting

Radionuclides sensitive to beta decay are deexcited by emitting an electron (e^-) or a positron (e^+), together with an antineutrino or neutrino, respectively. Beta radiation does not have discrete energies because the two emitted particles (e^- and antineutrino or e^+ and neutrino) share the energy of the radioactive decay, and therefore, the resulting spectra is a continuous distribution of energies from 0 to maximum energy of the decay. The β^+-decaying radionuclides can be analyzed by gamma spectrometry of two emitted photons with energy of 511 keV, during the annihilation of the e^+. If an electron from an atomic shell is captured by the nucleus, the decay process called electron capture (EC) can be registered. The emission of the X-ray and/or Auger electrons follows EC, and therefore, the EC decaying radionuclides can be determined by X-ray spectrometry of emitted X-rays or by liquid scintillation counting (LSC) of the Auger electrons.

TABLE 3.10 Radionuclides commonly determined by alpha spectrometry (Hou and Roos, 2008).

Radionuclide	Half-life[a] (years)	Energy of main alpha particles (MeV) (abundance)	Detection limit[b] (ng)
^{226}Ra	1599	4.78 (94.5%), 4.60 (5.5%)	1.95×10^{-6}
^{229}Th	7.93 k	4.85 (56.2%), 4.90 (10.2%) 4.81 (9.3%), 5.05 (6.6%), 4.97(6.0%) 4.84 (5.0%), 4.98 (3.2%)	9.05×10^{-6}
^{230}Th	75.6 k	4.69 (76.3%), 4.62 (23.4%)	9.34×10^{-5}
^{232}Th	14 G	4.01 (78.2%), 3.95 (21.7%)	17.55

The identification of the individual radionuclides from the spectrum of the beta particle is complicated, due to the continuous energy distribution in the spectrum of the emitted electrons in beta decay. Therefore, in practice, the identification of radioisotopes is based on the chemical separation of the radionuclide of interest, and low-level counting of beta emitters carried out by gas proportional counting (GPC) or LSC is used for the determination of activity. However, several radioisotopes can originate from one element (e.g., ^{89}Sr and ^{90}Sr), and despite the fact that some radioisotopes emit electrons with discrete energies (e.g., from internal transition and/or EC decay), the emitted electron cascade results in a complicated energy spectrum, which in parallel makes the accurate analysis of several beta decaying radioisotopes complicated.

During the LSC analysis, the radioactive sample solution is mixed with an organic liquid scintillator to form a homogeneous and colorless solution to minimize the self-absorption and maximize the counting efficiency. The activator molecules transform the released energy during the beta decay into excited states, and after their return to the ground state, photons are emitted. Photons are collected at the photocathode of the photomultiplier tube and converted to electrons, which are multiplied by the dynodes to form a pulse of several millivolts. The procedure of sample preparation for the LSC is relatively simple, together with using internal or external standards. LSC can be used also for isotopes decaying with the emission of conversion electrons or via EC (e.g., ^{41}Ca and ^{55}Fe). However, the counting efficiency for these decay modes is rather low (<30%), due to the low energy of the Auger electrons (<20 keV) (Hou and Roos, 2008; Povinec and Sanchez-Cabeza, 2006).

For the GPC, two approaches are used; in the first one, the sample is converted to the gaseous form and it is used as the filling for the detector. This method can be used for ^{3}H and ^{14}C, whereas methane is used as the filling gas. The second approach is similar to alpha spectrometry, where a thin sample is prepared and usually a Geiger–Muller (GM) detector with thin window is used for the counting of beta decays.

For the analysis of environmental samples, a low-level GPC is required. This can be achieved by passive (thick lead shield) and active shielding of the counter using an

anticoincidence mode with a detector surrounding the counter to suppress the counts coming from the natural background. A background count rate of 0.1 counts per minute (CPM) and the detection limit less than 1.5 mBq for ^{99}Tc and ^{90}Sr was reported for a commercial low-level GM counter produced at the Risø National Laboratory, Denmark (Hou et al., 2007). By using a multiwire proportional counter, Povinec (1978) achieved a background of 5 cpm with active anticoincidence shielding.

In comparison with the GPC, the background for the LSC is higher. With the use of the commercial QuantulusTM Ultra low-level LSC developed by Wallac (presently produced by Perkin–Elmer, United States), the background for the ^{3}H and ^{99}Tc window is about 0.5 and 1.5 cpm, respectively (Hou and Roos, 2008). Radionuclides commonly determined by beta spectrometry are listed in Table 3.11.

3. Gamma spectrometry

If the nucleus is in an excited state, i.e., as a consequence of alpha or beta decay, it can deexcite to the ground state by emitting gamma radiation with characteristic energy. Those emitted gamma rays can be registered by the spectrometer, and the source radionuclide can be identified and counted. Several or only one gamma ray can be emitted during the deexcitation process, and even more than one decay process may be observed. Gamma spectrometers are then designed to follow the decay modes of investigated radionuclides (Zvara et al., 1994).

Several types of detectors can be used for the registration and measurement of gamma rays, such as scintillation detectors (NaI, CsF, and ZnS), gas-filled detectors, and semiconductor detectors (based on Si, Ge, CdTe, and GaAs crystals). It is required that information about the deposited energy of the gamma ray in the detector can be recorded by the energy spectrum. The development of the high-purity germanium detectors (HPGe) in the 1980s was a great step in the maintenance of the detector, and the recent development of large-volume Ge crystals favors the use of germanium detectors by many laboratories. Small silicon (e.g., Si(Li) or silicon-drifted detectors [SDDs]) or planar germanium (low-energy germanium [LEGe]) detectors are

TABLE 3.11 Radionuclides commonly determined by beta spectrometry with detection limits for liquid scintillation counting (LSC) and gas proportional counting (GPC) (Hou and Roos, 2008).

routinely used for the measurement of low-energy gamma (<100 keV) and X-rays, with an energy resolution of about 130 eV for the 5.0 keV line of ^{55}Fe. Recently, BEGe (broad-energy germanium) detectors have become popular, offering higher detection efficiency for medium-energy gamma rays.

To sustain the counting efficiency, a thin window (usually from low Z material such as beryllium, carbon composite, or Si_3N_4) is required for good transition of gamma and X-rays to the crystal. Larger Ge detectors are better suited for gamma rays with higher energies (>30 keV), usually with an energy resolution of about 2 keV for the 1332 keV line of ^{60}Co. Due to the low absorption of gamma rays in the materials, radionuclides that emit high-energy gamma rays can be measured without any treatment or preparation. Therefore, radionuclides such as ^{60}Co, ^{65}Zn, ^{54}Mn, ^{94}Nb, ^{106}Ru, ^{133}Ba, ^{134}Cs, ^{137}Cs, ^{144}Ce, ^{152}Eu, ^{154}Eu, and ^{241}Am are routinely measured in environmental samples by gamma spectrometry.

To identify radionuclides in the spectrum, precise energy calibration is needed, constructed from energies of known standards. If the activity concentration is determined in the sample, efficiency calibration is required either from a standard with similar geometry and composition or by Monte Carlo simulations (Povinec et al., 2008; Povinec, 2012; Kováčik et al., 2013). A disadvantage of gamma spectrometry is normally a high background induced by cosmic ray interactions, radioactive contamination of construction materials of the detector, and surrounding environment. Therefore, shielding is necessary to achieve an acceptable detection limit. For the low-background gamma spectrometer on the surface, radioactive clean materials are needed for the construction of detectors and background shielding, whereas additional suppression of cosmic ray muons by anticosmic shielding is required for better sensitivity (Povinec et al., 2004, 2005; 2006; Sýkora et al., 2008). If a lower detection limit has to be reached, the detector efficiency needs to be increased and the detector background needs to be suppressed. To suppress the cosmic ray component of the detector background, it is useful to locate it deep underground (several thousand meters of water equivalent) (Laubenstein et al., 2004; Niese, 2008).

More information on low-level alpha- and beta counting using radiometric techniques (including underground detection systems) can be found in Chapter 5, Volume 2.

B. Low-energy inorganic mass spectrometry

Unlike in the case of radiometric methods, which are used to detect characteristic radiations emitted by the decay of radionuclides to determine their quality and/or quantity, inorganic mass spectrometry techniques are based on the direct measurements of atoms (ions) of radionuclides. Mass spectrometry is especially useful for the analysis of long-lived radionuclides because the longer the half-life, the lower is the radioactivity of the radionuclide and the more sensitive mass spectrometry techniques are in comparison with radiometry. Plentiful applications in various fields of radionuclide analysis, such as the determination of natural radionuclides in high-purity materials, environmental monitoring, characterization of nuclear materials, radiobioassay measurements, radioactive waste control, geochronology and geochemistry, and even health and food control, have proven how important the development of inorganic mass spectrometry has been. The mass spectrometry methods allow multielemental determinations of radionuclide concentrations at ultratrace levels (Becker, 2012).

Although there are several low-energy mass spectrometry methods available, basic principles are practically the same for all of them. Typical modern instrumentation for mass spectrometry is composed of three essential components. First, ions are produced, accelerated, and focused in an ion source, which is the signature part of every mass spectrometry technique. After the ion source, ions in the beam are separated according to their respective mass-to-charge ratios in the region called the analyzer. As the last step, the separated ion beams are measured by a collector, either sequentially (single collector) or simultaneously (multicollector). The detection of ions itself in the collector is most commonly achieved by a Faraday cup or electron multiplier.

Here, we shall briefly discuss conventionally exploited low-energy inorganic mass spectrometry techniques, namely inductively coupled plasma mass spectrometry (ICP-MS), secondary ion mass spectrometry (SIMS), resonance ionization mass spectrometry (RIMS), glow discharge mass spectrometry (GDMS), positive-ion mass spectrometry (PIMS), and ^{3}He ingrowth spectrometry for tritium analysis.

1. Inductively coupled plasma mass spectrometry

A possibility to combine the ICP source with a quadrupole mass analyzer was introduced in the 1980s (Houk et al., 1980). Since then, ICP-MS has been developed into the most successful and frequently used inorganic mass spectrometry technique for the determination of isotopic ratios in the trace and ultratrace concentration range. ICP-MS offers a few advantages over other analytical techniques. Current systems are capable of measuring many samples with high precision and accuracy in a relatively short time. Furthermore, the general design of the ICP source allows ionizing of the sample—the nebulized solution or laser-ablated material—directly under atmospheric pressure. This enables an easy coupling of ICP-MS with different separation techniques, such as liquid chromatography, gas

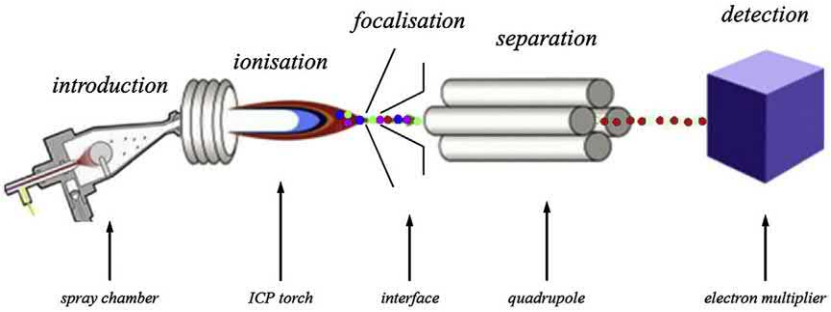

FIGURE 3.24 Simplified scheme of generic inductively coupled plasma mass spectrometry (ICP-MS) system. For the color version of the figure, the reader is referred to the online version of the book. *From Aceto (2016).* Printed with permission © Elsevier 2018.

chromatography, capillary electrophoresis, solid-phase microextraction, and others (Becker, 2012).

The generic scheme of the ICP-MS system and basic steps of any ICP-MS measurement are shown in Fig. 3.24. In the spray chamber, small droplets of the aerosol, produced from an aqueous sample by the nebulization process, are passed further into the plasma torch. There, chemical compounds are decomposed and ionized into atomic ions in argon plasma at the temperature of 6000−8000 K, with the typical efficiency better than 90% (Hou and Roos, 2008). The positively charged ions are focused by ion optics and extracted into the mass spectrometer through a sample and skimmer cones (interface). Well-designed ion optics can produce good detection limits, stable signal in sample matrices, and low background. Separation of ions based on mass-to-charge ratio is usually conducted by a quadrupole time-of-flight (TOF) analyzer or combination of electrostatic and magnetic sectors, where a double-focusing sector-field analyzer is generally considered to be superior to the quadrupole. In the end, the ions emerging from the mass analyzer are counted by a detector (electron multiplier or Faraday cup).

As in every mass spectrometry technique, ICP-MS is limited by the fact that the signal from ions of interest (e.g., $^{99}Tc^{+}$) can be disturbed by various interfering ions, such as polyatomic ions ($^{98}Mo^{1}H^{+}$), single isobaric ions ($^{99}Ru^{+}$), or single atomic ions causing tailing ($^{98}Mo^{+}$ or $^{100}Mo^{+}$). Some interference can be eliminated by increasing the resolution; however, others are more problematic and require the use of more advanced approaches, such as the exploitation of radiochemistry separation methods for sample preparation (Lehto and Hou, 2011), using more than one collector (Wieser and Schwieters, 2005), implementing dynamic collision/reaction cells to the system (Becker, 2012), coupling ICP-MS with a Fourier transform ion cyclotron resonance system (Barshick et al., 2000), or using the Orbitrap mass spectrometer (Koppenaal et al., 2011). Additionally, laser ablation, special sample introduction systems, electrothermal vaporization or hydride formation, or using cold plasma can also help to solve interference problems and matrix effect in ICP-MS measurements (Becker, 2012; Povinec et al., 2001).

After some necessary development, dynamic collision/reaction cells in ICP-MS have become more and more popular, especially for quadrupole systems (Tanner et al., 2002; Roos, 2008). In principle, collision/reaction gas (e.g., H_2, He, CO_2, NH_3, CH_4) presented in a cell reacts and collides with various ion molecules. As a consequence, polyatomic interfering ions are converted to noninterfering species, whereas the analyte can be transformed into another type of ion. Moreover, interfering isobars can also be removed due to different reaction rates of the analyte and isobar with the reaction gas. A typical collision cell, operating in the radio frequency (RF) mode, is positioned before the mass analyzer. A good example of the application of collision/reaction cells in ICP-MS are measurements of ^{129}I ($T_{1/2} = 1.57 \times 10^{7}$ years), which has a serious interferent ^{129}Xe present in the Ar carrier gas. In a hexapole cell, $^{129}Xe^{+}$ ions can react with the mixture of O_2 and He, transfer their charge to the gases, and get removed as neutral atoms before the mass analyzer. The polyatomic ions $^{127}I^{1}H^{2+}$ are also eliminated, which significantly improves the detection limit up to 0.4 pg g^{-1} (Becker, 2012; Lehto and Hou, 2011; Wyse et al., 2001). Other long-lived radionuclides (e.g., ^{93}Mo, ^{99}Tc, ^{107}Pd, ^{126}Sn, ^{151}Sm, ^{236}U, and ^{239}Pu) determined by quadrupole ICP-MS with a hexapole collision/reaction cell have the limits of detection in the range of 0.03 and 0.3 pg mL^{-1} (Becker, 2002).

Several parameters (abundance of interferents, background signal, measured element, sensitivity of the instrument) determine the detection limit for an ICP-MS measurement of radionuclides, which typically varies between 1 fg mL^{-1} and 10 ng mL^{-1}. Precision for isotopic ratio measurements by double-focusing sector-field ICP-MS can be as high as 0.02%, which is possible to improve by using a multiions collector device instead of a single collector by a factor of about 10, while it is a bit lower (0.1−0.5%) in the case of conventional quadrupole ICP-MS (Lehto and Hou, 2011). As isobaric interferences and background are generally higher for low-to-intermediate mass radionuclides, the limit of detection of ICP-MS is substantially better for high-mass radionuclides. Therefore, besides aforementioned radionuclides and some others (e.g., ^{79}Se, ^{90}Sr, ^{93}Zr, ^{135}Cs, ^{210}Pb, ^{226}Ra), isotopes of

actinides are most common radionuclides analyzed by ICP-MS (Nisi et al., 2009).

2. Thermal ionization mass spectrometry

Thermal ionization—ionization of atoms after contact with a very hot surface—has been known for several decades (first time observed in 1906); however, thermal ionization mass spectrometry (TIMS) has been profitably used since the 1980s. In TIMS, usually a small volume of liquid sample is evaporated and afterward ionized by resistive heating using a filament surface. Materials with high melting point and high purity, such as rhenium, tantalum, tungsten, and platinum are used as filament materials. Positive ions or molecules are generally used in TIMS; however, negative ions can be used, e.g., for boron, because of higher sensitivity of BO_2^- compared with $Na_2BO_2^+$, $Rb_2BO_2^+$, or $Cs_2BO_2^+$ (Klö;tzli, 1992). To eliminate the suppressive effects of ion formation by impurity elements in the solution, a pure chemical form is required for analyzed elements (Aggarwal, 2016), which results in time-consuming chemical preparation. Sample of about 0.5−1 μL aqueous solution with 1M HNO_3 is dried on the filament, and a particular ion is generated. To enhance the ionization yield of the measured element, ionization enhancers such as silica gel or H_3PO_4 and additives such as graphite and H_4SiO_4 can be used with the sample solution. After production, ions are accelerated to low energies, separated according to their mass, and registered usually in a multi-Faraday cup detection system.

With the development of fully automated systems for TIMS, the precision of isotopic ratio measurements is better than 0.01%, and by using normalization corrections for the isotope fractionation, the precision of 0.001% can be achieved (Hou and Roos, 2008). In comparison with other mass spectrometry techniques, the main limiting factors for the accuracy of TIMS in isotopic ratios measurements are the mass fractionation effects; however, by internal calibration and by using isotopic standard reference materials (e.g., from NIST—National Institute of Standards and Technology or IRMM—Institute of Reference Materials and Measurements) with known isotopic ratios, those effects could be minimized. The isotope dilution method, when a known amount of the precalibrated spike of long-lived isotopic solution of the same element, whose concentration needs to be determined, is added to the solution or solid, is frequently used. Since the determination of the studied isotope by isotope dilution mass spectrometry depends on the collected charge of the isotope−amount ratio, the data are not affected by incomplete recovery in chemical treatment.

The determination of ratios for radiogenic elements in geology, as well as tracer studies, is the primary application of TIMS. In geology, the determination of an age of a closed system could be measured by the ratio of the growth of daughter isotopes from radioactive decay and is referred as geochronology. TIMS is successfully used for dating of different matrixes by the determination of U-Pb (Crowley et al., 2015; Frechen et al., 2007; Waas et al., 2011; Zhong et al., 2017), Rb-Sr (de Meyer et al., 2014; Kanjanapayont et al., 2012; Li et al., 2008; Nebel and Mezger, 2008), and Nb-Sm (Guo et al., 2016; Henjes-Kunst et al., 2014). It is also used in cosmological studies for the analysis of different isotopes in extraterrestrial objects (Bermingham et al., 2018, 2016; Bonnand et al., 2016). Uranium isotopes can be precisely and accurately measured by TIMS in environmental monitoring (Taylor et al., 1998) and in nuclear forensic analysis (Bürger et al., 2007; Kraiem et al., 2011; Radulović et al., 2018; Rim et al., 2017). TIMS can be also used in environmental studies for the determination of plutonium isotopes (Lee et al., 2018; Xing et al., 2018).

3. Resonance ionization mass spectrometry

In resonance ionization, photons of precisely tuned lasers are used for excitation and ionization of valence electrons in the neutral atoms. RIMS combines the resonance laser ionization and mass spectrometry techniques. Before resonance ionization, only a neutral gas from sample material had to be produced by techniques such as laser evaporation, thermal evaporation by ion sputtering techniques, whereas the formation of ions had to be avoided or separated from produced gas. Sample material from a heated W or Re filament is usually thermally vaporized, and one or more lasers with chosen wavelength, according to the ionization scheme, are used for the ionization of only atoms of the element of interest. For resonant ionization, two or more precisely tuned lasers are used for excitation of the electron in ground state to intermediate excited states of hyperfine structure and excite the electron until it leaves the ionized atom. Whereas each element has a unique electron configuration, resonance ionization provides nearly complete isobaric suppression. High ionization efficiency, high transmission mass spectrometers, and low background ion detection enable a detection limit in the 10^{-15} to 10^{-18} g range and sensitivity better than 10^{13}, achieved by a combination of isotope selectivity of mass spectrometers and isobar selectivity in the laser resonant ionization (Hou and Roos, 2008). Although the basic principles of the resonant ionization were known for many years, described by Zandee and Bernstein (1979) and later Hurst and Payne (1988), the full utilization of the technique was achieved after the mid-1990s, when high enough power density lasers were developed. Due to its excellent sensitivity, resonant ionization is widely used in studies of nuclear structures (Fedosseev et al., 2012; Lassen et al., 2006). At present, there are no commercial RIMS instruments in the market; therefore, only several laboratories have developed the

technique for routine trace analysis. RIMS isotope analysis and the determination of many long-lived radioisotopes of interest such as ^{41}Ca (Bushaw et al., 2001), ^{90}Sr (Bushaw and W. Nortershauser, 2000), ^{135}Cs (Pibida et al., 2004), ^{236}U (Bushaw et al., 2007), and plutonium isotopes (Bürger et al., 2006; Raeder et al., 2012) have been developed and can be used for the analysis of environmental, biological, nuclear forensics, and technical samples (Erdmann et al., 2008; Wendt and Trautmann, 2005).

4. Glow discharge mass spectrometry

GDMS involves the sputtering of usually a solid sample (liquid as a dried solution) by Ar^+ ions produced in gas glow discharge. Typically, from 10 to 100 Pa of Ar is used to produce sufficient ions, which are accelerated toward the sample on the cathode surface, with energies from hundreds to thousands eV. Due to charge-up effects on the sample, the analysis of nonconducting materials is difficult by GDMS. Therefore, several techniques, such as mixing with high-purity metal powder or the use of a secondary cathode, have been applied during the analysis of electrically insulating samples. Neutral atoms sputtered from the sample are ionized in the glow discharge plasma, by Penning and/or electron impact ionization or charge exchange processes; the positively charged ions are extracted from the ion source to the spectrometer. The method was established as a powerful and efficient analytical tool for determination of trace elements analysis and depth profiling in bulk materials or thin films (Di Sabatino, 2014). With the microfabricated glow discharge plasma in the ion source, pixel mapping of the solid samples allows a relative fast determination of the surface distribution of the studied element (Gamez and Finch, 2018; Tian et al., 2016) and a 3D distribution by using depth profiling for each pixel. By using pulsed glow discharge in combination with gated TOF spectrometer, even spectra produced by different ionization mechanisms can be collected (Pereiro et al., 2011).

Although sputtering and ionization occurs at a different location in different times of the instrument, matrix effects are minimized and calibration with quantification of the device is much simplified. Since the sample preparation for GDMS analysis is very simple and samples can be directly analyzed, the risk of contamination is low. GDMS is used for the determination of trace elements in bulk solid samples, but it was also successfully applied for the fast analysis (without chemical separation, like for ICP-MS and TIMS) of uranium (Ganeev et al., 2017) and plutonium isotopes (Betti and Aldave de las Heras, 2004). However, the application of GDMS in the determination of radionuclides is limited due to its low sensitivity and limited accessibility (Hou and Roos, 2008).

5. Secondary ion mass spectrometry

In SIMS, the primary-focused ion beam of sufficiently high ion energy (up to 40 keV) is used to sputter the surface of the sample material. This is rather similar to GDMS, but the production of the primary beam is different. Depending on the analyzed element and required information, a primary ion beam made of, e.g., Ga^+, Cs^+, O_2^+, or O^-, can be chosen for high sputtering and ionization yield. Sputtered secondary particles, like clusters, neutrals, and about 1−5% sputtered ions, are after production and ionization in the ion source analyzed by mass spectrometry techniques. During the sputtering, molecular ion formation is often observed, and large matrix effects make the quantification of analytical results very difficult; nevertheless, by using a standard reference material, a precision of 0.002% can be reached (Hou and Roos, 2008). The main use of SIMS is in surface mapping and depth profiling of elements and isotopic ratios on solid samples with submicrometer resolution (Guerquin-Kern et al., 2005). Therefore, SIMS can be combined with a high-resolution spectrometric technique, such as TOF or accelerator mass spectrometry (AMS), to obtain unique information about surface distribution. It is often used for the identification and characterization of elements and isotopes in biological tissues (Shao et al., 2018a), small particles in aerosols (Huang et al., 2017), and liquid and solid samples. "Hot" particle identification and spatial distribution of radionuclides in nuclear materials can be determined with the SIMS technique by nuclear safeguards (Ranebo et al., 2007; Tamborini and Betti, 2000; Veniaminov, 2000).

6. ^{3}H-^{3}He ingrowth mass spectrometry

Due to its very low natural abundance ($^3H/^1H = \sim 10^{-18}$), direct analysis of tritium at trace levels by mass spectrometry techniques is still a challenge. To overcome this problem, ^{3}H-^{3}He ingrowth spectrometry has been developed, which is based on the determination of ^{3}He—produced by the decay of tritium—and back calculation of ^{3}H activity (Clarke et al., 1976). Currently, it is the most sensitive method for $^3H/^1H$ isotope ratios that can be measured down to 10^{-20}, which corresponds to the tritium activity of 0.01 TU or 1.19×10^{-3} Bq L^{-1}. The technique is mostly exploited for the analysis of seawater where the concentration of ^{3}H is beyond the measuring capabilities of radiometric methods; however, other types of water samples may be analyzed as well. To avoid possible contamination, the water sample is usually distilled prior its analysis. After that, the sample is transferred and hermetically sealed in a stainless steel container, where it is degassed by a vacuum pump. As tritium decays, the concentration of ^{3}He is slowly increased until the sufficient number of helium atoms is reached, which may take some

6 months. Before the measurement, the tritiogenic helium fraction is separated, purified, and isotopically diluted with a high-purity ^{4}He spike. The actual determination of ^{3}He/^{4}He can be conducted by a 90 degrees sector-field noble gas spectrometer (Palcsu et al., 2010; Papp et al., 2012).

7. Positive-ion mass spectrometry

Despite its overall versatility, AMS has some disadvantages, connected mainly with the need to use sputter negative ions sources (as discussed later). PIMS, recently developed and successfully tested by Freeman et al. (2015), might have the potential to overcome these limitations. The method is based on the opposite principle of the convenient tandem AMS, i.e., positive ion beam produced in the ion source (e.g., RF plasma source or electron cyclotron resonance ion source) is converted to the negative one with the use of a stripper channel, completely omitting acceleration. In radiocarbon measurements, the 140−280 keV carbon ion beams and N_2 or isobutane gases used for stripping showed enough efficiency to reproduce the >50,000 years radiocarbon age range of AMS. The mass separation of interfering ions (N^+, N^{2+}, CH^+, CH^{2+}, etc.) was performed by combining electrostatic analyzers (ESAs) with 90 degrees double-focusing magnets. PIMS could theoretically be more efficient and much faster than AMS, enabling high-precision analyses in seconds or even in real time. Besides radiocarbon, first results from the development of ^{26}Al-PIMS have been published as well (Shanks and Freeman, 2015).

C. Accelerator mass spectrometry

In mass spectrometry, the ions are formed from the sample, accelerated to energy E (ranging in keV) and afterward separated according to their mass. However, when studying some rare radioisotopes, the molecular interference becomes a problem; therefore, several methods were developed to suppress the formation and to separate the unwanted mimic molecules and ions. By accelerating the ions into higher energies (ranging in MeV), the ambiguities with identification of atomic and molecular ions with the same mass can be almost removed. This technique (called AMS) is able to measure isotopic ratios for specific elements to a level of 10^{-15} per ion. It was first used by Alvarez and Cornog (1939) for the detection of ^{3}He with the 88-inch Berkeley cyclotron, but the true potential of the technique was revealed by Muller (1977), where the method for the detection of ^{14}C and ^{10}Be by particle accelerator was described. Shortly afterward, AMS methods for other long-lived radionuclides were developed, including ^{10}Be (Raisbeck et al., 1978), ^{26}Al (Raisbeck et al., 1979), ^{36}Cl (Elmore et al., 1979), ^{41}Ca (Raisbeck and Yiou, 1979), and ^{129}I (Elmore et al., 1980).

Nowadays, AMS has evolved into an ultrasensitive technique for isotope analysis with a wide range of applications described in many articles and conference proceedings from 1978 up to 2017 (Gove, 1978; Gove et al., 1987; Henning et al., 1981; Wölfli et al., 1984; Yiou and Raisbeck, 1990; Fifield et al., 1994; Jull et al., 1997; Kutschera et al., 2000; Nakamura et al., 2004; Knezovich et al., 2007; Calcagnile et al., 2010; Zondervan et al., 2013; Braucher and Bourlès, 2015). The AMS became the most sensitive analytical technique for the analysis of radionuclides in the environment (Povinec, 2018a,b; Povinec et al., 2018ab). Long-lived radionuclides commonly measured by AMS are listed in Table 3.12.

1. Ion separation in accelerator mass spectrometry

Similar to conventional (low-energy) mass spectrometry, AMS does not directly measure the concentration in the

TABLE 3.12 Long-lived radionuclides commonly measured by accelerator mass spectrometry.

Radionuclide	^{10}Be	^{14}C	^{26}Al	^{36}Cl	^{41}Ca	^{129}I
Half-life (years)	1.51 M	5.73 k	720 k	301 k	103 k	15.7 M
Stable isotopes	^{9}Be	^{12,13}C	^{27}Al	^{35,37}Cl	$^{40\text{-}42,43,44}$Ca	^{127}I
Stable isobars	^{10}B	^{14}N*	^{26}Mg*	^{36}Ar*, ^{36}S	^{41}K	^{129}Xe*
Chemical form	BeO	C	Al_2O_3	AgCl	CaH_2/CaF_2	AgI
Sample size (mg)	0.5	0.01−1	2	1	10	2
Sensitivity (atom ratio)	2×10^{-15}	1×10^{-15}	2×10^{-15}	1×10^{-15}	5×10^{-15}	4×10^{-14}

*Does not form negative ions.

sample quantitatively but uses a stable nuclide, usually from the same element, as a reference. The result is therefore a ratio of trace to reference ions, called also the isotopic ratio. Before the ions are registered, they have to be produced from sample material and properly separated by using different trajectories in electric and magnetic fields. Often, the ions should be well focused for elimination of the suppressed background. By combination of the electric, magnetic, and radiofrequency fields, the chosen mass is filtered out from the produced ion beam. In ESA, a potential difference ΔU is applied between cylindrical or spherical electrodes at a distance d, whereas the ion beam follows a circular trajectory with a radius r_0. When an ion with charge q and energy E enters the ESA, the trajectory can be described by the equation:

$$\frac{E}{q} = \frac{\Delta U r_0}{2d} \tag{3.3}$$

Therefore, the ESA acts as a filter for the ions with the same E/q; and for ions with the small relative energy deviation, spatial separation at image position can be written as

$$\Delta x = r_0 \frac{\Delta E}{E} \tag{3.4}$$

Furthermore, the magnetic field separates the ions according to their momentum over charge. According to the Lorentz force, for the movement of the ion in the homogenic magnetic field perpendicular to the ion trajectory, the following equation can be written as

$$\frac{p}{q} = \frac{\sqrt{2ME}}{q} = Br_0 \tag{3.5}$$

where p is the momentum of the ion, M is the ion mass, B is the magnetic field strength, and r_0 is, in this case, the nominal beam radius of the magnet. Spatial separation of the ions with a small relative energy or mass deviation can be written as

$$\Delta x = 2r_0 \left(\frac{\Delta E}{E} + \frac{\Delta M}{M} \right) \tag{3.6}$$

By a combination of electric and magnetic fields, a velocity filter or Wien filter can be used. Uniform magnetic and electric fields at right angles and perpendicular to the incident beam can cancel the forces affecting the chosen ion and results in a straight nominal trajectory. Placing the electrostatic deflector plates with a distance d and a potential difference ΔU inside of a magnet with the field strength B, only the neutral or ion with velocity v will pass the filter

$$v = \sqrt{\frac{2E}{M}} = \frac{\Delta U}{Bd} \tag{3.7}$$

If the image is at a distance s from the center of the Wien filter with length l, the spatial separation can be obtained:

$$\Delta x = \frac{lsq\Delta U}{4Ed} \left(\frac{\Delta M}{M} - \frac{\Delta E}{E} \right) \tag{3.8}$$

Even by using the selectors or filters, different unwanted particles may reach the detector, which influence the detection limit of the spectrometer. This includes atomic and molecular isobars, ions with the same M/q and E/q as the chosen ion, ions with the incorrect mass, energy, or charge that mimic the path of the ions of interest in filters and selectors. Most of these limitations are drastically reduced by using the accelerator in the mass spectrometry system. A typical AMS facility consists of an ion source, injector (low energy separation), ion accelerator, analyzer (high-energy separation), and detection system for separated ions (Fig. 3.25).

2. Ion source

If the tandem accelerator is used for the AMS measurement, negative ions have to be produced from the sample material. Since noble gases do not form negative ions and intensive negative ions of some other elements (e.g., N, Mg, Mn, Zn, Cd, and Hg) are unstable to reach the terminal of the tandem accelerator, the AMS measurements of all elements are restricted. Due to a low ion current, the molecular ions such as hydrides or oxides are preferred for many elements (e.g., Be, Ca, Sr, Ba, U, Pu, etc.). For radionuclides, such as ^{14}C, ^{26}Al, and ^{129}I, the ion source is an important first step in isobar separation because of the instability of ^{14}N, ^{26}Mg, and ^{129}Xe negative ions. The choice of used ion depends on its production from sample material, negative ion yield, and suitable chemistry of preparation. For other types of accelerators such as Van de Graaff, cyclotron, or LINAC, a positive ion source is required.

In AMS applications, a Cs—sputter source (Middleton, 1983) is successfully used because of its relative stability, and because it can provide various ion beams with sufficient intensity. Several (up to 200 positions) samples of few milligrams (or less) are generally pressed into the metal holder and can be installed into the ion source. In the source, the Cs is evaporated from its reservoir, thermally ionized by hot surface, and the produced Cs^+ ions are accelerated and focused on the sample material, where these are used for sputtering of the sample ions (Fig. 3.26). Condensed Cs on the surface of the sample material provides additional enhancement of the negative ion yield (Nadeau et al., 1987). Negative ions produced by sputtering from the sample material are afterward preaccelerated to keV energies to undergo energy and mass separation and to reach the tandem accelerator.

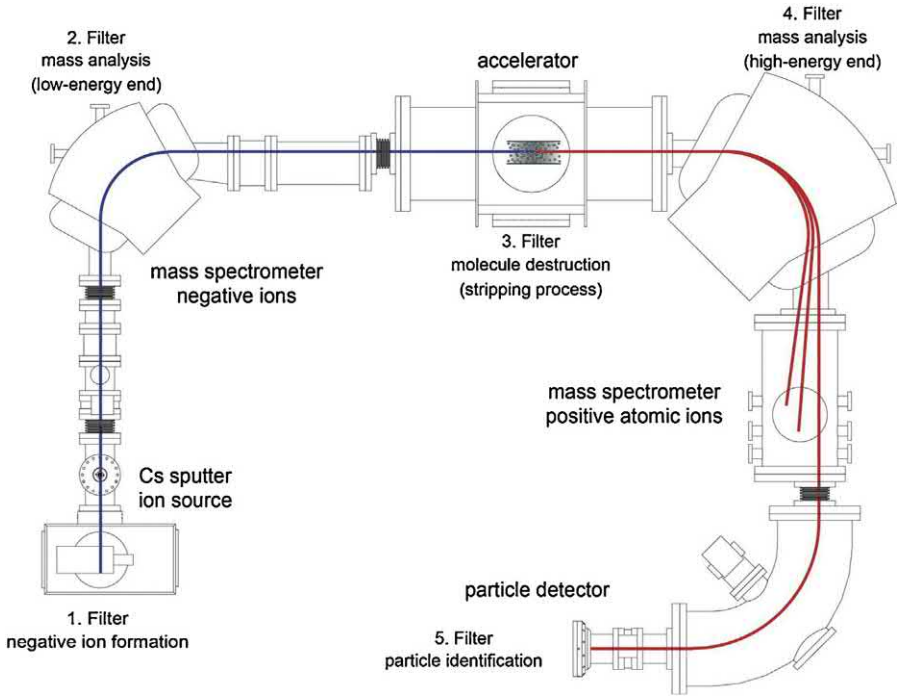

FIGURE 3.25 Scheme of small accelerator mass spectrometry (AMS) system used in ETH. For the color version of the figure, the reader is referred to the online version of the book. *From Synal (2013).* Printed with permission © Elsevier 2018.

If the samples in the ion source are close to each other, a small fraction of sputtered ions or vaporized atoms can be transferred from one sample to another or to nearby electrodes and insulators. By measuring the other sample, these transferred atoms could bias the results and are called "cross-contamination" or "memory effect." The microprobe ion source was developed by scanning the surface of the sample with focused Cs^+ beam. Secondary produced ions are afterward analyzed by AMS, and the surface profile of the studied radionuclide can be constructed (Döbeli et al., 1994; Freeman, 1993; Grabowski et al., 2007). Ion optics of the Cs^+ and extracted ions is crucial to reach the lowest detection limits. The Source of Negative Ions by Cesium Sputtering (SNICS) ion source for solid samples of the Centre for Nuclear and Accelerator Technologies (CENTA) laboratory at Comenius University, Bratislava, is shown in Fig. 3.27.

3. Injection system

The injector system includes the beam transport with beam analysis before entering the accelerator. This includes the

FIGURE 3.27 The SNICS ion source for solid samples of the CENTA laboratory. For the color version of the figure, the reader is referred to the online version of the book. CENTA, Centre for Nuclear and Accelerator Technologies; SNICS, Source of Negative Ions by Cesium Sputtering.

ESA and injecting magnet for the proper energy and mass separation of the ions produced in the ion source. As we mentioned before, the result of the AMS measurement is an isotopic ratio; therefore, the measurement of two masses is needed. In general, there are two ways for measuring the reference and the trace isotope. The first method is simultaneous injection, which uses usually two magnets (*analyzer* and *recombinator*) to inject two analyzed beams into the accelerator. Mass separation is done at the first magnet (*analyzer*), whereas the second magnet recombines the beams into one. While the simultaneous beams of the isotopes pass together through the ion beam elements, they experience all the fluctuations in the system together. However, the intensity of the trace element current is orders of magnitude lower than the current of the reference isotope injected simultaneously into the accelerator, and this can enlarge the background by charge-changing reactions in the stripper tube.

The second method uses sequential injection, where only one isotope is measured at a certain time and the other is measured in the sequence after. This requires periodical changes of the injection setup. Since the magnet design requires time in the order of several seconds for switching the mass of measured isotopes, rather than a magnetic field, the energy of the ions is adjusted. By applying a switched voltage to an insulated magnet box, the ions can be accelerated or decelerated in the order of microseconds. Fast-switched steerers are applied before and after the magnet for correction of unavoidable differences in the trajectories. Disadvantages of this method are that the variations of source current and ion transmission through the accelerator shorter than the rate of injection, cannot be observed, and that the trace isotope is counted only for a short time. Also, large variations in beam intensity can cause a problem for the accelerator and power supplies of the beam guiding elements. The injector comprises also focusing and beam shaping elements, together with beam intensity and position monitoring. For better suppression of isobaric ions, the laser photo detachment can be used in the injection part for AMS measurements (Berkovits et al., 1990; Forstner et al., 2008). Fig. 3.28 shows the injection part of the CENTA laboratory with the injection electromagnet.

FIGURE 3.28 The injection part of the CENTA laboratory with injection electromagnet. For the color version of the figure, the reader is referred to the online version of the book. CENTA, Centre for Nuclear and Accelerator Technologies.

4. Tandem accelerator

In the AMS system, tandem electrostatic accelerators are widely used, where the positive charged electrode, called the terminal, is used for acceleration of negative ions in the first step. When the beam is passing through the terminal, the ions undergo a so-called stripping process, where in charge exchange reactions with gas or foil, they will lose several electrons. Positive ions are again accelerated in second step, and the total energy of the ion after acceleration is given by

$$E = \left((V_{in} + V_T) \frac{M_{out}}{M_{in}} + qV_T \right) e \tag{3.9}$$

where $V_{in}e$ is energy of the injected ions (e is the electron charge), V_T is the terminal voltage, M_{in} and M_{out} are masses of the ions entering and leaving the accelerator (in case they are not equal), and q is the charge state of the positive ion. The choice of terminal voltage depends on the accelerator and radionuclide to be analyzed. Better identification can be achieved by higher charge states with higher energies, especially for stable isobar separation.

From 1977, where nuclear physics laboratories adopted their large tandems (6−15 MV terminal voltage) to AMS, more dedicated instruments were developed based mostly on 3 MV tandems, and recently, even compact AMS systems, with a terminal voltage down to 200 kV, were successfully used for the determination of standard AMS nuclides such as ^{10}Be, ^{14}C, ^{26}Al, and ^{129}I (Synal, 2013). Fig. 3.29 shows the Pelletron tandem accelerator (nominal voltage 3 MV) of the CENTA laboratory.

5. High-energy analyzer and ion detection

Before the trace isotope is counted in the detector, the separation and identification is needed. The apparent identification of an isotope requires the determination of its charge and nuclear mass. The most common approach combines two different types of analyzers, namely, magnetic to select an ion with required ME/q^2 and electrostatic for the proper E/q selection. Many different approaches were developed in AMS for isobar separation in the last

FIGURE 3.29 The Pelletron tandem accelerator (nominal voltage 3 MV) of the CENTA laboratory. For the color version of the figure, the reader is referred to the online version of the book. CENTA, Centre for Nuclear and Accelerator Technologies.

decades incorporating additional stripping stages followed by another energy and mass separation, gas-filled magnet, etc. (Miltenberger et al., 2017).

After the trace isotopes are filtered by high-energy separation, ions are registered as events in the ion detector. Identification of the ions in the detector is based on total ion energy, residual energy, rate of energy loss, velocity, range, and angle of registered ion. Solid-state detectors (e.g. surface barrier Si or Si diode detectors) are widely used because they are easy to handle, but they are vulnerable to radiation damage and their energy resolution is lower compared to other ion detectors. Ionization chambers have better energy resolution for heavy ions and for isobar discrimination, and chambers with multiple anodes can provide information about energy losses. Time-of-flight (TOF) systems have the highest mass resolution; however, energy and angular spread with no distinction against isobaric ions are main disadvantages. The high energy part of the CENTA laboratory is shown in Fig. 3.30.

V. Radionuclide analyses

A. Radioactive gases

Both naturally occurring and anthropogenically produced radionuclides can be present in the environment in gaseous form. Radioactive gases are of great interest from the radioecological point of view because of their high mobility in the environment and their contribution to both internal and external radiation doses. However, they have also been very useful as tracers of transport and mixing processes in the atmosphere and exchange processes between the environmental compartments (e.g., stratosphere–troposphere, northern–southern atmosphere, atmosphere–ocean, atmosphere–biosphere, atmosphere–pedosphere, etc.).

We will focus on sampling, sample preparation, and analysis of radioactive noble gases (radioisotopes of argon, krypton, xenon, and radon) and gases containing radiocarbon (CO_2, CO, and hydrocarbons) and tritium (water vapor, hydrogen gas, and hydrocarbons). These gases are sampled mainly from the atmosphere, but they are also present in soil air or dissolved in groundwater and oceans. A low abundance of these gases together with their low isotopic ratios results in the need for the collection of relatively large volume samples to obtain enough radioactive gas for analysis. This generates requirements not only for the characteristics of sampling process but also for sample preparation procedures and measurement methods. In general, sampling of gases from the atmosphere is based on pumping air through a medium that separates the gas of interest from the rest of the pumped sample by physical or chemical absorption. Prior to interaction with the separating medium, the sampled air is usually pumped through a filter to prevent any particulate matter from entering the gas handling part of the sampling apparatus. Sample preparation procedures aim to further separate the gas of interest from other gases and its purification for analysis. Both radiometric and mass spectrometry methods have been used to analyze concentrations of studied gaseous radionuclides.

1. Radiocarbon

Radiocarbon ($T_{1/2} = 5730$ y) is a part of the carbon cycle together with stable carbon isotopes; in the course of this cycle, radiocarbon can be found in several gaseous forms—CO_2, CO, CH_4, and other volatile hydrocarbons. Analysis of radiocarbon content in these gases can be used in environmental sciences and geosciences, e.g., in studies concerning fossil carbon emissions from industrial activities (Povinec et al., 2012c), and also to monitor ^{14}C releases from nuclear industry (Povinec et al., 2008).

Carbon dioxide is the most widely studied gas containing ^{14}C, and robust methodologies for its sampling have been developed over the years (Povinec et al., 1968). The sample air is pumped via an aerosol filter, and the CO_2 is captured and separated from the rest of the air. There are several methods for CO_2 capture—chemisorption in a hydroxide solution, cryogenic capture, and adsorption in molecular sieves and zeolites. Cryogenic capture is based on the freezing of gaseous CO_2 into dry ice at liquid nitrogen temperatures (−196°C). Such a sampling method requires a cryogenic system capable of maintaining these low temperatures. This method is rarely used for long-term sampling because of the relative complexity of such cryogenic systems and also because of its low selectivity. Other gases from the air will be partially condensed at liquid nitrogen temperatures, if the pressure inside the sampling system is not kept lower than the atmospheric pressure. However, liquid nitrogen is widely used for cryogenic transport of carbon dioxide in vacuum sample preparation lines for CO_2 samples obtained by other sampling methods. CO_2 can be separated from the sampled air in molecular sieves and zeolite materials (e.g., 13X molecular sieve). These materials have relatively high specificity and capture efficiency. After the sampling, they are placed inside a glass vacuum system, and the collected CO_2 is desorbed by heating the adsorbent. The desorption process needs to be optimized to avoid fractionation (change in isotopic ratios) and memory effects (contamination of subsequent samples) caused by incomplete desorption of CO_2 (Palonen and Oinonen, 2013). Water is usually adsorbed and desorbed together with CO_2 and needs to be separated after the desorption by a desiccant or by condensation/freezing. Molecular sieves and zeolites can be reused after desorption and thorough regeneration.

When using a hydroxide solution (most commonly NaOH) for a continuous sampling, the air is bubbled through this solution, and the chemical reaction between CO_2 and hydroxide creates carbonate (Na_2CO_3 when NaOH is used) that remains dissolved in the solution. Alternatively, a short-term sample can be taken in the field by exposing the hydroxide solution to air in a vessel with high surface area. The amount and concentration of hydroxide depend on the sampling flow rate, sampling period, and required sample size. After sampling, carbon in the form of carbon dioxide needs to be liberated from the exposed hydroxide solution. This can be achieved chemically by reacting the dissolved carbonates with barium chloride. The result of this reaction is barium carbonate, which is not soluble in water, and it precipitates from the solution. After sedimentation, it has to be separated from the solution and dried. Hydrolysis of the resulting barium carbonate with a concentrated acid in a glass vacuum line yields the sample CO_2 (Povinec et al., 2015). The same can be achieved by adding the acid directly into the exposed hydroxide solution (Svetlik et al., 2006). Carbonates in the solution react with the added acid, and CO_2 is released.

In addition to CO_2, other gaseous radiocarbon species can be sampled and analyzed—carbon monoxide and volatile hydrocarbons (C_nH_m). These analyses are usually done as a part of NPP monitoring studies, where ^{14}C is one of the most important radionuclides released into the environment during routine operation of NPPs. The aim of these studies is to determine the speciation of radiocarbon in gaseous releases. Differential samplers are used for simultaneous sampling of gases containing ^{14}C (Hertelendi et al., 1989). A diagram of such a sampler is shown in Fig. 3.31. First, CO_2 needs to be removed from the air by methods mentioned previously, and the CO_2-free air is pumped through a material that causes oxidation of CO to CO_2 (e.g., Hopcalite catalyst—mixture of manganese and copper oxides). CO_2 produced from CO is absorbed, and it can be analyzed separately. The air then passes through a heated palladium (or platinum–palladium) catalyst where methane and higher hydrocarbons are converted to CO_2.

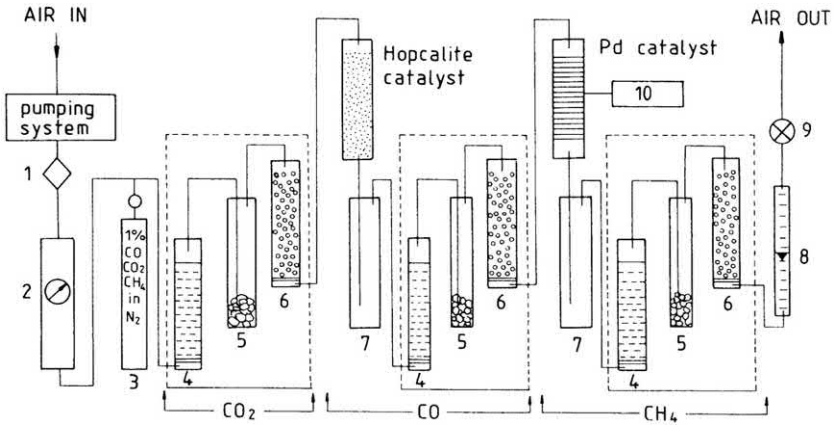

FIGURE 3.31 Schematic of a sampling system designed for separation of CO_2, CO and C_nH_m hydrocarbons from the sampled air. 1—aerosol filter, 2—gas meter, 3—carrier gas, 4—3M NaOH solution, 5—drop catcher, 6—drying columns, 7—buffer flask, 8—flow rate meter, 9—regulating valve, 10—regulated heater. *From Hertelendi et al. (1989).* Printed with permission © The American Journal of Science.

The resulting CO_2 is absorbed and represents another separate sample. The CO contribution to radiocarbon releases is usually negligible, and only CO_2 and C_nH_m are routinely sampled and analyzed. A different approach to CO_2 and C_nH_m sampling is using two parallel sampling systems, one only with CO_2 capture and the second with heated palladium−platinum catalyst followed by CO_2 absorption (Molnar et al., 2007). The sample from the first system represents CO_2 alone, and the second system represents sum of CO_2 and C_nH_m hydrocarbons.

Grab sampling of air for the purpose of radiocarbon analysis is also possible. If small samples are sufficient for analysis, evacuated vessels are opened to the air at the sampling location and sealed subsequently for transport into the laboratory (Graven et al., 2007). If larger samples are required, air is pumped with a compressor into empty pressure vessels (Tecl and Svetlik, 2009).

a. Gas proportional counting of ^{14}C

GPC is a measurement method that relies on the detection of electrons emitted from ^{14}C during its nuclear decay. Because the energy of these particles is very low (maximum energy of 156 keV), internal counters are necessary for these measurements. The radiocarbon sample needs to be a part of the counting gas itself. Several carbonaceous gases can be used as counting gas—carbon dioxide, methane, acetylene, and ethane. Use of CO_2 as counting gas is advantageous in the sense that in addition to release of the absorbed CO_2 sample, there is no further chemical sample treatment required. The disadvantage of CO_2 is that the electron drift velocity in carbon dioxide is relatively low, and therefore, it is very sensitive to electronegative impurities in the gas, e.g., oxygen (Povinec, 1992). Even small amounts of oxygen (ppm levels) can reduce the counting efficiency due to capture of drifting electrons by oxygen. Before using the CO_2 sample as filling for the gas proportional counter, it needs to be rigorously cleaned from these impurities. Purification methods include passing the CO_2 through an activated charcoal bed, heated elemental copper granules (removes oxygen), and heated silver wool (removes sulfur and halogens). Several cycles of purification may be necessary to achieve the required gas purity.

Hydrocarbon gases are much less sensitive to impurities and offer a good alternative as counting gases. However, additional sample preparation steps are necessary to transform the sample from carbon dioxide to hydrocarbon form. Methane is produced by cyclic hydrogenation of CO_2 in hydrogen gas catalyzed by ruthenium. Production of acetylene is done by reacting CO_2 with molten lithium metal and adding water to the resulting lithium carbide. Acetylene can be further used to prepare ethane by hydrogenation in the presence of palladium catalyst. The advantage of acetylene and ethane is that these molecules contain two carbon atoms, and therefore, twice the amount of carbon can be placed into the gas proportional counter of the same volume compared with methane or CO_2. These hydrocarbon-producing reactions have to be performed with highest possible efficiency to prevent any isotopic fractionation in the samples. The prepared gases also need to be purified from any unreacted reagents and impurities introduced during sample preparation. The additional preparation steps (chemical reaction as well as purification procedures) increase the risk of contamination by extraneous radiocarbon or ^{14}C-free carbon (from chemical reagents and catalysts). During sample preparation of gases for GPC, radon ^{222}Rn from radium impurities in catalysts, reagents, and purification mediums can be introduced into the sample (Horvatinčić et al., 1995). Its decay would increase count rate in the detector. While there are some methods for radon removal, it is much simpler to use the short half-life of radon (3.8 days) to remove its influence. The prepared samples are usually stored for 4−5 weeks before measurement to ensure that both radon and its daughter radionuclides decay to undetectable levels.

There are many variations of GPC detectors with different building materials, active shielding methods, anode and cathode geometries, etc. The sensitive volume of gas proportional counters is in the range of several tens of milliliters to several liters (Otlet et al., 1986). Fig. 3.32 shows an example of a large-volume gas proportional detector with sensitive volume of 4.6 L. Most of GPC systems were developed for relatively large environmental samples where it is usually possible to obtain large amounts of sample material. The advantage of large-volume GPC detectors is higher count rate and shorter counting time. But there are also many small-volume GPC systems for applications where sample size is limited. The low count rates require a much longer measurement time, and these systems have to be designed with very stable counting characteristics for long-time periods.

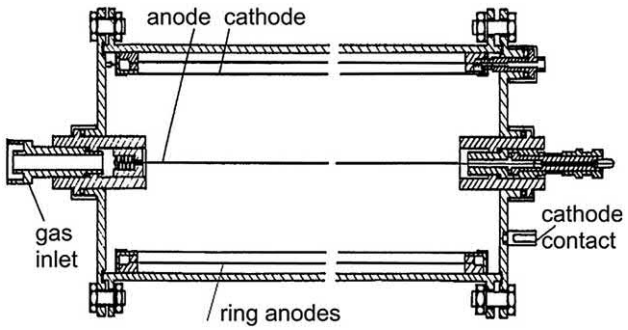

FIGURE 3.32 Schematic diagram of a multiwire gas proportional counter. The inner detector registers beta electrons from the sample, and the ring counter surrounding it is used as active shielding for background suppression. *From Povinec (1978).* Printed with permission © Elsevier 2018.

The background count rate of GPC detectors is lowered by placing them underground and surrounding them in shielding materials (old lead, electrolytic copper, iron, neutron-absorbing materials, etc.). This passive shielding is not enough to decrease the background to necessary levels, and active shielding is required. Guard counters (usually scintillation detectors or gas proportional counters) can be placed around the GPC detector inside the shielding, and the counts from them are used to veto nonsample counts by anticoincidence electronics. The guard counter can also be a part of the GPC detector's construction. The GPC detector can be made from two counters with the same cylindrical cathode—one cylindrical counter where the sample counts will be detected and the other one surrounding it and acting as active shielding (Povinec, 1978). The gas proportional counter in Fig. 3.32 uses this configuration.

In addition to GPC measurement of the sample itself, a standard reference material needs to be measured together with background samples. Standard reference materials are combusted in oxygen to produce CO_2, which is processed by the same methods as the analyzed samples. ^{14}C-free fossil gases are used as background. These measurements are evaluated according to ^{14}C data conventions (Stuiver and Polach, 1977). The further development of GPC detectors has diminished considerably with the advent of AMS, especially due to the introduction of affordable compact AMS systems specifically designed for ^{14}C measurements (Synal, 2013).

b. Liquid scintillation counting of ^{14}C

LSC is widely used for ^{14}C analysis because LSC systems often offer higher sample throughput compared with gas proportional counters. The basis of LSC measurement methods for ^{14}C analysis of gases is the conversion of the sample CO_2 into a suitable organic compound that can be used as solvent for the scintillation cocktail. The preferred solvent for use in LSC of radiocarbon is benzene, as its properties are compatible with its use as solvent for scintillation cocktails and its carbon content is higher than 90%. The sample CO_2 is reacted with molten lithium metal to produce lithium carbide. Addition of water converts the carbide into acetylene gas, which is then catalytically trimerized to benzene (Tamers, 1975). Yields of these chemical reactions need to be monitored, and consistent routine procedures need to be established and followed to exclude any fractionation or sample cross-contamination. Samples are stored for several weeks before their measurement to allow the radon and its daughters to decay below detectable levels. A modification of benzene recovery temperature from the catalyst can lead to removal of radon from the final benzene sample and can obviate the need for this waiting time (Hood et al., 1989). Modern LSC machines equipped with pulse shape discrimination systems can evaluate the radon contamination by identifying counts from radon progeny and calculating a correction factor for the measured ^{14}C activity (Theodórsson, 2005).

In certain applications, the sample hydroxide solution or other CO_2-absorbing chemical compounds (e.g., Carbosorb) can be mixed directly with certain liquid scintillation cocktails (Horvatinčić et al., 2004). This offers a quick and relatively simple method for LSC measurement of radiocarbon, but due to relatively low absorbing capacity of these chemicals, the carbon density of such samples is much smaller than benzene samples. This leads to lower precision and longer counting times.

Direct LSC measurement of $BaCO_3$ precipitate is also possible. The CO_2 is sampled by absorption in NaOH solution, and $BaCO_3$ precipitated from the sample solution can be added to certain scintillation cocktails and measured directly without hydrolysis and benzene synthesis. This method is used mainly in monitoring of gaseous radiocarbon releases in the vicinity of NPPs (Vokal and Kobal, 1997).

c. Accelerator mass spectrometry of ^{14}C

A general description of the AMS systems has been covered in Section IV.C; here, we shall focus only on the applications of AMS for ^{14}C analysis. The most important difference between AMS and decay counting methods is the required sample size. While GPC and LSC require samples with grams of carbon for routine measurement, optimal sample size for AMS analysis is milligrams of carbon, and with recent developments in ion source technology and sample preparation procedures, even samples with several tens of micrograms of carbon are available for AMS measurement. In addition, sample throughput of AMS can be much higher than that of decay counting methods.

Most AMS systems use solid graphite targets as sample matrix for ion beam generation. The sample CO_2 therefore needs to be converted into graphite form by catalytic reduction. Several methods for graphitization exist, each employing a different approach to reduction of carbon dioxide gas into graphite on an iron powder acting as catalyst (e.g., Liong Wee Kwong et al., 2004b; Povinec et al., 2015b). Other iron group metals can be used as well, but the majority of AMS laboratories use iron powder for this purpose. Hydrogen reduction method uses hydrogen gas as reducing agent (Němec et al., 2010a). The sample CO_2 and hydrogen gas are closed in a reactor volume with iron powder, which is heated to temperatures above 500°C. The chemical reaction $CO_2 + 2\ H_2 \rightarrow C + 2\ H_2O$ yields graphite and water. The produced water could interfere with the reaction and needs to be trapped in a part of the reactor either cryogenically or by a desiccant material

(e.g., magnesium perchlorate). The pressure of gases inside the reactor decreases due to deposition of graphite on the heated iron catalyst. This pressure decrease can be monitored by a pressure transducer, and the reaction yield can be calculated based on these data. The zinc method does not use any gases other than the sample CO_2, similarly as it has been used for CH_4 synthesis in GPC (Povinec, 1972). The sample is loaded into the reactor with separately placed zinc and iron powders heated externally by electric ovens. CO_2 is reduced to CO on the surface of hot zinc, and the reaction $2CO \rightarrow CO_2 + C$ produces graphite and carbon dioxide, which is again reduced on hot zinc (Slota et al., 1987). These methods can be relatively labor intensive, and to accommodate the high sample throughput of some AMS laboratories, sealed tube graphitization methods were developed. In these methods, the sample CO_2 is cryogenically transported into a glass test tube with the required reagents, and the tube is subsequently flame sealed and placed into a muffle furnace or an electrical heater. One of these methods uses iron powder as catalyst and substrate for graphite formation placed in a smaller tube inside the larger sealed tube and titanium hydride and zinc as reagents (Xu et al., 2007). In temperatures around 500°C, hydrogen is released from titanium hydride and the sample CO_2 is reduced to CO on hot zinc and in hot hydrogen. CO then reacts with hydrogen and is deposited as graphite on iron powder. Zinc also reacts with the water produced in this reaction and generates hydrogen. There is also a sealed tube method that uses zinc as the sole reduction agent without the use of titanium hydride as a source of hydrogen (Orsovszki and Rinyu, 2015). The graphitization process is very sensitive to impurities in the sample CO_2, especially sulfur and halogens, which can act as catalytic poisons for the graphitization reaction. CO_2 needs to be purified prior to reduction to graphite. Gas purification in heated copper and silver wool columns is routinely used. The graphite deposited on iron powder is removed from the reactor or graphitization tube and is pressed into metal cathodes suitable for the ion source.

Graphitization is a possible source of sample contamination with extraneous carbon. Because routine AMS samples are very small (around 1 mg of carbon), even relatively small contamination introduced in the sample preparation process can be significant and these procedures need to be rigorously studied and tested in regard to possible contamination sources. The contamination sources forming this background are the reactor materials, residual gas in the gas handling line, and chemical reagents. Blank samples from ^{14}C-free materials are also subjected to the same preparation procedures as samples and radiocarbon standards to determine background levels necessary for background corrections. In general, the ^{14}C background levels increase with decreasing sample size (Brown and Southon, 1997). Every measurement batch must have several standards and blanks for stable isotope and background corrections (Rom et al., 1997).

For very small samples (<50 μg of carbon), the graphitization process can be challenging due to lower yields and higher blank values. In recent years, gas ion sources utilizing CO_2 gas for ion beam generation have been developed and successfully applied for AMS analysis of small samples (Bronk Ramsey et al., 2004; Povinec et al., 2009a). The sample CO_2 is injected directly into cesium ion source in helium flow which produces negative ions that are necessary for tandem AMS systems. These gas ion sources generally produce low negative ion currents and in conjunction with a small sample size result in lower precision of ^{14}C results.

Fig. 3.33 shows the layout of a typical AMS system based on a tandem accelerator. The graphite target is sputtered, and negative ions are formed and extracted into the beam line. The ions are separated by mass in the injection magnet, and masses 12, 13, and 14 are sequentially injected into the accelerator. In the high voltage terminal in stripping medium (gas or foil), positive ions are formed and further accelerated into the high energy part of the system. The molecular ions with same mass as carbon ions are dissociated in this step. Following the acceleration, the ions are separated by their charge and energy in an ESA. The charge state for further analysis is chosen depending on charge state yields dependent on terminal voltage and stripping characteristics. Charge state 3+ is generally used in most systems with terminal voltage in megavolt range. A magnetic analyzer is used to separate $^{14}C^{3+}$ ions and direct them into an end detector. The masses 12 and 13 for the stable carbon isotopes are measured in Faraday cups. The $^{14}C^{3+}$ ions are counted in an energy-sensitive ionization detector, usually a semiconductor detector or gas ionization chamber.

Several compact AMS systems have been developed in recent years for ^{14}C-dedicated AMS (Synal, 2013). They are equipped with smaller accelerators with lower voltage and therefore have to use lower charge states. Modifications to the stripping process and accelerator construction enable efficient dissociation of interfering molecular isobars even at these charge states. The modern AMS systems could also avoid preparation of solid graphite targets, as a gas ion source containing the CO_2 sample can be used for ^{14}C measurements. A very recent promising development in ^{14}C mass spectrometry is the PIMS (for details, see Section IV.B).

Two sources have changed ^{14}C levels in the atmosphere: nuclear bomb tests and to a lesser degree also the nuclear industry. Radiocarbon was released in large quantities during atmospheric weapon tests during the 1950s and early 1960s, as well as during two major NPP accidents in Chernobyl (1986) and in Fukushima (2011). However, there is another anthropogenic effect caused by the fossil

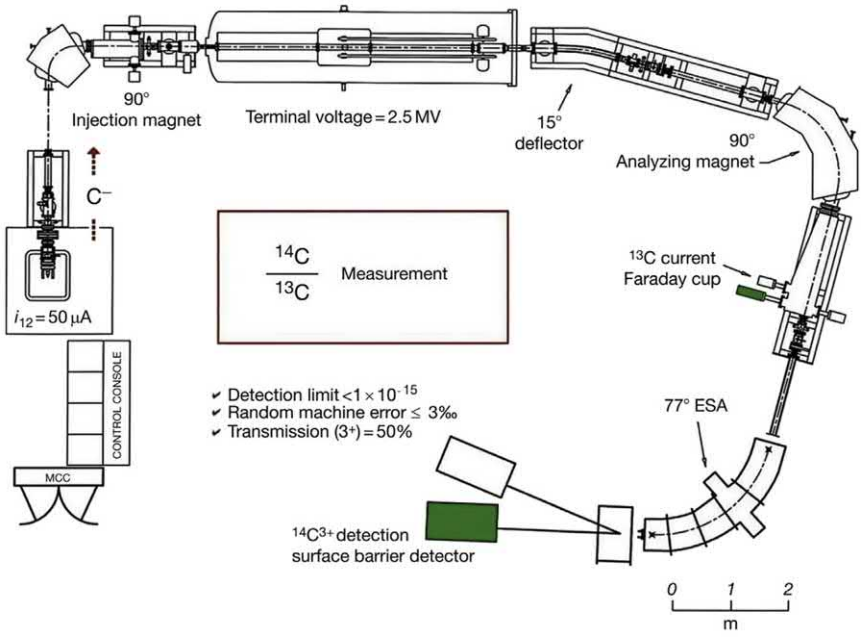

FIGURE 3.33 Example of a radiocarbon accelerator mass spectrometry (AMS) system (University of Arizona, Tucson, United States) and its component parts. *From Jull (2013).* Printed with permission © Elsevier 2018.

fuel combustion, which influences the ^{14}C concentration in the atmosphere (Levin et al., 1980; Levin and Kroner, 2004; Segl et al., 1983). This effect is well seen through the $^{14}CO_2$ season variations.

Radiocarbon results are presented as $\Delta^{14}C$ values, which were calculated relative to the NIST (National Institute of Standards and Technology, Gaithersburg, United States) ^{14}C oxalic acid standard, and corrected for the isotopic fractionation using the formula (Stuiver and Polach, 1977)

$$\Delta^{14}C = \delta^{14}C - \left(2\delta^{13}C + 50\right)\left(1 + \frac{\delta^{14}C}{1000}\right)\left(‰\right), \tag{3.10}$$

where

$$\delta^{14}C = \left(\frac{A}{A_S} - 1\right)1000 \quad \left(‰\right). \tag{3.11}$$

A represents the activity of a sample, A_s is the corrected activity of the NIST standard, and

$$\delta^{13}C = \left(\frac{\frac{^{13}C}{^{12}C}}{\left(\frac{^{13}C}{^{12}C}\right)_s} - 1\right)1000 \tag{3.12}$$

where $(^{13}C/^{12}C)_s$ is the isotopic ratio of the PDB standard. The uncertainty was estimated as a partial derivation of the above $\Delta^{14}C$ expression, which was mainly composed of statistical Poisson uncertainty of decay counting (~5‰ at 1 σ level); contributions from systematic sources (e.g., sample collection and preparation, gas pressure in the counter, barometric effect, and background) were estimated (on the basis of repeated analyses of the NIST ^{14}C oxalic acid standard, background, and cross-check samples) to be below 2‰.

As an example, we present in Fig. 3.34 results of measurement of atmospheric $^{14}CO_2$ activity in the vicinity of the Jaslovské Bohunice NPP and in Bratislava, which represents a heavily urbanized and industrialized area in Slovakia (about 60 km from Jaslovské Bohunice) (Povinec et al., 1968, 1986a,b, 2009b). These results show increased radiocarbon levels due to releases from the NPP and also extremely low levels caused by the dilution of radiocarbon in the atmosphere by ^{14}C-free fossil fuel emissions.

2. Tritium

Tritium ($T_{1/2}$ = 12.32 y) is sampled from the environment in these gaseous forms—tritiated water vapor (HTO, including DTO and T_2O), tritiated hydrogen gas (HT, including DT and T_2), and tritium-containing volatile hydrocarbons (often referred to as CH_3T). Measurement of tritiated gases has been carried out mainly in studies focusing on releases from reprocessing plants and NPPs (Connan et al., 2017; Zhang et al., 2018).

In air samplers for tritium analysis, the air is pumped into the sampling system through an aerosol filter, and the water vapor is collected as the first step. Molecular sieves, zeolites, and silica gel are widely used for this purpose. The amount and type of molecular sieve material depends on the sample size and its humidity. The hydrogen gas sample

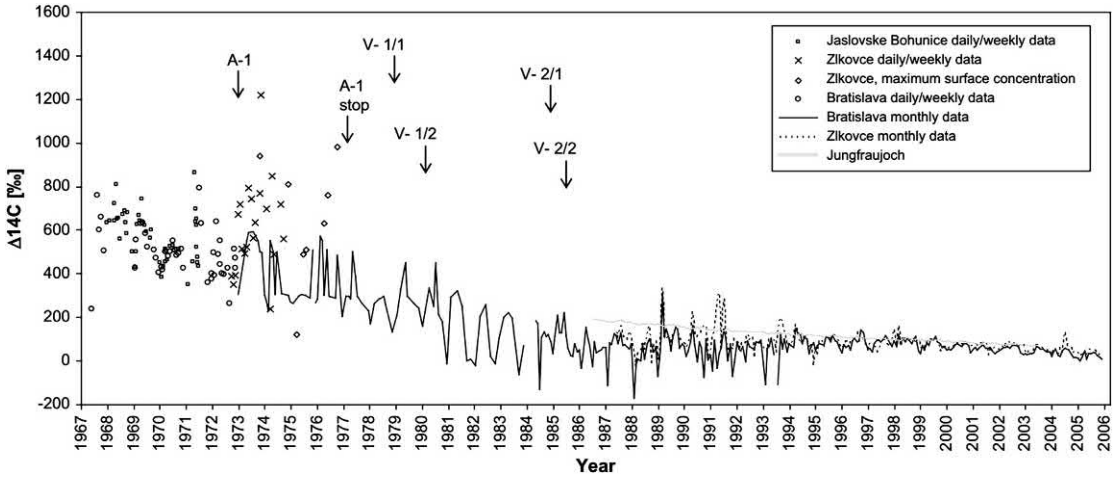

FIGURE 3.34 Radiocarbon in atmospheric CO_2 at the Bohunice NPP and Bratislava sampling station in Slovakia. $\Delta^{14}C$ is defined as relative enrichment or depletion of ^{14}C in the sample compared with international oxalic acid standard. Jungfraujoch data set (a thin gray line, Levin and Kromer, 2004) represents clean air background without any local fossil carbon sources or anthropogenic ^{14}C source. *From Povinec et al., (2009b).* Printed with permission © Elsevier 2018.

is collected next by converting the hydrogen to water by oxidation catalyzed by palladium or platinum at temperatures ranging from room temperature to 100°C. The resulting water is trapped in the same way as the atmospheric water vapor in the first step. The hydrocarbon sample is collected in the form of water after conversion of hydrocarbons to water by palladium catalyst at elevated temperatures (~300°C). The samples are then desorbed from the sorbents and condensed to liquid water. Fig. 3.35 shows an example of tritium sampler with HTO, HT, and hydrocarbon separation.

a. Gas proportional counting of ^3H

Similarly, as in the case of radiocarbon, the beta particles emitted by tritium during its nuclear decay have a low energy (maximum energy is 18.6 keV), and they need to be measured in internal counters. The tritium sample has to be used as a component of the counting gas. Methane is an ideal gas for this purpose; it can be labeled by radiocarbon and tritium (Povinec, 1980). Simultaneous measurement of both ^{14}C and ^3H is also possible by GPC (Povinec, 1975; Mace et al., 2017). Methane is synthesized from hydrogen and carbon dioxide in the presence of a heated ruthenium catalyst. To produce hydrogen from water, zinc powder is placed into the reactor volume together with sample water. Heating of the zinc powder and water causes a chemical reaction between zinc and water producing zinc oxide and hydrogen gas. Hydrogen reacts with CO_2, and methane is produced. Alternatively, reaction of sample water with heated aluminum carbide can be used for methane synthesis.

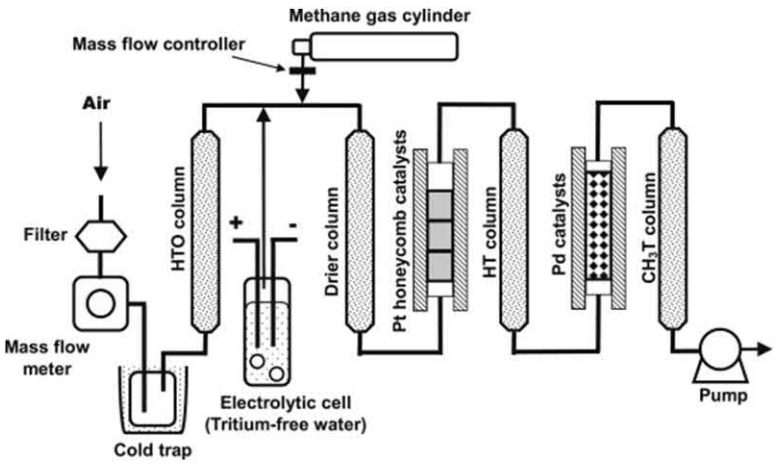

FIGURE 3.35 Tritium sampling system with HTO, HT, and hydrocarbon differentiation. *From Akata et al. (2011).* Printed with permission © Elsevier 2018.

In general, similar types of GPC detectors are used for tritium analysis as for radiocarbon measurement (see previous section). The same advantages and limitations apply for ^{3}H measurement as well. The GPC method of tritium measurement is still used in some laboratories, but because it requires additional and relatively complex sample preparation procedures, most laboratories use LSC for routine measurement of tritium samples.

The method of simultaneous ^{3}H and ^{14}C counting by GPC has been a trigger for development of the method for simultaneous activity and background measurement (Povinec, 1981).

b. Liquid scintillation counting of ^{3}H

LSC is by far the most used method for measurement of tritiated gases and sampled in the form of water, and water can be then mixed with a scintillation cocktail and measured by liquid scintillation. The sample preparation is based on removal of other radionuclides from the sample and its purification from any compounds that could react with the scintillation cocktail or act as a quenching agent during the measurement. Both of these goals can be achieved by distillation of the sample. The majority of radionuclides that could interfere with tritium detection has much higher boiling point than water and will be separated from the sample during the distillation process (Lehto and Hou, 2011). Impurities from the water are also removed in the course of distillation. The purity of the water can be determined by measurement of its conductivity, and the distillation step can be repeated several times to achieve the required water purity. Benzene synthesis as was described in previous section about radiocarbon can also be used to incorporate the sample hydrogen into solvent for the scintillation cocktail.

Current natural ^{3}H levels are usually too low for direct measurement with good precision, and tritium enrichment is necessary for these samples. The most widespread method is electrolytic enrichment. Sample water is loaded into an electrolytic cell with an anode and cathode. H^{+} ions are drawn to the cathode, and there, they produce hydrogen gas. OH^{-} ions move toward the anode where they produce oxygen gas and H^{+} ions. That means the water molecules gradually dissociate. The probability of dissociation of a water molecule containing tritium is lower than the probability for water molecule without tritium. Therefore, the gradual dissociation of the sample enriches it in tritium. The required enrichment level and sample size depends on the characteristics and detection limits of the LSC system, but in general, ^{3}H enrichment by a factor 10–50 can be achieved (Lehto and Hou, 2011). The electrolytic enrichment is done in batches, and in every batch, a number of samples with known ^{3}H activity and tritium-free samples (old water) are enriched together with the unknown samples. This way, the recovery efficiency of the enrichment process and any ^{3}H contamination can be determined and taken into account during data evaluation. The enriched sample is distilled again to purify it, and then, it can be added into a suitable scintillation cocktail for direct measurement by LSC.

The precision of the results depends on counting time and characteristics of the LSC system used. There are many LSC systems commercially available, and their counting characteristics are the dominant factor influencing the measurements. Background of the LSC detection system itself and quality and radiopurity of the scintillation vials are also contributing factors (Liong Wee Kwong et al., 2001).

c. ^{3}H-^{3}He ingrowth mass spectrometry

For samples with low tritium content, mass spectrometry of ^{3}He (decay product of tritium) can be used to determine the tritium activity. This measurement technique is called the ^{3}He ingrowth method (see also Section IV.B), and it is used mainly for water samples, but the gaseous forms of tritium are sampled in the form of water, and if the volume of the sampled air is large enough, this method can in principle be used for these measurements as well. The sample water needs to be degassed first to remove any helium already present in the sample, and the sample is then sealed and stored. Over the course of the storage, tritium decays and produces ^{3}He in the sample. The length of the storage period (from several weeks to months) depends on the presumed tritium levels, sample size, and detection limits of the mass spectrometer (Jean-Baptiste et al., 1992; Palcsu et al., 2010). After the storage period, the ingrown helium is released, purified, and measured in a noble gas mass spectrometer. The results of the mass spectrometric measurements together with the duration of the ingrowth period are then used in the calculation of tritium levels in the sample.

d. Accelerator mass spectrometry of ^{3}H

Previous methods described require relatively large samples, but the AMS allows tritium analysis of small samples in the region of milligrams. The samples in the form of water need to be converted into solid form suitable for cesium ion sources used in AMS systems. The optimal sample preparation appears to be synthesis of titanium hydrides. The sample is loaded into a glass tube with zinc powder or granules at the bottom and titanium powder in a smaller tube. Water is cryogenically frozen inside the tube, and when reasonable vacuum is achieved, the glass tube is flame sealed and placed into a muffle furnace at 400–550°C (Chiarappa-Zucca et al., 2002; Pánik et al., 2017). The water vapor will react with zinc to produce hydrogen gas, which in turn reacts with titanium yielding

titanium hydrides. Titanium hydrides can be then pressed into cathodes and placed into an AMS ion source. The measurement of ^{3}H using AMS follows the same principles as described in the previous section dealing with ^{14}C. Because of very low $^{3}H/^{1}H$ isotopic ratios in the environment and background problems (of the order of 10^{-18}), the AMS technique has not been applied in environmental studies. The ^{3}H AMS analysis has been used mainly for biomedical applications and biogenic tritium studies (Love et al., 2002; Roberts et al., 1994).

As a typical example of ^{3}H measurements in the atmosphere, we present in Fig. 3.36 a Chernobyl ^{3}H record measured in Bratislava.

3. Argon, krypton, and xenon

Radioactive isotopes of these noble gases are used for dating in hydrogeology (Collon et al., 2004b), monitoring of NPP and reprocessing plants (Cimbák et al., 1986; Igarashi et al., 2000), and also global monitoring of nuclear weapon tests (Wernsperger and Schlosser, 2004), recently organized in the framework of the CTBTO (for details, see Section VI.A). Most important radionuclides from this group with their respective half-lives are shown in Table 3.13. ^{39}Ar and ^{81}Kr are long-lived radionuclides, and their production in nuclear fission is negligible. On the other hand, ^{37}Ar, ^{131m}Xe, ^{133}Xe, ^{133m}Xe, and ^{135}Xe are short-lived and are efficiently produced in nuclear fission, and they act as indicators of nuclear weapon tests.

Generally, relatively large volumes of air were required, ranging from 1000 L (Cimbák et al., 1986) to more than 10,000 L (Nitta et al., 2014; Yokochi et al., 2013) for sampling of noble gases in the atmosphere and subsequent analysis by GPC. However, the newly developed measurement techniques allow krypton and xenon analysis of air volumes in range 1−50 L possible (Tu et al., 2014). Sampling by continuous air flow is done in laboratories where continuous monitoring of radioactive noble gases in the atmosphere is the purpose of these measurements (Cimbák and Povinec, 1985; Igarashi et al., 2000). In the field, grab sampling is used—samples are collected by an air compressor unit and stored in pressure vessels for transport to the laboratory where the separation of noble gases takes place. Other radioactive gases can be separated from these grab samples in addition to noble gases prior to their extraction from the sample (Tecl and Svetlik, 2009). In some cases (sampling in difficult terrain, remote areas, etc.), transport of large quantities of bulk gas in pressure vessels is impractical, and preconcentration of noble gases is necessary (Yokochi et al., 2013).

TABLE 3.13 Most important radioisotopes of noble gases (NuDat, 2018).

Nuclide	Half-life
^{37}Ar	35.04 days
^{39}Ar	269 years
^{81}Kr	2.29×10^{5} years
^{85}Kr	10.74 years
^{131m}Xe	11.84 days
^{133}Xe	5.24 days
^{133m}Xe	2.2 days
^{135}Xe	9.14 hours

For noble gases, the most widely used adsorption medium is granulated activated charcoal at low temperatures. These low temperatures are achieved either by placing the column with activated charcoal into Dewar vessel filled with liquid nitrogen or by cryogenic air chillers (Bowyer et al., 1997, 1999). Lower pressure is maintained in these adsorption columns to prevent condensation of oxygen and nitrogen at liquid nitrogen temperatures. High water vapor content in the sampled air can negatively influence adsorption on activated charcoal, as water vapor can block some of the capillaries in the charcoal and effectively decrease its active surface area (Scarpitta and Harley, 1990). Therefore, when sampling gases with high humidity, water vapor traps have to be placed before the activated charcoal bed. These can be in the form of glass or metal vessels cooled to lower temperatures to promote water condensation and freezing or packed with water-absorbing material such as silica gel or molecular sieves. In recent years, alternative materials to activated charcoal have been studied for use in noble gas sampling, and some polycarbonate materials (e.g., Makrolon, Makrofol, and their equivalents) show good absorption abilities for radon and other noble gases (Mitev et al., 2018; Möre and Hubbard, 1997). However, further studies of their properties in regard to noble gas sampling are required before

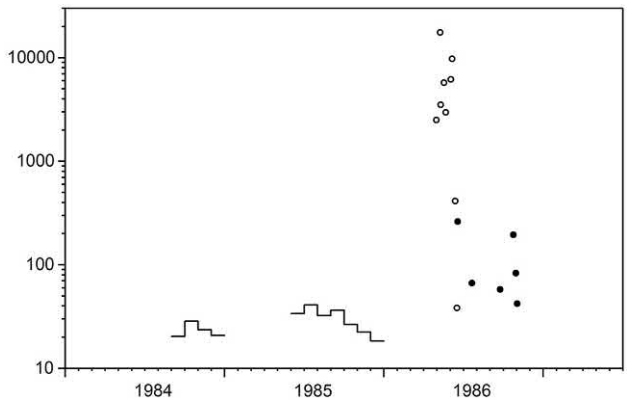

FIGURE 3.36 Tritium in the Bratislava air (*open dots*) and rain (*full dots*) after the Chernobyl accident.

they are widely used in these measurements (Pressyanov et al., 2004).

Some of the radioactive noble gases (e.g., ^{81}Kr, ^{85}Kr, and ^{39}Ar) can be used for radioisotope dating of groundwater, and they need to be extracted from water. Low solubility of noble gases in water means that large water samples are required. As an example, 1 liter of ocean water contains on average about 0.5 mL of argon and 0.1 μL of krypton (Collon et al., 2004b). Due to this fact, noble gases are most commonly extracted in the field by degassing. There are two types of degassing systems—vacuum cylinder extraction and membrane extraction. In vacuum cylinder extraction systems (Collon et al., 2000; Sturchio et al., 2004), sampled water is pumped from the studied reservoir and sprayed into an evacuated cylindrical container. According to Henry's law, the gases dissolved in water will be transferred to the gas phase to achieve solubility equilibrium, and the released gases can be compressed into pressure vessels for transport to the laboratory. A second approach to extraction is using hydrophobic semipermeable membranes (Yokochi, 2016). In these systems, water is pumped around a cylindrical hydrophobic membrane that prevents liquid water to penetrate inside, but allows gases to permeate through its pores into the volume enclosed by the membrane. Gases from this volume are then pumped into storage vessels for transport.

The basis of sample preparation procedures for the analysis of radioactive noble gases is the separation of the noble gas from other gases present in the bulk sampled gas and removal of any impurities that could influence the measurement characteristics. For grab samples, adsorption of noble gases on an activated carbon bed must be done prior to these procedures. The pressure vessel is connected to a gas handling line at the laboratory, and its contents are ventilated into the line with cooled activated carbon bed. In this step, water vapor and carbon dioxide are removed from the bulk gas. Water is either cryogenically trapped or absorbed in some hygroscopic material (silica gel, molecular sieve, zeolites, etc.). Carbon dioxide can be removed by a soda lime column, molecular sieve, or similar materials with high CO_2 affinity. In continuous flow sampling systems, these molecules are also removed from the pumped air before noble gas adsorption.

In the first step of sample preparation, any incondensable gases in the volume with cooled activated charcoal can be removed by evacuating this volume while increasing the activated carbon temperature (but not heating it to more than room temperature). Pumping can also remove any condensed gases like oxygen from the charcoal. Alternatively, the charcoal column is allowed to warm to room temperature, and most of these gases can be pumped out, whereas noble gases are retained in the activated charcoal (Igarashi et al., 2000). Pumping can lead to some sample loss, so flushing with helium is also a possible way to remove these additional gases. Small amounts of oxygen can be removed by oxidation of copper in a column heated to 600°C (Purtschert et al., 2013). The noble gases can be further purified by cascade desorption at different temperatures, repeated desorption, and resorption in another activated carbon column and cryogenic distillation. Especially in radiometric analysis of xenon isotopes, the presence of radon in the final purified sample can interfere with the radiometric measurement of noble gases because decays of radon progeny can significantly affect signals from radioxenon. This is particularly important for radioxenon measurements of subsurface air, which has usually much higher radon concentration than surface air. The adsorption coefficient of radon in activated charcoal is several times higher than that of xenon, and thus, the addition of a small activated charcoal bed to the sample purification process can effectively remove radon interference from the sample (Zhou et al., 2013b).

Further purification is done by means of gas chromatography. Noble gases are desorbed by heating the adsorbent and transported in a carrier gas through a gas chromatography column. The gases eluted from the column are monitored by a thermal conductivity detector. The detector can distinguish noble gases from other gases (mainly O_2 and N_2) and allows discarding them, hence purifying the noble gases. This process can be repeated, if necessary, to achieve the required gas purity. Most widely used carrier gases are helium, methane, and nitrogen (Bowyer et al., 1999; Igarashi et al., 2000; Yokochi, 2016). To be able to calculate the specific activity of noble gases in the sampled air, the amount of recovered noble gas needs to be determined. This information can be obtained during gas chromatography by calculating the area under the peak corresponding to the studied noble gas in the response of the thermal conductivity detector with a standard calibration curve (Zhou et al., 2013a).

a. Gas proportional counting of radioactive noble gases

GPC is best suited for radionuclides with short and medium half-lives—^{37}Ar, ^{39}Ar, ^{85}Kr, and radioxenon isotopes. ^{39}Ar and ^{85}K decay by emission of beta particles; therefore, GPC is the most widely used method, but other detectors such as GM counters (Nitta et al., 2014) or scintillation crystals can also be applied (Wilhelmová et al., 1986). A large number of possible gas proportional counter configurations and sizes and filling pressures have been employed in these analyses. The counter characteristics are determined by size of the air sample, final sample volume, required precision, and other factors. The amount of separated noble gases is not large enough to fill GPC detectors; the sample is added to a suitable counting gas. Methane or P10 counting gas (10% methane + 90% argon) to fulfill this role in most GPC detectors for noble gas measurement. ^{37}Ar decays by

EC, and its detection by GPC is based on the detection of X-rays or Auger electrons that accompany this decay (Aalseth et al., 2011).

The long-lived ^{81}Kr was first detected by GPC (Loosli and Oeschger, 1969), but its long half-life and low isotopic abundance make the GPC method too inefficient for its practical use for air or water samples (typically about 0.5 mL of krypton gas can be extracted from 500 L of air or 16,000 L of water). The increased ^{85}Kr activity in modern krypton also makes it impossible to detect ^{81}Kr by decay counting methods in air samples.

b. Gamma spectrometry of radioactive noble gases

Radioxenon isotopes are measured by high-resolution gamma spectrometry using high-purity germanium (HPGe) detectors or beta−gamma coincidence using scintillation detectors. These methods allow the simultaneous measurement of all four radioxenon isotopes (Table 3.13). This makes it possible to calculate their activity ratios, and that provides the possibility of source identification in nuclear weapon tests monitoring. When using high-resolution gamma spectrometry, the extracted xenon sample is placed into a gas cell, which is adjacent to the crystal of the detector. The gamma rays from the decay of radioxenon isotopes are detected in the spectrometer and the individual radioxenon isotopes, and their activity can be determined. Most systems use one HPGe detectors for the measurement (Fontaine et al., 2004; Zhou et al., 2013a), but to increase the full energy peak efficiency, two HPGe detectors can be placed onto the sample gas cell (Xie et al., 2014). A typical gamma spectrum of ^{131m}Xe and ^{133}Xe is shown in Fig. 3.37. Peaks from gamma rays emitted by radon progeny ^{212}Pb and ^{214}Pb are also visible in the spectrum, but their activity is lower than ^{133}Xe activity. This has been achieved by a very efficient radon removal step in the sample preparation methodology (Zhou et al., 2013b).

BEGe detectors offer energy resolution comparable with HPGe detectors, but they have a higher detection efficiency for X-rays and low-energy gamma rays. BEGe detectors have been utilized therefore for detection of both gamma rays and X-rays emitted by radioxenon to improve the detection limits (Le Petit et al., 2006).

Systems utilizing beta−gamma coincidence detection for radioxenon measurement use the gas cell with the sample for the detection of emitted beta particles and a scintillation crystal surrounding this cell for the detection of gamma rays. An example of such system is shown in Fig. 3.38. The walls of the gas cell are manufactured from a plastic scintillator material, and the attached photomultipliers detect the beta particles. The sample xenon may diffuse into these materials and cause a memory effect, but a suitable coating for the cell walls can minimize this effect (Bläckberg et al., 2011).

Low-level decay counting requires background reduction, which is achieved by both passive and active shielding. The passive shielding is in the form of radiopure shielding materials (lead, copper, iron, neutron-absorbing materials, etc.). Active shielding is realized by guard counters (gas proportional counter, scintillation detectors, etc.).

c. Accelerator mass spectrometry of radioactive noble gases

AMS is routinely used for the analysis of long-lived cosmogenic radionuclides by employing a tandem accelerator. However, this method cannot be used for noble gases because it relies on the production of negative ions, and these gases do not easily form stable or metastable negative ions. With certain modifications, AMS with

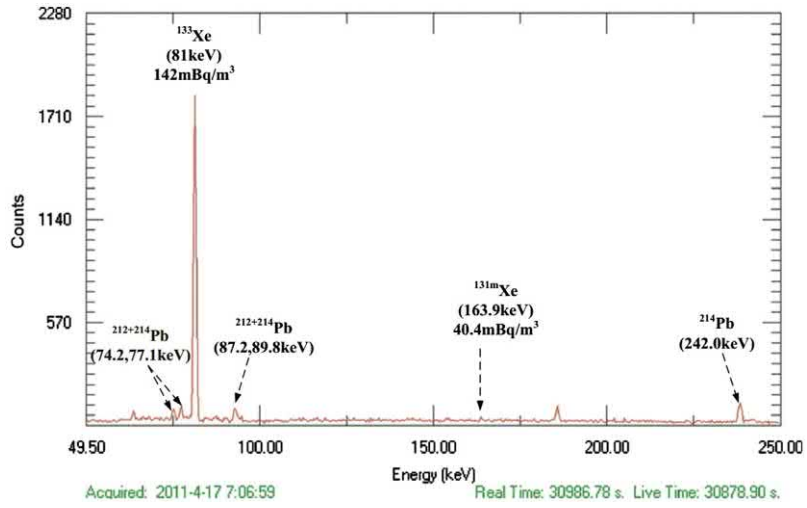

FIGURE 3.37 Gamma spectrum of a xenon sample containing ^{131m}Xe and ^{133}Xe. Peaks from radon progeny ^{212}Pb and ^{214}Pb are also visible, but their activity is very low due to efficient radon removal in sample preparation process. *From Zhou et al. FIGURE 3.38 A schematic diagram of beta–gamma coincidence detection system for radioxenon measurements. *From Ringbom et al. (2003).* Printed with permission © *Elsevier 2018.*

positive ions was used for analysis of two long-lived noble gas radionuclides—^{39}Ar and ^{81}Kr. In both cases, an ECR (electron cyclotron resonance) ion source was used to produce positive ions from Ar and Kr gas samples. For ^{81}Kr analysis, the full stripping method was used to separate ^{81}Kr from its main isobaric background ^{81}Br (the source of bromine at these levels is not known). For efficient full stripping to the $^{81}Kr^{36+}$ charge state in a beryllium foil, ions produced in the ECR had to be accelerated in a superconducting cyclotron to 3.6 GeV and only then could these ions be separated in a mass spectrometer and identified in ΔE-E detector (Collon et al., 1997). Full stripping cannot be used for ^{39}Ar (with ^{39}K as its main isobaric background) because it only works in cases when the proton number of the measured isotope is higher than the proton number of the interfering isobar. Therefore, AMS with a gas-filled magnet was used for this separation. Positive ^{39}Ar ions accelerated by linear accelerator to 232 MeV entered the gas-filled magnetic analyzer, where their trajectories were bent due to the presence of the magnetic field, and their different interaction with gas in the analyzer made it possible to separate ^{39}Ar and ^{39}K (Collon et al., 2004a). These measurements show the possibility of using AMS for ^{39}Ar and ^{81}Kr, but the technical complexity of these methods prevents them from being used routinely at the current stage of development.

d. Atom trap–trace analysis

Atom trap–trace analysis (ATTA) is an atom-counting system developed for analysis of krypton isotopes ^{81}Kr and ^{85}Kr (Chen et al., 1999). The schematic of an ATTA system is shown in Fig. 3.39. A separated krypton gas sample is fed into the ATTA system through a discharge zone, where a part of the krypton atoms is excited by the discharge to metastable level $5s[3/2]_2$. An atomic beam of thermal krypton atoms is transversely cooled and focused prior to entering a Zeeman slower. In this part of the apparatus, the atomic beam is cooled down and subsequently injected into a magnetooptical trap (MTO). It consists of a spatially variable quadrupole magnetic field and focused laser beams. Laser beams with a wavelength of 811 nm repeatedly excite the $5s[3/2]_2$–$5p[5/2]_3$ cycling transition, thereby trapping the $5s[3/2]_2$ atoms in the magnetic field of the MTO. The trapping laser beam induces fluorescence emission from the trapped atoms. When frequency of this laser matches very precisely the resonance frequency for this transition, small isotopic shifts in the atomic transition frequency between isotopes make it possible to distinguish individual isotopes and trap them atom by atom. The photons from fluorescence emission of the chosen isotope are detected by a photodiode detector or a CCD camera. In addition to the measurement of the number of ^{81}Kr and ^{85}Kr atoms, the capture rate of stable isotope ^{83}Kr with known isotopic abundance needs to be determined to evaluate the ^{81}Kr/Kr and ^{85}Kr/Kr ratios. They are required for calculations of the ^{81,85}Kr specific activity in the measured sample. The ATTA method can also be used for the analysis of ^{39}Ar (Welte et al., 2010). The amount of sample required for ATTA analysis is much smaller than for other analytical methods. ATTA can measure ^{81}Kr and ^{85}Kr in samples as small as 1 L of air and ^{39}Ar in 0.1 L of air (Lu et al., 2014; Tu et al., 2014).

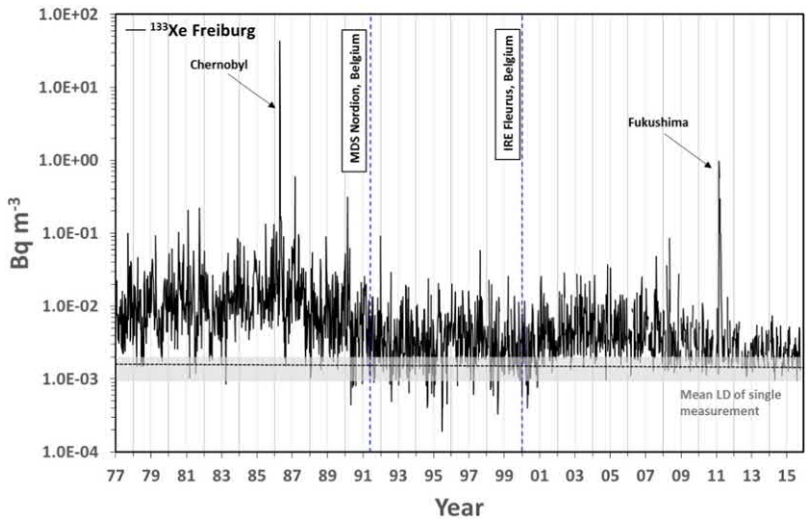

FIGURE 3.40 ^{133}Xe activity concentration in air sampled in Freiburg, Germany. *From Schlosser et al. (2017).* Printed with permission © *Elsevier 2018.*

As a typical example of measurements of radioactive noble gases in the atmosphere, Fig. 3.40 illustrates results of ^{133}Xe measurements in Freiburg (Germany) covering the period of 1977−2015. Distinct peaks from ^{133}Xe released during the Chernobyl and Fukushima nuclear accidents are clearly visible in the data. The ^{133}X activity concentration slowly decreases due to improvements in nuclear reprocessing and medical isotope production technologies (Schlosser et al., 2017).

4. Radon

Radon concentration in the air has been measured by many different types of detectors, for example, by scintillation detectors (Lucas cells), ionization chambers (suitable for continual monitoring), electret detectors, track detectors, and thermoluminescent detectors for integral measurements. Each detector has its advantages and disadvantages. Radon in the air has been measured either by directly passing the air through the detector or indirectly by the absorption of the air on a suitable medium, e.g., an activated charcoal. Radon from larger volumes of the air can be collected by cooling of the charcoal column. Radon is then transferred from the charcoal column to the scintillation chamber (Beláň et al., 1992). There are also available commercially produced instruments (e.g., AlphaGUARD, RAD-7), which have detection sensitivities good enough to perform many radon investigations in the environment.

As an example, we present a large-volume (4.5 L) cylindrical scintillation chamber used for radon monitoring of the ground-level air in Bratislava (Beláň et al., 1992). The air is sucked through the scintillation chamber (located 1.5 m above the land) with a flow rate of 0.5 L min^{-1}. At the entrance of the chamber, a filter removing aerosols and radon progeny was installed (Figs. 3.41 and 3.42). A 10 L delay volume was incorporated in the intake line to ensure that the air entering the chamber will no longer contain thoron (^{220}Rn) with a half-life of 56 s. Subsequently, radon activity concentrations belonging to 2−h intervals were calculated using the Ward and Borak (1991) method. To achieve favorable geometrical conditions for the efficient

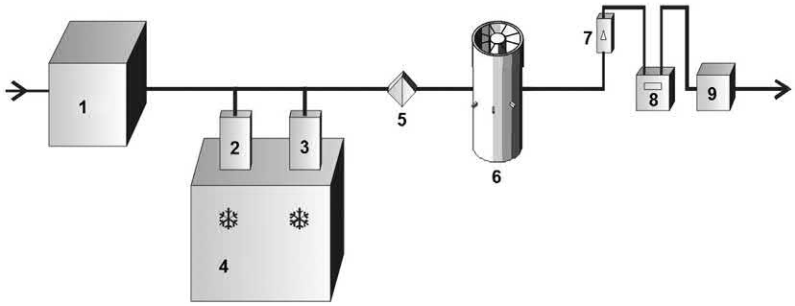

FIGURE 3.41 Air supply line for the large-volume scintillation chamber: 1−10 L delay volume, 2—water trap (−30°C), 3—column filled with granulated silica gel, 4—cooler, 5—aerosol filter, 6—large-volume scintillation chamber, 7—flow rate meter, 8—gas-meter, 9—pump. *From Beláň et al. (1992).*

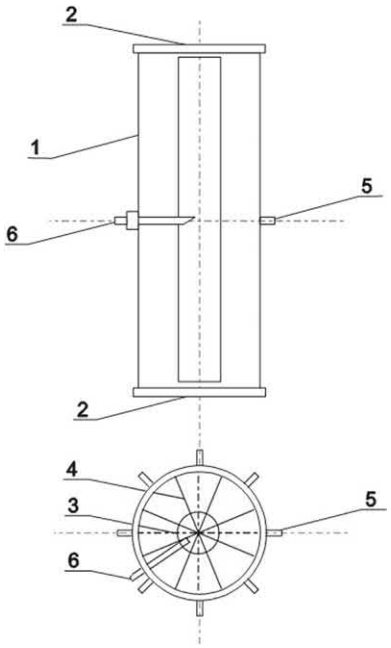

FIGURE 3.42 The large-volume scintillation chamber: 1—chamber tube, 2—glass windows, 3—central sector, 4—compartments, 5—gas inlets, 6—gas outlet. *From Beláň et al. (1992).*

detection of radon, the inner space of the chamber is divided into nine sectors (Fig. 3.41). The detector has a response time (time to half-peak magnitude) of 30 minutes, and a lower limit of detection of 1.7 Bq m^{-3} with uncertainty of 30% (Bulko et al., 2018).

As an example of the long-term monitoring of radon levels in the atmosphere, we present in Fig. 3.43 the average monthly radon activity concentrations for the years 1991−2005 measured in the Bratislava ground air. Spring minima and maxima occurring in various months of the second half of the year can be seen in the annual ^{222}Rn courses for all the years. However, the individual years differ from each other quite considerably. Fig. 3.44 shows the mean daily courses of ^{222}Rn activity concentration for individual months in the Bratislava air from 1991 to 2006. The monthly mean diurnal waves of the ^{222}Rn activity concentration are also shown. The average daily courses of ^{222}Rn activity concentrations have a form of waves with a maximum in the morning and minimum in the afternoon. These variations are directly connected with variations of the solar radiation flux during a day. Nocturnal accumulation of radon typically occurs in shallow mixing layers caused by temperature inversions. When the sun rises in the morning and heats the ground, which in turn warms the surface layer of the atmosphere, the temperature inversion is destroyed, and remixing of radon takes place in increasingly higher layers, with a consequent decrease in radon concentration near the ground. Minimum radon concentrations are normally reached in the late afternoon, corresponding to the maximum depth of the mixing layer. The composite seasonal cycle of outdoor radon is illustrated in detail in Fig. 3.45 with minima in April and maxima in January (Bulko et al., 2018), which reflect seasonal bias in the stability of the lower atmosphere, with more frequent, prolonged inversion periods during autumn and winter months as compared with summer.

A comparison of ^{222}Rn and ^{210}Pb (a daughter product) records in the Bratislava air is presented in Fig. 3.46. Generally, the ^{210}Pb activity concentrations (measured on aerosols) follow the radon ones as expected. This documents again that the ^{222}Rn activity concentrations are influenced mainly by radon exhalation rates from the ground and by turbulent diffusion in the atmosphere.

B. Radionuclides on aerosols

1. Properties of aerosols

An aerosol can be defined as an in-air particle, which is so small that their gravity fall is much smaller compared with in-air velocities. Aerosol particles can be divided into

- **(i)** Dust—solid particles abraded from surfaces and dispersed into air
- **(ii)** Smokes or fumes—solid or liquid particles condensed from the vapor phase
- **(iii)** Mist—droplets of water with other matter in solution or suspension

Dust is formed during the breakdown of solid material and is characterized by irregular and flaky shape. Fume is formed during the condensation of vapor as very small primary particles with spherical or crystalline shape. The formation of an aerosol from a pure radioactive substance is unusual (Chamberlain, 1967). Usually, radioactive substances are adsorbed on, attached to, or incorporated in the particles of other matter. In the atmosphere, some radioactivity is in gaseous form, but much of it is presented as aerosol particles. The main natural sources of aerosols are sea salt particles emitted from the oceans by evaporated sea spray, mineral dust from soils and rocks, volcanic dust, biogenic particles (e.g., pollen), and the reaction products of atmospheric gases as a result of heat and the influence of sunlight. Aerosols of anthropogenic origin include emissions during domestic heating using coal or wood, from industrial plants, from transportation, from agricultural activities, or from large forest fires. Radioactive aerosols often carry electric charge as a result of attached ions produced by cosmic rays and other ionizing radiation. The small particles also serve as nuclei for the condensation of water and other vapors. Therefore, size distribution of aerosol particles consists of several modes:

- **(i)** Aitken nuclei (<0.1 μm)
- **(ii)** Accumulation mode (0.1 μm < and <2.0 μm)
- **(iii)** Coarse mode (>10.0 μm)

Several main categories of aerosol particles can be classified by their physical characteristics. This is important for the characterization of aerosol health effects. An inhalable fraction contains the largest particles, which can enter the nose or mouth under average conditions. Inhalable particles that can reach the thorax are known as the thoracic fraction. These particles are also called coarse particulate matter (PM) and are composed of solid particles or liquid droplets with an average diameter greater than 2.5 μm and less than 10 μm (called also PM-10).

Particles that can reach the alveolar region of the lungs are known as the respirable fraction, but do not necessarily deposit there. These particles are usually in an accumulation mode, and there is a strong tendency for them to stay in suspension in air. They are called fine particulate matter and usually referred to as PM-2.5 (average diameter is less than 2.5 μm).

2. Sampling of aerosols

Depending the needs for radiometric measurements, aerosol radioactivity monitoring can be done by continuous and integral sampling. Both solutions require different arrangements of the sampling devices and have their advantages and disadvantages. Continuous online systems are frequently used for local monitoring, where the possible source of radioactive contamination is located (i.e., surroundings of NPPs), and therefore, information is needed as fast as possible about increased radioactivity levels. Aerosols are usually sampled by collecting on different kinds of filters by passing the sampled air through the filter. For the online sampling, the concept of the moving band is used, where aerosols are collected on filter in shape of a band, which is moving by at constant velocity, while aerosols are deposited in a dedicated part of the band. This step-like deposition represents the time development of the radioactive aerosols with time resolution of about several minutes. By moving the band, much less aerosols are collected in comparison with fixed filters, even though a comparable pumping system is used, and therefore, the detection limit is much higher for online systems. More detailed information about online monitoring systems can be found in documents from the International Electrotechnical Commission (IEC, 2002a; IEC, 2002b).

For regional monitoring, where the radioactivity from a distant source is much diluted due to the atmospheric dispersion processes, the fixed filters are preferred over those of fast response. Expected slow buildup rates of radioactivity on the filters require much larger samples to reach better detection limits. High-capacity pumping and large-area filters result in a high sampling rate, which together with relative long exposure times allow the achievement of detection levels of a few mBq m^{-3} (Schulze et al., 2000).

The task of aerosol sampling is to get a representative sample of particles from the air into the measuring device. Pumping of the ambient air through the filtration system by the vacuum pump at the end of the system is frequently used. Collection of aerosols from the atmosphere by using the filtration is relative straightforward; however, several conditions need to be followed. Since the radionuclide concentrations are reported per unit volume of air (Bq m^{-3}), usually an integrating flow meter is used to give a total volume of sampled air per known period of time. All the particles from a known volume of air have to be collected, without loss, breaking up particles or losing particles by evaporation or gaining them by condensation. Flow rate in the inlet of the sample device has to be the same as the flow rate in the device, to ensure representativeness of the sample. When the sampling velocity is equal to the velocity inside the device, it is called isokinetic sampling; otherwise, discrimination can occur for smaller or larger particles. If the velocity of the sample airstream is larger than the velocity of the airstream in the device, then the larger particles cannot make the abrupt change and are discriminated in the sample, i.e., the smaller particles are collected more efficiently, and vice versa (Macášek, 2008). Attention has to be paid to a correction for a sampled volume of air because the flow meters are usually calibrated in standard conditions (101 kPa atmospheric pressure and 20°C ambient temperature), and by using volume measured at different conditions can lead to 5% difference in activity concentration. The real volume V_R can be calculated as

$$V_R = V_M \frac{\rho_{20} p_0 T}{\rho_0 p T_0} \tag{3.13}$$

where V_M is the measured air volume, $\tilde{n}_{20}$ is the air density corresponding to standard conditions (1.205 kg/m^3), p_0 is the atmospheric pressure at 0°C (101,325 Pa), T is air temperature during the sampling in K, $\tilde{n}_0$ is air density at 0°C (1.293 kg/m^3), p is atmospheric pressure during the sampling in Pa, and T_0 is temperature of 0°C (273.15 K). During the evaluation of especially short-lived radionuclides, the corrections for decay during the sampling t_1, between sampling and measurement t_2, and during the measurement t_3 have to be applied as follows:

$$A_{corr} = A_{meas} \frac{t_1 ln2}{T_{1/2}\left(1 - 2^{-t_1/T_{1/2}}\right)} 2^{t_2/T_{1/2}} \frac{t_3 ln2}{T_{1/2}\left(1 - 2^{-t_3/T_{1/2}}\right)} \tag{3.14}$$

where $T_{1/2}$ is the half-life of the measured radionuclide.

The most commonly used device for aerosol sampling is a high-volume sampler. An air turbine is used to pull an air sample of about 2000 m^3 or more through a filter sheet. For specific purposes, proper filter media may be desirable. According to desired needs, such as high collection efficiency, particle size selectivity, low-flow resistance, high mechanical strength, low-background activity, temperature stability, retention of gaseous fraction, and ease of radiochemical analysis, the proper filter type should be selected. If complete particle size spectra are of interest, the multichannel (parallel) or multistage (series) arrangement of filters is used. The size of particles passed through several filters can be calculated from the hydrodynamic parameters of sampling (Maher and Laird, 1985). Depending on the monitored radionuclide, the filter after collection is prepared for analysis by, e.g., pressing to standard shape, burning, dissolving in organic solvents, or washing by oxidizing agents.

When particle size classification is needed, electrostatic precipitators, cyclone collectors, and cascade impactors can be used for sampling. For the impactors or impingers, the particles are collected on a selected surface, as the airstream is sharply deflected. As the sampled air flows into the first cascade of jets in the impactor, large particles with

significant momentum strike the collecting surface and remain trapped on this stage. Smaller particles with less momentum are diverted away from the collecting surface by the diverted airstream and continue to the next stage. As the air proceeds further into the impactor, smaller and smaller jets are used to force the air to higher velocities, and when smaller particles receive sufficient kinetic energy, they stay trapped on the collecting surface of the size-depending stage. By coating the collection surface with a thin layer of grease or adhesive, the tendency to stick the particles on the collecting surface can be increased. After collection, the impactor is carefully disassembled with each stage containing different sizes of collected aerosols. The sorted collected material provides information about particle size distribution, and when it is used for activity measurements, size distribution of radionuclide carrying particles can be obtained.

For the collection of condense water vapors or liquid aerosols, a condensation or dehumidifier sampling device can be used. A liquid nitrogen or refrigeration unit is used to cool the condensation surface where the liquid sample is collected for further analysis.

3. Examples of radionuclides on aerosols

a. Tritium

The main forms of tritium in the atmosphere are water vapor (HTO), as well as tritiated hydrogen (HT), tritiated methane, and other organic gases. It is also present in the form of tritiated aerosol particles; however, this form of aerosols is poorly documented. Usually, it corresponds to artificially produced tritiated molecules arising from resuspensions of labeled soil particles, bioaerosols composed of bacteria, aerosols emitted from terrestrial biomass, or aerosols produced by industrial operations handling tritium (Eyrolle et al., 2018). It is expected that tritium retention in plasma facing materials such as tungsten is a major concern for future fusion reactors.

b. ^{7}Be

One of the most abundant cosmogenic radionuclides in the atmosphere is ^{7}Be with a production rate of about 400 atoms $m^{-2}s^{-1}$ (Masarik and Beer, 2009). It decays by EC to ^{7}Li with 10.3% probability of emission of the 477.6 keV gamma ray, and therefore, it can be relatively easily determined by gamma spectrometric techniques. However, AMS can be used as well for the determination of ^{7}Be and with several orders of magnitude better sensitivity compared with gamma counting (Hidy et al., 2018; Raisbeck and Yiou, 1988).

^{7}Be is produced mainly in the stratosphere (about 70%); however, about 30% is produced also in troposphere (Masarik and Beer, 1999). A steep vertical concentration gradient between the upper and lower troposphere was observed as a result of relatively high production rates of ^{7}Be in the upper troposphere in combination with its transport from the lower stratosphere to the upper troposphere (Feely et al., 1989).

The residence time of ^{7}Be was estimated to be of 25–30 days in the troposphere and ~1 year in stratosphere (Raisbeck et al., 1981). Further details about particles size distributions carrying ^{7}Be can be found in Chapter 4, Volume 2. There are different concentrations of ^{7}Be depending on altitude and latitude as illustrated in Fig. 3.47. The dominant modulation of GCRs, which are mainly responsible for production of cosmogenic nuclides, is solar activity. Several authors reported a variation of ^{7}Be concentrations depending on the 11-year solar cycle (Ďurana et al., 1996; Cannizzaro et al., 2004; Steinmann et al., 2013), which can be seen in Fig. 3.48. Variations in the production of the ^{7}Be are not the only reason for variations of the activity concentrations in the ground-level atmosphere. Meteorological factors are also responsible, such as exchange of air masses between stratosphere and troposphere, vertical transport of air masses, horizontal transport of air masses from higher to lower latitude, and scavenging by precipitations (Feely et al., 1989). ^{7}Be is therefore widely used as a tracer for atmospheric dynamics and transport processes. The Be concentrations during the year show seasonal changes with high values in spring–summer and low values in autumn–winter months. The amplitude of the seasonal pattern also varies at the same latitude from year to year. Sýkora et al. (2017) reported a weekly trend of ^{7}Be in ground level atmosphere of Bratislava in Fig. 3.49. Elevated ^{7}Be concentrations during the warm season appear to be a result of the vertical transport of air masses during this season. Furthermore, in mid-latitudes (above 40°N), during the summer months, the tropopause is higher than in winter (Gerasopoulos et al., 2001). In winter, the atmosphere is more stable, and the tropopause is lower than in summer; therefore, ^{7}Be values in surface air are lower. During the spring period, stratosphere to troposphere exchange processes are enhanced, which result in a significant increase of the ^{7}Be concentration. Gerasopoulos et al. (2001) studied the changes of the ^{7}Be concentration at high altitudes due to meteorological conditions. They have found positive correlation between tropopause height and ^{7}Be concentration at the three Alpine stations, as well as negative correlation between ^{7}Be values and the relative humidity. The negative correlation with humidity can be related to wet scavenging; however, Steinmann et al. (2013) reported for ^{7}Be concentrations similar variations as for precipitations. They explained this unexpected correlation by additional ^{7}Be input during the summer due to the stratospheric contribution, which compensates wet deposition of ^{7}Be in this time.

c. ^{10}Be

^{10}Be is another beryllium isotope, which is produced in the atmosphere by cosmic rays. Compared with ^{7}Be, it is a long-lived radioisotope with half-life of 1.5×10^{6} years, and the production pattern in the atmosphere is more or less similar to ^{7}Be; however, the dynamics of ^{10}Be in atmosphere is more complicated. It undergoes beta decay to ^{10}B, but due to its very long half-life, the AMS technique is successfully used for the determination of ^{10}Be in various samples. Freshly produced ^{10}Be is normally of interest, which becomes part of aerosols in the accumulation mode, and this is known as "atmospheric ^{10}Be." However, ^{10}Be produced in the Earth's surface layers and deposited aerosol particles with ^{10}Be on the surface can enter the atmosphere in the form of dust as well, and this is known as "terrestrial ^{10}Be." It is complicated to separate these two fractions of aerosols; therefore, the sampling location can be chosen to minimize the terrestrial fraction (high altitude, arctic, and Antarctic region), or a correction for this fraction can be applied, when the abundance of terrestrial ^{10}Be in aerosol is known or measured. The same chemistry of ^{10}Be as ^{7}Be predestined the accumulation in the same aerosol mode.

Since sample preparation for AMS requires the destruction of the sample, nondestructive analysis, like gamma spectrometry, is performed before the AMS ^{10}Be measurement. The main isobar, responsible for background in AMS measurement of ^{10}Be, is ^{10}B, and therefore, the main objective of chemical preparation is to minimize boron content in the sample. Depending on the filter used for aerosol collection and further analysis of additional radionuclides (such as ^{26}Al and ^{36}Cl), the sample is spiked with a known amount of ^{9}Be as a carrier and leached with HNO_3 and/or HCl solution. To separate the beryllium from boron, iron, and aluminum, cation exchange process (e.g., DOWEX 50W x 8 resin) and/or solvent extraction (e.g., ethylene diamine tetraacetic acid [EDTA] for Al content reduction) can be used. After purification, $Be(OH)_2$ is precipitated by diluted ammonia and transformed to BeO, which is used as sample material in the ion source, by heating to 800–950°C. For better electric and thermal conductivity, the sample powder is mixed with pure Nb or Ag. During the AMS measurement, $^{10}Be^{16}O^{-}$ ion is produced in the ion source, and $^{10}Be^{3+}$ ion is accelerated and separated for the ^{10}Be/^{9}Be determination. For normalization during the measurement, NIST SRM 4325 standard (^{10}Be/^{9}Be $= 2.68 \times 10^{-11}$) can be used. Generally, the statistical and instrumental error of the measurement is below 5%, and the background ^{10}Be/^{9}Be in the order of 10^{-15} can be achieved (Tuniz et al., 1998).

Together with ^{7}Be, ^{10}Be is used as a tracer of stratospheric circulation and stratosphere–troposphere exchange processes. Yamagata et al. (2010) showed that the concentration of ^{10}Be and ^{7}Be in the troposphere is not decreased by the precipitation, without a cyclonic pressure drop. Beryllium isotopes penetrate into the upper troposphere in spring season and mix uniformly; therefore, the ^{10}Be/^{7}Be ratio is a sensitive tracer of stratospheric air. Jordan et al. (2003) described that ^{10}Be/^{7}Be ratios can provide valuable information about various mechanisms of stratospheric-to-troposphere exchange, including changing seasonal structure of the stratosphere, tropopause folding, and the effect of synoptic systems. They observed seasonality in the ^{10}Be/^{7}Be ratios as a result of downwelling of air with elevated ratios from higher stratosphere in the spring and summer (for midlatitudes) and from the ^{7}Be decay during descent in the winter polar vortex (for high latitudes).

^{10}Be carrying aerosols can be stored also in natural reservoirs, such as sediments and ice (glacier and continental glacier) (Smith et al., 2000). Due to its long half-life, it can serve as a probe to past atmospheres by using deep profile of such a reservoir. The past solar activity was successfully reconstructed by using ^{10}Be in the ice core from Dome Fuji, as can be seen in Fig. 3.50 by comparison with ^{14}C in tree rings record. Within the Greenland Ice Sheet Projects (GISP1 and 2), several ice cores were drilled in Greenland, and different characteristics and radionuclides, including ^{10}Be, were measured between 3288 and 40,055 years BP (Finkel and Nishiizumi, 1997). Beer et al. (1990) used the distribution of ^{10}Be in 300 m ice cores for the determination of past 11-year solar cycles.

d. ^{14}C

Carbon is one of the main components of atmospheric aerosols. Total carbon (TC) in carbonaceous aerosols

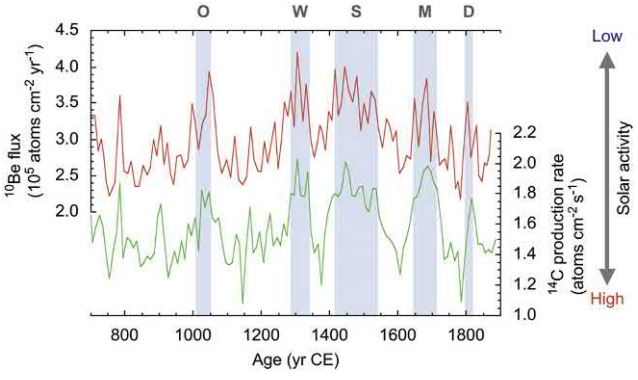

FIGURE 3.50 The comparison of ^{10}Be and ^{14}C record of the ^{10}Be flux of the Dome Fuji ice core and the ^{14}C production rate for 700–1900 years CE. The five-point averaged δ^{18}O values were used for the estimation of the snow accumulation rate for calculating the ^{10}Be flux (O: Oort (1010–1050 years); W: Wolf (1280–1340 years); S: Spörer (1420–1540 years); M: Maunder (1645–1715 years); D: Dalton (1795–1820 years)). From Horiuchi et al. (2008). *Printed with permission* © Elsevier 2018.

consists of elemental (EC) and organic (OC) carbon. There is also a small fraction of carbonate carbon (CC), but it is often neglected except for a few particular situations such as erosion, sand storms, and building constructions, which are reported in the literature (Cuccia et al., 2011; Querol et al., 2009; Yubero et al., 2011). EC is produced mainly by the incomplete combustion of fossil and biomass fuels, and it is the most refractory carbon fraction with high efficiency of solar light absorption. OC is carbon accommodated in organic matter, which is composed of thousands of chemical constituents, which makes a complete characterization difficult.

Carbon aerosols can be directly released into the atmosphere as primary particles from anthropogenic and biogenic sources. Major anthropogenic emissions to the atmosphere result from fossil fuel combustion and biomass burning. Biogenic aerosols mainly include pollen, plant debris, fungal spores, and bacteria as primary particles; however, it can be generated also from a gaseous precursor as secondary organic aerosol (SOA) (Jacobson et al., 2000; Schell et al., 2001). Sources of SOA are important regarding biogenic versus anthropogenic precursors and its contribution to primary OC (Kavouras and Stephnou, 2002). ^{14}C determinations offer a unique possibility for source identification of carbonaceous aerosol particles, such as apportionment of fossil/nonfossil sources (Currie, 2000). This isotopic method permits a direct distinction of contemporary and fossil carbon in ambient aerosols because fossil materials are so old, which ^{14}C has already decayed. In atmospheric studies, $^{14}C/^{12}C$ ratios are often given as fractions of contemporary carbon, f_C (Currie et al., 1989). This parameter includes a correction of the fraction of modern carbon (f_M) for the residual ^{14}C from nuclear bomb excess, and Levin et al. (2003) suggest that biogenic aerosol originates from fresh organic material.

^{14}C is a beta decaying radionuclide that can be determined by LSC and GPC; however, for atmospheric studies, the mass of the collected aerosol is in order of mg, and therefore, the AMS technique is widely used. Most of the filters contain fossil or modern carbon, which can significantly influence results. Quartz fiber filters are successfully used for sampling of carbonaceous aerosol; however, semivolatile organic carbon (SVOC) can adsorb on the quartz surface. Szidat et al. (2004) estimated that SVOC contributes $8 \pm 5\%$ to total OC and therefore can be neglected. After collection, aerosols are combusted to CO_2 in a vacuum apparatus and separated to EC and OC fractions according to thermal separation. It has been noted also that water-soluble organic carbon (WSOC) can undergo pyrolysis (Yu et al., 2002) and the inorganic compounds produced can catalyze precombustion (Wang et al., 2010); therefore, WSOC is frequently removed (Szidat et al., 2009; Zencak et al., 2007). Separation of the OC fraction is usually performed by sample precombustion at about 340°C in oxygen atmosphere for several minutes (about 10 minutes are usually sufficient) to avoid EC contamination (Zhang et al., 2010). After cryogenic separation of the CO_2 produced from OC, the residual sample is combusted at about 650°C for EC determination. To separate the different carbon fractions, the approach proposed by Szidat et al. (2006) can be used (Fig. 3.51). For the AMS measurement, CO_2 can be directly used in the ion source; otherwise, graphite is produced and sputtered for C^- ion beam creation (for details, see Section V.A).

Bernardoni et al. (2013) analyzed emissions of fossil fuel in Milan (Italy) during the winter time. OC was dominated by modern carbon contributions (63%), and EC was of fossil fuel origin (84%). In TC emission, modern nonfossil sources (55%) prevailed on fossil fuel contribution (45%). Szidat et al. (2004) observed the same trend in the urban background area in Zürich (Switzerland), where biogenic OC dominated the composition of total OC and TC concentrations, whereas anthropogenic OC strongly correlates with EC. They attributed the result to the formation of SOA, which was indicated also by correlation with other meteorological factors, such as maximum temperature, ozone maxima, and biogenic isoprene concentrations. Chen et al. (2015) used ^{14}C and $\delta^{13}C$ in EC as a tracer of dust source regions in Beijing (China).

By aerosol sampling methods, natural archives (ice and sediments) can be used for the analysis of OC and EC concentrations in the past. For ice sampling, it is suitable to use a drilling technique without organic solution. After separation of the core to time-related sections, the ice is slowly melted to reduce stress and crack formation. Aerosols are separated from the melted sample by filtration with a quartz fiber filter. The next step in the preparation is the same as for the aerosols collected from the atmosphere. Jenk et al. (2006) reported a long-term record (covering the period 1650–1940) of water-insoluble OC and EC

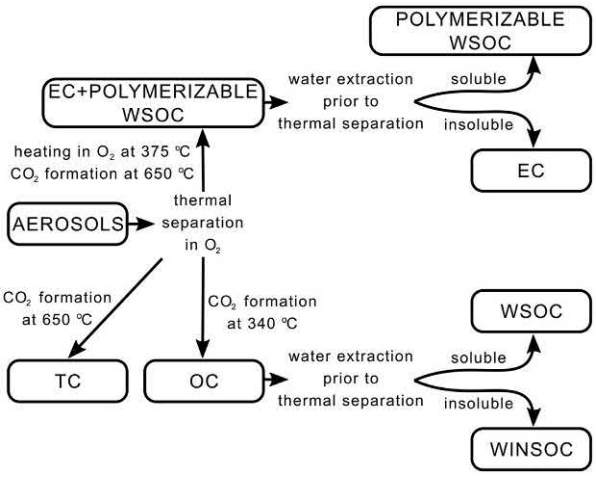

FIGURE 3.51 Principal steps for separation of different carbon fractions.

fractions based on ice core samples from the Fiescherhorn glacier in Switzerland. They published that a concentration of OC in 1940 was a factor of 3 higher than the biogenic background level in 1850 (24 ± 7 μg kg^{-1} of ice) and the anthropogenic input of EC (in 1940) to be 50 ± 9 μg kg^{-1} of ice.

As ice cores, sediments can be used for anthropogenic identification of carbonaceous aerosols as well; however, the separation of each fraction is more complicated, and therefore, many studies quantify only bulk characteristics. The general strategy in the separation of total OC from sediment includes the removal of carbon bound in carbonate fraction from soils and minerals by diluted HCl (2%), homogenization, drying, and combustion of the sample in oxygen atmosphere at 850−900°C. Guo et al. (2004) used the CTO375 method for the determination of EC in Siberian Arctic coastal sediments and confirmed the preservation of terrestrial organic matter from the west to the east Arctic coast, which is in agreement with the distribution pattern of permafrost zone.

e. ^{22}Na

^{22}Na is a cosmogenic radionuclide with a half-life of 2.602 years. It is produced by spallation reaction with argon, primary in the atmosphere. As other cosmogenic radionuclides, it is relatively fast oxidized and becomes part of the atmospheric aerosol. ^{22}Na has a similar behavior in the atmosphere as ^{7}Be; however, its production rate is only about 8.6×10^{-3} atoms m^{-2} s^{-1} (Lal and Peters, 1967). It is a β^+ decaying radionuclide with emission of gamma photons with energy of 1275 keV and, therefore, can be determined by gamma spectrometry. Due to its very low concentration in the atmosphere (below 0.5 μBq m^{-3}), the determination of ^{22}Na is problematic, and high-volume aerosol samplers are needed (in the order of 100,000 m^3), which use rather big filters (e.g., ASS 500 using Petryanov filtering cloth with dimensions of 0.57×0.45 m). For better detection efficiency, the large filters are usually compressed to smaller discs. With this sampling method and by using a HPGe detector with 25% efficiency situated in a low-level background shield with anticosmic veto, a detection limit of 0.1 μBq m^{-3} (1 week of measurement) for ^{22}Na can be achieved (Błażej and Mietelski, 2014).

Information about the ^{22}Na concentration can be used for studies of atmospheric processes, such as vertical turbulent movement, stratosphere-to-troposphere transport, and washout from the atmosphere. Hoffman et al. (2017) published a multiyear worldwide database and data set of ^{22}Na concentrations from 54 monitoring sites. Steinmann et al. (2013) observed the same increase in ^{22}Na activity as ^{7}Be in ground level air in Switzerland during March and May caused by stratosphere-to-troposphere exchange.

f. ^{26}Al

In addition to ^{10}Be, ^{26}Al is another long-lived cosmogenic radionuclide with a half-life of 0.708×10^6 years, which has been rarely applied to climate and atmospheric studies. It can be produced in the atmosphere with a production rate of 1.4 atoms m^{-2} s^{-1} by spallation of argon (known as atmospheric ^{26}Al), and it is further produced in the terrestrial environment by spallation of silicon (known as terrestrial ^{26}Al). Another source of ^{26}Al is material of extraterrestrial origin, such as interplanetary dust or meteorites (known as extraterrestrial ^{26}Al).

^{26}Al is β^+ decaying to stable ^{26}Mg with the emission of characteristic 1808.7 keV (99.7% probability) and 1129.7 keV (2.5% probability) gamma photons. Therefore, it can be determined relatively well by gamma spectrometry; however, the detection limit for ^{26}Al is in the order of 0.4 mBq g^{-1} (Povinec et al., 2009c) for a surface laboratory and in the order of 0.05 mBq g^{-1} by using a coincidence technique in an underground laboratory (Arnold et al., 2002). This is far above the ^{26}Al activity concentration in the atmosphere, that is, in the order of pBq g^{-1}, and therefore, AMS must be used for analysis (Middleton and Klein, 1987).

^{10}Be and ^{26}Al behave in many respects similarly, and therefore, the procedure for sample preparation of ^{26}Al is the same as for ^{10}Be, with the exception of the last chemical step before Al precipitation. After leaching the filter with collected aerosols in HCl, aerosols are separated by filtration and Al is extracted by ion exchange, precipitated as hydroxide and after washing with double-distilled water converted into oxide during the heating at 700−900°C. The main isobar affecting the detection limit of ^{26}Al AMS measurement is ^{26}Mg. Because Mg does not form stable negative ions, and by using $^{26}Al^-$ as injection ions, even tandems with relative low terminal voltage (Raisbeck et al., 1987 successfully used 1.9 MV) can be used for the acceleration of 3^+ charge state to achieve reasonable sensitivity. It is known that Al_2O_3 does not yield high-intensity Al^- beams; therefore, large tandems (with a terminal voltage above 6 MV) with AlO^- as injection ion are used, where better separation by using 7^+ charge state can be obtained and therefore higher sensitivity can be reached (^{26}Al/^{27}Al in the order of 10^{-16}).

The production rate of ^{26}Al in the atmosphere is about 300 times lower than that of ^{10}Be and 6 times higher in surface rocks; therefore, the ^{26}Al/^{10}Be ratio can be used to study the terrestrial and extraterrestrial contribution to atmospheric ^{26}Al and ^{10}Be. Auer et al. (2009) determined ^{26}Al/^{10}Be ratios in aerosol samples from both hemispheres to be constant and equal to 1.89×10^{-3}. This ratio has not differed from the ratio measured in Antarctic surface fin. These measurements indicate a minor influence of in situ

produced and resuspended to atmospheric ^{26}Al as well as no significant impact of the stratosphere-to-troposphere exchange. The constant $^{26}Al/^{10}Be$ ratio in Antarctic fin and atmospheric aerosol predisposes the suitability of use of the ratio as chronometer of old archives, such as glacier ice.

g. ^{131}I

Iodine-131 is a short-lived isotope of iodine, which exists in the atmosphere in several forms, as particle-associated iodine (particulate iodine), inorganic gaseous iodine (I_2, HI, HOI), and organic gaseous iodine (CHI_3, CH_2I_2, $CH_3CH_2CH_2I$, etc.) (Yoshida and Muramatsu, 1995). Iodide, iodate, and organic iodine are soluble species of iodine that exist in the aerosol form (Hou et al., 2009a). Molecular iodine (I_2), which may be released, i.e., from seaweed, could be converted to active I and react with O_3 to form IO, which leads to the production of new particles. Because of its bioavailability, especially concentrated in thyroids, isotopes of iodine are important for health and in radiological studies. They are highly mobile in the environment and follow usual transfer processes in the atmosphere. After deposition, iodine can be taken up by plants and enter the food chain.

^{131}I is a fission product of uranium and plutonium, which can be released to the atmosphere during a NPP accident or from a radionuclide production facility. It has been used for medical purposes, mainly for the treatment of thyroid diseases. It decays with a half-life of 8.02 days by β^- decay to ^{131}Xe, accompanied by the emission of gamma rays with energy 364.5 keV (81.7%), 637 keV (7.2%), and 284.3 keV (6.1%). Therefore, ^{131}I can be determined relatively easily by gamma spectrometry, and it is monitored around nuclear facilities. A higher concentration of ^{131}I was registered after the accidents in Chernobyl (Fig. 3.52) and Fukushima by many laboratories.

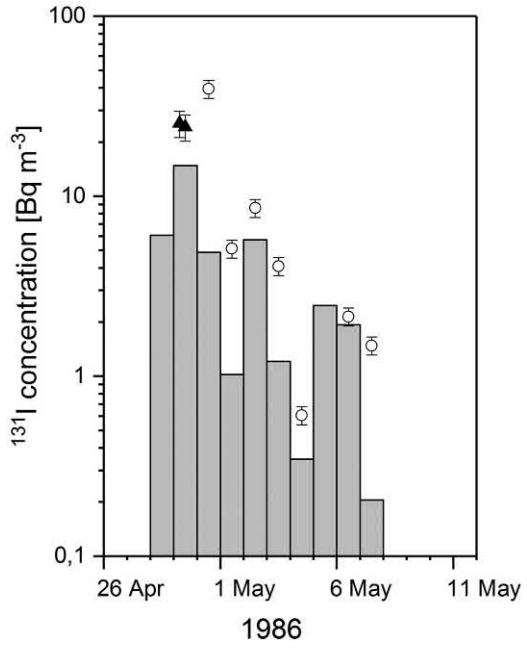

FIGURE 3.52 ^{131}I in the Bratislava air after the Chernobyl accident. *After Povinec et al. (1988).*

h. ^{129}I

The longest-lived isotope of iodine is ^{129}I ($T_{1/2} = 15.7 \times 10^6$ years), which decays by emitting beta particles ($E_{max} = 154.4$ keV), gamma rays (e.g., 39.6 keV) as well as X-rays. Although it can be measured by gamma, X-ray spectrometry, and LSC beta counting, neutron activation analysis, ICP-MS, and AMS are common techniques used for the registration and determination of ^{129}I. After collection, iodine in aerosols can be sequentially extracted in different forms using deionized water and sodium hydroxide solution (for the water-soluble and organic fractions), followed by alkaline ashing and water leaching (for the insoluble fraction) (Zhang et al., 2015b). Iodide and iodate can be further separated using anion exchange techniques (for more detailed description of sample preparation and measurement techniques, see Section V.C). It is produced naturally by reactions of cosmic rays with Xe and by fission of uranium. The main contribution to the environment is, however, from human nuclear activities, where discharges from nuclear reprocessing plants dominate. Zhang et al. (2015a) concluded that the main source of ^{129}I in the aerosols in Denmark is the reemission of marine discharged ^{129}I in the surface water near the European nuclear reprocessing plants.

^{129}I was demonstrated to be a useful geochemical tracer in the marine environment and in the atmosphere, since the identification of natural ^{127}I sources is difficult, and it can be used as a proxy for the reconstruction of the ^{131}I concentration during nuclear accidents. Wershofen and Aumann (1989) studied the chemical forms of iodine released from the WAK nuclear fuel reprocessing plant in Germany. They found that the dominant release of ^{129}I is in gaseous organic iodine species (in 1987, it was 66%−34%, relative decreasing of specie with increasing distance); however, the particulate contribution was relatively low (in 1987, it was 1.7%−9.7%, relative increasing of specie with increasing distance). Similar results were observed in Lithuania and Japan for the speciation of iodine during the Chernobyl accident, where 60%−80% was identified in organic gaseous form, 10% in the inorganic gaseous component, and less than 35% in aerosol form (Nedveckaite and Filistowicz, 1993; Noguchi and Murata, 1988). The high fraction of organic form of ^{129}I and consequently also ^{131}I may be associated with conversion of speciation during long-distance transport (Hou et al., 2009a). A major form of ^{129}I as $^{129}I_2$ released from the damaged nuclear reactor during the Fukushima accident might be in Tsukuba

aerosols attributed to a large fraction of inorganic ^{129}I. This agrees with the finding that most of the ^{129}I in the seawater is in the form of iodide, whereas the iodate form contains most of the ^{127}I (Hou et al., 2013). However, a large fraction of ^{129}I in organic-bound iodine might be associated with the $^{129}I_2$ released from Fukushima reactors, which has a high reactivity with the organic particles from vegetation and therefore can be I_2 in the atmosphere converted to organic associated iodine (Xu et al., 2015).

i. ^{137}Cs

^{137}Cs is a relatively long-lived radionuclide produced anthropogenically by nuclear activities without a natural contribution. It is beta decaying to ^{137}Ba and ^{137m}Ba, which can deexcite by emission of 661.7 keV gammas with 0.851 probability to the ground state, which is the most common way to analyze ^{137}Cs in the environment. To reach the lowest detection limit, HPGe detectors with high efficiency are widely used for the determination of ^{137}Cs, and a large volume of air must be filtered. Quartz fiber filters are frequently used for sampling, but if the determination of other radionuclides does not involve chemistry, cellulose and nucleopore filters can be used as well. For a sample collected from about 50,000 m^3 of air and with the use of a HPGe detector with 70% relative efficiency situated in a low-level background shield, a detection limit of 0.05 μBq m^{-3} (for 1 week measurement) can be achieved for a surface laboratory (Povinec et al., 2012a). Because of its high abundance and accumulation in human tissue, ^{137}Cs has been important from the point of view of delivering radiation doses to the public. Cesium has similar physical and chemical properties as potassium and rubidium, and because of its solubility in water, it is frequently found in the aquatic environment and can easily enter biological organisms. After its release into the atmosphere, ^{137}Cs is rapidly associated with aerosol particles, or it can become part of aerosols during their formation, e.g., during biomass burning and formation of dust particles, or after graphite fires and fuel melting (e.g., as during the Chernobyl accident). ^{137}Cs in the terrestrial environment exists mainly in vegetation and soil, where it was deposited by dry and wet deposition usually in the past. The highest ^{137}Cs levels in the atmosphere were registered in 1963 after the atmospheric nuclear weapon tests carried out in 1961−62 at Novaya Zemlya, which together with previous tests resulted in a global contamination of the environment (global fallout) (Povinec et al., 2013a). In Europe, the atmospheric ^{137}Cs levels were strongly influenced by the Chernobyl (Ukraine) accident in 1986, during the reactor core burning. In 2011, during the accident in Fukushima (Japan), the NPP Dai-ichi released to the atmosphere a significant amount of ^{137}Cs, which was registered above natural background almost all around the world (Masson et al., 2011; Povinec et al., 2013a,b,c; Povinec and Hirose, 2015).

^{134}Cs is another radioactive isotope of cesium, which is produced artificially by nuclear fission. It decays by beta decay to ^{134}Ba with a half-life of 2.06 years and the emission of several gammas, among which the most intensive are the 604.7 keV (with 97.6% probability of emission) and 795.9 keV (85.5%) lines. Therefore, it can be measured directly with ^{137}Cs by gamma spectrometry. Due to its relative short half-life, compared with ^{137}Cs, it can be used as an indicator of a "fresh" release from NPPs, reprocessing plants, or release during an accident. Kobayashi et al. (2015) estimated the $^{134}Cs/^{137}Cs$ ratio after the Fukushima accident, corrected to March 11, 2011, due to their different radioactive decay, to be 1.06 ± 0.04. Most of the ^{137}Cs presently found in the ground-level atmosphere comes from resuspension of this deposited cesium in soil and from biomass burning. The local resuspension of ^{137}Cs is influenced by factors such as wind velocity, intensity and frequency of rainfall, type and structure of soil, and moisture content of the soil (Kulan, 2006); therefore, seasonal variations can be observed (Ješkovský et al., 2018) as can be seen in Fig. 3.53. Although the ^{137}Cs levels in the Bratislava are increased by about five orders of magnitude, the ^{7}Be activity concentrations were still higher, as can be seen from a comparison presented in Fig. 3.54.

^{137}Cs on atmospheric aerosols has also been used to qualitatively and quantitatively identify natural atmospheric events, such as long-range dust transport (Igarashi et al., 2005, 2011; Pham et al., 2017; Sýkora et al., 2017) or biomass burning (Bourcier et al., 2010). Resuspension of soil particles (Lee et al., 2002; Kulan, 2006; Pham et al., 2011; Povinec et al., 2012a,b,c; Sýkora et al., 2012) and biomass burning (Bourcier et al., 2010; Masson et al., 2009; Stoulos et al., 2014) represent at present the major sources of ^{137}Cs variations in the atmosphere, in contradiction to past variations, which were due to transport of bomb produced ^{137}Cs from the stratosphere to the troposphere. Most of the events with higher ^{137}Cs concentrations were observed during winter, which could be due to the biomass burning with higher concentrations of Chernobyl-derived ^{137}Cs involved in wood (Ješkovský et al., 2018).

j. ^{40}K

Potassium-40 enters the air via resuspension from the surface soil. The main source of ^{40}K in the air is its transport by wind from the soil. High correlation between the average ^{137}Cs and ^{40}K activity concentrations has been found (Sýkora et al., 2017), confirming similar origin (a resuspension from soil) and behavior of these radionuclides in the atmosphere. The concentrations of ^{137}Cs and ^{40}K in the ground-level air are characterized by seasonal variation with winter maxima and summer minima. The increased atmospheric ^{137}Cs and ^{40}K levels observed during the autumn−winter season may be mainly due to surface soil resuspension, biomass burning, radionuclide transport by

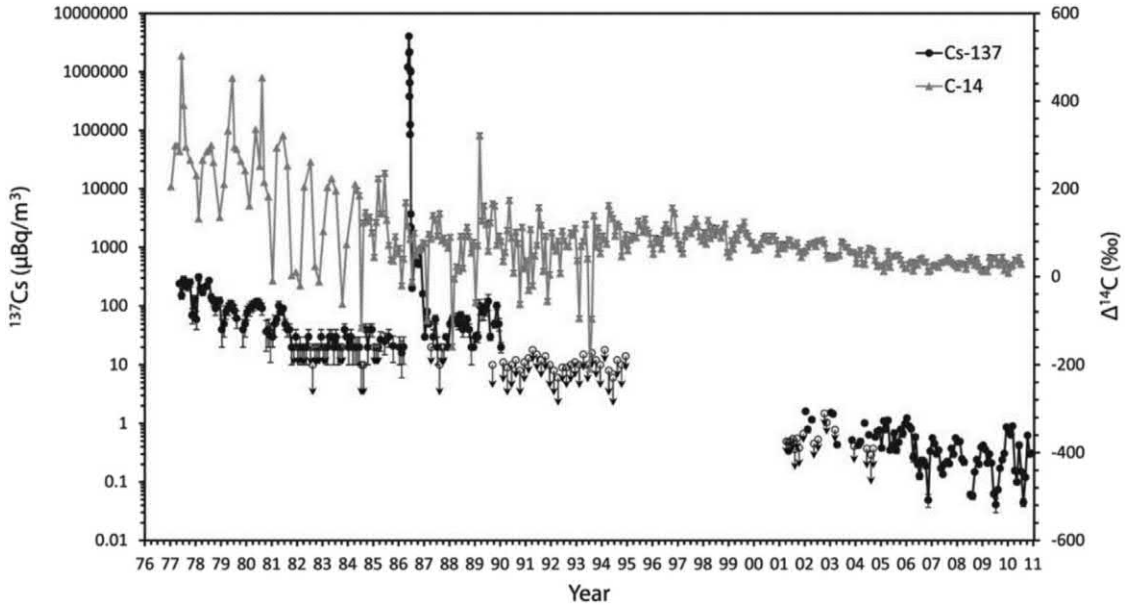

FIGURE 3.53 Atmospheric levels of ^{137}Cs and ^{14}C in Bratislava before and after the Chernobyl accident (Povinec et al., 2012a,b,c). *Printed with permission* © Elsevier 2018.

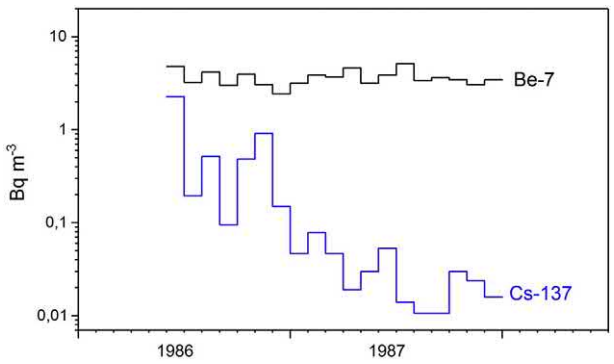

FIGURE 3.54 Comparison of ^{7}Be and ^{137}Cs activity concentrations in the Bratislava air during the Chernobyl accident.

winds, and specific meteorological conditions during winter with temperature gradient inversions. The ^{137}Cs/^{40}K activity ratio for the surface air (0.07) is close to the value observed in soil (0.05), which indicate a predominance of soil resuspension processes on the atmospheric concentrations of these radionuclides during the winter season (Sýkora et al., 2012). ^{40}K has been found as the best tracer to study a resuspension of radionuclides from soil, including its comparison with possible resuspension of ^{137}Cs from surface soil.

k. Radon and its daughters

Uranium and thorium primordial isotopes in the soil and rocks decay following their decay chains. The radionuclides radon (^{222}Rn) and thoron (^{220}Rn) of the uranium and thorium decay chains are noble gases formed by decay of ^{226}Ra and ^{224}Ra, respectively. These gases can emanate from the soil grains to the air-filled pores and are transported through the pores of the material by molecular diffusion or by convection until they enter the atmosphere. The exhalation rate of radon and thoron depends on several factors, such as the soil type, and ^{222}Ra and ^{224}Ra concentrations in the soil; however, at a given location, it can be considered roughly constant. They are released to the atmosphere, where they are, together with their daughters, distributed by turbulent air mixing. The difference in the half-life of ^{222}Rn (3.8 d) and ^{220}Rn (55 seconds) is important for the release from the ground and the distribution in the atmosphere above the ground. Radon daughters can be divided into "short-lived" radionuclides ^{210}Po (3.05 minutes), ^{214}Pb (26.8 minutes), ^{214}Bi (19.7 minutes), and ^{214}Po (164 µs) with half-lives below 30 minutes, and "long-lived" radionuclides ^{210}Pb (22.3 years), ^{210}Bi (5.01 days), and ^{210}Po (138.4 days). All thoron daughter products can be considered as "short-lived"; however, the most important radionuclide is ^{212}Pb (10.6 hours).

These daughters are often electrically charged and become attached to aerosol particles in the atmosphere with high mobility. After the radon radioactive decay, the freshly produced radionuclides react very fast (<1 seconds) with air vapors and trace gases, whereas small particles, called clusters, with diameters from 0.5 to 5 nm are formed. In addition to the cluster formation, decay products can attach to the existing aerosol in the atmosphere within 1−100 seconds, which results in the formation of radioactive aerosols with radon and thoron decay products. The

removal of these radionuclides from the atmosphere occurs by radioactive decay or by atmospheric processes, such as dry deposition, rainout, or washout. The size distribution of the decay products formed aerosols is an important parameter for the estimation of radiation dose by inhalation because the deposition of aerosol particles in the human lung depends primarily on particle size.

Besides the impact on the human health, radon with the daughters can be used as a tracer of atmospheric transport and identification of air masses derived from continental areas. Short-lived daughters of radon can be continuously monitored by an alpha detector, registering ^{214}Po on aerosols collected by pumping the air through a measured particle filter (Stanys et al., 1998). The measured signal is a representation of all precursors (^{212}Po, ^{214}Pb, and ^{214}Bi) attached to aerosols. Thoron can be monitored only in the lower atmosphere because of its short half-life, but at larger distances, the longer-lived decay product ^{212}Pb can be used. The activity of the ^{212}Pb can be determined by alpha measurements of the decay products (^{212}Bi and ^{212}Po).

From "long-lived" daughters of radon, ^{210}Bi and ^{210}Po can be registered by beta counting after chemical separation from several days of collected aerosols (Zhang and Luo, 1983; Carvalho, 1995; Jia et al., 2001; Sethy et al., 2015; Jia, 2018). ^{210} Pb decays by β^- decay; it can be, however, determined by γ-spectrometry with registering of the 46.5 keV gammas. This is a low-energy gamma, and therefore, a Ge detector with a low Z window (made of Be or C) must be used for getting sufficient detector efficiency.

Although the half-life of ^{210}Pb is 22.26 years, the residence time of ^{210}Pb in the lower troposphere is about 1–2 weeks (Papastefanou, 2006). This means that aerosols scavenging by precipitations and gravitational settling on the Earth's surface are responsible for the removal of ^{210}Pb from the atmosphere. Concentrations of ^{210}Pb in the atmosphere are influenced by mineral content of local soil, continentality of the region, precipitations, and anthropogenic factors. Since ^{210}Pb in continental air originates from the Earth's surface, its concentrations decrease with increasing altitude and distance from the shore. The seasonal variations of ^{210}Pb were observed by several authors with higher concentrations in late autumn and winter, and minimum in summer (Vecchi et al., 2005). The maximum ^{210}Pb can be attributed to frequent inversion conditions in surface layers and the resulting buildup of radon and its daughters. In winter months, this process can be hindered by low emanation of radon from the frozen and/or snow-covered soil (Hötzl and Winkler, 1987). Lower activity concentrations of ^{210}Pb in summer months can be related to a higher intensity of vertical mixing within the troposphere in this season and by higher precipitation removing the aerosols, which may result in a decrease of activity. Due to different origins, ^{210}Pb is usually compared with ^{7}Be activities, which allows quantification of the stratospheric influence in the surface level. The annual cycles of ^{10}Be, ^{7}Be, and ^{210}Pb were recorded at coastal Antarctica for 25 years and can be seen in Fig. 3.55. The ^{7}Be/^{210}Pb ratio helps assess the amount and timing of other stratospheric species to surface levels of atmosphere. ^{210}Pb is also released during industrial activity such as coal mining and burning, melting of ores in steelworks, and use of agricultural fertilizers.

C. Radionuclides in freshwater systems

The selection of the best suited sampling equipment and related supplies mainly depends on the chemical form of the target radionuclide and what kind of water is going to be sampled. Regardless of the type, water samples are generally processed right after their collection to avoid potential irreversible physicochemical changes of radionuclide species (Macášek, 2008). If this is not the case, water samples should be stored in hermetically sealed containers to prevent volatile radionuclides from being evaporated. To reduce adsorption of radionuclides onto the walls of the container, suitable amounts of carriers may be added, together with HNO_3 or HCl to lower their pH value to some 1–3. However, for some radionuclides, e.g., radiocarbon or radioiodine, this step cannot be applied, as it could result in their partial or even complete loss. Water samples are often prefiltrated through a filter paper, and if finer filtration is required, the standard 0.45 μm membrane filters can be used as well. Filters are made of various inert materials (fluorocarbon or polyethersulfone polymers, cellulose, polycarbonate) so that they do not bias the analysis of radionuclides of interest. In this part, we shall focus only on terrestrial water samples, as seawater samples are comprehensively discussed in Chapter 5, Volume 2.

1. Sampling of water

a. Precipitation

Precipitation is typically sampled integrally on a weekly/monthly basis or discretely (separately). Polyethylene or fluorocarbon polymer reagent bottles and stainless steel pot collectors can be exploited for collection of rainwater and snow. In the case of radionuclides prone to evaporation, it is reasonable to use a funnel type collector. Wet deposition is clearly accompanied by dry deposition, though collection of the latter can be simply avoided by covering of the sampling container with a plastic film or sheet, removable during precipitation. A protective net that prevents different debris from mixing with the sample is normally installed over the top of the container. An upgrade of a funnel collector with an ion exchange column enables one to preconcentrate more than 90% of the most important radionuclides that are extracted on the column as the precipitate passes through it (Lehto and Hou, 2011).

b. Groundwater

Groundwater samples can be collected from monitoring wells by suction lift and positive displacement pumps that are preferably selected because they do not generate a vacuum, which is also true for submersible pumps. A bailer or similar thief-type sampler and pumps installed in supply wells are used to sample groundwater as well. For the collection of groundwater under natural gradient conditions, specifically designed multilayer samplers have been developed (Margaritz et al., 1989). Sampling at remote sites from ephemeral, urban storm drains, and small streams is sometimes conducted with automatic pumping samplers that have fixed-depth intake (Macášek, 2008). In some cases, it is important to isolate borehole inflows from their underlying or overlying strata during the sampling to prevent mixing of waters (Povinec et al., 2010, 2013d).

c. Surface and depth water profiles

Surface water samples from lakes and rivers can be collected with a polyethylene bottle, barrel, or bucket ($<$20 L) or by a submersible pump if larger volumes are needed ($>$20 L). In special cases, a screen can also be used. The sampling container is usually washed with the sampled water, which is then discarded. Cross-contamination of the samples can be easily avoided by discarding first several liters of the water. A surface water sampling device installed on a ship enables continuous sampling, which is especially useful if a greater number of samples are taken. Such a device is also equipped with various sensors for the determination of the physicochemical parameters (e.g., temperature, salinity, Eh, pH, dissolved oxygen concentration) of the water (Lehto and Hou, 2011). It is important to note that there might be a difference between surface samples collected by containers and those collected by screens due to the surface microlayer, generally enriched in heavy metal, organic, and bacterial species (Macášek, 2008).

If one is interested in the vertical distribution of radionuclides, it is necessary to sample the water core. Sampling of the depth profile in a shallow lake or river can be conducted by a single submersible pump. The precise depth of sampling is determined by the length of the sampling cable/tube. To keep it straight so that the depth measurement is accurate, some kind of heavy weight is normally attached to it. For sampling of deeper water bodies, a Nansen or later developed Niskin bottle equipped with different sensors can be used, as they are commonly exploited in the seawater sampling (see Chapter 5, Volume 2). Circular frame rosette systems, which can mount up to 36 bottles, are available for large-scale simultaneous sampling (Lehto and Hou, 2011).

d. Sediment pore water

In general, pore water can be extracted either in the laboratory after coring the sediment or in situ using one of many available sampling devices. Although the former method is straightforward and easy to conduct, it has some disadvantages, i.e., it may alter the composition of the sample due to transport, redox variations, temperature and pressure changes, and solid−solution interactions during extraction and storage (Lehto and Hou, 2011). Thus, special systems for in situ extraction of the pore water have been developed in a way that they usually ensure that no further manipulation with the water is needed after the sampling. Despite the fact that the in situ water extraction method can significantly lower the risk of composition changes in the sample, the procedure is more complex and reliably useable only to the depth of several meters.

e. Ice cores

Different types of drilling systems, which can be used even at high elevation and work at relatively fast rate (e.g., 1.65 m h^{-1}; Iizuka et al., 2016) producing ice cores as long as tens to thousands of meters, have been developed for sampling of ice. After drilling, the surface of the ice sample can be washed with warm deionized water to remove external impurities. For further separation of atmospheric and in situ−produced radionuclides, the ice must be melted, either spontaneously or with the use of a heating device, such as microwave oven. Depending on the radionuclide(s) of interest, filtration may be applied, and the pH of the obtained water should be adjusted accordingly.

2. Examples of radionuclides in water systems

a. Tritium

Tritium is one of those rare radionuclides whose concentration in waters is effectively measurable by both radiometric and mass spectrometry techniques. For a sample with the ^{3}H activity concentration above $\sim$1 Bq L^{-1}, tritium is easily determined by LSC, after the sample is mixed with appropriate scintillation cocktail. However, as a low-energy beta emitter, tritium is sensitive to quenching effects and the presence of interfering radionuclides. Thus, the water sample is distilled (usually at pH > 9) prior to the LSC measurement to remove possible sources of interferents (Lehto and Hou, 2011). GPC was also used for tritium determination in earlier days (Povinec et al., 1972); however, nowadays mostly LSC is used, except in the cases when small samples should be analyzed (e.g., a direct analysis of methane).

In principle, conventional radiometric methods, namely LSC, can be used for samples with the tritium activity concentration beyond their limit of detection, if ^{3}H in the water is first enriched by electrolysis. The process is based on electric decomposition of water molecules into gaseous oxygen and hydrogen, which are then released from the sample. As dissociation of tritiated water (HTO) is slightly less probable than normal water (H_2O), the concentration of tritium is increased with the decreasing volume of the sample. For example, a sample with the original volume of 0.1−0.5 L is concentrated into the 3−10 mL volume, whereas tritium is enriched by a factor of 10−50, resulting in an improvement of the detection limit for LSC to the level of 0.1−0.02 Bq L^{-1} (Lehto and Hou, 2011). A standard of known tritium activity, usually prepared from water without ^{3}H, must be processed and measured the same way as the sample in order to determine the enrichment factor of electrolysis.

The most sensitive method for tritium analysis in water is definitely ^{3}H-^{3}He ingrowth mass spectrometry, which can measure the $^{3}H/^{1}H$ isotopic ratio down to 10^{-20} (Clarke et al., 1976; Palcsu et al., 2010; Papp et al., 2012). This exceptional technique, which utilizes the determination of stable ^{3}He produced by the decay of tritium to back-calculate the original ^{3}H activity in the sample, has already been discussed (Sections IV.B and V.A). AMS may also be used for the determination of tritium; however, its detection limit is by five to seven orders of magnitude lower if compared with ^{3}He ingrowth mass spectrometry (Roberts et al., 2000). AMS is thus potentially exploitable mainly for waters with a relatively high activity of tritium (e.g., liquid discharges from nuclear installations) or ^{3}H-labeled samples in various biological experiments (Dingley et al., 1998; Love et al., 2004; Brown et al., 2005). Of course, nontrivial sample preparation is necessary for tritium AMS as well. First, water is let to react with elemental zinc powder at the elevated temperature to produce hydrogen, which is then absorbed on pure Ti to obtain titanium hydride, an excellent material for sputtering in the ion source of AMS. Both reactions run at the elevated temperature (450−550°C), which can be conducted in a single sealed quartz tube (Chiarappa-Zucca et al., 2002; Pánik et al., 2017).

Controlled liquid discharges from NPPs containing large activities of tritium can significantly affect the reservoir into which they are released. On the other hand, increased concentrations enable an easier tracing of tritium in various fractions of living organisms, such as plants, which are grown in the reservoir or in its vicinity. Long-term monitoring of surface water of the Mohelno reservoir in Czechia, where both inlet and outlet of the cooling water for the Dukovany NPP are located, showed fluctuating activity concentrations of ^{3}H up to 700 Bq L^{-1} (Fig. 3.56; Svetlik et al., 2014). As a consequence of discharging, high activities were also found in various plant species, which were sampled in the Mohelno reservoir or its adjacent parts. The mean activity concentration of nonexchangeable organically bound tritium (NE-OBT) and tissue-free water tritium (TFWT) fractions was determined to be roughly 24 Bq kg^{-1} and 35 Bq L^{-1}, respectively (Simek et al., 2017). The more distant from the outlet, lower activity of NE-OBT and TFWT was measured in plants from the reservoir (Kořínková et al., 2016). Experimental results like these may be used to study metabolic pathways and kinetics of the release of different ^{3}H chemical forms.

b. Radiocarbon

Radiocarbon can be found in water in the form of dissolved inorganic carbon (DIC) and dissolved organic carbon (DOC), partially as particulate matter as well. The fraction that passes through a filter contains dissolved carbon. The procedures applied for further sample processing depend on the selected method for analysis of ^{14}C content. In the case of AMS, where only low amounts of samples are necessary, DIC is usually extracted and cleaned from water vapor and other impurities in a dedicated vacuum line (Bard et al., 1989; Molnár et al., 2013; Kaizer et al., 2016a; Povinec et al., 2016). After addition of acid to reduce CO_2 solubility, high-purity inert gas (He or N_2) is bubbled through the water sample, or the sample can also be heated to obtain the same result (Molnár et al., 2013). This way, released CO_2 is passed through a system of water traps, until it is frozen in final trap(s) with liquid nitrogen. Extraction of organic carbon can be achieved by combustion, or potassium perchlorate and oxygen reactions, supported by ultraviolet light (Purdy et al., 1992; McNichol et al., 1994). The carbon dioxide sample, thus obtained, is either converted to graphite, as was discussed in the previous section, or directly introduced into the ion source of the AMS.

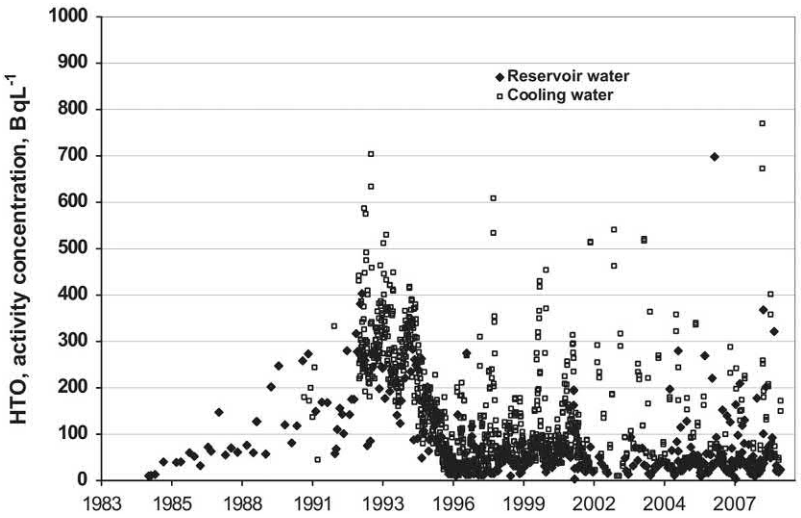

FIGURE 3.56 Time series of the tritium activity concentration (Bq L^{-1}) in the Dukovany NPP's cooling water and in the Mohelno reservoir. *From Svetlik et al. (2014).* Printed with permission © *Elsevier 2018.*

For radiometric analytical methods, the initial volume of samples is generally much higher than for AMS. While the DIC is typically extracted in the form of $BaCO_3$ precipitate, which is produced by reaction with a Ba^{2+} solution, organic forms of dissolved carbon can be converted to CO_2 by wet oxidation at elevated temperatures. For LSC, carbonates can be directly mixed with the scintillation cocktail (Svetlik et al., 2017) or they can be converted to benzene (C_6H_6), which is a better scintillation solvent. Another advantage of benzene is that its synthesis, which is based on trimerization of acetylene generated from the sample CO_2, results in an almost quantitative transfer of sample carbon to solvent carbon (Polach, 1987). In the case of GPC, carbonates are acidified, e.g., by H_3PO_4, to back-release carbon oxide that is used to produce methane (Povinec, 1972), as was described earlier for gas samples.

Radiocarbon together with stable isotopes has been frequently exploited to study the origin and dynamics of groundwater and to better understand its formation, age, infiltration areas, and vulnerability to contamination. For example, investigations of the spatial distribution of ^{14}C and $\delta^{13}C$ of the mineral and thermal waters in Slovakia showed quite large isotopic variability. The corrected radiocarbon apparent ages of the studied groundwater samples were determined to be between 7000 and 32,000 years, suggesting that the waters recharged mainly during the early Holocene, Würm 3, and Würm 2−3 periods (Povinec et al., 2010). The consequent research of the largest Central Europe underground water source, Žitný Island of southwestern Slovakia, showed that the majority of groundwater samples are of recent origin (Fig. 3.57). The results of the study also indicated that a confined aquifer was formed in the eastern part of the island, and the Danube River system is the main source of groundwater at Žitný Island (Povinec et al., 2013d).

Monitoring of anthropogenic radiocarbon in waters is also important. To assess its radiological impact, ^{14}C concentration in the effluents from NPPs or other nuclear installations has to be first evaluated. In the case of two Czech pressurized water reactor (PWR) NPPs, Temelín and Dukovany, the mean activity concentration values for the sum of all chemical forms of ^{14}C in the liquid effluents in the year 2015 were conservatively determined to be around 1.6 and 0.1 Bq L^{-1}, respectively. In the same year, the cumulative discharge of radiocarbon was 738 GBq for the Dukovany NPP and 584 GBq for the Temelín NPP, whereas the volume of 2.7×10^4 m^3 and 3.1×10^4 m^3 was overall released in the liquid form from the latter and the former, respectively. This would mean the instantaneous ^{14}C releases into the water streams would be about 0.007% and 0.0004% of the total quantity of the radiocarbon discharged into the environment for Temelín and Dukovany NPPs, respectively (Svetlik et al., 2017). Interestingly, the determined ^{14}C releases are much lower when compared with the values for other PWR-type NPPs reported elsewhere (Kunz, 1985; Magnusson et al., 2008).

c. Chlorine-36

As a long-lived radionuclide, ^{36}Cl is commonly exploited in dating of groundwater or as a tracer in environmental processes, in which its concentration is so low that it can be determined only by AMS. Radiometric methods, i.e., LSC, could be useable for waters originating from nuclear waste processing, though such applications are quite off the scientific interest. The detection limit for AMS is around 1 nBq or the $^{36}Cl/^{35}Cl$ isotopic ratio of 10^{-15} (Synal et al., 1994). The main challenge in the AMS determination of ^{36}Cl is the stable ^{36}S isobar with the relative abundance of 0.02%. A detector can have a count rate 100 times greater

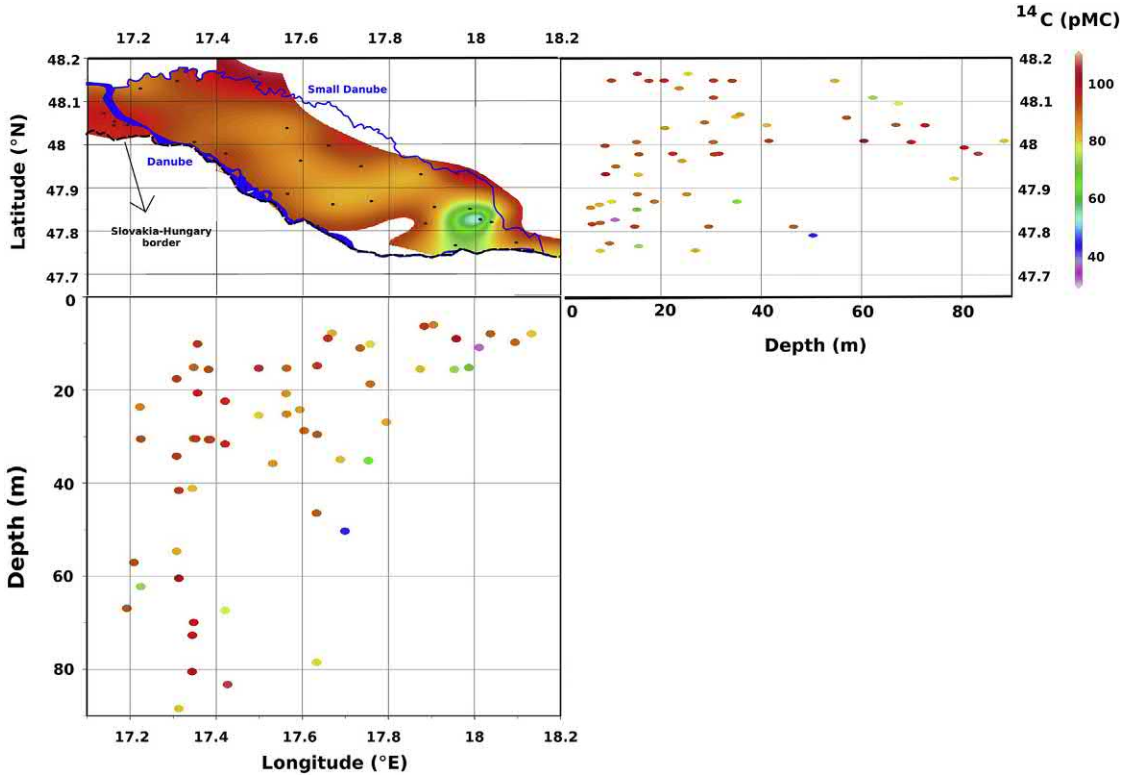

FIGURE 3.57 Latitudinal and longitudinal spatial and vertical distribution of radiocarbon (pMC) in groundwater of Žitný ostrov (100% pMC = 0.236 Bq g^{-1} C). *From Povinec et al. (2013d).* Printed with permission © Cambridge University Press.

than that from a sample with the $^{36}Cl/^{35}Cl$ ratio of 10^{-12} if nanograms of sulfur are present in the ion source target (Tuniz et al., 1998). To reduce the background from ^{36}S, one can use novel techniques to improve the measuring system for isobar suppression (Wilcken et al., 2010; Martschini et al., 2013) and try to remove sulfur as much as possible during the chemical separation of ^{36}Cl from the sample.

Separation of chlorine from the sample in the form of Cl^- ions is fairly simple. By adding stable chloride carrier and a small excess of Ag^+ ions to the acidified sample (pH = 1−2), water-insoluble silver chloride is formed, which is the preferred AMS target material. Because there is no suitable tracer, the chemical yield of ^{36}Cl separation is controlled gravimetrically, though the precipitation is usually close to being quantitative. However, silver sulfate salts are readily formed as well. This problem can be solved by dissolving the precipitate in pure NH_3(aq) and adding saturated barium nitrate solution. The precipitate of formed $BaSO_4$ is discarded, and AgCl is reprecipitated if the solution is again acidified (Fig. 3.58; Tosaki et al., 2007). Moreover, sulfur can also be effectively removed by methods based on ion exchange column chromatography (Nakata and Hasegawa, 2011).

With the development and increasing availability of AMS, dating of water reservoirs using ^{36}Cl has become much more feasible, though its reliability might be questionable in some cases. Although an overall good correlation was found between dating with the use of ^{81}Kr and ^{36}Cl for 1-million-year-old Saharan groundwater, two results from this study showed significantly higher (lower) $^{36}Cl/Cl$ ratio. It was suggested that these discrepancies might have been caused by the subsurface input of nucleogenic ^{36}Cl, or chlorine having lower $^{36}Cl/Cl$ ratio, which demonstrate that ^{36}Cl dating may be susceptible to additions of Cl along a flow path (Sturchio et al., 2004). Furthermore, results from dating of the Vostok snow indicated that ^{36}Cl data in central Antarctic regions, where accumulation of ice is rather low, are most likely unreliable due to various postdeposition processes affecting the gaseous form of chlorine (Delmas et al., 2004). On the contrary, the ^{36}Cl bomb pulse was successfully used for dating of modern groundwater (Tosaki et al., 2007).

d. Technetium-99

The determination of beta-emitting ^{99}Tc can be conducted by LSC or GPC in the activity range of 1−100 mBq, after its separation from water and purification, whose chemical yield is trackable with the use of short-lived gamma-emitting ^{99m}Tc ($T_{1/2}$ = 6.01 hours), or one of the stable isotopes of rhenium, the closest element to technetium (Lehto and Hou, 2011). Mass spectrometric methods, such

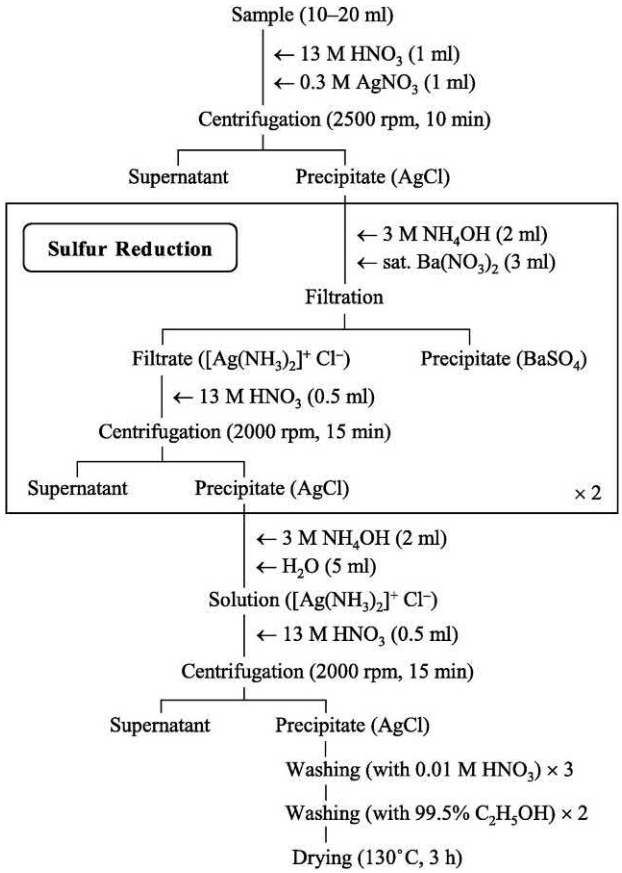

FIGURE 3.58 Schematic diagram of sample preparation for accelerometer mass spectrometry (AMS) determination of ^{36}Cl concentration in water. *From Tosaki et al. (2007).* Printed with permission © *Elsevier 2018.*

as ICP-MS RIMS, TIMS, and AMS can be also used to measure ^{99}Tc in water, reaching the detection limit up to 1−10 μBq in a sample (Hou and Roos, 2008). The most common form of technetium present in oxic water is the quite soluble and mobile pertechnetate ion that only sparingly creates complexes and that can be reduced to Tc(IV). For large-volume samples (50−200 L), the preconcentration of ^{99}Tc by anion exchange column chromatography or iron hydroxide precipitation is usually the first step in its radiochemical separation. Further separation from interferents can be achieved by solvent extraction, ion exchange, and extraction chromatography.

For the extraction of ^{99}Tc from matrix elements, chromatographic methods are generally exploited more than solvent extraction. As both anion exchange and extraction chromatography have some specific disadvantages, their combination results in better removal of matrix and interfering components (Shi et al., 2012). An example analytical procedure for the determination of low-level ^{99}Tc by ICP-MS based on a two-step chromatographic separation from large-volume water samples is shown in Fig. 3.59. After the acidified sample is heated at 90°C sufficiently long to decompose organics, saturated NaOH solution is added to remove actinides and transition metals by precipitation. Neutralized supernatant is then loaded on the first column filled with anion exchange resin (Bio-Rad AG1-X4). Dilute nitric acid is used to wash out most of the cations, while retained ^{99}Tc is eluted by 10 M HNO_3. Following evaporation of the eluate to near dryness, technetium is separated from Mo and Ru on an Eichrom UTEVA resin column in a similar way than in the case of the anion exchanger (Keith-Roach et al., 2002). If AMS is employed for ^{99}Tc determination instead of ICP-MS, the HNO_3 eluate is mixed with aluminum containing Re or Nb, evaporated to dryness, and baked at 400−450°C to obtain metal oxides, which are used as sputtering material (Wacker et al., 2004). The potential of technetium fluoride for sputtering in AMS has been recently studied as well (Zhao and Litherland, 2010).

Assessment of fission-produced ^{99}Tc might be important for the evaluation of the impact of nuclear installations, such as facilities for the production of nuclear weapon material or reprocessing plants, which have discharged radioactive liquid wastes into freshwater ecosystems. One of such facilities was the Savannah River Site in the United States, where a monitoring study showed slightly higher activity concentrations of ^{99}Tc (0.02−0.04 Bq L^{-1}) in several freshwater samples. Groundwater migration from beneath old seepage basins, used for the disposal of wastewater-containing radionuclides from the site, was identified as the reason for elevated values (Beals and Hayes, 1995). Another example is the Russian Mayak reprocessing plant, where the ^{99}Tc activity concentration up to 2.15 Bq L^{-1} was determined for one of the freshwater samples (Skipperud et al., 2007).

e. Iodine-129

Depending on its activity concentration, ^{129}I in water can be measured by radiometric methods (gamma- and X-ray spectrometer, LSC), neutron activation analysis (NAA), ICP-MS, or AMS. While radiometric methods and ICP-MS can be normally used to determine higher activities of ^{129}I (e.g., in spent fuels), NAA and AMS are capable of measuring of low-level water samples, reaching the detection limit of 1 μBq and 1 nBq, respectively (Povinec et al., 2000; Hou and Roos, 2008). NAA of ^{129}I is based on the reaction (n,γ), yielding short-lived ^{130}I ($T_{1/2}$ = 12.3 hours), which decays to a stable isotope of xenon, while emitting high-energy gamma rays. Except for direct measurements of mid-to-high-level waters by radiometric methods or ICP-MS, radiochemical separation of iodine is mandatory for its determination. If no carrier is added to the sample before separation, NAA can be used also for the determination of stable ^{127}I and consequently the $^{129}I/^{127}I$ isotopic ratio (Hou et al., 1999, 2009a).

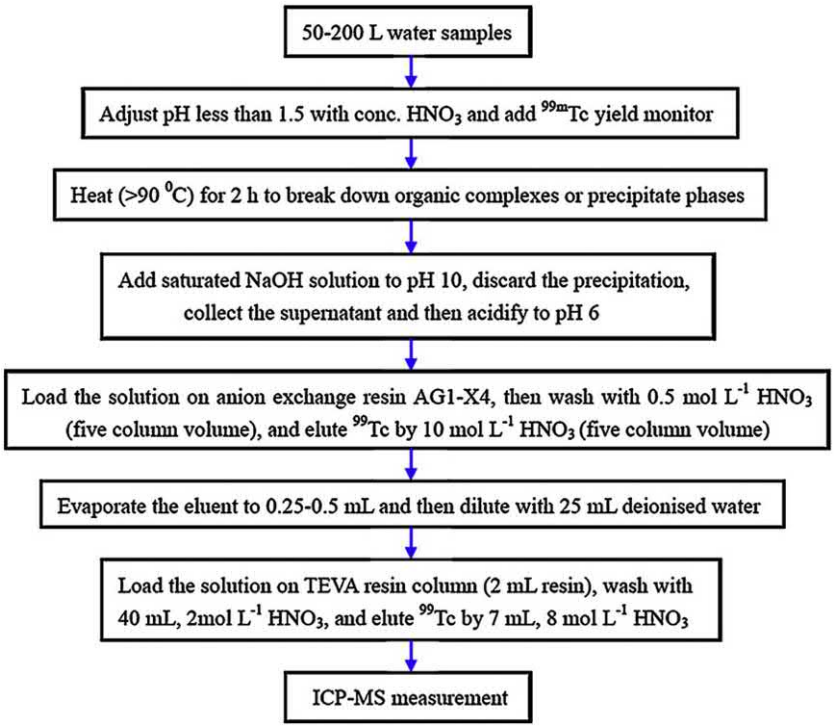

FIGURE 3.59 Diagram of radiochemical procedure for measurement of ^{99}Tc in water samples, combining anion exchange and extraction chromatography. *From Shi et al. (2012).* Printed with permission © *Elsevier 2018.*

Procedures applied for the separation of iodine from natural waters are usually the same, regardless of the analytical technique. Iodine is present in natural waters in the inorganic (as iodide and iodate) and organic form. Radiochemical separation of total inorganic ^{129}I can be conducted by two principle methods: solvent extraction and ion exchange chromatography (Lehto and Hou, 2011; Povinec et al., 2015a). In the case of the former, which is based on the solubility difference of iodine in immiscible aqueous and organic phases, stable iodine carrier (e.g., Woodward Iodine with the ^{129}I/^{127}I ratio of 10^{-13}) is first added to the filtered acidified (pH ~ 2) sample. Then, all iodate is converted to iodide by a reducing agent, such as $NaHSO_3$, and consequently, iodide is oxidized to elemental iodine (I_2) by $NaNO_2$ that can be easily extracted by some organic solvents ($CHCl_3$ or CCl_4). After separation of two phases, iodine in the form of I^- is back-extracted to a fresh portion of deionized (distilled) water. The preparation of the final target depends on the selected analytical method (Hou et al., 2009a). For example, iodine is typically precipitated as AgI, which is mixed with high-purity silver powder after being cleaned and dried, and then pressed into a target holder for AMS measurement (Povinec et al., 2000, 2015a).

Ion exchange chromatography exploits a very high affinity of iodide ions to bind to the exchanger, which is part of a resin, generally packed in a column. If only total inorganic iodine in water is to be determined, the first steps (acidification, carrier addition, conversion to I^-) are identical to those mentioned above (Povinec et al., 2015). After loading the sample on the column with the anion exchange resin in the nitrate form, ions of interfering elements (e.g., Cl^-) are washed out by the 0.1−0.2 M HNO_3 or $NaNO_3$ solution, and strongly bound iodide is eluted with 0.5−2 M HNO_3 or $NaNO_3$ (Hou et al., 2009a; Kaizer et al., 2016a,b). Another option is to convert iodide to iodate, which has a very low affinity to the exchanger, and thus is easily eluted from the column (Lehto et al., 2012). The chemical yield of ^{129}I separation for both described procedures can be determined gravimetrically from the mass of the final target (e.g., AgI for AMS), or by the addition of gamma ray−emitting ^{125}I ($T_{1/2} = 59.4$ days) tracer to the sample before the separation.

The distribution of ^{129}I species, which influences its biological uptake and mobility, is analyzed to assess consequences of radioactive contamination in the environment (Salbu, 2007). The combination of solvent extraction and anion exchange chromatography is often used for the separation of different iodine species from waters (Hou et al., 2009a; Lehto et al., 2012). An example flowchart of such combination is depicted in Fig. 3.60. While subsequent anion exchange chromatography steps are necessary to completely separate the organic fraction, inorganic iodide is preconcentrated on the first column, eluted, and processed by solvent extraction. Similarly, the iodate fraction is eluted from the second chromatographic column and converted to

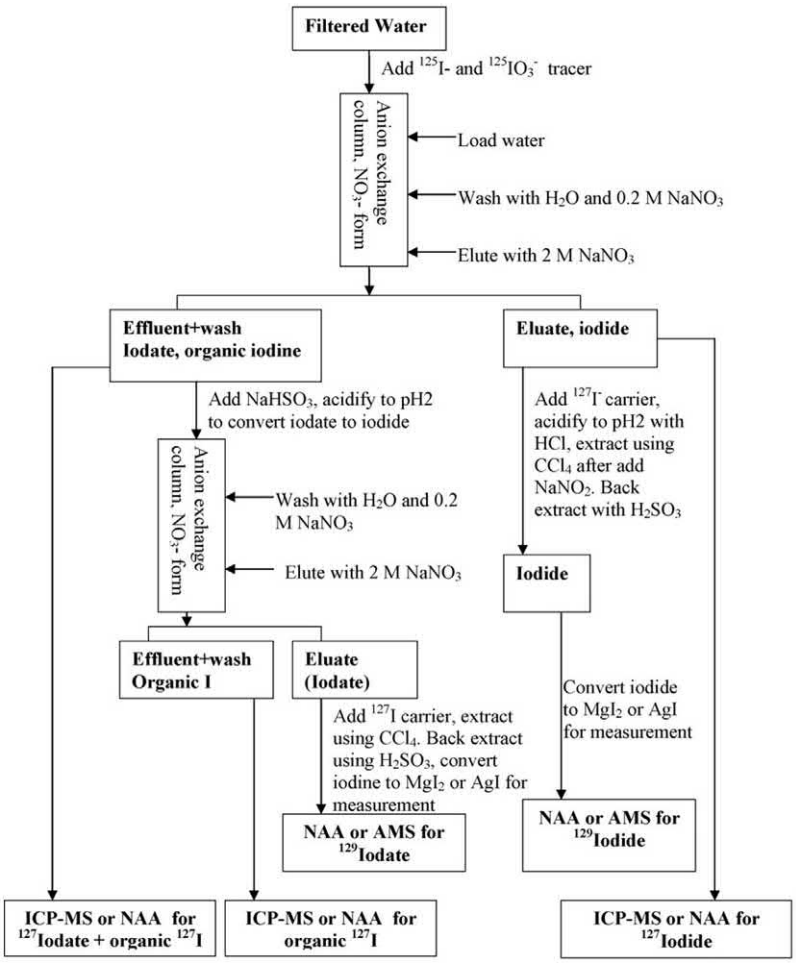

FIGURE 3.60 Diagram of analytical procedure for speciation analysis of iodine in water. *From Hou et al. (2009a).* Printed with permission © *Elsevier 2018.*

the target. The chemical yield of the method is above average (~75%; Hou et al., 2001); however, it is unusable for the determination of organic ^{129}I. Heating of the water sample in hydroxide and ethanol mixture before the separation, which should decompose organic materials and convert released organic iodine into the inorganic form, has been suggested as a possible solution (Schwehr et al., 2005).

Isotopes of iodine, ^{129}I and ^{127}I, and their speciation in natural waters have been studied frequently to evaluate the contribution of various anthropogenic sources of ^{129}I and their transfer between the atmosphere and hydrosphere compartments. In the Scandinavian countries, the $^{129}I/^{127}I$ ratio and the concentration of ^{129}I in rain waters in the range of $(13.9-46.9) \times 10^{-8}$ and $(0.04-29.8) \times 10^{9}$ at L^{-1}, respectively, were observed, which was by at least one order of magnitude lower than in the sea. Similar but less varying values were determined for lakes as well. The iodide form was found to be dominant in the ^{129}I speciation in precipitation (Aldahan et al., 2009; Hou et al., 2009b; Lehto et al., 2012). The annual wet deposition of total inorganic ^{129}I in Finland was calculated to be around 5.4×10^{-4} Bq m^{-2}, which was by about three orders of magnitude lower than the ^{90}Sr deposition at that time (Paatero et al., 2010; Lehto et al., 2012). Reemission from seas, which are affected by discharges from La Hague and Sellafield reprocessing plants, and consequent precipitation over the land are regarded as the main source of increased concentrations of ^{129}I in the terrestrial waters in current-day Europe (Hou et al., 2009a,b; Lehto et al., 2012; Michel et al., 2012).

f. Radiocesium

Similar to other alkali metals, cesium is readily dissolved in water in the form of hydrated Cs^+—only a small portion (<1%) is attached to the particulate matter. Due to the fact that both ^{134}Cs and ^{137}Cs emit high-energy gamma radiation, their activities can be quite easily determined by gamma spectrometry (see Section IV.A), where aerosol samples have been discussed. In the case of low-level samples, where direct measurements by gamma

spectrometry are not possible, radiocesium can be preconcentrated from water samples by cation exchange resin, evaporation, or precipitation with the use of highly selective reagents, such as ammonium phosphomolybdate (AMP) or transition metal hexacyanoferrates. Adsorption on cation exchange resin is suitable for terrestrial water, as its capacity is usually sufficient to extract all cations from several tens of liters. Although the precipitation method is widely exploited for pretreatment of seawater (Roos et al., 1994), it is in principle useable for freshwater as well. Copper hexacyanoferrate complex is slightly advantageous over AMP, as it tends to adsorb less of interfering ^{40}K, and unlike precipitation by AMP, which requires acidification of the sample to pH 1.5−2.0, copper hexacyanoferrate works in the natural pH range.

The limit of detection for the determination of radiocesium in water by gamma spectrometry is typically 50 mBq for a 50 mL sample (Hou and Roos, 2008); however, this value is strongly dependent on the detection efficiency, background of the detector, detector setup, and time of measurement. Thus, the limit of detection can be further enhanced by changing the stated parameters. One of the options is to use a Marinelli beaker, which fits well around the HPGe or scintillation detector (Ahmed et al., 2009). This improves the detection efficiency and consequently the detection limit for low-level environmental water samples (Lavi et al., 1997). Another possibility is to use a HPGe spectrometer with anticosmic/antiCompton shielding or to operate the spectrometer in a shallow or deep underground laboratory (Povinec et al., 2004, 2005, 2008, 2011; Aoyama et al., 2011, 2016), which can improve detection limits at least by an order of magnitude.

Capabilities to monitor radiocesium in the environment have proved to be very important, especially after the NPP accidents in Chernobyl and Fukushima. In the case of the Fukushima accident, the origin of radioactivity in wet deposition could be identified by the ^{137}Cs/^{134}Cs activity ratio of around 1, which could be measured by not only gamma spectrometry but also ICP-MS (Ohno and Muramatsu, 2014). The Fukushima signal was detected in rainwater samples all over the globe, as summarized by Lee et al. (2013). In Western Europe (France), radiocesium activity in rainwater peaked at the level of ∼10 mBq L^{-1}, approximately 3 weeks after the accident (Masson et al., 2015), which is similar to the Central Europe data for total (wet plus dry) deposition reported by Povinec et al. (2012a), who also documented a decrease of the ^{137}Cs activity with the increasing precipitation rate, as opposed to cosmogenic ^{7}Be (Fig. 3.61).

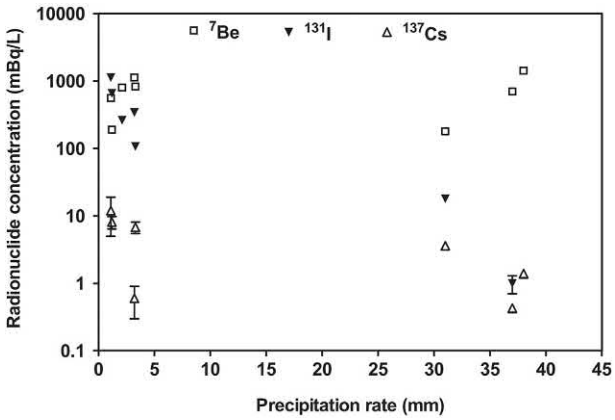

FIGURE 3.61 Correlation between concentration of ^{7}Be, ^{131}I, and ^{137}Cs and precipitation rate, determined in Bratislava after the Fukushima accident. *From Povinec et al. (2012a).* Printed with permission © *Elsevier 2018.*

g. Radon

Radon (mostly ^{222}Rn) can be simply determined by gamma spectrometry of its daughter nuclides or by LSC, if its concentration in water is high enough. Another possibility is to use in situ underwater gamma spectrometry (Povinec et al., 1996), which can also provide monitoring time series of its concentration in water (for details, see Chapter 5, Volume 2). If the concentration is too low to be measured directly, radon must be preconcentrated. This can be accomplished by bubbling nonactive carrier gas (e.g., helium) through the sample and collecting the gas fraction into a cooled activated carbon cartridge for later analysis, or directly into an evacuated measuring cell. Radon determination is most frequently conducted by the cell of the Lucas type that utilizes zinc sulfide (ZnS) painted (sprayed) on the inside walls as a scintillator (Lucas, 1957). Silica gel and cotton wool can be placed into a tube, which connects the Lucas cell and sampling bottle, to prevent water droplets produced during the bubbling to be introduced into the cell. When the radioactive equilibrium between radon and its progenies is established, which takes some 4 hours, radon activity is counted and its concentration in the original water sample is back-calculated. Using the described method, the detection limit of 1 Bq L^{-1} for radon in water is reachable (Blahušiak et al., 2017). Another option for radon measurement is to use a flow-through scintillation flask instead of collection cell (Ward and Borak, 1991).

Monitoring of radon concentration in groundwater sources is important for assessment of radiological risk from radon exposure, especially at places like thermal spas. Additionally, estimating the correlation between the meteorological parameters and radon concentration may help to correctly determine the radon risk. For example, the mean radon activity concentration (RAC) in fountain water at different thermal spas in Slovakia was found to be 62.3 Bq L^{-1}, corresponding to the annual dose due to ingestion of ^{222}Rn for adults of 13.1 μSv, which is by a factor of about

12 lower than the dose due to inhalation of radon, determined for the very same places (Blahušiak et al., 2017). The results from another investigation suggest that rainfall may significantly influence the content of radon in borehole water. In fact, each increase of RAC in borehole water analyzed in this study was preceded by heavy rainfall. On top of that, radon water content was in a positive correlation with the state of the water in the borehole. It is also interesting to point out that the observed decrease of RAC in the October–March period was much slower than anticipated, probably due to the horizontal movement of water (Fig. 3.62) (Smetanová et al., 2010).

D. Radionuclides in soil

1. Preparation of soil samples for radionuclide analysis

Soil samples are usually collected according to IAEA guidelines from a 1 m^2 area up to depth of 10 cm. After the sampling process, soil samples are dried at 105°C during 24 hours to remove any available moisture. Stones and plant roots are removed from the soils before soil is crushed and prepared for gamma spectrometry and the determination of main physical and chemical soil characteristics.

The soil samples are then homogenized, weighed, and hermetically sealed in the plastic containers, for example, Marinelli beakers, for 30 days. This is the time required for reaching the radioactive equilibrium between radon and its decay products, required for proper gamma spectrometry analysis. The radon decay products are then identified usually using a high-purity germanium (HPGe) detector. Gamma spectrometry is a sensitive method of analysis that can yield analytical data for several different nuclides in a single sample analysis. HPGe detectors should be shielded in suitable lead/iron/copper shields to achieve a low background (e.g., Sýkora et al., 2008). The concentrations of radionuclides are then calculated from peak areas of registered gamma rays after appropriate efficiency and energy calibration. The ^{226}Ra concentration is usually calculated from the peaks of ^{214}Bi and ^{214}Pb with energies of 609 and 352 keV, respectively. The ^{232}Th concentration is usually calculated from the peaks of ^{208}Tl (583 and 860 keV). The ^{40}K concentration is determined from the peak area of registered gamma rays with the energy of 1460 keV, and the ^{137}Cs concentration is calculated from the peak with the energy of 662 keV. Nondestructive gamma spectrometry measurements are possible, however, only for radionuclides emitting gamma rays. Other radionuclides emitting alpha rays or beta rays require chemical separations, similar to those described in Sections IV.A, B, C and V.B, C, E.

2. Examples of radionuclides in soil

We shall focus in this section only on two radionuclides, one is representing a radiogenic radionuclide (^{222}Rn), and the second one is representing anthropogenic radioactivity of soil (^{137}Cs). The other interesting radionuclides from the natural sources would be ^{40}K and U and Th and their decay products. From the anthropogenic radionuclides, it would be mainly ^{90}Sr.

a. Radon

The radon (usually ^{222}Rn) concentration in soil can be measured by grab sampling or continuously with a suitable monitor. Soil air is sucked into the scintillation cell (e.g., Lucas cell) through a collection rod from a depth of 0.8 m. For continual monitoring of ^{222}Rn in the soil, air is sucked from the depth of 0.8 m, dried in the refrigerator (at −30°C), and then is allowed to enter the Lucas cell (Müllerová et al., 2014). The flow rate and route length before detector are chosen in such way that no thoron (^{220}Rn) reaches the detector. Aerosols with radon decay products are captured on filter, so only ^{222}Rn enters the detector. The ^{222}Rn concentration has been calculated according to the method published by Ward and Borak (1991). The monitor allows the measurement of radon activity concentration in the soil air at the level of about 10 kBq m^{-3} with a relative uncertainty of 1.5% for a 1-h-long measuring interval. This precision is also sufficient for the study of daily radon variations in the soil air.

The character of the annual course of the radon activity concentration in the soil air depends mainly on the soil type and on the temperature variations of the outdoor atmosphere during a year and on the precipitations and the soil moisture. The typical annual course of the radon activity concentration in the soil air show courses with summer minimum and winter maximum. During hot and dry summer, an increase of ventilation at the surface is observed, which can cause a decrease of the radon activity concentration in the soil. From Fig. 3.63, it can be seen that typical annual courses of radon activity concentration occur in the soil air with summer minima and winter maxima (Müllerová et al., 2014). The typical annual courses can be modified not only by precipitation (at the end of April and in May 2006) but also by mild winters. Because of low quantity of snow precipitation and because of the higher temperature of the outdoor atmosphere, increases of the radon activity concentration in autumn months or maximum in winter months in 2006 were not observed. With the use of these annual courses of the radon concentration, there is the possibility of observing an anticorrelation between the radon concentration in the soil and atmospheric temperature. For years when precipitation is high, no correlation between the course of the radon activity concentration in the soil air and temperature of the outdoor atmosphere is observed (Müllerová et al., 2008). The influence of precipitation is strongest in the lower (0.4 m) than deeper (0.8 m) layers of the soil. It was also found that the time lag between precipitation and increased radon activity concentration was dependent on the depth at which radon was measured (Müllerová et al., 2014). Characteristic annual courses of radon activity concentration in the soil air (with summer minima and winter maxima) can be disturbed also by mild winters.

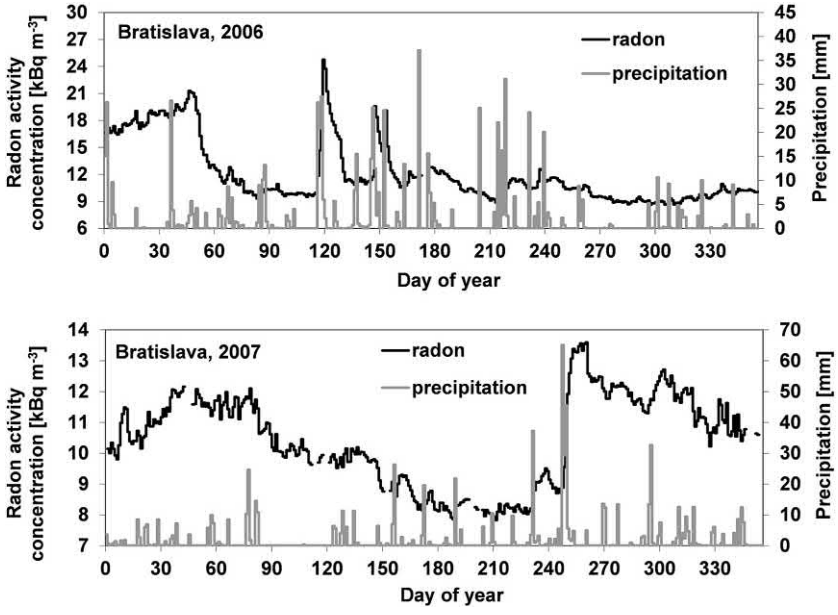

FIGURE 3.63 Average daily values of the radon activity concentration in the soil air and of precipitation in Bratislava in 2006 and 2007 (Müllerová et al., 2014).

Daily variations of the radon concentration in the soil air could be considered as short-term changes from the point of view of the half-life of radon. The analysis of the data confirms that regular daily changes of radon concentration in the soil air are connected with daily changes of atmospheric pressure. An increase of atmospheric pressure leads to a decrease of the radon concentration in the near-surface layer of the soil air and vice versa. In common soils, the radon concentration decreases toward the surface very markedly, as radon is released into the outdoor atmosphere on the surface. This process is called exhalation. Numerical values of the measurements of ^{222}Rn exhalation from the soil have applications in meteorology, determining the equivalent mixing height, testing of pollutant transport models in the atmosphere, engineering geology, as well as in other fields. The radon exhalation rate is influenced by a lot of varying factors like physical and chemical characteristics of the soil, soil structure, ^{226}Ra content, emanation coefficient, permeability, soil humidity, variations of meteorological parameters (temperature, pressure, precipitation), and others. Numerous authors compared the values of radon exhalation rate with meteorological parameters (Dueñas et al., 1997; Koarashi et al., 2000; Mazur and Kozak, 2014; Ferry et al., 2001; Prasad et al., 2012; Müllerová et al., 2018), radium content in the soil (Sahoo et al., 2010; Lawrence et al., 2009), or their dependence on grain size (Immé et al., 2014). The influence of rainfall has also been discussed in several works. In other works, Dueñas et al. (1997), Ferry et al. (2001), and Müllerová et al. (2018) observed that increased soil humidity as a consequence of rainfall caused a decrease in radon exhalation rate. Others (Lawrence et al., 2009; Faheem and Matiullah, 2008) found that initially radon exhalation rate increased with the increase in water content, but as the water content increased even more, it started to decrease. However, the results are unequivocal and differ for various types of soil as well as for climate regions.

b. ^{137}Cs

The main reservoirs of the anthropogenic ^{137}Cs in the present day are soil and vegetation, which took the ^{137}Cs from the soil, where it was deposited in the past, mainly due to global fallout and the Chernobyl and Fukushima NPP accidents. During the nuclear weapon tests, ^{137}Cs was mixed in the stratosphere and deposited on the terrestrial surface as global fallout, reflecting atmospheric circulation and its latitude dependence. In contrast, ^{137}Cs atmospheric deposition after nuclear accidents displayed heterogeneously mostly locally or regionally, mostly depending on the weather conditions that prevailed shortly after the emissions (Chartin et al., 2013; Korsakissok et al., 2013). ^{137}Cs released from all sources has primarily been deposited on the Earth's surface by dry and wet deposition. The concentration of ^{137}Cs in the soil depends on factors such as wind velocity, intensity and frequency of rainfall, type and structure of soil, and moisture content of the soil (Kulan, 2006). The major way of ^{137}Cs deposition is wet fallout; it is therefore strongly dependent on the precipitation. ^{137}Cs may then migrate in soil depth at a rate depending on processes controlling this transfer and on soil characteristics. The migration of ^{137}Cs in soils is governed by a combination of different physicochemical factors, for example, the type of soil, soil chemistry, organic carbon content, biological activity, climatic conditions, the pH, and organic matter content (Kirchner et al., 2009; Valcke and Cremers, 1994; Staunton et al., 2002). The most important determining factor, however, is the qualitative and quantitative clay content of the soil.

The penetration of ^{137}Cs into soil is a very slow process (Krstić et al., 2004; Szabó et al., 2012). The geochemical analysis supports the idea that the ^{137}Cs gets adsorbed by the clay minerals illite and kaolinite during the migration process. The concentration of ^{137}Cs in undisturbed soil profiles decreases with depth. ^{137}Cs is characterized by a strong affinity for fine soil particles, and this is therefore widely used to quantify soil erosion, but it is also employed to quantify the relative contribution of sources delivering sediment to rivers (Ben Slimane et al., 2013). However, its ability to trace vertical transfers of solid matter in soils was much less investigated. Although the soil formation occurs over much longer periods, individual pedological processes may be characterized by temporal variations with a succession of active and inactive periods throughout the entire story of soil development. The use of ^{137}Cs as a tracer provides therefore a relevant tool to understand and quantify those variations during the last 50 years (Jagercikova et al., 2015). The concentration of ^{137}Cs is significantly higher in undisturbed soils compared with agricultural soils (Mesrar et al., 2017). Forest soils are the richest in ^{137}Cs; fallow and cropland soils contain less of this radionuclide. The content of ^{137}Cs in soils decreased as the soil reaction increased; however, it was increasing with higher organic carbon content (Królak et al., 2008).

E. Radionuclides in biota

Biota samples represent a very wide spectrum of sample types from biosphere, including animal tissues and remains, vegetation samples, plant remains, biomedical samples, and foodstuffs. The measurement of miscellaneous radionuclides in these samples is used in radiation monitoring, radiometric dating, environmental studies, and geosciences. Because the biosphere is intimately connected to other radionuclide compartments, a whole range of radionuclides from these compartments can be present in biota samples as well. There are a large number of radionuclides present in the biosphere; this section focuses on some of the most

frequently analyzed radionuclides in biota samples—^{14}C, ^{3}H, $^{134,137}Cs$, ^{90}Sr, and ^{131}I.

1. Radiocarbon and tritium

a. Carbon-14

Carbon-14 as the radioisotope of the main biogenic element can be present in all organic molecules. Vegetation samples are one of the most studied sample types in terms of radiocarbon levels because they are linked with radiocarbon in the atmosphere via photosynthesis. Annual growth rings of trees in particular are very useful samples for ^{14}C analysis; they can be used as a record of past radiocarbon levels in the biosphere. The radiocarbon tree ring record has been dendrochronologically extended as far as 14,000 years into the past (Hua et al., 2009). Measurements of past ^{14}C levels are used for calibration purposes in radiocarbon dating (Reimer et al., 2013) and for studies of solar cycles (Miyahara et al., 2008; Povinec et al., 1983) and solar or extrasolar phenomena (Jull et al., 2018). Tree ring samples have also been used to retrospectively study radiocarbon activity influenced by excess ^{14}C around a radioactive waste disposal facility (Janovics et al., 2016), in the vicinity of NPPs (Ežerinskis et al., 2018; Janovics et al., 2013; Ješkovský et al., 2015) and ^{14}C levels influenced by fossil CO_2 sources in urbanized and industrialized areas (Kontul' et al., 2017; Rakowski et al., 2008). Fig. 3.64 shows results from ^{14}C measurement in annual growth rings in the vicinity of a PWR-type NPP in Slovakia. Comparison of tree ring and atmospheric CO_2 measurements shows that an excess ^{14}C released into the atmosphere outside the vegetation season of the tree is not recorded in growth rings. Other plant materials have been used to determine the impact of NPPs on the surrounding biosphere (Svetlik et al., 2012).

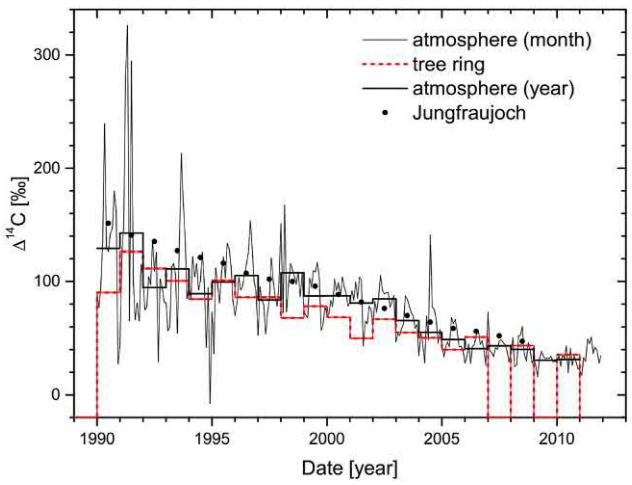

FIGURE 3.64 Tree ring and atmospheric radiocarbon data from Žlkovce sampling station in the vicinity of Bohunice nuclear power plant (NPP) in Slovakia. *From Ješkovský et al. (2015).* Printed with permission © *Elsevier 2018.*

Biota samples are very diverse, and therefore, it is hard to generalize any sampling methods for radiocarbon analysis. In cases where no specialized sampling procedures are necessary, the general rule of sampling needs to be followed—the sample should be representative of the studied attribute or process. For example, when vegetation is sampled, it should be considered what biomass accumulation period is represented by different parts of the plant. Sampling methods also depend on the required sample size given by the measurement method used. AMS requires samples with milligrams of carbon or less, whereas radiometric methods (GPC and LSC) require samples larger by several orders of magnitude (grams of carbon). Tree ring sampling illustrates this point very well—when GPC and LSC were the dominant ^{14}C measurement methods, whole tree sections had to be sampled to reach the required sample size and in the case of AMS a core from an increment borer provides enough material for analysis.

Sample preparation procedures aim to remove any contamination from the samples and extract a suitable material or chemical fraction for subsequent combustion. For plant and animal remains, specific carbonaceous compounds are chosen, which best represent the sample material (cellulose from wood, collagen from bones and teeth, etc.). While bulk wood samples can yield good results, measurement of cellulose extracted from these samples is considered more reliable because once cellulose is formed during plant growth, it is not mobile and is confined to material from the given growing season. Widely used cellulose extraction methods are based on removal of lignin by bleaching agents (Němec et al., 2010b). Most organic materials contain a mixture of organic compounds, and if radiocarbon levels in individual compounds are of interest, compound-specific radiocarbon analysis is applied. For ^{14}C analysis of all biota samples, the sample carbon needs to be converted into CO_2 by combustion or chemical oxidation. Large biota samples for radiometric measurements are combusted in a stream of pure oxygen (Kaizer et al., 2018b). Smaller samples for AMS analysis are usually combusted in a closed volume. The oxygen necessary for oxidation of carbon into CO_2 can be provided in the form of oxygen gas or solid materials CuO and MnO_2. Combustion with CuO or MnO_2 permits this process in flame-sealed glass tubes placed into a muffle furnace, which considerably increases sample throughput. The produced CO_2 is then released and collected by cracking the glass tubes in vacuum. Recently, a sealed tube method for organic materials combining combustion and graphitization into a one-step procedure has been developed.

When the samples are in the form of CO_2, the subsequent sample preparation methods and measurement

techniques are the same as described in the section dealing with radiocarbon in gases (Section V.A).

b. Tritium

Hydrogen is an inseparable component of a living organism, and the concentration of its radioactive isotope ^{3}H is of great interest in health and nuclear safety studies as well as environmental and biomedical sciences. Two chemical forms of tritium are present in biota samples—tritiated water absorbed in the sample material and organic-bound tritium. Tritium is widely used as a tracer for labeled molecules in biomedical research and the measurement of ^{3}H in organic matter can be used to determine the impact of nuclear installations on organisms living in their surrounding area (Krištof et al., 2017). Tree rings represent a well-defined record of past tritium levels similar to ^{14}C, and they have been successfully used to reconstruct past ^{3}H levels around tritium labeling facilities and nuclear weapon test sites (Love et al., 2004), NPPs, and reprocessing plants (Fuma and Inoue, 1995). Tree ring data set in Fig. 3.65 represents organic-bound tritium concentration in biosphere of Japan during the period of numerous nuclear weapon tests and subsequent years. The decrease of tritium levels after the test ban treaty in Tokai has been perturbed due to releases from nuclear facilities operating close to this site.

Tritiated free water and organic-bound tritium can be extracted and processed separately. The sample is dried in an apparatus with a water trap for the evaporated free water. Azeotropic distillation is an alternative method of free water extraction (Vagner et al., 2014). The dried sample is combusted in oxygen or oxidized in plasma. CO_2 and H_2O are produced during this process, and the water is recovered and used to represent the activity of organic-bound tritium in the sample. In analysis of tritium-labeled molecules or detailed studies of ^{3}H activity in different compounds of the sample, complex chemical procedures to isolate the individual compounds may be necessary prior to combustion/oxidation.

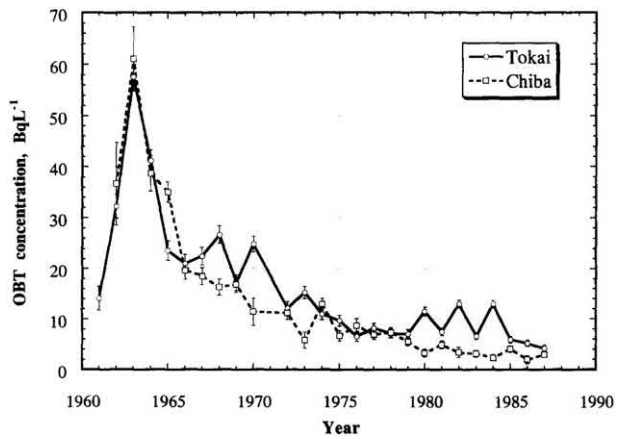

FIGURE 3.65 Concentration of organic-bound tritium (OBT) in tree rings from Tokai village (close to a nuclear power plant and nuclear reprocessing plant) and Chiba city. OBT concentration is decay corrected to the growth year of the ring and is expressed as tritium activity Bq/L of combustion water. *From Fuma and Inoue (1995).* Printed with permission *© Elsevier 2018.*

The subsequent sample preparation procedures for the separated water and ^{3}H measurement methods are the same as described in previous sections dealing with tritium in other sample types (Sections V.A and V.C). For tissue samples measured by LPC, a solubilization sample preparation method is often used—corrosive, and oxidative compounds (e.g., perchloric acid, sodium hypochlorite, hydrogen peroxide, and other commercial solubilizers) are added into the sample. The sample material is digested into compounds soluble in appropriate scintillation cocktails. Choice of solubilizer and solubilization protocol must be chosen according to type of sample tissue so that the scintillation mix is stable, colorless, and with minimal quenching.

2. Radiocesium and radiostrontium

a. Radiocesium

Radiocesium isotopes (^{134}Cs, ^{135}Cs, ^{137}Cs) belong to the most important fission and neutron activation products released into the environment, and their levels in the biosphere are frequently measured to assess doses originating from these radionuclides and to study their migration between and within different radionuclide compartments. Analysis of these radioisotopes in plant and animal tissues has been used in connection with the impact of global nuclear tests fallout and Chernobyl and Fukushima nuclear accidents (Falandysz et al., 2015; Mahara et al., 2015; Strandberg, 1994). The measurement of $^{134}Cs/^{137}Cs$ ratio can be used for biospheric radiocesium source apportionment (Chino et al., 2016).

Both ^{134}Cs and ^{137}Cs are gamma emitters, and their activity in biota samples is measured mainly by gamma spectrometry. After representative biota samples are taken, they are homogenized and dried. In most cases (especially when dealing with samples with enhanced radiocesium activity), no further sample preparation is necessary before gamma spectrometric measurement. Samples have to be placed in a container or pressed into shape appropriate for the detection system geometry. ^{134}Cs and ^{137}Cs are then identified by their gamma lines (^{134}Cs—604 keV and 795 KeV, ^{137}Cs—662 keV). Samples with very low radiocesium content need to be concentrated prior to measurement. Radiocesium enrichment of biota samples is done by heating the samples to several hundreds of degrees (ashing). Ashing removes most of the organic sample matrix, considerably decreasing sample size and enriching the sample in cesium. The ashing temperature should not be higher than 450°C to prevent volatilization of cesium (Koh et al., 1999). In principle, radiocesium can be leached and

extracted from samples by precipitation with ammonium phosphomolybdate or potassium cobalt hexacyanoferrate (Lehto and Hou, 2011).

Because of its long half-life (2.3×10^6 years) and emitted soft beta radiation ($E_{max} = 269$ keV), cesium-135 is radiologically not very important; however, it has been of interest as a tracer of environmental processes. Its analysis in the environment is a challenge; recently, however, there have been new developments in the ICP-MS and AMS sectors.

b. Radiostrontium

Radiostrontium isotopes (^{89}Sr, ^{90}Sr) are fission products, which can be released into the environment from various nuclear installations. Since strontium has similar chemical properties as calcium, it is retained in bones (Froidevaux et al., 2010) and therefore needs to be monitored in a range of environmental samples, including biota samples. Milk, meat, and other foodstuffs are often analyzed mainly for its ^{90}Sr content (as ^{89}Sr has a much shorter half-life, 50.57 days) in regard to radiation doses received by ingestion (Rantavaara, 2008). Measurements of ^{90}Sr in human bones and teeth can also help in reconstruction of ^{90}Sr fallout from nuclear weapon tests and Chernobyl accidents (Stamoulis et al., 1999). ^{90}Sr is also of interest in radionuclide transfer studies (Outola et al., 2009; Semioshkina et al., 2007).

Strontium needs to be chemically separated from the sample matrix, and two ^{90}Sr separation methods most widely used are coprecipitation and extraction chromatography. They are both designed to separate strontium from the sample; in particular, they focus on the separation of strontium from chemically very similar calcium. The simplest coprecipitation method uses sample mixed with fuming nitric acid to precipitate strontium, whereas calcium remains in solution. This precipitation step needs to be repeated several times before all calcium is extracted, and other elements can be removed by coprecipitation (Shao et al., 2018b). The main disadvantage of this method is the danger of working with fuming nitric acid. Extraction chromatography on the other hand uses resin with high strontium affinity for its separation from interfering elements (Grahek et al., 2018). Prior to strontium separation, the sample may need to be ashed or dissolved; it depends on the method and specific separation protocol used.

^{90}Sr is a pure beta emitter ($E_{max} = 0.54$ MeV), and it decays into ^{90}Y, which is beta emitter as well ($E_{max} = 2.27$ MeV). The measurement methods are based on the detection of the emitted beta particles by GPC or LSC. When a gas detector is used, the strontium precipitate from the chemical separation is filtered and dried and placed onto the detector window. In the case of the LSC method, the dried precipitate is dissolved and mixed with a suitable scintillation cocktail. ^{90}Sr can be measured immediately after the chemical separation by beta spectrometry. In this rapid method, the beta spectrum of ^{90}Sr decay is measured and evaluated before ingrowth of its daughter nuclide ^{90}Y. Another approach is to store the samples for several weeks to wait for ingrowth of ^{90}Y (secular equilibrium of ^{90}Sr and ^{90}Y is reached after 2 weeks) and then measure the combined beta spectrum of ^{90}Sr and ^{90}Y. There is also a possibility to measure and evaluate beta spectrum of ^{90}Y alone; however, it requires chemical separation of Y from Sr in the sample after ^{90}Y ingrowth.

Cherenkov counting can also be used for ^{90}Sr (^{90}Y) determination. The chemically separated strontium precipitate is dissolved in aqueous HNO_3 solution and after ^{90}Y ingrowth placed in a vial into LSC detection system (no scintillation cocktail is added). The emitted beta particles have a high enough energy to produce Cherenkov radiation in aqueous solutions, and the LSC system detects these light signals and ^{90}Sr activity in the sample can be determined based on the measured spectra.

In addition to radiometric methods, ICP-MS has been shown to be applicable for ^{90}Sr analysis. Several problems complicate the use of this measurement technique for ^{90}Sr (interference from ^{90}Zr and polyatomic isobars, peak tailing from ^{88}Sr) resulting in higher detection limits compared with radiometric methods. New technical and methodological improvements for ^{90}Sr ICP-MS measurements are being developed (Russell et al., 2017). At this stage, this method offers considerably higher sample throughput compared with radiometric methods at the expense of higher detection limits and is used mainly for samples heavily contaminated with ^{90}Sr.

3. Radioiodine

a. Iodine-131

Fission product ^{131}I ($T_{1/2} = 8.02$ days) is a very important radionuclide in view of radiation protection because it can be released from various nuclear installations and its volatility makes it highly mobile in the environment. Because of its relatively high bioavailability, it readily enters the biosphere and propagates through the food chain. Milk and milk products in particular are analyzed for ^{131}I activity. Studies focused on ^{131}I activity in milk have been performed following the Chernobyl and Fukushima accidents (Martin et al., 1988; Perrot et al., 2012). Fig. 3.66 shows the activity of ^{131}I in cow milk from Slovakia following the Chernobyl accident in 1986. Transport of iodine from feed to milk has been studied in several controlled feeding experiments (Howard et al., 1993; Vandecasteele et al., 2000).

^{131}I can be measured by beta or gamma counting. Counting of 364.5 keV gamma rays by HPGe or NaI(Tl) detectors and LSC are widely used for ^{131}I analysis. In

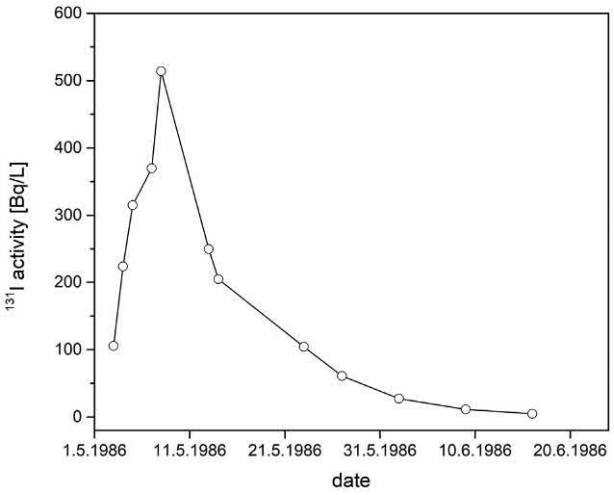

FIGURE 3.66 Iodine-131 activity in cow milk in Slovakia following the Chernobyl accident in 1986.

principle, samples containing ^{131}I may be measured directly without any pretreatment (gamma spectrometry), but usually some sample volume reduction and preconcentration are necessary. Evaporation, ashing, and chemical digestion can be employed to this effect. The LSC measurement requires a suitable form of the preconcentrated sample to facilitate its uniform mixture with liquid scintillator. Iodine separation methods detailed in Section V.C dealing with water samples can be used for ^{131}I extraction as well.

b. Iodine-129

Iodine-129, because of its very long half-life (15.7×10^6 y) and soft beta radiation ($E_{max} = 154.4$ keV), is radiologically not very important; however, it can be used for reassessment of radiation doses, which were delivered by ^{131}I. It has also been used as a useful environmental tracer. ^{129}I in environmental samples has been analyzed mostly by AMS or ICP-MS.

F. Analysis of actinides

Environmental radioactivity is usually associated with the presence of NORMs in the Earth's crust. The most important alpha emitters representing the group of NORM radionuclides are ^{238}U and ^{232}Th, as well as their decay series. Besides the NORM, there are a number of artificial radionuclides released into the environment during the nuclear explosion and as a result of nuclear accidents, among them alpha-emitting actinides.

Naturally occurring radionuclides are present in the Earth's crust, in raw materials and minerals. Although human activities related to the natural resources, involving minerals and raw materials, produce large amounts of waste, they cannot cause significantly greater exposure levels in comparison with normal background levels and usually are not of concern for radiation protection. Nevertheless, industrial activities that exploit these resources can result in enhanced exposures required to be controlled by regulations. The main regulatory attention has been focused on industries working on the mining and processing of uranium ore due to a direct consequence of the radioactivity in the ore and as a part of the nuclear fuel cycle. However, activity levels of thorium and uranium at the industrially exploited rare earth deposits exceed average worldwide reported values for soil up to 30 and 200, respectively (IAEA, 2011). Natural and artificial radionuclides found in the environment, as well as their inclusion in terrestrial and aquatic food chains, could have adverse health effects due to their transfer to humans via ingestion of food or inhalation of particulate matter.

Radiological protection in response to growing concerns about environmental pollution and public exposure resulting from the use of nuclear energy and commercial activities related to natural resources requires the development of reliable radioanalytical methods and standard reference materials (Calmet, 2014; Maringer et al., 2017). In addition, sensitive methods are needed for the applications of natural and anthropogenic radionuclides as tracers to study environmental processes (e.g., Chamizo et al., 2015; Povinec et al., 2004, 2016).

Alpha spectrometry is one of one of the most widely used techniques for the isotopic composition measurement of actinides (such as thorium, uranium, neptunium, plutonium, americium, curium, polonium, and radium) in the environmental samples. In recent years, however, there has been growing interest in low- and high-energy mass spectrometry methods, as already discussed in Sections IV.B and IV.C. Critical comparisons of radiometric and mass spectrometric techniques for the quantitative determination of alpha-emitting radionuclides in environmental, biological, and nuclear waste samples were provided in many publications during the last decade (Gascó et al., 2002; Hou and Roos, 2008; Ayranov et al., 2009; Aggarwal, 2016; Van Es et al., 2017). Among the advantages of the mass spectrometric techniques—fast analyses, improved data quality for ^{238}U/^{235}U ratios, measurements of ^{239}Pu and ^{240}Pu isotopes separately, and improved sensitivity for long-lived nuclides are usually mentioned. The main problems such as isobaric interferences, polyatomic interferences, peak tailing, isotopic fractionation, beam instability, and matrix effects have been indicated as well. The main advantages of alpha spectrometry are high sensitivity, reliability, application of alpha-emitting internal standards, and low sensitivity of alpha detectors to beta and gamma radiation and removal of competing radionuclides during radiochemical procedures (Levy et al., 2011). In some environmental radionuclide studies, it is advantageous to analyze actinides by LSC, e.g., in the case of ^{241}Pu (Liong Wee Kwong et al., 2004a).

1. Sampling and pretreatment

Depending on the objective of the radionuclide analysis, the appropriate measurement and processing technique could involve various steps, adjusted to meet particular requirements: sampling, preservation, pretreatment, separation, source preparation, measurement, and evaluation. Samples should be collected using the appropriate equipment, and several procedures have already been described, e.g., Csuros (1994), Koide and Bruland (1975), Martin and Hancock (1992). Usually, there are no requirements for field preparation and preservation of soil and sediment samples for actinide analyses. Although in some sampling protocols during shipping and storage, it is recommended to keep soil samples at 4°C; however, this is not normally applied for the radiochemical analysis. Water samples are generally acidified after collection. Generally, soil, sediment and biota samples are usually dried at 80−110°C for 12−48 hours and then ashed at 450−800°C for 12−48 hours to destroy organic matter. If samples contain nonashed carbon particles, it is recommended to moisten the residue with concentrated nitric acid, fume it off to dryness, and ash the sample again (e.g., Pimpl and Higgy, 2001). Other samples can have specific requirements for the field sample preparation and preservation, such as filtering and acidification of water samples as well as freezing samples at −20°C to reduce biological activity or chemical preservations of radionuclides or media.

Radioanalytical separation must ensure the separation of matrix elements abundant in environmental samples and remove alpha-emitting radionuclides, interfering with the peaks in the spectrum. In addition, sample preparation should provide a thin source for the best spectral resolution. Radioanalytical procedures involve preconcentration, the chemical separation of analytes (e.g., precipitation, coprecipitation, distillation, ion exchange, solvent extraction, and extraction chromatography), and the source preparation for measurements.

Decomposition of solid samples can be achieved by means of different methods (dry or wet ashing, dissolution in various acid combinations or fusion techniques) providing complete or partial access to analytes (Bock, 1979). In the analyses of actinides, samples are usually ashed at 450−550°C for 16 hours. The application of higher temperatures is not recommended because of the formation of refractory particles. However, a decrease in ^{239,240}Pu activity concentrations in soil was observed when the ashing temperature exceeded 450°C. It was found that ashing of soil samples at temperatures of 600°C for 4°h resulted in losses of about 40% of ^{239,240}Pu activities (Wang et al., 2015). The formation of refractory materials, such as plagioclase-like silicate insoluble in nitric acid, was confirmed by the XRD analysis of soil samples. Volatile radionuclide ashing requires much lower temperatures, e.g., to avoid losses. Samples for polonium analysis cannot be heated at a temperature higher than 150°C but can be digested by wet ashing using HCl and HNO_3, including aqua regia (Martin and Hancock, 1992; Vaaramaa et al., 2010). However, the Po losses at 70−80°C during wet ashing of ∼30% for open glass beakers, ∼ 20% for Kjeldahl flasks, and ∼17% for the microwave digestion were reported by Henricsson et al. (2011).

Complete or nearly complete dissolution of the solid matrix can be achieved by the application of concentrated or fuming nitric acid, aqua regia, sulfuric acid, or mixtures of concentrated nitric acid with perchloric acid or hydrofluoric acid. Pu and Am from environmental samples were leached with concentrated nitric acid and 30% hydrogen peroxide after ashing at 450°C for 8°h, and the microwave digestion treatment using HF was applied for residue (Sekine et al., 1987), while Hamato (1982) applied nitric acid and hydrogen peroxide after soil ashing at 550°C for Am determination. A choice of the dissolution procedure can affect results and usually requires additional studies. Although 8 mol L^{-1} HNO_3 is most commonly used in the actinide sample preparation, the application of HF acid is important for extraction of Pu isotopes from samples containing "hot" particles. The leaching ability of different reagents toward Pu isotopes in the Chernobyl soil indicated that the amount of extracted Pu could vary by a factor of 10 in samples containing "hot" particles depending on the method (Lujaniene et al., 2002, 2009). Three methods—leaching with 0.1 mol L^{-1} HNO_3 or 8 mol L^{-1} HNO_3 and decomposition with $HF + HNO_3 + HClO_4$—were compared to check the optimal condition for measuring the global fallout ^{236}U in the Hiroshima soil samples. The concentration estimated from the 0.1 mol L^{-1} HNO_3 leaching was obviously lower as compared with 8 mol L^{-1} HNO_3 leaching and complete decomposition. The amount of ^{236}U extracted with 8 mol L^{-1} HNO_3 and $HF + HNO_3 + HClO_4$ decomposition was similar; thus, leaching with 8 mol L^{-1} HNO_3 was recommended for the soil sample preparation (Sakaguchi et al., 2012). Pimpl and Scuettelkopf (1986) applied two-stage leaching of 8 mol L^{-1} HNO_3/0.9 mol L^{-1} HF and 5 mol L^{-1} HNO_3/1 mol L^{-1} $Al(NO_3)_3$ to dissolve refractory material (PuO_2) from 100 g of soil ash or up to 20 g of other samples, after the addition of ^{236}Pu as an internal standard for the chemical yield estimation. Nevertheless, Benedik and Trdin (2017) showed a discrepancy in activity concentrations of ^{237}Np obtained using different decomposition procedures.

The leaching and decomposition can be accelerated by applying high-pressure and microwave techniques (Amoli et al., 2007; Khattab, 2016). Yoshida et al. (2007) developed a microwave decomposition system to prepare samples for measuring ^{240}Pu/^{239}Pu atom ratios by high-resolution ICP-MS. Concentrations of ^{239,240}Pu in soil samples after the microwave decomposition were found to

be higher than those after the nitric acid extraction and the $^{240}Pu/^{239}Pu$ ratio lower by 1%. Soil and sediment samples for U measurements by alpha spectrometry were ashed at 550°C and digested with concentrated acids (HNO_3:HCl:HF—5:5:3 mL, respectively) in closed PTFE-vessels using a Mars 5 (CEM, USA) microwave system (Popov, 2013).

A fusion technique is appropriate for sample decomposition in the presence of refractory particles as well as for geological samples, and it may include the application of hydroxides, peroxides, fluorides, pyrosulfates, carbonates, or borates (Bock, 1979; Dean, 1995; Warwick et al., 2001; Galindo et al., 2007; Huang et al., 2007). Among advantages of the fusion method are the disuse of highly toxic reagents (e.g., HF), more complete dissolution of refractory material, simplicity, and reproducibility (Huang et al., 2007). Complete soil sample dissolutions can be achieved using the potassium fluoride–pyrosulfate fusion technique for actinide determination (Smith et al., 1992). Although the fusion technique is one of the convenient methods for digestion of soil samples, it is not suitable for all radionuclides.

2. Separation of actinides

A special case we shall deal with is ^{236}U, which has been recently frequently used in terrestrial and marine tracer studies thanks to the development of AMS measurement techniques. Solvent extraction but more often anion exchange and extraction chromatography are utilized for the separation of uranium from low-level water matrices and its consequent purification. The procedures are based on the fact that metallic elements in HCl and HNO_3 media adsorb differently to anion exchange or extraction chromatography resins, i.e., while uranium can, in principle, form both nitrate and chloride complexes, it is adsorbable on various resins; this is not true for most elements occurring in their typical valence states (Faris and Buchanan, 1964; Kraus and Nelson, 1955). A single column filled with Eichrom UTEVA or DOWEX resin can be used for the separation of uranium from possible interferents; however, the second column may be applied to ensure their complete removal (Quinto et al., 2009; Eigl et al., 2013). In short, uranium from water is preconcentrated on $Fe(OH)_2$ precipitate, and then it is leached in HNO_3 solution, which is loaded on the column with the preconditioned resin. The elution of uranium retained on UTEVA and DOWEX can be achieved by 0.01 M HCl and 7.2 M HNO_3, respectively. After evaporation of the eluate to dryness, fuming of the residue with, e.g., H_2O_2 and dilution in a small amount of HCl or HNO_3, uranium is once again coprecipitated on ferric hydroxide. The precipitate is separated, dried, and calcinated to finalize the target material for AMS.

Due to the low specific activity and abundance of ^{236}U, the only possibility to determine ^{236}U in environmental water samples is by AMS, which enables the measurement of the $^{236}U/^{238}U$ isotopic ratios down to 10^{-15} using high-energy filters while reaching the detection limit of 10^4 atoms (Tuniz et al., 1998). ICP-MS and TIMS could be also used; however, their sensitivity is by some six orders of magnitude lower (Steier et al., 2008; Sakaguchi et al., 2009). Conventionally, a solid target for AMS measurements of ^{236}U is prepared in the form of uranium oxide coprecipitated on ferric oxide. A more novel approach has been developed, which exploits UF_4 as the target material (Wang et al., 2013). Although the preparation of the latter is more complex, similar or even higher ionization yields have been reported for uranium fluoride (Povinec et al., 2015b). Uranium, together with other actinides, is typically scavenged from freshwater, which was beforehand spiked with a known amount of ^{233}U ($T_{1/2} = 1.59 \times 10^5$ years), by ferric hydroxide precipitate.

Liquid–liquid extraction, ion exchange chromatography, and extraction chromatography as well as precipitation and/or coprecipitation were generally applied for the separation of actinides from various matrixes. Liquid–liquid extraction procedures received a wide application for the actinide separation and purification from environmental samples. Tributyl phosphate (TBP), methyl-i-butyl ketone (MIBK), bis-2-ethylhexyl-phosphoric acid (HDEHP), dibutyl-N,N-diethylcarbamoylphosphonate (DDCP), thenoyl-tri-fluoroacetone (TTA), tri-n-octylamine (TNOA), phenyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP), t-octylphosphine oxide (TOPO), and carbamoylmethyl-phosphine oxide (CMPO) in a mixture with carbamoylmethyl-phosphine oxide (CMPO) used for extraction chromatography are mostly used in analytical procedures for the determination of actinides.

HDEHP is a common extractant used in Am, Cm, Pu, and Th separations. HDEHP has been used for the separation of Am together with Cm and the lanthanides. Bernabee et al. (1980) extracted Am and trivalent lanthanides from 72% $HClO_4$ by 15% HDEHP in n-heptane. Then, 99.8% of Am was back-extracted with 4 mol L^{-1} HNO_3, whereas Pu(IV) remained in the organic phase. Holm et al. (1979) extracted Am(III) and Th(IV) from 0.01 to 0.001 mol L^{-1} HNO_3 and back-extracted Am(III) and rare earth elements with 4 mol L^{-1} HCl. Murray and Statham (1976) applied 9 mol L^{-1} HC1 for the back extraction. It was found that iron extracted with Am and high manganese concentrations resulted in reduced recoveries. The techniques were optimized by the separation of plutonium isotopes using anion exchange as well as by the removal of iron using solvent extraction and manganese elimination by cation exchange (Livens and Singleton, 1989).

HDEHP was studied for the separation of neptunium, plutonium, americium, and curium in the presence of large amounts of uranium. U(VI), Np(VI), Pu(IV), Pu(VI), Am(III), and Cm(III) were extracted with 1 mol L^{-1} HDEHP in kerosene from 0.1 mol L^{-1} HNO_3. Am and Cm were back-extracted in 5 mol L^{-1} HNO_3. Then, Np was back-extracted with 1 mol L^{-1} $HNO_3/NH_2OH{\cdot}HNO_3$ followed by the back extraction of Pu(III) with 3 mol L^{-1} $HCl/TiCl_3$ (Ramebäck and Skillberg, 1998).

In the separation of Am from soil samples, Am (III) and lanthanides were extracted into the DDCP from 12 mol L^{-1} nitric acid and then back-extracted into 2 mol L^{-1} nitric acid (Ballestra and Fukai, 1983). TTA was used to purify americium. Am(III) along with lanthanides was extracted into 0.5 mol L^{-1} TTA in xylene at pH 4.0 and back-extracted into 1 mol L^{-1} nitric acid. A reduction in Am recovery during extraction was observed when pH values were lower than 3 (to about 70% at pH 3 and 35% at pH 2.5). The recovery was improved by the use of 0.1 mol L^{-1} TTA in isobutanol (Sekine et al., 1987).

Hursthouse et al. (1991, 1992) used TTA to extract Np(IV), after oxidation state adjustment using $NH_2OH{\cdot}HCl$, in soil and sediment sample preparation for ICP-MS, alpha spectrometry, and NAA. High decontamination factors (DFs) and recovery of 56% were reported for Pu separation from marine sediment samples prior to measurements of ^{239}Pu, ^{240}Pu, ^{241}Pu, and ^{242}Pu by sector-field inductively coupled mass spectrometry (SF-ICP-MS). An extraction with 0.5 mol L^{-1} TTA in xylene was used to separate Pu isotopes from uranium, americium, and curium, followed by purification using anion exchangers (Donard et al., 2007).

TTA was also widely applied in combination with anion exchange for ^{237}Np determinations in soil and sediments by alpha spectrometry, ICP-MS, and NAA. Neptunium is usually extracted from 1 mol L^{-1} solutions into 0.5 mol L^{-1} TTA in toluene or xylene after Np(VI) and Np(V) oxidation state adjustment to Np(IV) (Hursthouse et al., 1991, 1992). The similar analytical method was applied to separate ^{237}Np from environmental water samples after iron-oxy-hydroxide coprecipitation in the presence of sulfite. Residue was redissolved in 9 mol L^{-1} HCl and loaded onto the anion exchange column. Np oxidation state adjustment was performed with $NH_2OH{\cdot}HCl$. Np was eluted from the column with 5 mol L^{-1} HCl, extracted with TTA/xylene, and back-extracted from the organic phase with 8 mol L^{-1} HNO_3. The chemical yield of the separation procedure was estimated by the gamma counting rates before and after Np extraction, using ^{239}Np as a tracer. An internal standard—^{242}Pu was added to the samples prepared for AMS measurements (Keith-Roach et al., 2001).

Lindahl et al. (2004) applied TTA extraction in combination with the ion exchange anion column (BioRad AG1 1-x4, analytical grade 100−200 mesh chloride form) for Np separation from Swedish lichen (*Cladonia stellaris*). Samples in 9 mol L^{-1} HCl were passed through an ion exchange anion column. Np(IV) was eluted with 4 mol L^{-1} HCl, evaporated and dissolved in 1 mol L^{-1} HCl. Aqueous ferrous(II) chloride solution was used to reduce Np(V) to Np(IV). The Np(IV) was extracted into 0.5 mol L^{-1} TTA in xylene and back-extracted with 9 mol L^{-1} HCl. Then, samples were passed through a final ion exchange anion column. The chemical yield was monitored by measuring the activity of ^{239}Np (Ec = 104 and 107 keV) with a high-purity germanium (HPGe) detector. ^{242}Pu was used as an internal standard for the high-resolution inductively coupled plasma mass spectrometry (HR-ICP-MS) measurements.

Microthene-710 (microporous polyethylene, 50−100 mesh) and the KL-I-IDEHP resin (50% di(2-ethyl-hexyl) phosphoric acid, 60−100 mesh) were used for plutonium and americium determination in lichen and moss as indicators of atmospheric radioactivity. Pu was separated from HCl solutions by a Microthene-TNOA column, while for americium, separation and purification with a KL-HDEHP column and PMBP-TOPO extraction were applied (Jia et al., 1997).

In the sequential separation method for Pu, ^{241}Am, and ^{90}Sr determination in soil samples developed by Jia et al. (1998), Pu was separated by a Microthene-TNOA column, whereas ^{90}Y (for ^{90}Sr determination) was separated from Am using an HDEHP column. Then, Am was finally purified on another HDEHP column and MBP/TOPO extraction prior to preparation of alpha sources. The DFs of Pu and Am from ^{210}Po and of ^{90}Y from ^{210}Bi were $> 10^5$, 10^6, and 10^4, respectively. The reported detection limits were 1.2 mBq kg^{-1} for Pu and 1.7 mBq kg^{-1} for Am. Pimpl and Scuettelkopf (1986) applied TOPO/cyclohexane for Pu extraction from large soil samples and air filters (up to 100 g). Coprecipitation with LaF_3 and anion exchange with Dowex 1x2, 50−100 mech followed by the TOPO/cyclohexane extraction was used for the final purification. The TOPO/cyclohexane extraction followed by the subsequent TEVA, TRU-TEVA separation of Pu, Am, and Cm from the soil, and aerosol samples was reported (Pimpl and Higgy, 2001; Ayranov et al., 2005; Lujaniene and Sapolaite, 2005; Lujaniene, 2013).

Diglycolamides (DGAs), such as *N*,*N*,*N*′,*N*′-tetraoctyl diglycolamide (TODGA) and *N*,*N*,*N*′,*N*′-tetradecyl-diglycolamide (TDDGA), were applied for the determination of actinides in environmental samples due to high distribution coefficients for actinides and lanthanides in the strong acid range (>3 mol L^{-1} HNO_3) (Sasaki and Choppin, 1996).

a. Coprecipitation

Coprecipitation techniques are well established and are in regular use in environmental radionuclide sample preparation for measurements. Coprecipitation is an important part of chemical separation, purification, and source preparation for alpha counting. Coprecipitation has been widely used for the preconcentration and elimination of matrix elements from both liquid samples and extracts following leaching or complete dissolution of solid samples as well as for the separation of interfering radionuclides and the improvement of the DF of analytes. The coprecipitation behavior of radionuclides is discussed in detail in following reviews and textbooks:

i. fluorides such as NdF_3, LaF_3, CeF_3, CaF_2 (Rao and Cooper, 1995; Lindahl et al., 2004; Maxwell and Culligan, 2006; Varga et al., 2007a,b; Vajda et al., 2009a,b; Maxwell et al., 2010a; Maxwell et al., 2011a; Wang et al., 2017b; Luo et al., 2018),
ii. ferric and ferrous hydroxides—$Fe(OH)_2$ and/or $Fe(OH)_3$ (Keith-Roach et al., 2001; Chen et al., 2002; Giardina et al., 2006; Qiao et al., 2010; Lemons et al., 2018),
iii. phosphates—$CaHPO_4$, $Ca_3(PO_4)_2$ (Kimura, 1990; Thakkar, 2001; Hölgye, 2007; Maxwell 2006, 2008a; Maxwell et al. 2010a, 2011b; Maxwell and Culligan, 2009a, 2011a),
iv. oxalates (CaC_2O_4) (Salminen et al., 2009; Kenna, 2009),

which are the most commonly used carriers for the actinide coprecipitation and the matrix element removal during chemical separation from water, soil, sediments, and biological samples.

Although coprecipitation with MnO_2 was mainly used for high salinity (seawater, high-salinity spring water) samples, MnO_2-impregnated cellulose, and MnO_2-coated discs were also applied for Ra preconcentration from continental river, ground, and tap water samples (Eikenberg et al., 2004; Bojanowski et al., 2005; Sharabi et al., 2010; Rodríguez et al., 2016).

Preconcentration and separation of ^{226}Ra (also used for ^{238}U determination) from the matrix elements of various samples (water, soil, and biological samples) were performed using $PbSO_4$ (Sill, 1987a; Kehagia et al., 2007), $Pb(NO_3)_2$ (Lozano et al., 2010), and $BaSO_4$ (Bojanowski et al., 2002; Rodríguez et al., 2016; Straub et al., 2018). Coprecipitation of Ra with $Ba(Ra)SO_4$ based on the method developed by Sill (1987b) was also commonly used for Ra source preparation (e.g., Medley et al., 2015). According to recent studies, the matrix effect should be taken into account, which could significantly reduce the recovery of Ra during the preconcentration using $BaSO_4$, MnO_4, and RadDisc techniques (Nelson et al., 2014). Suarez-Navarro et al. (2017) successfully applied [Ba + Fe] coprecipitation techniques for the determination of U, Pu, Th, and Po in water samples.

b. Ion exchange

Ion exchange resins are frequently used for the separation and preconcentration of radionuclides from environmental samples due to their low cost and broad application ranges. Among the most commonly used cation exchangers, there are strongly acidic sulfonated resins containing $-SO_3^-$ groups and less acidic phosphorylated and carboxylated resins. The affinity of the cations for exchange sites increases with the increasing charge and decreasing hydrated ion radius. Anion exchangers contain amines as functional groups. Strongly basic anion exchangers with substituted quaternary amines are capable of retaining tetra- and hexavalent actinides from concentrated nitric and hydrochloric acid solutions.

c. Cation exchange

Cation exchange resins have been used to preconcentrate actinides from groundwater (Fjeld et al., 2005). Cation exchange chromatography (Bio-Rad AG 50WX8 or Dowex 50WX8 resins) is frequently used for Ra preconcentration and separation from the matrix elements, e.g., Ca and Mg (Saito et al., 2003; Larivière et al., 2005; Al-Mukren et al., 2015; Dulanská et al., 2018). Samples can be loaded on the resin in dilute HCl and HNO_3 and Ra stripped with 4–9 mol L^{-1} HCl or 4–5 mol L^{-1} HNO_3. Separation of Ra from Ba is a crucial interference in mass spectrometry, and the source preparation for alpha spectrometry can be achieved in combination of cation exchange with complexing agents, e.g., EDTA, which was recently replaced by the application of strontium-specific resin (Volpe et al., 1991; Larivičre et al., 2007; Copia et al., 2015; Zhang et al., 2015; Dalencourt et al., 2018).

Cation exchange chromatography was applied to separate Am from the lanthanides on the column with the temperature-controlled jacketed (87°C) using hydroxy-isobutyric acid (α-HIBA) and aminopolyacetic acids (e.g., EDTA and DTPA) as eluents (Choppin and Silva (1956). Cation exchange chromatography with gradient elution using 0.16–0.4 mol L^{-1} α-HIBA allowing the separation of Am and Cm from lanthanides when large environmental samples of 100–200 g were analyzed (Ageyev et al., 2005).

The separation of Am from lanthanides on anion exchangers is based on Am(III) adsorption from methanol–nitric acid systems: 0.5 mol L^{-1} HNO3–95% MeOH (Guseva et al., 1976), 1 mol L^{-1} HNO_3–93% MeOH (Holm et al., 1979; Livens and Singleton, 1989; Hamato, 1982), 1 mol L^{-1} HNO_3–90% MeOH (Holm and Fukai, 1976; Bains and Warwick, 1993). Methanol–HNO_3 and HCl systems with 0.5–1.0 mol L^{-1} HNO_3 and 90%–96% methanol for load and stripping with HCl (Livens and

Singleton, 1989) or HNO_3 (Bains and Warwick, 1993) were applied for environmental sample analyses.

Trivalent actinides were separated from lanthanides using concentrated (>8 mol L^{-1}) NH_4SCN solution as eluent (Surls and Choppin, 1957), whereas the best separation was achieved with 1−2 mol L^{-1} NH_4SCN solution containing 50%−70% methanol, ethanol, or propanol (Guseva and Tikhomirova, 1974). This procedure was applied for the final purification of the Am fraction from the interfering components in large environmental samples (Holm et al., 1979). One mol L^{-1} HNO_3/93% methanol solution containing Am and lanthanides was loaded on an anion exchange resin column; lanthanides were removed with dilute HCl/NH_4SCN/methanol followed by Am and Cm stripping using 1.5 mol L^{-1} HCl/80% methanol. In a similar procedure for final Am purification from 50 g of soil, Hamato (1982) used 1 mol L^{-1} HNO_3/93% methanol, 0.1 mol L^{-1} HCl/0.5 mol L^{-1} NH_4SCN/80% methanol, and 1.5 mol L^{-1}HCl/86% methanol solutions as load, wash, and strip solutions, respectively. Am separation from lanthanides (based on these procedures) has been applied for various environmental matrixes (e.g., IAEA, 2014).

Anion exchange chromatography was widely applied for the separation and purification of plutonium isotopes from environmental matrixes (LaRosa et al., 2005; Jakopic et al., 2007). Pu can be loaded on an anion resin in tetravalent oxidation state in 8 mol L^{-1} HNO_3 and matrix elements, and Am and U are removed by washing with 8 mol L^{-1} HNO_3. The possible interferences, primarily Th, can be eluted with 9 mol L^{-1} HCl and then Pu(III) stripped by freshly prepared 9 mol L^{-1} HCl solution containing 0.1 mol L^{-1} NH_4I as a reducing agent (IAEA, 2014). On anion exchange resins, Pu can also be separated from HCl solutions. Pu(IV) is loaded on the column in 9 mol L^{-1} HCl, and after washing, Pu is stripped using a reducing agent e.g., 0.36 mol L^{-1} HCl/0.01 mol L^{-1} HF (Lee et al., 2008).

Neptunium can be separated from complex environmental matrixes by anion exchange chromatography from nitric and hydrochloric acid solutions. The separation of Np from Pu is achieved when Np and Pu are reduced to tetravalent and trivalent states, respectively. Nitrate complexes of Np(IV) and Th(IV) are adsorbed from 8 mol L^{-1} HNO_3 on the anion exchange resin (Germian and Pinte, 1990). Another most common analytical method involves adsorption of anionic nitrate complexes of Np(IV), Pu(IV), and Th(IV) from 8 mol L^{-1} HNO_3 on the anion exchange resin and their sequential separation. The reduction/oxidation cycle using hydrazine sulfate (reduction step) and $NaNO_2/H_2O_2$ (oxidation step) was applied. Thorium was eluted with 9−10 mol L^{-1} HCl, plutonium elution was performed with a mixture of 9−10 mol L^{-1} HCl + NH_4I (or HI), and finally, neptunium was stripped with 4.5 mol L^{-1} HCl + HF or 1−4 mol L^{-1} HCl (Michel et al., 1999; LaRosa et al., 2005; Benedik and Trdin, 2017). Pu and Np can be stripped in the same fraction when both radionuclides are measured together (Qiao et al., 2011).

3. Extraction chromatography

Despite the wide application and certain advantages of the conventional anion exchange techniques, they suffer from the lack of selectivity in comparison with liquid−liquid extraction analytical methods. However, the main disadvantage of the solvent extraction is the large amount of organic waste generated during the separation procedure. Extraction chromatography (EXC) resins were developed over the past 30 years to overcome these problems and to improve selectivity, to provide higher separation efficiency, and to reduce the amount of hazardous waste produced during the separation. In addition, newly developed methods with folding resins in a multistage column ensure rapid sequential analyses. The use of vacuum boxes and small-sized resin facilities is important for time saving and is critical for emergency response methods.

New developed EC materials for the separation of actinides with well-defined physical and chemical properties, distribution coefficients, and extraction kinetics have become commercially available from EiChrom Co. and Triskem SAS. The EC materials or so-called solid-state extraction chromatography were applied for the environmental radioactivity needs by developing analytical separation procedures for environmental samples.

a. TEVA resins

The TEVA resin composed of quaternary amine-based (Aliquat 336) liquid anion exchanger supported on the inert material of Amberchrom CG-71 ms was developed by Horwitz et al. (1995) for the separation of tetravalent actinides. The TEVA resin has been widely applied for Pu and Np analysis due to its high capacity factors (k′) for Pu(IV) 3×10^4 and Np(IV) 4×10^3 in 6 mol L^{-1} HNO_3 as compared with k′ for Th and U(VI) in HNO_3 solutions and comparatively low selectivity for U and Th in concentrated HCl solutions.

TEVA resin was applied for the separation of Pu from environmental samples (1−5 g) after a CaF_2 coprecipitation (Varga et al., 2007a). The oxidation state of Pu(IV) was adjusted by $NaNO_2$. The sample was loaded in 3 mol L^{-1} HNO_3 followed by rinsing with 3 mol L^{-1} HNO_3 and 6 mol L^{-1} HNO_3, and then, Pu was stripped with 0.1 mol L^{-1} HNO_3/0.1 mol L^{-1} HF. The reported Pu recovery was 72%−93%, and the DF for U, Th, and Am was $\sim 10^5$.

Pu separation (Pu recovery > 60 and DF for U > 100) for AMS measurements from environmental samples with TEVA was used by Chamizo et al. (2008). Pu(IV) was loaded on the column in 3 mol L^{-1} HNO_3/$Al(NO_3)_3$,

followed by washing with 6 mol L^{-1} HCl and stripping with 0.5 mol L^{-1} HCl. TEVA resins were also used for Pu separation from environmental samples (soil and sediments) for plutonium measurements by mass spectrometry including the atom ratio determination (e.g., Momoshima et al., 1997). A simple, express online analytical method for Pu separation from soil and sediment samples and measurement by quadrupole ICP-MS was developed by Epov et al. (2007). Flow injection chromatography using TEVA resin was optimized to preconcentrate and separate Pu from the sample matrix elements, including ^{238}U. L-Ascorbic acid was found to be most suitable for the Pu oxidation state adjustment to Pu(IV) prior to EC.

Anton et al. (2006) used TEVA for the separation of Np from soil contaminated with weapons grade Pu. After acid leaching with HNO_3/HF, Pu was separated using anion exchange chromatography, whereas TEVA was used for the separation of Np from U and Th. $NaNO_2$ was used for the oxidation state adjustment. Np was stripped from the column with 0.02 mol L^{-1} HNO_3/0.02 mol L^{-1} HF. Np and Pu recoveries were 68%−89% and 53%−89%, respectively.

Pu and Np were separated from river sediments and measured by ICP-MS or SF-ICP-MS. The adjustment of the oxidation state was performed with hydroxylamine hydrochloride or $FeSO_4$+$NaNO_2$ followed by separation using TEVA with high recoveries for Pu 90% and Np 70% (Kenna, 2002, 2009).

A rapid method for the determination of ^{237}Np and Pu isotopes in large soil samples (up to 200 g) has been developed by Maxwell et al. (2011a). They applied acid leaching with 15 mol L^{-1} HNO_3, Fe/Ti hydroxide precipitation, and an LaF_3 matrix removal step followed by a rapid column separation process with TEVA resin resulted in the high chemical recoveries (88% for Pu), effective removal of interferences, and reduced analytical time.

TEVA resin was applied for the separation of Am(III) from lanthanides, which was performed by loading the sample in 2 mol L^{-1} NH_4SCN−0.1 mol L^{-1} formic acid solution followed by the elution of lanthanides with 1 mol L^{-1} NH_4SCN−0.1 mol L^{-1} HCOOH, and Am and Cm were eluted with 0.25−2 mol L^{-1} HCl (Horwitz et al., 1995).

b. UTEVA resins

UTEVA resin composed of dipentylpentylphosphonate−impregnated Amberlite XAD-7 EC was developed by Horwitz et al. (1992) to separate U and tetravalent actinides. The estimated k′ capacity factors for Pu(IV), Np(IV), U(VI), and Th(IV) in 8 M HNO_3 are 10^3, 4×10^2, 4×10^2, and 2×10^2, respectively. UTEVA is not often used as a single column for the separation of actinides; however, a single UTEVA column can be applied for the separation of thorium and uranium (Pilvio and Bickel, 2000). High recoveries of >90% and DFs of >2000 for U in Pu and Np fractions were reported for a single UTEVA column procedure developed for the determination of uranium, neptunium, plutonium, and americium in synthetic mixtures (Morgenstern et al., 2002). The oxidation state adjustment was performed with 0.3% H_2O_2 in 6 mol L^{-1} HNO_3; then, samples loaded on UTEVA column were followed by washing of the column with 6 mol L^{-1} HNO/0.3% H_2O_2. Pu was stripped from the column with 2 mol L^{-1} HNO_3, containing ascorbic acid and hydroxyl ammonium nitrate, Np with 2 mol L^{-1} HNO_3/0.1 mol L^{-1} oxalic acid, and finally, Np was eluted with ammonium bioxalate, $(NH_4)_2C_2O_4$.

A single UTEVA column coupled online to an ICP-MS detector was applied for the separation and detection of U, Th, and Np in environmental samples. Mohr's salt and $NaNO_2$ were used to convert the Pu and Np oxidation state to the (IV) and to retain tetra- and hexavalent actinides on UTEVA in 3 mol L^{-1} HNO_3. 0.1 mol L^{-1} oxalic acid was used as eluent (Perna et al., 2001). UTEVA was used in an ion chromatograph directly connected to ICP-MS for express (within 60 minutes) analyses of environmental samples of 1 g (Ohtsuka et al., 2006).

The separation of Pu, Np, Th, and U from environmental samples using a single UTEVA column and two-stage UTEVA EC was used for alpha spectrometry source preparations with the reported recoveries of 69%−92% for Pu as well as 65%−82% and 66%−93% for Pu and Np, respectively (Vajda et al., 2003; Osvath et al., 2009, 2010). A single UTEVA column was also applied for Pu and U separation and Pu measured by alpha spectrometry, while U was measured using TIMS (Croudace et al., 1998).

c. TRU resins

TRU resin composed of a tri-n-butyl phosphate (TBP) solution of the bifunctional organophosphorous extractant octyl(phenyl)-*N*,*N*-di(iso-butyl)-carbamoyl-methyl-phosphine oxide (CMPO) adsorbed on Amberlite XAD-7 was developed to separate all transuranium elements except the tetra- and hexavalent species (Horwitz et al., 1993). High capacity factors were found for Pu(IV), Np(IV), Th, and U(VI), in HNO_3 ($k' \sim 10^3$−10^5), while for Am the k′ is ~100.

In sequential separation of actinides using a single TRU column recommended by Horwitz et al. (1993), the sample was loaded onto a column in 2 mol L^{-1} HNO_3 after Pu reduction to Pu(III). The first Am was eluted with 4 mol L^{-1}HCl, followed by Pu stripping with 4 mol L^{-1} HCl/0.1 mol L^{-1} hydroquinone, and finally, Th, Np, and U were eluted with 1.5 mol L^{-1} HCl, 1 mol L^{-1} HCl/0.03 mol L^{-1} oxalic acid, and 0.1 mol L^{-1} ammonium bioxalate, respectively.

Am, Pu, and U were frequently separated from air filter and water samples. The sample was loaded in 8 mol L^{-1} $HNO_3/NaNO_2$. Am was eluted with 0.025 mol L^{-1} HNO_3, and Pu and U together with bioxalate. According to recommendations, due to possible cross-contamination, firstly, Pu should be separated using anion exchange chromatography, and the TRU resin used only for Am purification. This procedure was followed by many laboratories later, including the IAEA Laboratories at Seibersdorf and Monaco (Moreno et al., 1997, 1998; IAEA, 2014; LaRosa et al., 1989, 2001; 2005; Povinec, 2004; Lee et al., 2005; Levy et al., 2011).

Truscott et al. (2001) developed the online solid phase extraction method for the determination of ^{232}Th, ^{237}Np, ^{238}U, ^{239}Pu, ^{240}Pu, ^{241}Am, and ^{243}Am in environmental samples with a column containing TRU-SpecTM resin coupled with SF-ICP-MS. Sequential separation of Pu and U was achieved by on-column reduction of Pu with titanium(III) chloride, and Am and Pu were eluted with a solution of 0.006 mol L^{-1} titanium(III) chloride in 4 mol L^{-1} HCl, and then the other analytes were eluted with 0.1 mol L^{-1} ammonium hydrogen oxalate. Absolute detection limits were 0.7, 0.85, 0.6, and 0.65 fg for ^{237}Np, ^{239}Pu, ^{241}Am, and ^{243}Am, respectively.

Vajda et al. (2009b) slightly modified the TRU EC procedure of Horwitz et al. (1993) and applied it for the rapid determination of Am, Pu, Th, and U in small environmental samples (1 g) by alpha spectrometry. The procedure evolved $LiBO_2$ fusion and CaF_2 coprecipitation, Pu oxidation state adjustment to Pu(IV) using $NaNO_2$. The sample was loaded in 2 mol L^{-1} HNO_3. Am was eluted with 4 mol L^{-1} HCl, and Pu was stripped after on-column reduction with 4 mol L^{-1} HCl/0.1 mol L^{-1} $TiCl_3$. High recoveries were reported for both Am (96%) and Pu (85%).

4. Multistage extraction chromatography column methods

The most frequently used multistage techniques for actinide separation from environmental samples are based on the tandem column set of UTEVA-TRU (Thakkar, 2001). This method involved preconcentration of actinides with calcium phosphate (pH = 9), dissolution in 3 mol L^{-1} HNO_3/1 mol L^{-1} $Al(NO_3)_3$, and Pu oxidation state adjustment to Pu(III) with ferrous sulfamate and ascorbic acid. The tandem columns of the UTEVA (first) and the TRU (second) were used for the separation. The columns were separated after the sample loading and washing. Th and Np were subsequently eluted with 5 mol L^{-1} HCl/0.05 mol L^{-1} oxalic acid, respectively. On the TRU column, Pu was oxidized to Pu(IV) with 2 mol L^{-1} HNO_3/0.1 mol L^{-1} $NaNO_2$ and stripped with 4 mol L^{-1} HCl, and then Am was eluted with 0.1 mol L^{-1} ammonium bioxalate. This method with high recoveries (>80% for Pu, > 72% for Am, and >79% for U) and with comparatively high DF > 10^4 for U in the Pu fraction was slightly modified and applied in different standard procedures for the determination of actinides in biological and environmental samples (e.g., Jakopic et al., 2007; Varga et al., 2007a, 2007b).

A simple automated separation system was developed using UTEVA, TRU, and Sr resins for the determination of uranium, thorium, plutonium, americium, and strontium in water and urine samples by alpha spectroscopy, ICP-QMS, and multi-low-level counter (Zoriy et al., 2010). The method provides the rapid (from 60 to 100 minutes) and accurate separation of the elements with recoveries from 68% to 98%.

a. DIPEX resins

DIPEX (ACTINIDE) resin is a diphosphonic acid extractant supported on an inert polymeric substrate (Horwitz et al., 1997). The resin has high affinity for actinides from dilute acid solutions ($k' \sim 10^7$ for Pu(IV) and Np(IV), while $\sim 10^8$ for Am). In addition to the high affinity for actinides in the tri-, tetra-, and hexavalent oxidation states, the DIPEX resin has excellent selectivity for Am(III) over Al(III) or Fe(III) in comparison with the DIPHONIX chelating ion exchange resin. The resin can be used to preconcentrate actinides from bulk samples or complex matrices followed by the stripping of actinides from the resin together with the extractant using alcohol or wet oxidation. Actinides from soil solutions and large volume water samples were preconcentrated by DIPEX resin (Burnett et al., 1997). The extractant was removed from the resin by isopropanol, sodium hydroxide fusion was applied to oxidize the DIPEX, and actinides were precipitated using calcium phosphate. Actinides were separated on a UTEVA-TRU tandem column setup with variable recoveries (31%−1% for Pu, 22%−99% for Am, and 60%−85% for U). High Pu recoveries (>80%) were reported by Qu et al. (1998) after Pu and Am preconcentration from human tissue by the DIPEX resin, followed by the separation of Pu using anion exchange chromatography.

b. DIPHONIX resins

DIPHONIX resin (Chiarizia et al., 1997; Horwitz et al., 1997) is the chelating ion exchange resin containing the geminally substituted diphosphonic acid groups chemically bound to a styrenic-based polymer matrix. The DIPHONIX capacity factors for the actinide retention from dilute acids are close to those of its analog the DIPEX resin. The DIPHONIX resin received limited application due to problems with the removal of actinides, which can be eluted with strong complexing agents (e.g., HEDPA (1-hydroxyethylidene diphosphonic acid). Kim et al. (2000) oxidized HEDPA by ozonation or by Fenton's reagent to remove actinides from the DIPHONIX after

preconcentration. Although large loss of uranium was found, high recoveries (~85%) for Am, Pu, and U and high selectivity for Am, Pu, and U separation from large soil and sediment samples were claimed. Maxwell and Nichols (2000) applied a microwave digestion technique to remove actinides from the DIPHONIX resin. Actinides were separated using TEVA-UTEVA-TRU columns from large soil samples with high selectivity, consistent tracer recoveries, and minimal waste. High recoveries (70%−78%) for Am and inconstant (37%−93%) for Pu were reported for actinide stripped from DIPHONIX resin with 6 mol L^{-1} HNO_3 and 4 mol L^{-1} HCl/0.015 mol L^{-1} $TiCl_3$, respectively.

c. DGA resins

DGA resins (Horwitz et al., 2005) consists of *N*,*N*,*N*′,*N*′-tetra-octyldiglycolamide sorbed onto Amberchrom CG-71 resin (DGA Resin, Normal) or *N*,*N*,*N*′,*N*′-tetrakis-2-ethylhexyldiglycolamide (DGA resin, branched). DGA can strongly retain Am ($k' > 10^4$ in concentrated > 1 mol L^{-1} HNO_3 solutions) and Pu(IV) ($k' > 10^3$ in 0.1−10 mol L^{-1} HNO_3). DGA resin can be used for the separation and purification of americium and curium from various complicated environmental matrices, such as soil and water.

Recently, a single DGA column method was developed to separate Am and Pu from soil and sediments (10 g) for alpha spectrometry and AMS measurements. Samples were digested with 16 mol L^{-1} HNO_3 at 110°C for 24 hours. Sodium nitrite was applied for oxidation state adjustment, and the load solution was 8 mol L^{-1} HNO_3/0.05 mol L^{-1} $NaNO_2$. The column was subsequently rinsed with 8, 3, and 0.1 mol L^{-1} HNO_3, then Am was eluted with 0.1 mol L^{-1} HCl, and finally, Pu was stripped with 0.1 mol L^{-1} HCl/0.02 mol L^{-1} $TiCl_3$. NdF_3 coprecipitation was used for alpha spectrometry source preparation and adapted as the source for AMS. A simple chemical separation method in combination with the solid phase extraction (SPE) vacuum manifold resulted in a separation turnover of a total of 60 samples a day. The reported recoveries were 95 ± 10−99 ± 6 for Am and 97 ± 5−98 ± 6 for Pu. This method enabled the reduction of the amount of waste solutions generated during the procedure, as well as the time and costs required to separate these analytes. The method was validated using standard reference materials IAEA-384 and IAEA-385 obtained from the International Atomic Energy Agency (Kazi et al., 2014).

A rapid method using stacked TEVA-TRU-DGA cartridges for the determination of actinides in large soil samples (up to 200 g) by alpha spectrometry was reported by Maxwell and Culligan (2006) and Maxwell (2008a). The technique involves NaOH fusion followed by actinide preconcentration with $Ce(OH)_3$, coprecipitation with CeF_3, and dissolution in 8 mol L^{-1} HNO_3. Th and Pu(IV) ware separated on TEVA, whereas Am/Cm separated with the TRU-DGA multistage column. Americium eluted from TRU with 4 mol L^{-1} HCl was transferred to the DGA column and stripped from DGA with diluted 0.25 mol L^{-1} HCl solution. Recoveries for the whole procedure were 76%−98% for Am and 61%−92% for Pu. A similar technique was applied for the analysis of water (up to 1 L) samples (Maxwell, 2006).

A rapid method for the separation and preconcentration of actinides in urine samples was developed for measurements of longer-lived actinides (^{239}Pu, ^{242}Pu, ^{237}Np, ^{243}Am, ^{234}U, ^{235}U, and ^{238}U) by ICP-MS and short-lived actinides (^{236}Pu, ^{238}Pu, ^{239}Pu, ^{241}Am, ^{243}Am, and ^{244}Cm) by alpha spectrometry (Maxwell and Jones, 2009). The stacked TEVA-TRU-DGA resin columns and vacuum box technology were used to ensure rapid separations. From large urine aliquots (100 mL), actinides were preconcentrated with calcium phosphate. The final load solution contained 3 mol L^{-1} HNO_3/1 mol L^{-1} $Al(NO_3)_3$. The reduction/oxidation cycle using sulfamic acid and ascorbic acid to reduce Pu to Pu(III), ferric nitrate to facilitate ^{237}Np (if separation was desired) reduction to Np(IV), and sodium nitrite to oxidize Pu to Pu(IV) was applied. Pu/Np and Th were separated on TEVA, and Pu/Np was stripped with 0.25 mol L^{-1} HCl−0.005 mol L^{-1} HF−0.0001 mol L^{-1} $TiCl_3$. Am/Cm was eluted from TRU resin onto DGA resin with 4 mol L^{-1} HCl. The TRU resin cartridges were removed, and the DGA resin was rinsed with 1 mol L^{-1} HNO_3 and 0.1 mol L^{-1} HNO_3 to remove any residual uranium. Am and Cm were eluted using 0.25 mol L^{-1} HCl. The application of DGA allows Am/Cm elution with 0.25 mol L^{-1} HCl, which is more suitable for ICP-MS measurements, and can provide additional decontamination from U. The simplicity, speed (24 samples in <3 h), and high recoveries (>90%) of this method make it attractive for radiological emergency response. A multidimensional (MD) separation method using TEVA/DGA EC for the analysis of actinides in environmental samples was developed and tested for alpha spectrometry and ICP-MS. To remove interferences and enable proper identification and quantification, actinides (Th, U, Np, Pu, and Am) were separated after oxidation state adjustment firstly in 9 M HCl, and secondly in 3 M HNO_3. High separation selectivity and recoveries (98, 100, 94, 98, and 99 ± 2% for Th, U, Np, Pu, and Am, respectively, were achieved. Reusability of the resins was found to be ≤ 9. The separation technique was tested on reference material (CRM-IAEA-384). Data obtained of actinide measurements by alpha spectrometry and ICP-MS agreed well with absolute relative bias of 1.9%−23% (Guérin and Dai, 2013).

A rapid simplified method for the determination of Pu and Np in water samples using a stacked column set of TEVA and DGA resins was developed by Maxwell et al. (2011a). Pu(IV) and Np(IV) were retained on a TEVA

column, and then Pu was reduced to Pu(III) and transferred to a DGA column together with U. From the DGA, U was eluted with 0.1 mol L^{-1} HNO_3 and Pu(III) was stripped with 0.02 mol L^{-1} HCl/0.005 mol L^{-1} HF/0.0005 mol L^{-1} $TiCl_3$. ^{239}Pu, ^{242}Pu, and ^{237}Np were measured by ICP-MS, whereas ^{236}Pu, ^{238}Pu, and ^{239}Pu were counted by alpha spectrometry. High recoveries and DFs for U (from Np—10^4 and Pu—10^5) were reported. The TEVA and DGA resin column method was also applied for the separation Pu, Np, and Am from 10 to 20 g completely dissolved soil samples using sodium hydroxide fusion (Maxwell et al., 2015). The method has allowed the reduction of sample time processing and enabled lower detection limits for plutonium, neptunium, and americium in environmental soil samples.

Stacked TEVA, TRU, and DGA resin cartridge separation techniques followed by accelerated furnace heating, a rapid sodium hydroxide fusion method, and a lanthanum fluoride matrix removal step were widely applied for rapid actinide analyses in environmental, food, and bioassay matrices using alpha and/or mass spectrometry (Maxwell et al., 2011b, 2012, 2013, 2014). Chemical separation using TRU, DGA-N, and DGA-B EC resins was also employed to remove interfering elements, including Bi, Hf, Hg, Pb, Pt, Pu, and Tl in the complex environmental samples prior to ^{241}Am measurements by mass spectrometry (Wang et al., 2017).

5. Combined procedures for the determination of neptunium and other actinides

The separation of radionuclides from complex environmental matrices usually requires a combination of methods to ensure sufficient decontamination or separation of several elements from a single sample. There are a huge number of combined procedures, many of which have been discussed above as examples of particular techniques and in various reviews dedicated to a certain radionuclide. Various combinations of ever developed techniques have been used for the separations, if they produced a positive result: solvent extraction and anion exchange chromatography or EC, two-, three-stage columns were frequently used for actinide separation. However, newly developed highly selective materials allow the efficient separation of actinides from 10 g soil using a single DGA column (e.g., Kazi et al., 2014). Nevertheless, combined procedures are still in range, due to various reasons, involving newly developed techniques and conventional methods.

The TEVA-UTEVA-TRU column set was applied for the separation of actinides by Horwitz et al. (1995). Later, various modifications of this method or new developments were applied for the analysis of radionuclides in environmental and biological samples (e.g., Mathew et al., 1981; Smith et al., 1995; Moody et al., 1998; Pilvio and Bickel, 1998; Maxwell and Culligan, 2006; Maxwell, 2006; Lee et al., 2007; Maxwell, 2008b; Maxwell and Faison, 2008, Maxwell et al., 2010a,b,c; 2011c; La Rosa et al., 2010; Qiao et al., 2014 etc).

Recently developed combined methods, most frequently based on DGA resin due to its high affinity for actinides (as mentioned above), are cost-effective, extremely selective, fast (to meet emergency response requirements) and produce sources suitable for measurements using alpha and mass spectrometry.

A new and rapid separation method for ^{234,235,236,238}U, ^{230,232}Th, ^{239,240}Pu, ^{237}Np, ^{241}Am, and ^{90}Sr using TEVA-DGA columns was reported by Habibi et al. (2015). After Pu and Np oxidation state adjustment to Pu(IV) and Np(IV), samples were loaded on TEVA-DGA in 3 mol L^{-1}. Th(IV), Pu(IV), and Np(IV) were retained on the TEVA resin, whereas Am(III), U(VI), and Sr(II) on the DGA one. The matrix elements were removed by washings with 3 mol L^{-1} HNO_3. Columns were separated, the following fractions were obtained: (1) Th, Np, and Pu were eluted with 2.5 m mol L^{-1} HEDPA as the fraction from TEVA, (2) U and Sr were stripped from the DGA column with 0.1 mol L^{-1} HNO_3, (3) Am, Y, and Zr (naturally present in the sample) were eluted from the DGA using 2.5 m mol L^{-1} HEDPA. The three fractions can be measured immediately after their collection due to compatibility with ICP-MS. The overall yields exceeded 80% for all radionuclides. The radiochemical separation time (including counting time) required < 7 hours for eight river water samples analyses.

The extraction behavior of interfering elements on TEVA resin; decontamination of U using TEVA, UTEVA, and DGA resins; and the effect of coprecipitation on Pu detection using ICP-MS were studied by Wang et al. (2017a) with the aim of developing a new chemical separation method for rapid Pu determination in soil and sediment samples. The developed method involved: HNO_3 leaching; CaF_2/LaF_3 coprecipitation to remove matrix elements and U; the TEVA + UTEVA + DGA procedure for the removal of U, Pb, Bi, Tl, Hg, Hf, Pt, and Dy; and ICP-MS measurements. The method was tested for $^{239+240}$Pu activity as well as for ^{240}Pu/^{239}Pu and ^{241}Pu/^{239}Pu isotopic ratio measurements by analyzing soil, freshwater sediment, and ocean sediment standard reference materials. These studies resulted in stable and high Pu recoveries (90%−97% for soil; 92%−98% for sediment) and high DF of U (1.6×10^7) and the short analytical time of 12 hours. In addition, the lowest detection limits yet reported in the literature estimated for ^{241}Pu on the basis of a 1 g soil sample of 0.56 μBq g^{-1} (0.24 fg g^{-1}) for ^{239}Pu, 1.2 μBq g^{-1} (0.14 fg g^{-1}) for ^{240}Pu, and 0.34 mBq g^{-1} (0.09 fg g^{-1}) were achieved.

Stacked columns of AGMP-1M-DGA resins were used to simultaneously separate Pu and Am/Cm from a complex

matrix of large-size soil and sediment samples (20 g) with total sample dissolution using lithium metaborate fusion (Luo et al., 2018). Matrix elements were successfully removed using hydroxide and CeF_3 coprecipitation. The oxidation state was adjusted with $NaNO_2$, then the sample was loaded onto AGMP-1M-DGA columns, and the columns were rinsed with 8 mol L^{-1} HNO_3 and disconnected. From the AGMP-1M column, Th was eluted with 12 mol L^{-1} HCl followed by Pu stripping with 0.2 mol L^{-1} HNO_3+0.05 mol L^{-1} HF and Pu coprecipitated with HTiO. The precipitate was dissolved in 1 mL of concentrated HNO_3, and after oxidation state adjustment with $NaNO_2$, the sample was loaded onto a preconditioned 0.1g TEVA column. The column was rinsed with 12 mol L^{-1} HCl and 8 mol L^{-1} HNO_3. Finally, Pu was eluted with 0.1 mol L^{-1} HCl+0.05 mol L^{-1} HF. An aliquot of 1 mL of the Pu eluate was used for analysis of ^{239}Pu and ^{240}Pu by ICP-MS and the rest—for the counting by alpha spectrometry. From the DGA resin, after rinsing with 11 mol L^{-1} HCOOH to remove the residual HNO_3 and $NaNO_2$, Am and Cm were eluted together with a prepared solution (20 mL of 0.05 mol L^{-1} HCOOH, 10 mL of 12 mol L^{-1} NH_4SCN, and 0.5 mL of 4 mol L^{-1} HCOOH). The solution was loaded onto on anion AGMP-1 M resin column and preconditioned with 2 mol L^{-1} NH_4SCN+0.5 mol L^{-1} HCOOH. The column was rinsed with 1.5 mol L^{-1} NH_4SCN+0.5 mol L^{-1} HCOOH to remove lanthanides, and Am/Cm was then eluted with 0.25 mol L^{-1} HCl. Then, an additional purification was performed using coprecipitation with HTiO, and TEVA and DGA columns (filled with 0.1 g of resin). Am/Cm was eluted from the DGA resin with 0.05 mol L^{-1} HCl. The solution was used for alpha counting source preparation by CeF_3 microprecipitation. The reported average chemical recoveries were 84 ± 10% for Pu and 91 ± 7% for Am. The estimated time required for analysis of a batch of 12 samples, including coprecipitation and separation, was typically 2.5 days.

An analytical method for simultaneous determination of Cs and Pu isotopes in river suspended particles of small sample size (1−2 g) was developed to monitor the transport and fate of ^{135}Cs and ^{137}Cs as well as ^{239}Pu and ^{240}Pu in the land−ocean system (Cao et al., 2016). Cs and Pu were sequentially preconcentrated using ammonium molybdophosphate and ferric hydroxide coprecipitation, respectively. Two-stage anion exchange (using AG 1x8-AG MP-1) chromatography was applied for Pu chemical separation and purification for Pu separation and purification (Bu et al., 2013). Pu was eluted from AG MP-1 with concentrated HBr. The sample was evaporated, heated to destroy HBr traces, and redissolved in 4% HNO_3 in the preparation for measurements, and finally, Cs and Pu isotopes were measured by ICP-MS/MS and SF-ICP-MS, respectively. The developed method allowed the removal of the interfering elements of U ($^{238}U^1H^+$ and $^{238}U^2H^+$ for ^{239}Pu and ^{240}Pu, respectively) and Ba ($^{135}Ba^+$ and $^{137}Ba^+$ for ^{135}Cs and ^{137}Cs, respectively) with DFs of $1-8 \times 10^6$ and 1×10^4, respectively. Soil reference materials were used to test the method. The detected ^{135}Cs/^{137}Cs and ^{240}Pu/^{239}Pu atom ratios and ^{239,240}Pu activities were a good agreement with the certified/information values. In addition, the developed method was employed for the determination of Cs and Pu in the suspended particles in land and water samples collected from Fukushima Prefecture after the FDNPP accident. The ^{135}Cs/^{137}Cs atom ratios (0.329−0.391) and ^{137}Cs activities (23.4−152 Bq g^{-1}) indicated that the contamination of the suspended particulate matter was mostly derived from the FDNPP accident, whereas ^{240}Pu/^{239}Pu atom ratios (0.182−0.208) were of global fallout origin. Cs isotopes were separated using AGMP-1M −AG 50Wx8 resin columns. Mo, Sb, and Sn were retained on the AGMP-1M anion exchange column, whereas Cs was adsorbed on AG 50Wx8 cation exchange column. The AG 50Wx8 column was rinsed with 1 mol L^{-1} NH_4OH, and H_2O and Cs were eluted with 1.5 mol L^{-1} HCl, whereas Ba remained on the AG 50Wx8 resin.

A rapid method for ultratrace Pu detection in urine sample with high ^{238}U decontamination factor ($DF = 3.8 \times 10^6$) was reported (Ni et al., 2018). The technique involves acid digestion, coprecipitation with CaF_2/LaF_3, EC separation (based on the method by Wang et al., 2017b), and SF-ICP-MS measurements. The separation of Pu was performed using TEVA-UTEVA-DGA resin cartridges. TEVA-UTEVA-DGA resins were preconditioned with 3 mol L^{-1} HNO_3. The sample was loaded onto the TEVA resin followed by rinses with 3 mol L^{-1} HNO_3 to remove Ca, Fe, and rare earth elements, 1 mol L^{-1} HNO_3 to remove U, Pb, Tl, and Pt, and 9 mol L^{-1} HCl to remove Th, Bi, and Hf. The TEVA (1) was connected to UTEVA (2) and DGA (3) cartridges, and 3 mol L^{-1} HNO_3−0.1 mol L^{-1} ascorbic acid−0.02 mol L^{-1} Fe^{2+} was used to elute Pu from TEVA resin onto DGA resin by reducing it from Pu(IV) to Pu(III). From the DGA resin, U was eluted with 0.1M HNO_3, and finally, Pu was stripped with 0.5M HCl−0.1M $NH_2OH{\cdot}HCl$. The final eluent was evaporated and redissolved in 0.7 mL of 4% ultrapure HNO_3 with 0.02 ng mL^{-1} Rh as internal standard in preparation for SF-ICP-MS measurement.

The ^{242}Pu recovery was stable for 20 and 100 mL urine bioassays with an average value of 72.7 ± 5.5%. The reported detection limits for ^{239}Pu, ^{240}Pu, and ^{241}Pu were 0.016, 0.016, and 0.019 fg mL^{-1} for 20 mL as well as 0.003, 0.002, and 0.003 fg mL^{-1} for 100-mL urine samples, respectively. The time required for completing procedures for 20- and 100-mL urine bioassays were 9.5 and 11 hours, respectively, and 1 day for analysis of 10 samples. The developed technique can become a promising tool

for rapid response to radiological emergencies and rapid screening of unexpected occupational exposures due to low detection limits and high sample throughput.

A new sequential separation method was developed for the determination of Po and Pu, Am, and U in drinking water samples for emergency response or routine water analyses (Benedik et al., 2009; Fernández et al., 2012; Lemons et al., 2018). TEVA chromatography was for the first time applied to polonium and plutonium separation. This method involves a rapid Fe^{3+} coprecipitation to remove matrix interferences, Pu oxidation state adjustment to Pu(IV), and an incubation (~1 hours at 50–60°C) for Po(II) to turn to Po(IV). The Po and Pu were separated on a TEVA column, whereas Am and U separation was performed on a TRU column. Microprecipitation of Po with copper sulfide (CuS) and micro-coprecipitation of actinides using neodymium fluoride (NdF_3) were applied for source preparation for alpha spectrometry measurements (Lemons et al., 2018).

6. Source preparation

Proper source preparation is an important part of sample processing, as it can improve DFs for the entire procedure and provide accurate measurements. There are three known methods for the preparation of a source for alpha spectrometry: evaporation, microcompound, and electrodeposition. Coprecipitation using a microcrystalline precipitate and electrodeposition methods are most often used to obtain a source for alpha spectrometry (ASTM standards D3084-05).

Micro-coprecipitation of actinides on rare earth fluorides (Nd, Ce, or La), often with NdF_3, followed by filtration on a smooth surface membrane filter of fine pore size (0.1–0.2 μm), yields a good-quality alpha source (ASTM Test Method C1163, Sill, 1987a,b; Hindman, 1983). The membrane filter preconditioning can improve peak resolution. The preparation of sources for alpha spectrometry involves NdF_3 coprecipitation, the filter pretreatment with CeF_3, or NdF_3 substrate solution and filtration through a 0.1-μm membrane filter. CeF_3 microprecipitation for the preparation of Am/Cm sources for alpha spectrometry is described by Dai, X. (2011). The most frequently used method for Ra source preparation is coprecipitation with $BaSO_4$ (Sill, 1987a,b).

During the electrodeposition procedure, actinides are electrochemically plated from an electrolyte solution onto a cathode planchet of polished metal (usually stainless steel). The anode is typically Pt wire or gauze, often rotating to mix the solution; alternatively, sufficient agitation can be provided by gas formed at the anode. Electrodeposition is usually carried out at a constant current density (0.5–1 A cm^{-2}) and low voltage (<10 V) for ~2 h. A standard procedure for electroplating actinide ammonium sulfate solutions was published in 2000 and reapproved in 2010 (ASTM C1284-00). A variety of electrolytes (sulfate, oxalate, acetate buffers, etc.) and electrodeposition cells (depending on the size of cathode) have been used. Deposition recoveries are usually in the range from 90% to 99% depending on the method.

Recently developed setups for the electrodeposition involve disposable electrodeposition cells made from scintillation vials, an ultrasonic bath, and a rotating Pt anode based on the methods by Talvitie (1972), Hallstadius (1984), and Tomé and Sanchez (1991).

Optimization of electrodeposition procedures for the preparation of ^{238}U sources for high-resolution alpha particle spectrometry indicated that the best energy resolution was achieved with sources produced in saturated NH_4NO_3, on polished stainless steel discs using a spirally wound platinum anode (Jobbágy et al., 2012). The best sources were in a diameter of ~20 mm with a maximum surface density of 26 μg cm^{-2}.

The optimized copper sulfide (CuS) microprecipitation (0.05 mg of Cu^{2+} in 10 mL of 1 M HCl) was applied to prepare thin-layer polonium (Po) sources for alpha spectrometry counting (Guérin and Dai, 2013). It was reported that the procedure is simple as well as faster, cheaper, and more convenient in comparison with the traditional spontaneous plating on metallic discs, and the obtained yields were comparable (80%–90%). The effects of Cu^{2+}, Ag^{+}, Fe^{3+}, Fe^{2+}, Pb^{2+}, and Ni^{2+} on the yield and the resolution of the alpha peaks were estimated.

We may conclude at the end of this section that significant efforts have been made to assess the feasibility of detection techniques (e.g., alpha spectrometry and mass spectrometry), to compare and evaluate or/and reestimate the accuracy of conventional techniques, e.g., anion exchange and extraction chromatography as well as electrodeposition and coprecipitation for sample preparation (Oh et al., 2014; Krmpotić et al., 2018; Vasile et al., 2018).

A special attention has been paid to complete sample dissolution and to development methods for the separation of radionuclides from complex environmental samples as well as to estimate analyte losses at the all stages of sample preparation: digestion, separation, source preparation, and measurement (Epov et al., 2005a,b; Henricsson et al., 2011; Maxwell et al., 2011a,b,c; Wang et al., 2017b).

Recent studies have shown that ICP-MS can provide a relatively fast and accurate determination of long-lived actinides in environmental samples (see also Section IV.B). New developments in the online detection system showed obvious advantages and led to a high sample throughput in comparison with other radiometric and mass spectrometric techniques. Progress in the analytical separation, careful selection of eluents compatible with the mass spectrometric approach, and the use of highly selective EC materials, such as DGA, TEVA, and UTEVA allow a significant reduction in problems associated with

interferences and matrix effects (Ito et al., 2011; Habibi et al., 2015; Wang et al., 2017a; Ni et al., 2018). Measurements of isotope ratios (e.g., $^{239}Pu/^{240}Pu$ and $^{236}U/^{238}U$) by ICP-MS to estimate the source of radionuclides in the environment are the most promising for future applications (Yang et al., 2017); however, a combination of alpha and mass spectrometric techniques is useful in determining plutonium isotope ratios, including $^{238}Pu/^{239}Pu$ (Esaka et al., 2017).

Progress in recent developments of new AMS methods to measure actinides in environmental samples (see also Section IV.C) benefits the future application of this sensitive analytical technique at ultratrace levels required for environmental studies (Quinto et al., 2009; Christl et al., 2014; Kazi et al., 2014; Cornett et al., 2015; Schneider et al., 2017). The development of new automatic systems with the use of new advanced materials and technologies in combination with improved analytical methods (e.g., a single DGA column) will provide lower detection limits, increase the analytical throughput of environmental samples, and reduce the cost of analysis (e.g., Qiao et al., 2011; Yang et al., 2016).

Recently developed radioanalytical procedures can provide sources of equally high quality, both for alpha and mass spectrometric measurements. Nevertheless, in the case of inadequate quality of a source, the nondestructive alpha spectrometry method allows for additional purification of the sample. Despite the fact that general trends indicate a rapid improvement of mass spectrometric techniques, alpha spectrometry will remain in demand as a simple, cost-efficient, and highly selective technique for a long time.

New methods based on modern materials, such as the dibenzo-18-crown-6 ether (DB-18CE-6)-functionalized silica (SiO_2) disk for the rapid analysis of ^{226}Ra by alpha spectrometry and a phosphate–sulfate bifunctional polymer layer surface-grafted membrane, suitable for the alpha spectrometric measurements due to high affinity for Pu(IV), are rather promising for the future monitoring and rapid response to radiological emergencies (S. Paul et al., 2015; Mohamud et al., 2017).

7. Examples of actinides in the environment

a. Uranium-236 in terrestrial waters

Uranium-236 is the most commonly applied isotope of uranium in environmental trace studies, both in the terrestrial and in the marine environments. Latest developments in AMS and radiochemical separation techniques have enabled the reliable determination of ^{236}U concentrations even in relatively small water samples (1.5–2 L), supporting the potential of this radionuclide to be a very good tracer of hydrological processes. If we look at the results of recent measurements of ^{236}U and natural uranium in terrestrial waters, we can see that the $^{236}U/^{238}U$ ratios are higher for rivers (rivulets) than for seas and oceans (Table 3.14). Such a difference may be attributed to the surface runoff of global fallout ^{236}U deposited on land, which is accumulated in rivers, but diluted in oceans by large amounts of natural uranium. The values of the $^{236}U/^{238}U$ isotopic ratio above 10^{-9} indicate that the samples were clearly affected by anthropogenic nuclear activities, expect the sample from Gastein whose ratio was determined to be by a factor of about 10 times lower than for high-grade ore (Steier et al., 2008). Very high concentrations of ^{236}U found in Irish Sea is due to the contribution of the Sellafield reprocessing plant (Eigl et al., 2013, 2016).

b. Transuranics on atmospheric aerosols

Measurements of transuranics in aerosol samples started after nuclear weapon tests when large amounts of anthropogenic radionuclides were released into the atmosphere, which led to global fallout with impact on the total environment. The burn-up of the SNAP 9A satellite in the

TABLE 3.14 Concentration of ^{236}U and $^{236}U/^{238}U$ isotope ratios in various water samples.

Sample	Sample type	$^{236}U/^{238}U$	^{236}U (mBq L^{-1})	^{236}U (atom L^{-1})
Rio Negro	River	2.73×10^{-8}	4.9×10^{-6}	5.2×10^{6}
Danube	River	1.08×10^{-8}	2.3×10^{-5}	2.5×10^{7}
Salzburg	Rivulet	$(2.1–11.4) \times 10^{-8}$	$(0.8–3.5) \times 10^{-4}$	$(0.8–3.7) \times 10^{8}$
	Well water	2.1×10^{-8}	1.1×10^{-4}	1.2×10^{8}
Gastein	Well water	$(6.2–7.0) \times 10^{-12}$	–	–
Black sea	Seawater	3.63×10^{-9}	2.8×10^{-5}	3.0×10^{7}
Irish sea	Seawater	2.04×10^{-6}	1.3×10^{-2}	1.4×10^{10}
Hawaii	Seawater	5.74×10^{-9}	3.5×10^{-5}	3.8×10^{7}

After Steier et al. (2008); Srncik et al., 2010; Eigl et al. (2013).

atmosphere had a global impact as well, as it caused a several-fold increase in the $^{238}Pu/^{239,240}Pu$ activity ratio in 1964. Contributions of other sources, e.g., from the Chernobyl and Fukushima accidents, had only local/regional or continental impacts, similarly, as well as accidents of US warplanes in Greenland and Spain carrying Pu (UNSCEAR, 1982; Vintró et al., 2000).

Temporal variations of $^{239,240}Pu$ concentrations in stratospheric and surface air of the Northern Hemisphere have recently been summarized by Hirose and Povinec (2015). The highest Pu activity concentrations were detected in the upper stratosphere at 20–40 km height in 1963 (Fig. 3.67), following the former Soviet Union large-scale atmospheric nuclear weapon tests in Novaya Zemlya in 1961 and 1962. An increase in stratospheric $^{239,240}Pu$ activities (Fig. 3.67B) was also observed after the Chinese nuclear tests (6.5 Mt in October 14, 1970, 2.5 Mt in June 27, 1973, and 4 Mt in November 17, 1976) in the 1970s (UNSCEAR, 2000). It is believed that fine aerosol particles carrying radionuclides could remain in the stratosphere until the 2000s. To support this hypothesis, Alvarado et al. (2014) measured the increase in Pu activity concentrations in the troposphere, observed during the Eyjafjallajökull eruption in Iceland in 2010, which was explained by the scavenging effect of volcanic ash particles on stratospheric aerosol carrying Pu isotopes and their increased transport into the troposphere. After careful analyses of long-term experimental data, including measurements during volcanic eruptions, published by different laboratories, Hirose and Povinec (2015) showed that the activities of stratospheric plutonium exponentially decreased with an apparent residence time of 1.5 ± 0.5 years. Authors concluded that the surface plutonium until the early 1980s was controlled by the stratospheric inputs, while global dust events and biomass burning were responsible for wide variations in the lower stratospheric and upper tropospheric activity concentrations and ratios of Pu isotopes in the 2000s. The mean tropospheric residence time of 71 days was estimated for plutonium-bearing aerosol particles after atmospheric nuclear weapon tests, consistent with other researches (Holloway and Hayes, 1982; Warneke et al., 2002).

Activity concentrations of ^{238}Pu, $^{239,240}Pu$, and ^{241}Pu in aerosol samples collected at Sodakylä, Finland (67°22′N, 26° 39′E) in 1963 were $<0.1-3.6 \pm 0.5$ μBq m^{-3}, $0.4 \pm 0.1-95 \pm 3$ μBq m^{-3}, and $<16-1730 \pm 70$ μBq m^{-3}, respectively. Clear seasonal variation with the highest activities found in spring and summer was explained by the springtime-enhanced transport of plutonium-bearing aerosol particles from the stratosphere to the troposphere. The reported $^{238}Pu/^{239,240}Pu$ activity ratios (from 0.014 ± 0.003 to 0.32 ± 0.11) were characteristic of the global fallout from nuclear weapon testing (Salminen and Paatero, 2009).

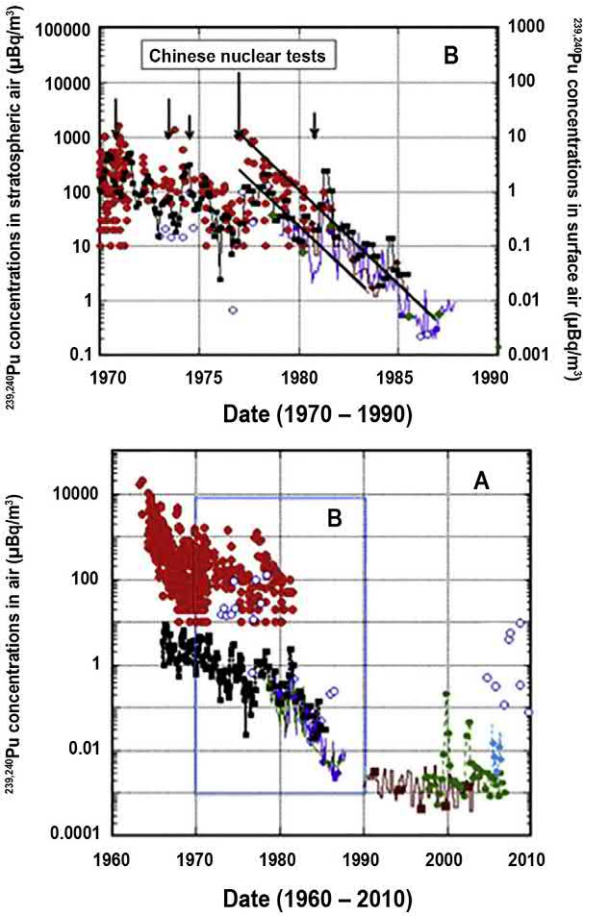

FIGURE 3.67 Temporal variations of $^{239,240}Pu$ concentrations in stratospheric and surface air of the Northern Hemisphere (after Hirose and Povinec, 2015). Closed red circles: the upper stratosphere, 20–40 km height (Leifer and Juzdan, 1986; EML, 1999); open blue circles: the lower stratosphere, 10.1–14.2 km height (Alvarado et al., 2014); closed black squares: the surface air, New York (EML, 1999); brown closed rhombic: the surface air Beaverton Oregon (EML, 1999); green closed rhombic: the surface air, Milford Haven (Playford et al., 1993); purple squares: the surface air, Tsukuba (Hirose and Sugimura, 1984, 1990); brown closed squares: the surface air (Wershofen and Arnold, 2005); green closed circles: the surface air, Prague (Hölgye, 2008); blue closed rhombic: the surface air, Vilnius (Lujaniene et al., 2006, 2012a). For the color version of the figure, the reader is referred to the online version of the book. *Licensed under a Creative Commons Attribution 4.0 International License.*

The $^{240}Pu/^{239}Pu$ atom ratio in air filters collected at Sodankylä in 1963 (later measured using SF-ICP-MS) ranged typically from 0.15 ± 0.01 to 0.30 ± 0.06, indicating that global fallout was the main Pu source (Salminen-Paatero et al., 2012). Transport of aerosol particles from the Novaya Zemlya test site as a possible source of Pu pollution was identified by a set of three-dimensional air mass back-trajectories ending at Sodankylä during 1963 calculated using the trajectory model Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT).

Plutonium and uranium concentrations and atom ratios in archived air filters collected at ground level at nine stations in Norway during 1957−58 and 1961−62 (measured using AMS) showed large variations of ^{236}U (0.17−23 nBq m^{-3}) and $^{239,\ 240}$Pu (1.3−782 μBq m^{-3}). The ^{240}Pu/^{239}Pu (0.0517−0.237) and ^{236}U/^{239}Pu (0.0188−0.7) atom ratios indicated tropospheric fallout from the Semipalatinsk or Novaya Zemlya test sites (Wendel et al., 2013).

Alteration in data on activity concentrations and ratios obtained by different researches can be attributed to sampling location, season, and duration as well as to the efficiency of used filters for submicron particles (typical for stratospheric aerosols), the losses of which can significantly alter Pu isotopic ratios and result in incorrect estimation of the contamination source (Valmari et al., 2002; Hirose and Povinec, 2015).

The main source of the ^{238}Pu in the stratosphere was derived from the burn-up of the SNAP-9A satellite over the South Pacific Ocean in 1964, as the nuclear test-derived ^{238}Pu constituted only about 2% of the stratospheric inventory of ^{238}Pu in 1966 (Krey, 1968). It was reported that about 24% over the northern hemisphere and about 76% of the SNAP-9A-derived ^{238}Pu was deposited over the southern hemisphere during the period from 1965 to 1986 with a residence time of 1.2 years (Thakur et al., 2017) or with apparent stratospheric residence time of 1.7 ± 0.4 years (Hirose and Povinec, 2015). Higher activities of ^{238}Pu detected in the lower stratosphere during the 2000s resulted not from the SNAP-9A burn-up accident or the atmospheric nuclear weapon tests, but from other unknown sources. The ^{238}Pu activity concentrations in surface air in 1990−2007 measured by Kierepko et al. (2016) in Krakow (Poland) ranged from 0 to 2.1 μBq m^{-3} (average value of 0.00024 μBq m^{-3}) and in Bialystok (Poland) varied from 0.059 to 87.1 μBq m^{-3} (average value of 0.002 μBq m^{-3}). Low activities of ^{238}Pu in surface air were also found in Prague (Hölgye, 2008) and in Braunschweig (Wershofen and Arnold, 2005). However, unusually high ^{238}Pu concentrations were detected in air samples in Paris in 1988, in samples collected at Astana (51.2°N, 71.4°E, Kazakhstan, about 600 km west from Semipalatinsk) in 2001, at Mayak and other Siberian regions (Martin and Thomas, 1988; Oughton et al., 2001; Salminen et al., 2004).

The southern hemisphere was less polluted by radionuclides since 90% of the nuclear weapon tests were conducted in the northern hemisphere. The southern hemisphere data from the French monitoring Program at Mururoa Island (1986−1991) in the South Pacific and from the Environmental Measurement Laboratory (EML) database (1965−1985) were summarized by Thakur et al. (2017). The EML is now the National Urban Security Technology Laboratory.

After the Chernobyl accident, an increase in the ^{239,240}Pu activity concentrations in the surface air was detected at many European monitoring stations (Sinkko et al., 1987; Rosner et al., 1990. Irlweck et al., 1993; Manić-Kudra et al., 1995) with the highest activities up to 140 μBq m^{-3} found at Dukovany, located about 200 km southeast of Prague (Hölgye and Filgas, 1987). High activities of actinides (up to 10,000 μBq m^{-3} for Pu) detected in aerosol samples in Vilnius were attributed to the short distance (∼480 km) from the damaged reactor and transport of "hot" particles (on large-diameter aerosols) of different activities and composition (Lujaniene et al., 2009). A large number of "hot" particles (up to 10,000 particles per m^3), including ^{233}U, ^{234}U, ^{235}U, ^{238}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, ^{242}Cm, and ^{244}Cm, were found in air filters exposed on April 28−29 and on April 30, 1986 (Lujanas et al., 1994). Measurements of ^{238}Pu/^{239,240}Pu activity (0.44−0.50) and ^{240}Pu/^{239}Pu atom (0.41−0.42) ratios confirmed that Pu in "hot" particles was derived from the Chernobyl accident. In spite of the fact that "hot" particles of 0.5−150 μm in diameter were mainly deposited within the 30-km restriction zone (Sandals et al., 1993), they were detected in the former USSR and many European countries (Lujanas et al., 1994; Pöllänen et al., 1997, 2002; Gerstmann et al., 2004; Salminen-Paatero et al., 2012).

Measurements of ^{240}Pu/^{239}Pu atom ratio (0.13 ± 0.01−0.53 ± 0.03) in aerosol, lichen, peat, grass, and hot particle samples collected in Finland immediately after the Chernobyl accident in 1986 showed the global fallout from nuclear weapon testing and deposition from the Chernobyl accident as the main Pu sources (Salminen-Paatero et al., 2012). The contribution of the Chernobyl-derived ^{239}Pu in aerosol, grass, and two hot particle samples was estimated to be 90%, 100%, 75%, and 100%, respectively.

Activity concentrations of ^{239,240}Pu in surface atmosphere at Milford Haven, Neuherberg, and Braunschweig in 1986−2003 were <2.5−9.5, 0.53−8.1, and 0.39−4.5 nBq m^{-3}, respectively (Playford et al., 1993; Pan and Stevenson, 1996; Wershofen, and Arnold, 2005), whereas higher activities from 0.53 to 217 nBq m^{-3} were found in Prague during the period from 1997 to 2006 (Hölgye, 2008). A decrease of the Chernobyl-derived radionuclides in the atmosphere was observed about 1 year after the accident, and variations in the airborne activity concentrations were linked to the resuspension, dust storms, and biomass burning events (Lujaniene et al., 1999, 2009).

b. Transuranics in soil

Transuranics in soil varied widely depending on the distance from the Chernobyl and on the meteorological conditions at different locations during the accident and passage of the Chernobyl plume. The observed contamination levels presented in several publications

(e.g., De Cort et al., 1998) provide useful information on the behavior of radionuclides of global fallout and after the Chernobyl accident in soil. Great efforts have been made to study the migration behavior of Pu, Am, and Np in soil after nuclear explosions and the Chernobyl accident (e.g., Livens and Baxter, 1988; Pavlotskaya et al., 1991, 1994, 1995; Bunzl et al., 1994; 1995; Lujaniene et al., 2002; Carbol et al., 2003). The effect of soil mineralogical and granulometric compositions, content of organic matter (including humic and fulvic acids), and speciation of radionuclides on the migration rate and bioavailability were studied in laboratory as well as in field experiments.

The sequential extraction procedure was used to study bonding of ^{239,240}Pu and ^{241}Am (derived from the global fallout) with various soil components in six successive layers of an undisturbed grassland soil. It was found that >57% of the studied radionuclides were mostly associated with the soil organic matter. The activity of actinides 30−40 years after their deposition in readily exchangeable fractions was <1% for Pu and on average by a factor of 7 higher for Am, and almost identical migration rates were found for both radionuclides (Bunzl et al., 1990, 1992, 1995).

The migration rates of the Chernobyl-derived ^{137}Cs and ^{239,240}Pu originated mainly from the atmospheric nuclear tests studied at three sites in undisturbed grassland soils in the Czech Republic. A compartment model was applied to calculate the migration rates of ^{239,240}Pu and ^{137}Cs. The migration rate studied in convection transport increased with depth for both radionuclides. The estimated migration rates of ^{239,240}Pu and ^{137}Cs, using the diffusion transport model, varied from 0.65 to 0.94 and from 0.18 to 0.99 cm year^{-1}, respectively (Hölgye and Malý, 2000).

The interaction of Am and Pu with organic matter in a gley soil from the west Cumbria (UK), with massic activities in its surface horizon of 5−10 kBq kg^{-1} for ^{239,240}Pu and comparable ^{241}Am levels, was investigated by Livens and Singleton (1991). Humic and fulvic acids were isolated by conventional alkali extraction and then studied by gel filtration, treatment with organic solvents, and differential flocculation procedures. Actinides were found to be bound mainly with clay-humite fractions. Am should be more mobile due to its greater association with fulvic acids. Higher ^{241}Am mobility as compared with Pu isotopes in the Chernobyl soil was reported by Lujaniene et al. (2002). Higher Chernobyl-derived ^{241}Am mobility was confirmed by measurements of ^{241}Am/^{239,240}Pu ratios in water and sediments in Finish lakes (Lehto, 2009; Lusa et al., 2009). In addition, authors reported higher ^{241}Am uptake by fish in comparison with Pu isotopes.

Complicated behavior of ^{137}Cs, ^{90}Sr, ^{241}Am, and ^{239,240}Pu radionuclides was reported from two radioactive fallout plumes at the Semipalatinsk test site. The studied radionuclides were mainly found in the soil fraction of 500−1000 μm, with enrichment factors ranging from 1.2 to 3.8, at the plume generated by the surface nuclear test, whereas radionuclides were associated with the soil fraction of 250−500 μm (enrichment factors 1.1 − 5.1) in samples from the plume where surface nuclear tests were not conducted (Kabdyrakova et al., 2018).

Transfer factors (Tfs) for ^{137}Cs, ^{90}Sr, ^{241}Am, and ^{239,240}Pu radionuclides obtained for the spots with different contamination type at the Semipalatinsk test site showed wide variations. The highest Tfs were characteristic of radioactive stream flows and warfare radioactive agent (WRA) test zones. The transfer factors decreased in the following order: ^{90}Sr > ^{137}Cs > ^{239,240}Pu > ^{241}Am; in addition, the ^{90}Sr Tf was higher by a factor of 8 in comparison with the ^{137}Cs Tf and by a factor of 16 as compared with the ^{239,240}Pu Tf, while the ^{239,240}Pu Tf exceeded the ^{241}Am Tf by a factor of 3. As an exception, the Tf of studied radionuclides decreased in the sequence: ^{90}Sr > ^{239,240}Pu > ^{137}Cs in the WRA test area (Larionova et al., 2018).

^{239,240}Pu and ^{137}Cs association with soil particles of different sizes was also studied in soil samples from the natural environment collected at two locations in China. The highest activities of ^{137}Cs and Pu isotopes were found in the fraction of < 2 μm. An increase in ^{239,240}Pu/^{137}Cs activity ratios in coarse soil fractions showed a lower transport potential for Pu isotopes as compared with the ^{137}Cs, indicating suitability of Pu isotopes for application as soil erosion tracers (Xu et al., 2017).

Recently, Pu isotopes were applied to estimated soil erosion rates in different regions (Meusburger et al., 2018; Portes et al., 2018).

Speciation of radionuclides (including redox speciations) in environmental samples was intensively studied to explain behavior as well as to predict migration and bioavailability (e.g., Moulin and Moulin, 2001; Choppin, 2007; Geckeis and Rabung, 2008; Kenna, 2009). Special interest was focused on the effect of microorganisms on the migration and speciation of radionuclides related to the prediction of radionuclide migration around the radioactive waste repositories and remediation of the contaminated sites (e.g., Shuklaet al., 2017).

Vegetation, litter, and soil drill core samples were collected in the contaminated area at Fukushima in 2013 and 2015 to study the origin of ^{240}Pu/^{239}Pu and ^{236}U/^{238}U ratios using AMS. ^{240}Pu/^{239}Pu ratios indicated the global fallout as the main source in the samples, whereas the Fukushima-derived reactor plutonium was identified unambiguously in some vegetation and litter samples. This assumption is confirmed by the detection of ^{236}U. The strong localization indicated that the small quantities of Pu isotopes were most likely released in the form of particulate matter (Schneider et al., 2017). The release of Pu isotopes into the environment during the Fukushima accident was also reported in several studies (Zheng et al., 2012;

Schneider et al., 2013; Yamamoto et al., 2012, 2014; Xu et al., 2016; Imanaka et al., 2012; Tanaka et al., 2014; Steinhauser et al., 2015) and ^{236}U (Sakaguchi et al., 2014; Shinonaga et al., 2014; Yang et al., 2016).

c. Pu isotope ratios

Progress in analytical and instrumental techniques for long-lived radionuclides, such as the development of new selective materials for radioanalytical separation, AMS (ICP-MS) as well as the need of the fingerprinting and contamination sources estimation, resulted in a growing interest in the estimation and reevaluation characteristic atom and activity ratios of radionuclides in environmental samples. Wide variations of Pu atom ratios derived from different sources were demonstrated, e.g., by Taylor et al. (2001), Warneke et al. (2002), Ketterer et al. (2004) and others as shown in Fig. 3.68.

Further achievements in this field have enabled the application of Pu as a new tool to study environmental processes such as the transport of Saharan dust in Europe (Pham et al., 2005 Povinec et al., 2008), North America dust sources (Arimoto et al., 2005), transport of dust from China deserts in Asia (Choi et al., 2006; Igarashi et al., 2009), and other environmental processes in Europe and worldwide (Lee et al., 2002; Chamizo et al., 2010; Hirose et al., 2010).

Large variations of the Pu isotope ratios observed during nuclear weapon tests were attributed to different Pu atom ratios, which resulted from the low- and high-yield tests and mixing rates in the stratosphere and troposphere, as indicated by $^{240}Pu/^{239}Pu$ atom ratios in daily aerosol samples collected in Finland in 1963 (Salminen-Paatero et al., 2012). Measurements of $^{240}Pu/^{239}Pu$ ratios in polar ice sheets as well as in archived samples of grass, roe deer antlers, and corals showed that differences in these ratios for premoratorium and postmoratorium periods offer possibility of using these ratios as a geochronological tool for marine, glacial, lake, and soil studies (Fig. 3.69).

The $^{240}Pu/^{239}Pu$ atom ratios estimated at the contaminated sites are important for source identification, e.g., for the Semipalatinsk NWT site ($^{240}Pu/^{239}Pu = 0.044$), for the Nuclear Complex Mayak ($^{240}Pu/^{239}Pu = 0.028$), and for the Siberian Chemical Complex Tomsk-7 ($^{240}Pu/^{239}Pu = 0.049 - 0.051$) (Yamamoto et al., 1996; Beasley et al., 1998; Gauthier-Lafaye et al., 2008; Stille et al., 2008).

The atom ratios of Pu isotopes and of ^{237}Np measured in archived soil samples collected in the 1970s from 54 locations around the world were reported for the Northern hemisphere to be $^{240}Pu/^{239}Pu = 0.180 \pm 0.014$, $^{241}Pu/^{239}Pu = 0.00194 \pm 0.00028$, $^{242}Pu/^{239}Pu = 0.0039 - \pm 0.0007$, and $^{237}Np/^{239}Pu = 0.48 \pm 0.07$ and for the Southern hemisphere to be $^{240}Pu/^{239}Pu = 0.185 \pm 0.047$, $^{241}Pu/^{239}Pu = 0.0020 \pm 0.0009$, $^{242}Pu/^{239}Pu = 0.0048 - \pm 0.0021$, and $^{237}Np/^{239}Pu = 0.34 \pm 0.03$ (Kelley et al., 1999).

Studies of the $^{240}Pu/^{239}Pu$ atom ratio variability in Australian soil showed ranges from 0.045 to 0.197, with average values of 0.139 ± 0.017, 0.111 ± 0.052 and 0.160 ± 0.027 in the $10-20^{o}S$, $20-30^{o}S$, and $30-40^{o}S$ latitudes, respectively. It was found that the $^{240}Pu/^{239}Pu$ atom ratio of 0.069 estimated for Central Australia corresponds to local fallout from the nuclear weapon tests carried out by the United Kingdom in Australia (Maralinga: 0.113 and Montebello: 0.045), whereas the average ratios

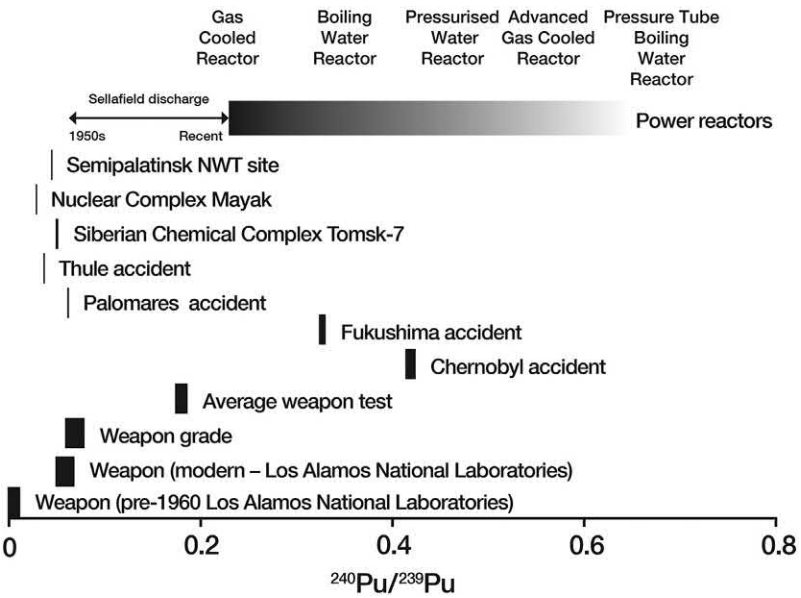

FIGURE 3.68 $^{240}Pu/^{239}Pu$ atom ratios from different nuclear sources. *Updated from Taylor et al. (2001).*

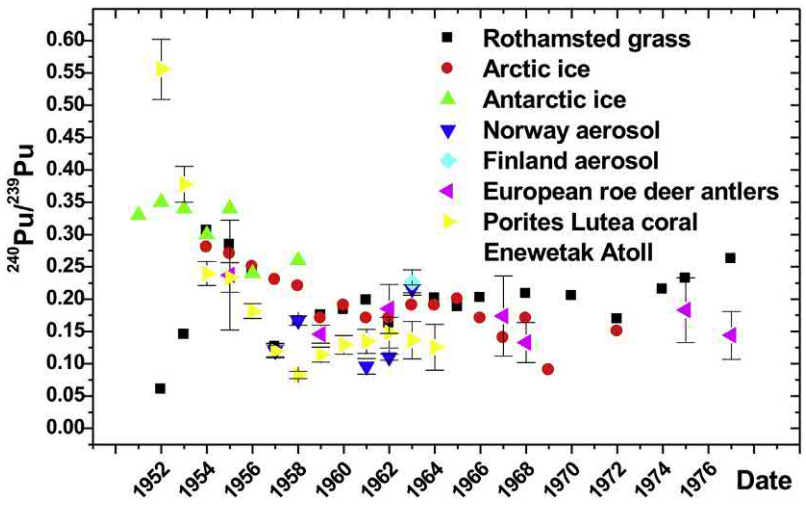

FIGURE 3.69 $^{240}Pu/^{239}Pu$ atom ratios in the Arctic and Antarctic ice sheets (average values, data from Koide et al., 1985), as well as in archived samples of grass, aerosol, roe deer antlers, and corals (data from Warneke et al., 2002; Salminen-Paatero et al., 2012 (average value); Wendel et al., 2013 (average values); and Froehlich et al., 2016, 2017). For the color version of the figure, the reader is referred to the online version of the book.

for the 20−30°S and 30−40°S bands are mainly characteristic for global fallout with average values of 0.139 and 0.177, respectively. The slightest deviation of 6% from the typical value of the $^{240}Pu/^{239}Pu$ ratio for the southern hemisphere (0.171) was found for soil samples collected at the 30−40°S latitude band (Lal et al., 2017).

The characteristic Pu isotopes atom ($^{240}Pu/^{239}Pu$) and activity ($^{238}Pu/^{239}Pu$) ratios in soil and sediments after the B-52 aircraft accident with Pu bombs were estimated as follows: for the Thule (Greenland) samples $^{240}Pu/^{239}Pu = 0.033 \pm 0.003$ and $^{238}Pu/^{239}Pu = 0.0150 \pm 0.0017$, while for the Palomares (Spain) samples, the ratios were higher, $^{240}Pu/^{239}Pu = 0.056 \pm 0.003$ and $^{238}Pu/^{239}Pu = 0.0275 \pm 0.0012$ (Mitchell et al., 1997). The differences in atom and activity Pu ratios for the Thule and Palomares samples were attributed to conditions (e.g., reactor types, operating history, integrated neutron flux, etc.) under which the plutonium was originally produced.

High $^{238}Pu/^{239,240}Pu$ activity ratios (0.014−0.5) and $^{240}Pu/^{239}Pu$ atom ratios (0.10−0.44) were measured in aerosol samples collected in April−May 1986 after the Chernobyl accident at Braunschweig (Germany, Arnold and Wershofen, 2000; Wershofen et al., 2001), in Krakow and Bialystok (Poland, Kierepko et al., 2016), Prague (Czech Republic, Holgye, 2008), Nurmijarvi (Finland, Salminen-Paatero et al., 2012), and Vilnius (Lithuania, Lujaniene et al., 2012a). In Tsukuba (Japan, Hirose and Sugimura, 1990), the $^{238}Pu/^{239,240}Pu$ activity ratio during the period from May 3 to June 1, 1986, ranged from 0.08 to 0.33 with an average value of 0.19 (Fig. 3.70). In spite of the sharp decrease of Pu activity concentrations during 1986, higher $^{238}Pu/^{239,240}Pu$ activity ratios were still found in the atmosphere even 20 years after the Chernobyl accident, which were attributed to the transport of Pu isotopes with aerosol and hot particles released during the Chernobyl accident, as well as to resuspension of the Chernobyl-derived plutonium from soil.

The Chernobyl-derived $^{240}Pu/^{239}Pu$ atom ratios in the troposphere have been studied worldwide, including speciation and particle size distributions of aerosol and soil samples inside the restricted Chernobyl zone. Large variations in the $^{240}Pu/^{239}Pu$ atom ratios outside of the Chernobyl zone, from about 0.05 to 0.5, have been observed (Fig. 3.71). Dust storms (resuspension from soil) and, to a lesser extent, biomass burning were responsible for redistribution of the Chernobyl-derived plutonium in the troposphere. An exponential decrease in the $^{240}Pu/^{239}Pu$ atom ratios from 0.30 to 0.19 was observed during 1995−2003 (Lujaniene et al., 2009), which was attributed to a decrease in the amount of the Chernobyl-derived Pu in the atmosphere due to its deposition and mixing with global fallout Pu. The residence time of the Chernobyl-derived Pu in the atmosphere for this period was found to be 1.6 ± 0.4 y. This value is not consistent with the mean tropospheric residence time of plutonium-bearing aerosols (71 d), observed after atmospheric nuclear weapon tests (Holloway and Hayes, 1982). The difference may reflect the Pu behavior in the atmospheric and terrestrial environments, including the resuspension and transport of Pu from the contaminated regions.

The frequency distribution of the $^{240}Pu/^{239}Pu$ atom ratio in aerosol samples collected during 1995−2006 shows a lognormal bimodal distribution (Lujaniene et al., 2012b). The first mode with median value of 0.195 (0.155 − 0.215) corresponds to the global fallout ratio of 0.17−0.19 characteristic for the northern hemisphere (Kelley et al., 1999). The second mode with median value of 0.253

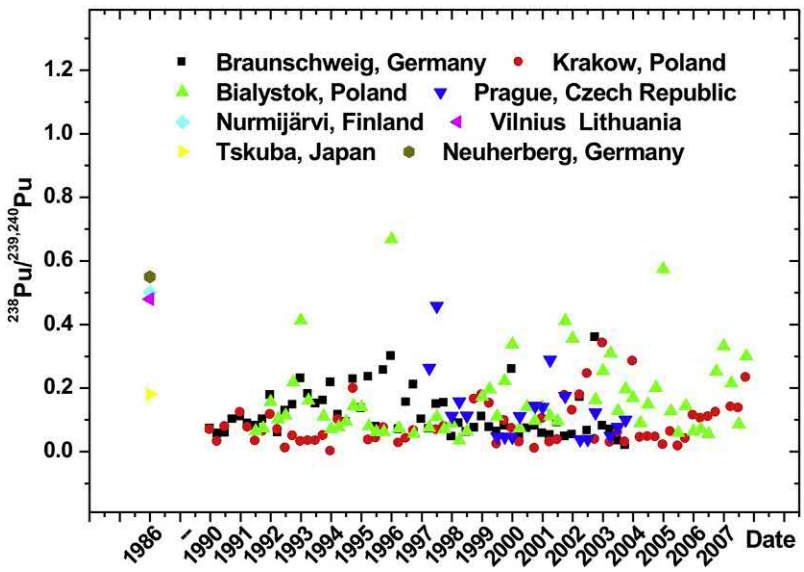

FIGURE 3.70 $^{238}Pu/^{239,240}Pu$ activity ratios in aerosol samples collected after the Chernobyl accident in Japan (Hirose and Sugimura, 1990), Germany (Rosner et al., 1990; Wershofen and Arnold, 2005), Czech Republic (Hölgye, 2008), Lithuania (Lujaniene et al., 2009), Finland (Salminen-Paatero et al., 2012), and Poland (Kierepko et al., 2016). For the color version of the figure, the reader is referred to the online version of the book.

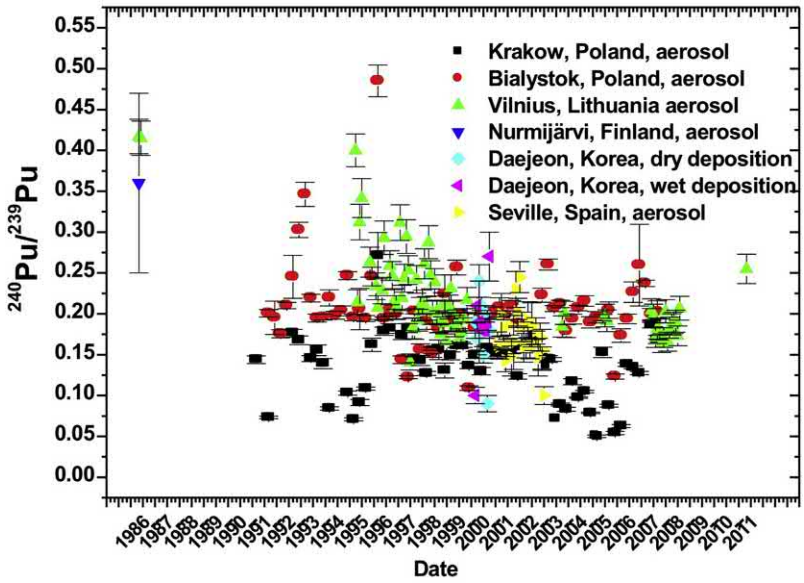

FIGURE 3.71 $^{240}Pu/^{239}Pu$ atom ratios in atmospheric samples collected after the Chernobyl accident in Poland (Kierepko et al., 2016), Lithuania (Lujaniene et al., 2009, 2012b), Finland (Salminen-Paatero et al., 2012), South Korea (Hirose et al., 2004), and Spain (Chamizo et al., 2010). For the color version of the figure, the reader is referred to the online version of the book.

(0.225 − 0.285) could be attributed to the nuclear reactor Pu with characteristic $^{240}Pu/^{239}Pu$ atom ratio of 0.23−0.67 (Warneke et al., 2002).

On the other hand, the characteristic Fukushima-derived Pu activity ratios—$^{238}Pu/^{239,240}Pu$ (1.2), $^{241}Pu/^{239,240}Pu$ (102), and $^{240}Pu/^{239}Pu$ atom ratio of 0.30−0.33—were measured in upper soil layers, in litter, and in black dust samples (Zheng et al., 2012, 2013; Sakaguchi et al., 2014; Yamamoto et al., 2014). The bimodal frequency distribution of $^{240}Pu/^{239}Pu$ atom ratios was found in soil samples after the Fukushima accident with the first peak close to the global fallout value and the second peak at 0.245−0.312 with different contributions of the Fukushima-derived Pu (Yang et al., 2017).

Because of low-release rates of Pu during the Fukushima accident, and long-range transport from Japan to Europe, the observed activity concentrations were below detection limits. Successful Pu measurements were mostly carried out only in soil samples collected in Japan, and in river or coastal sediments. A statistically significant increase in the $^{240}Pu/^{239}Pu$ atom ratio of 0.244 ± 0.018 (Fig. 3.71) was found in large-volume aerosol samples collected during March 23−April 15, 2011 in Vilnius (Lithuania), which could be attributed to the Fukushima

accident (Lujaniene et al., 2012a). However, similar increases in the $^{240}Pu/^{239}Pu$ atom ratios were observed in Europe during pre-Fukushima time as well, which were probably associated with Pu resuspension from soil or biomass burning.

VI. International networks for monitoring of environmental radionuclides

A. International monitoring system of CTBTO

The Comprehensive Nuclear-Test-Ban Treaty (CTBT) was opened for signature in 1996. When the Treaty entered into force, it banned atmospheric, underwater, and underground nuclear explosions. The International Monitoring System (IMS) is being set up with the aim of detecting violations of the CTBT. It is a global system utilizing the most modern technology available, which besides seismic, hydroacoustic, and infrasound stations also includes radionuclide monitoring stations for monitoring of radioactive aerosols and of radioactive noble gases. It should be able to detect any nuclear explosion conducted in the underground, underwater, or atmosphere. The IMS consists of 321 monitoring stations to monitor the planet for any sign of a nuclear weapon test, and presently, about 90% of monitoring stations have already been installed (www.CTBTO.org).

The monitoring network includes 80 radionuclide monitoring stations carrying out a continuous worldwide observation of aerosol samples of radionuclides. The network is supported by 16 radionuclide laboratories hosting expertise in environmental monitoring, providing independent additional analysis of IMS samples, assisting in data evaluation and identification of measured radionuclides. The laboratories also analyze samples collected and measured at monitoring stations to provide quality control of a station's air sample measurements. The radionuclide stations are capable of detecting radioactive debris from atmospheric explosions or vented by underground or underwater nuclear explosions. The 80 radionuclide stations operate in four world regions: Europe and Eurasia, Mediterranean and Africa, Asia and Oceania, and America. Each region is supported by four radionuclide laboratories. It should be stressed that the modern radionuclide technology is the only one that can unambiguously confirm an explosion connected with a nuclear weapon test.

Half of all radionuclide stations is equipped with technology capable of monitoring of radioactive noble gases. This technology is crucial for the detection of nuclear explosions carried out underground or underwater when aerosol releases may be delayed or not detectable at all. From radioactive noble gases, the best candidates for tracing nuclear explosions are radioisotopes of xenon, namely ^{133}Xe ($T_{1/2} = 5.2$ d) and ^{135}Xe ($T_{1/2} =$ 9.1 hours) and two isomers, ^{131m}Xe ($T_{1/2} = 11.8$ d) and ^{133m}Xe ($T_{1/2} = 2.2$ d) due to their suitable half-lives and decay modes with emissions of beta rays and/or gamma rays. The argon and krypton radioisotopes, e.g., ^{85}Kr ($T_{1/2} =$ 10.7 y), because of their excessively long half-lives, decay modes, and large releases from nuclear and pharmaceutical industry are not first-class nuclear test tracers.

Xenon radioisotopes together with ^{85}Kr have been measured in the atmosphere from 1970s, mostly applied cryogenic separation and gas counting techniques (Kunz and Paperiello, 1976; Stockburger et al., 1977; Cimbák and Povinec, 1985; Cimbák et al., 1986; Igarashi et al., 2000, 2005). IMS radionuclide monitoring stations should be capable, however, to monitor radioxenon concentrations in the atmosphere continuously; therefore, continuous air sampling and measurements should be carried out (Schulze et al., 2000; Bowyer et al., 2002; Saey and De Geer, 2005; Plastino et al., 2010) (see also Section V.A.3). Usually, HPGe gamma spectrometers or beta−gamma coincidence spectrometers based on plastic and NaI(Tl) scintillation detectors have been used, which enable the calculation of activity ratios of xenon radioisotopes in collected air samples. Typical detection limits are below 1 mBq m^{-3}. Complementary to radionuclide aerosol monitoring, the International Noble Gas Experiment (INGE) was established in 1999 to test the measuring of radioactive noble gases released by nuclear explosions (Auer et al., 2004, 2010).

However, even with the development of sophisticated radioxenon monitoring systems, an unambiguous detection of nuclear explosions is a very difficult task because of variations of xenon radioisotopes in the atmosphere connected with different release rate scenarios (nuclear fuel reprocessing facilities, nuclear reactors, radiopharmaceutical industry), meteorological conditions, etc. Therefore, a proper understanding of background and atmospheric variations of radioactive xenon isotopes in the atmosphere is crucial for assessing undeclared nuclear activities (Schulze et al., 2000; Schöppner and Plastino, 2014; Saey, 2007, 2009; Postelt, 2014). Atmospheric transport modeling in support of CTBT verification, especially analysis of backward trajectories, has become therefore as important as direct experimental monitoring of radioxenon levels in the atmosphere (De Geer et al., 1996; Wotawa et al., 2003; Stocki et al., 2005; Stohl et al., 2005; Becker et al., 2007; De Meutter et al., 2016; Bianchi et al., 2018; Longo et al., 2018).

The accident at the Fukushima NPP on March 2011, which originated due to a devastating tsunami damaging the NPP's infrastructure, was a good cross-check for performance of adjacent IMS radionuclide stations operating in East Asia, as well as for modeling groups assessing the radioxenon release-rate scenarios and modeling atmospheric radionuclide transport. Reported experimental

TABLE 3.15 List of underground nuclear weapon test carried out by North Korea.

Date	Oct 9, 2006	May 25, 2009	Feb 12, 2013	Jan 6, 2016	Sept 9,2016	Sept 3, 2017
Yield (eq. kt TNT)	0.6–2	2–5.4	6–16	7–16	15–25	70–280

activities at the IMS radionuclide stations as well as atmospheric modeling results, estimation of radioxenon release rates, and tracing atmospheric processes contributed to the assessment of the Fukushima impact on the regional and global scales (Stohl et al., 2012; Povinec et al., 2013a; Eslinger et al., 2014).

Presently, the IMS has mostly been focusing on assessment of signals from nuclear weapon tests carried out by North Korea. Altogether six tests were declared between 2006 and 2017 (Table 3.15). The last one with a yield of 70–280 TNT (eq.) was declared to be a hydrogen bomb but may only be a boosted fission bomb (Saey et al., 2007; Ringbom et al., 2009, 2014; De Meutter et al., 2017, 2018). The situation is complicated by the fact that only 6–8 weeks after the test, increased levels of some of the xenon radioisotopes were observed in a few radionuclide monitoring stations.

A good example is the third test carried out in 2013 when suspicious detections of ^{131m}Xe and ^{133}Xe were made by one IMS station in Japan and one in Russia (Ringbom et al., 2009; De Meutter et al., 2018). The experimental signal was attributed to a nuclear explosion, mainly based on their unusual occurrence compared with the station's record (Ringbom et al., 2014). An inverse atmospheric transport and dispersion modeling showed that the nuclear test could be the source of radioxenon; however, a second source in East Asia should be considered also as a civilian background source (De Meutter et al., 2018). Bayesian methods to find source parameters have also confirmed the nuclear test as a radioxenon source (Eslinger and Schrom, 2016).

Another example could be the nuclear test carried out in 2016 when elevated ^{133}Xe concentrations were measured by the IMS radionuclide stations (De Meutter et al., 2017). However, the lack of presence of other radioxenon isotopes could indicate a civilian source or at least a contribution from this source.

Gathered experience with assessment of North Korean nuclear weapon tests clearly shows that further developments, both on experimental and on modeling sides, will be required. Continuous and simultaneous measurements of all four xenon radioisotopes will be a must, especially in critical regions where nuclear tests could be expected (Kalinowski et al., 2010; Topin et al., 2015). Together with atmospheric transport and dispersion modeling, this will provide a powerful tool for assessing undeclared nuclear weapon tests, although radioxenon contributions from regional civilian sources remain a great challenge, especially if their locations are not well known (Achim et al., 2016; Eslinger et al., 2016).

B. European network "Ring of Five"

Ring of Five (Ro5) is an unformal group of European laboratories exchanging data on atmospheric radioactivity, which triggered studies in several countries, evaluating obtained results and writing joint publications. Originally, only five countries were included in this network; however, presently almost all European countries have been engaged in the Ro5 activities. Large-scale investigations started with measuring and evaluation of the Fukushima accident impact on the European countries (Masson et al., 2011).

In January–February 2017, traces of particulate ^{131}I were detected by about 30 monitoring stations in the European atmosphere with concentrations ranging from 0.1 to 10 μBq m^{-3} (except at one location in Russia with mBq m^{-3}). Inverse modeling indicated that a combination of multiple sources was responsible for the elevated ^{131}I levels, namely a radiopharmaceutical production unit in Western Russia and medical uses of ^{131}I in Europe (Masson et al., 2018a,b).

More recently, in October 2017 and several months afterward, more than 30 European laboratories reported the presence of ^{106}Ru in the atmosphere with concentrations from about 10 μBq m^{-3} to more than 100 mBq m^{-3} (Masson et al., 2018b). The ^{106}Ru was also detected in rain samples as well as in grass. The widespread detection at such considerable levels suggested a source term that would meet or exceed the criteria of an accident at level 4–5 of the International Nuclear Event Scale (INES). The data evaluation and computer modeling suggested that the release could originate in Russia, in the Southern Urals region (Russia).

VII. Conclusions

We have covered in this chapter the analysis of radionuclides in the terrestrial environment, as the marine environment has been covered in Chapter 5, Volume 2. We have seen that great progress has been made both in radioanalytical aspects and in environmental radioactivity studies either for radioecological purposes or in applications of radionuclides as tracers of processes in the atmosphere–hydrosphere–pedosphere–biosphere ecosystems.

Great developments have been made in radioanalytical technologies when, from simple gas counting systems, we moved to very sophisticated accelerator-based technologies not only decreasing required sample size from kilograms to milligrams but also improving the sensitivities by five to six orders of magnitude. Large-volume Ge detectors (frequently operating deep underground) have been the most important breakthrough for the analysis of short- and medium-lived radionuclides in the radiometrics sector, whereas ICP-MS and AMS revolutionized the analytical technologies for long-lived radionuclides.

Radionuclides of very different origin found in the terrestrial environment, from the primordial ones (^{40}K, ^{235}U, ^{238}U, ^{232}Th) to radiogenic (radium isotopes, ^{222}Rn, ^{210}Po, ^{210}Pb, etc.), cosmogenic (^{3}H, ^{7}Be, ^{10}Be, ^{14}C, ^{22}Na, etc.), and finally anthropogenic radionuclides (^{3}H, ^{14}C, ^{90}Sr, ^{137}Cs, ^{236}U, transuranics, etc.) have been investigated for assessment of the impacts of the nuclear industries on the total environment (including humans), as well as for a better understanding of their transport between environmental compartments and resulting variations in their concentrations.

We have not finished yet our work on the development of new radioanalytical technologies with the aim to further increase detection sensitivities, which would open doors for new environmental studies using radionuclides as valuable tracers, including climate change investigations, and specifically, a clear identification of natural and anthropogenic impacts on climate, which represent one of the most important challenges for the future environmental radioactivity research.

Acknowledgments

The authors are indebted to their institutional colleagues for cooperation in the development of radioanalytical methods and their applications in environmental radioactivity studies. Special thanks go also to our foreign colleagues, namely P.K. Aggarwal, R. Golser, K. Hirose, Y. Igarashi, K.G.W. Inn, A.J.T. Jull, W.E. Kieser, O. Masson, S.-H. Lee, M. Molnár, U. Morgenstern, N. Ogrinc, L. Palcsu, M.K. Pham, W. Plastino, P. Steier, I. Svetlik, and F. Terrasi for long-term fruitful collaboration in environmental radioactivity studies. The Bratislava group acknowledges support provided by the EU Research and Development Operational Program funded by the ERDF (projects 26240120012, 26240120026 and 26240220004), by the International Atomic Energy Agency (projects SLR 0/008, SLR 0/009, SLR 1001 and RER 7008), by the Slovak Research and Development Agency (Projects APVV 15-0576 and APVV-0516-10), and by the VEGA Scientific Granting Agency of Slovakia (Projects 1/0891/17 and 1/0783/14).

Miroslav Ješkovský

Dr. Miroslav Ješkovský finished his PhD studies at the Comenius University in Bratislava (Slovakia) in 2009. Afterward, he continued his research as an Assistant Professor at the Faculty of Mathematics, Physics, and Informatics of the Comenius University. The main objectives of his research have been focused on natural and anthropogenic radionuclides in the environment. He used gamma spectrometry methods for the identification and quantification of radionuclides in various environmental samples and contributed to the development of a low-background HPGe spectrometer used in the Department of Nuclear Physics and Biophysics. After establishment of the new CENTA facility in Bratislava, Miroslav Ješkovský concentrated his work on the development and utilization of accelerator techniques such as accelerator mass spectrometry (AMS) and ion beam analysis (e.g., PIXE, PIGE, RBS, etc.) for the determination of stable and long-lived radioisotopes in the environment. In recent years, he has been participating in the development of radiometric and mass spectrometry methods for radiopurity measurements with detection limits down to nBq g^{-1} for underground physics experiments searching for rare nuclear processes and decays.

Jakub Kaizer

Dr. Jakub Kaizer finished his PhD in environmental physics at the Comenius University in Bratislava in 2015, and in the same year, he joined the research staff of the Department of Nuclear Physics and Biophysics of the Faculty of Mathematics, Physics, and Informatics of the Comenius University. He has been contributing to the ongoing development of the Centre for Nuclear and Accelerator Technologies (CENTA) since 2013, the scientific program of which is devoted to radiocarbon dating, studies of long-lived radionuclides in the environment, and ion beam analyses. In his research, he is mainly focused on low-level radioactivity environmental studies (e.g., impact of the Fukushima accident), development of accelerator mass spectrometry and ion beam techniques, and radiopurity measurements of various materials used in the large-scale physics experiment, such as the SuperNEMO experiment. He has (co)authored 17 papers in peer-reviewed scientific journals.

Ivan Kontul′

Dr. Ivan Kontul' received his PhD in environmental physics at the Comenius University in Bratislava (Slovakia) in 2019. His research is focused on the development of analytical methods for the analysis of cosmogenic radionuclides (mainly radiocarbon, ^{14}C) using radiometric and accelerator mass spectrometry, as well as on their applications in radiocarbon dating and environmental radioactivity studies. He also takes part in regular monitoring of radiocarbon activity of atmospheric carbon dioxide in heavily industrialized and urbanized regions as well as in the areas in the vicinity of nuclear power plants, including transfer of radionuclides to biota (e.g., in tree rings).

Galina Lujanienė

Dr. Galina Lujanienė received her PhD at the Vilnius University (Lithuania) in 1993. She then worked as a permanent research scientist at the Institute of Physics, as well as a visiting scientist in several European institutes. She has 30 years' experience in environmental radioactivity investigations—assessment of consequences of the Chernobyl and Fukushima accidents, monitoring of radionuclides in the environment, estimation of radionuclide sources in the environment (forest fires, dust storms, hot particles, aerosols, and suspended particles in the atmosphere, fresh- and seawater, and sediments), studies related to the radionuclide migration in soil and clay minerals, speciation of radionuclides and development of new radioanalytical and radiochemistry methods. Galina Lujanienė was involved as a leading scientist in more than 10 international and national projects. Since 2010, she has been the head of Radiochemical Laboratory at the SRI Centre for Physical Sciences and Technology in Vilnius. Currently, her research focuses on applications of radionuclides in traces studies and development of methods for removing radionuclides from contaminated liquid matrices. She was a principal supervisor of six PhD students. Galina has published more than 100 scientific papers in recognized journals and delivered many invited lectures at international conferences.

Monika Müllerová

Dr. Monika Müllerová received her PhD from the Comenius University in Bratislava (Slovakia) in 2009. She has been working as a scientific researcher at the Faculty of Mathematics, Physics, and Informatics of the Comenius University. Her research interests have focused on the monitoring of radionuclides in the environment, specifically on the study of radon behavior in the environment, as well as on the development of detectors for environmental radioactivity monitoring. In recent years, she has focused her research mainly on radon in houses, workplaces, and kindergartens, and on the calculation of effective radiation doses to the public from radon.

Pavel P. Povinec

Prof. RNDr. Pavel Povinec, DrSc., obtained his PhD degree in Physics from the Comenius University in Bratislava in 1974. He worked at the Department of Nuclear Physics of the Faculty of Mathematics and Physics of the Comenius University as an assistant professor, associated professor (1978), and professor of Physics (1984), also as the head of the Department (1981−1992), focusing on developments of radiometric methods for the analysis of radionuclides at very low levels with wide applications in nuclear (rare nuclear decays), environmental (radionuclides as tracers, radiocarbon dating), and space physics (radionuclides in lunar samples and meteorites). From 1993 to 2005, he worked at the IAEA's Marine Environment Laboratories in Monaco as the head of the Radiometrics Laboratory responsible for the development of radiometric (including underground laboratory) and mass spectrometry methods (ICP-MS, AMS) for marine radioactivity studies. Pavel Povinec has led several international projects on assessment of dumping of radioactive wastes, on impacts of nuclear weapon test sites, on worldwide marine radioactivity studies (WOMARS), on submarine groundwater discharge studies, on the development of global marine radioactivity databases (GLOMARD/MARIS), etc. After his return to the Comenius University, he established at the Faculty of Mathematics, Physics, and Informatics a Centre for Nuclear and Accelerator Technologies (CENTA) focusing on the development of IBA and AMS methods and their wide applications in nuclear, material, environmental, and biomedical sciences. He supervised 26 PhD students, published more than 20 books and book chapters and more than 700 referred papers with more than 13,000 citations, organized more than 20 international conferences, and delivered more than 50 invited talks.

I. Introduction

A. What is a radioactive aerosol?

An aerosol, in general, is the system of liquid or solid particles suspended in a gas medium. In the atmosphere, the gas medium is air, and the system is the atmospheric aerosol. It is often that aerosol particles contain natural or anthropogenic radionuclides. In that case and in terms of their composition and activity, the term radioactive aerosol applies. The size of aerosol particles ranges from a few nanometers (10^{-9} m) to several hundreds of micrometers (10^{-6} m). Various names, such as Aitken nuclei, smoke, fume, or haze (for the smaller particles) and dusts, mists, fogs, or ashes (for larger ones), have been used in the nomenclature of atmospheric aerosols.

All aerosol particles are formed by chemical reactions of precursor species, condensation of gases or vapors or by mechanical processes. They may be transformed by coagulation or condensation of semivolatile species, and their concentration in air may change during aerosol transport, mixing with a different aerosol and dilution. They may be removed from the atmosphere and settle on surfaces, which act as a sink. The residence time of aerosol particles in the atmosphere varies from some days near the earth's surface in the troposphere to a year or more in the stratosphere.

Atmospheric aerosol transport and interaction with surfaces is mainly governed by the particle mechanical properties, condensation or evaporation of species as well

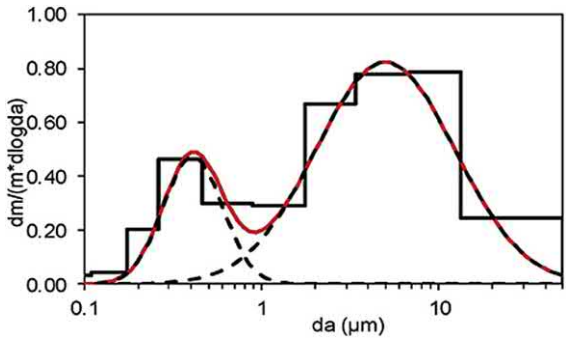

FIGURE 4.1 Average mass size distribution of ambient aerosols in terms of aerodynamic diameter during Sahara dust events measured by Berner impactors. The mass distribution was normalized by total mass concentration. The *red line* displays the inverted size distribution assuming a sum of lognormal modes. The *black broken line* displays these two modes (coarse and fine). For the color version of the figure, the reader is referred to the electronic version of this book. *From Vasilatou et al. (2017).*

as their electrical charge. All these properties are strongly dependent on their size.

The definition of fine and coarse particles as smaller and larger than 1 μm diameter, respectively, originated from the fact that the most frequent atmospheric aerosol size distribution is bimodal, i.e., one mode occurs below 1 μm diameter, and the other above 1 μm diameter (Whitby, 1975; NRC, 1979). Fig. 4.1 shows that more coarse particles are observed during Sahara dust events due to the dominance of mineral dust even within an urban area (Athens, Greece). In atmospheric aerosol particle-size distributions, fine particles result from nucleation processes involving natural and anthropogenic gaseous precursors, primary anthropogenic emissions (usually combustion) and condensation and coagulation of the former, whereas coarse particles are produced by mechanical processes. Some particles serve as nuclei, cloud condensation nuclei, and ice nuclei depending on their hygroscopic properties and meteorological conditions. Small and large ions carry electrical charges. Small ions are clusters of atoms or molecules carrying a charge. Their stability depends on their charge. Larger ions are merely aerosol particles that carry one or more electric charges. Large particles of 0.1−1.0 μm in diameter and giant particles of above 10.0 μm diameter are terms also applied in characterizing the atmospheric aerosol particles.

Aerosol particles are considered those solid or liquid particles with sizes between 1 nm and 100 μm. The size of an atom is of the order of 10^{-10} m or 10^{-4} μm or 0.1 nm (the Bohr radius $r_1 = 0.5292 \times 10^{-10}$ m), while the size of an atomic nucleus is of the order of 10^{-14} m or 10^{-8} μm or 10^{-5} nm. An aerosol particle having a diameter of some nanometers (or 10^{-2} μm) is a hundred times or more, larger than an atom, and thus consists of few atoms, clusters of atoms, or molecules.

Primary particles, such as road dust, sea salt spray from oceans, and cement dust, do not change form after emission, whereas a substantial fraction of mass of the secondary particles, such as photochemically produced sulfates and photochemical smog, is formed by in situ chemical reactions involving gases.

Monitoring and particular aerosol characterization studies have led to a revolution in both our knowledge and our understanding of atmospheric aerosols. Atmospheric sciences, particle technology, industrial hygiene, and health effects studies of pollutants are different fields in that way.

B. Radioactive aerosol formation

When a radioactive nuclide decays, electrons are stripped from the parent atom by its recoil, and decay products are formed as positive ions. These ions can attract liquid and even solid material, thus forming clusters of atoms or particles in the submicron region ranging from 0.001 to 0.01 μm. Air is permanently ionized by radiation from natural radioactivity of air and by cosmic radiation, which consists mostly of positively charged particles, 85% protons, 10% alpha particles, and, in smaller percentage, stripped nuclei of heavier elements being positively charged, such as Fe, Co, and Ni. Production of an ion pair requires 35.6 eV, if ionization is by alpha particles and 32.5 eV, if ionization is by fast electrons. In the free atmosphere, the rate of production of small ions is in balance with the rate of neutralization by recombination and the rate of attachment to condensation nuclei. Condensation nuclei are mostly the Aitken nuclei, which are submicrometer particles in the range of 0.005−0.01 μm.

In air containing water vapor, the positive ions are mostly hydrated protons, p^+ or H^+ $(H_2O)_n$, where n may be any number between 1 and 8. Negative ions are probably mostly hydrated O^- or OH^-. The formation of clusters of water molecules around ions is very rapid, but the clusters do not grow beyond about 0.001 μm (1 nm) diameter and remain as small ions until they become attached to condensation nuclei. They then become large ions. Large ions themselves can be classified into two size ranges. The nuclei mode (Aitken nuclei) centered on 0.01 μm (10 nm) is distinct from the accumulation mode, centered on 0.1 μm (100 nm). The number of particles in the nuclei mode is greater than the number in the accumulation mode, but their total surface area is less, and it is surface area, which determines the probability of attachment of small ions to particles with diameter of order of 0.1 μm (100 nm) or less (Papastefanou and Bondietti, 1987; Gini et al., 2013). Thus, the large ions are mostly in the accumulation mode. The distinction between small and large ions is well established in atmospheric electricity. The existence of intermediate ions in the size range of 0.001−0.010 μm (1−10 nm) has

been confirmed. If sulfate or nitrate vapors are present in air, their molecules would be dissolved in the water clusters, and these will then grow into the intermediate ion range.

A possible mechanism for formation of radiolytic nuclei is radiolysis of water, leading to formation of H_2O_2, which then oxidizes traces of SO_2 to give H_2SO_4. Addition of O_3 to the air can also increase nuclei production, whereas addition of NO, a well-known radical scavenger, can inhibit it.

The radionuclide ions in the atmosphere exist in two forms: (1) as "unattached clusters" with a diffusion equivalent diameter size ranging from 0.5 to 5 nm and (2) as "aerosol-attached clusters" with particle diameters varying between 5 and 3000 nm. Reported values of the diffusion coefficients in the literature range from 0.01 to 0.1 cm^2/s (Raabe, 1968; Porstendörfer and Mercer, 1979). Most of the previous studies on the diffusion coefficient did not consider the importance of the electrical charge of the radionuclide ions and the air humidity. Neutralization of radionuclide ions depends on their concentrations and on the humidity in air.

Dankelman et al. (2001) determined the neutralization rates of ^{218}Po ions in air by electron transfer process in "normal" environmental outdoor and indoor air with natural trace gases and found that it is small and can be neglected under "normal humidity" (RH: 30−95%) and radionuclide concentrations.

Radioactive aerosols emit charged particles and, thus, themselves become charged (Barrett et al., 2009). A common case is the beta-emitting aerosols, such as the radioactive fission products, that could be released into the atmosphere in certain conceivable (although extremely unlikely) accidents in nuclear reactors (Chernobyl reactor accident, April 26, 1986). The emitted beta particles will cause ionization in the atmosphere, and these ions can subsequently attach to the aerosol. Due to the highly ionized environment, the net mean charge on the aerosol is small, although it may be sufficient to affect coagulation (Clement et al., 1995). However, Clement and Harisson (1992, 2000) have noted that, in the environment, charging effects can be important.

Vivas et al. (2008) developed a low-level radioactive charger based on ^{241}Am (0.24 μCi). The performance of the weak radioactive ^{241}Am ionizer was assessed experimentally and by means of a numerical model based on Fuchs theory. The results showed that the ^{241}Am ionizer charges to steady-state aerosol particles less than 250 nm at number concentrations up to 106/cm^3 at a maximum flow rate of 2.51/min. These conditions correspond to values of the particle to ion concentration ratio less than unity and a residence time of 5 seconds. For particle to ion concentrations above unity, the model predicts that the time to steady state increases strongly with both particle size and aerosol particle concentration. Aerosol particle charging can be controlled and brought to an equilibrium charge distribution when exposed to an excess of an ionized air stream by means of a radioactive source. The charge distribution of what is defined a Boltzmann equilibrium has been empirically calculated by Wiedensohler (1988).

II. Radioactive aerosol sampling and measurement

A. Aerodynamic particle sizing

Very early, Aitken (1923) showed that most particles in the atmosphere were smaller than 0.1 μm diameter and that their concentration varied from some hundreds per cm^3 over the ocean to millions per cm^3 in urban areas. Junge (1955, 1963, 1972) measured the atmospheric aerosol number size distribution and concentration in urban and nonurban areas as functions of altitudes and site. He established the standard form for plotting size distribution data: log of dN/dD_p versus log D_p, where N is the number and D_p is the particle diameter. He observed that this plot was a straight line that could be described by the equation: $dN/dDp = AD_p^{-k}$, where A and k were constants. He also noted that in the range from 0.1 to 10.0 μm particle diameter, k was approximately equal to 4.0. This distribution mode was widely known as "Junge distribution" or "the power law distribution."

Friedlander (1961) later showed that by balancing the aerosol source and removal rates, a portion of the resultant theoretical number distribution steady state could be fitted reasonably well by Junge distribution. Clark and Whitby (1967), by fitting the Junge distribution to 52 atmospheric distributions, found that the constant A was equal to 0.4 multiplied by the aerosol volume concentration ($\mu m^3/cm^3$). This agrees with the value predicted by Friedlander.

Whitby et al. (1972, 1975) found that, although the number size distribution established by Junge was not a good model, the surface and mass or volume-size distribution was normally bimodal, with one mode being approximately 0.3 μm diameter and the other ranging from 5.0 to 15.0 μm diameter.

In Fig. 4.2 (Seinfeld and Pandis, 2016), the normalized frequency plots of number, surface, and volume or mass distributions are presented. Note the bimodal distribution of mass. Each weighting shows features of the distribution not shown by the other plots. In Fig. 4.2, the apparent area under the curves is proportional to the number, surface area, and volume or mass in a given size range. Most particles, i.e., the number distribution, are <0.01 μm diameter. The number of particles decreases sharply with increasing size. The volume or mass distribution is bimodal: one mode is approximately 0.7 μm diameter, and the other is approximately 7.0 μm diameter. The mass of

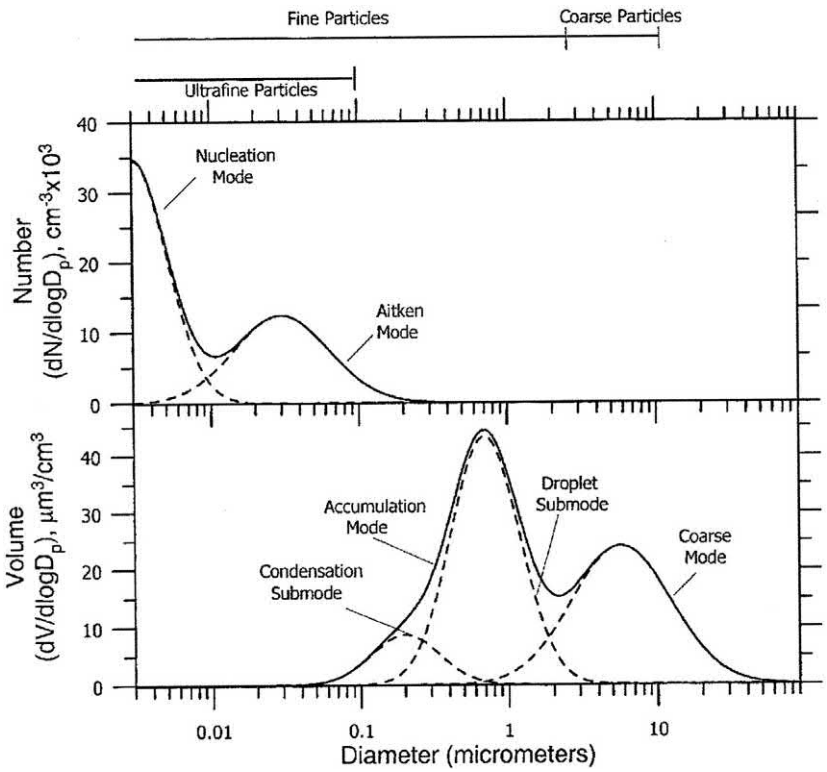

FIGURE 4.2 Typical number and volume distributions of atmospheric particles with the different modes. *From Seinfeld and Pandis (2016); reprinted with permission from John Wiley and Sons © 2016.*

fine particles of size smaller than 2.0 μm is almost equal to the mass of coarse particles with size larger than 2.0 μm.

Atmospheric aerosol size distributions consist basically of three separate modes:

1. Aitken nuclei mode for smaller than 0.1 μm diameter particles, i.e., 0.015 μm
2. Accumulation mode for smaller than 2.0 μm but larger than 0.1 μm diameter particles, i.e., 0.3 μm
3. Coarse mode for larger than 2.0 μm diameter particles, i.e., 10.0 μm

Depending on their source, there may be from one to three distinct maxima as peaks in the surface and volume or mass distributions. *The activity size distribution of radionuclide-associated aerosol particles is surface distribution* (Gini et al., 2013, 2016).

Washout by rain greatly reduces the Aitken nuclei mode and coarse-particle mode but has little effect on the accumulation mode in the trimodal size distribution (Whitby, 1975). The origin of each mode of atmospheric aerosol size distribution can be associated with various aerosol formation mechanisms, such as Brownian motion of particles smaller than 0.1 μm in diameter, which causes the particles to diffuse and by collisions to coagulate to larger sizes. Coagulation generates multimodal distributions and affects the shape and the chemical composition of particles. The aerodynamic size distribution of radionuclide-associated aerosol particles is, as mentioned above, a surface distribution, and so it is trimodal, the first mode being the so-called Aitken nuclei mode, the second the accumulation mode, and the third the coarse-particle mode. Analytically, these modes can be summarized as follows.

1. Aitken nuclei mode particles

The nuclei or Aitken nuclei mode accounts for most of the Aitken nuclei count and originates primarily from the condensation and coagulation of highly supersaturated vapors. There is evidence that a prominent nuclei mode in the size distribution indicates the presence of substantial amounts of fresh aerosol. Many particles in the nuclei mode raise the Aitken nuclei. Usually, they do not greatly increase the aerosol mass concentration because the nuclei mode rarely accounts for more than a few percent of the total mass.

Whitby et al. (1975) found that the nuclei mode might contain over 25 mg/m^3 of aerosol. Whitby et al. (1976) also observed distributions in which the nuclei mode contained more volume than the accumulation mode. Because particles may serve as nuclei for the condensation of water vapor, condensation is an important growth mechanism for submicrometer aerosol particles. Examples are fogs and hazes formed when the humidity exceeds 60%.

2. Accumulation mode particles

The twin mechanisms of coagulation and heterogeneous nucleation (condensation of one material to another) tend to accumulate the submicrometer aerosol particle mass in this mode (Whitby and Cantrell, 1976; Willeke and Whitby, 1975). Because of the sharp decrease in the particles, larger than 0.3 μm in diameter, little mass is transferred from the accumulation mode to the coarse-particle-size range. Sedimentation and impaction tend to increase the relative concentration of the smallest mechanically produced particles and then accumulate in this mode. Salt from sea spray is typically present as particles in the 1−5 μm size range, outside the normal accumulation mode.

The radionuclide-associated aerosols (radioactive aerosols) peak in the accumulation mode, as this mode is the main one in terms of surface area distribution (Papastefanou and Bondietti, 1987; NRC, 1979) (Fig. 4.2).

3. Coarse-particle mode particles

In the coarse-particle mode, practically all aerosol particles at a relative humidity (RH) below 100% originate from mechanical processes. Most of the particles originate from condensation processes occurring in the atmosphere. Coarse particles are produced from natural and/or man-made (anthropogenic) mechanical processes. The origin, behavior, and removal processes of fine particles are almost entirely independent of the coarse particles.

The multimodal nature of the size mass distribution is supported by evidence from the size distributions of chemical elements, radionuclides, or compounds in aerosols. These are emitted as smokes or fumes and exist mostly in the fine particle size range. These aerosols eventually coagulate and become mixed throughout the accumulation mode. In the accumulation mode, the geometric mean size is nearly equal to the mass or volume geometric mean size. Elements in the soil, e.g., silicon, are mostly in the coarse-particle-size range. Elements, such as sulfur, which are produced by condensation processes from anthropogenic sources, are principally in the fine particle-size range. The size distribution of elements in the soil is similar to the mass distribution of the coarse-particle mode.

B. Instrumentation

The great diversity of application, the size range of atmospheric aerosol particles, the physical and chemical concentration variations, and the variety of measurement principles available imply many different combinations of application and measurement methods and procedures. It is impossible to obtain particle size information on the entire five-decade size range of 0.001−100 μm. Therefore, one expects to apply different instrumental techniques, measuring different size parameters, for submicrometer versus supermicrometer-sized aerosols. The methods applied for atmospheric aerosol sampling include filters and cascade impactors, which collect the aerosol particles onto a surface. The collected sample must therefore be evaluated for size and composition. Because accumulation mode aerosols (fine aerosol particles) contain a substantial fraction of liquid material at normal temperatures and humidity, these fine aerosol particles must be sized in situ without precipitation. In some extreme cases, such as the case of Los Angeles smog, the liquid content may be as high as 75% or 80% of the total mass (Ho et al., 1974).

Many aerosol measuring techniques (methods), such as the condensation nuclei counter (CNC), and filter collectors, integrate some response function of the instrument with the particle-size distribution. In the particle-counting method, the response is essentially equal to the integral of the number distribution weighting. By weighing the filter, the integrating measurement is the integral of the mass weighting of the distribution. Cascade impactors, such as Lundgren impactors, designed with inlet cutoffs well above those used for atmospheric aerosol sampling, showed that particles up to several hundreds of micrometers in diameter were present in the atmosphere under certain conditions (Lundgren, 1973). Most mass sampling methods, including the high-volume sampler (Stevens et al., 1976), truncate the distribution, thereby giving concentrations less than those actually existing.

Due to the simplicity of construction and use and the relative sharp cutoff characteristics, cascade impactors have been widely used for the size classification and size-classified chemical analysis of aerosols. Table 4.1 lists the most important integrating sampling methods with their main characteristics. Table 4.2 gives the most important differential, size-resolving methods used by aerosol cascade impactors to sample and measure atmospheric aerosol particles. The part of the particle-size distribution and the modes that dominate the sensitivity of the methods are indicated. The upper and lower size limits are nominal values for the most commonly used methods. Cost, complexity, operational requirements, calibration problems, and the demands of the particular evaluation to be used also affect the choice of methods. For example, chemical analysis usually requires that a sample be collected and then taken to the evaluation device. This normally requires a collection-type method, such as the high-volume filter collectors. Simplicity during sampling may mandate the use of a particular collection method despite its disadvantages. The rapid development of modern electronics and inexpensive acquisition systems has led to in situ, automatic, and complex monitoring techniques. Collection methods are being replaced with both physical and chemical analyses in situ, automatic methods, and digital electronic devices.

TABLE 4.1 Major integral sampling and measurement methods used for measuring atmospheric aerosols.

Method or instrument	Effective size limit (μm)		Lower concentration limit	Measurement principle
	Lower	Upper		
Hi-vol filter and other filters—measures all of the nonvolatile mass in accumulation mode and most of that in the coarse-particle mode depending on sampling efficiency.	None	25	2 $\mu g/m^3$	Filter weighing
Integrating nephelometer—essentially responsive to the in situ mass in the accumulation mode only.	0.15	2	1% of air scattering (about 1 $\mu g/m^3$)	Light scattering
Condensation or Aitken nuclei counter (ANC)—for combustion-dominated aerosols, measures the nuclei mode; for aged aerosols, measures number in accumulation mode.	0.0035	0.05–0.2	1 cm^3	Condensation—high supersaturation
Electrostatic charger—with diffusion charging upper limit is about 2 μm; senses both nuclei and accumulation modes.	0.007–0.02	2–25	1 $\mu g/m^3$	Charging and precipitation
Cloud condensation nuclei counter (CNC)—lower size limit depends on supersaturation and design; measures part of nuclei mode and most of accumulation mode.	0.01	1	100 cm^3	Condensation – low supersaturation
Ice nuclei counter (INC)—measures only those few particles capable of causing supercooled water drops to freeze; responsive to part of the accumulation mode sizes and most of the coarse-particle mode sizes.	None	Unknown	10^{-5}/L	Ice nucleation
Quartz crystal—electrostatic version measures nuclei and accumulation modes and part of coarse-particle mode; impaction version measures two-thirds of accumulation mode and most of the coarse-particle mode.	0.01 electrostatic; 0.3 impactor	10; 20	1 $\mu g/m^3$	Frequency charge of crystal
β attenuation—performance dependent on counting period, collection surface mass.	None (on filter)	20	2–5 $\mu g/m^3$	*β* attenuation
Contact electrification—useful only for high concentrations; sensitivity varies over 50/1 range for different materials.	10	1000	100 $\mu g/m^3$	Impact and charge measurement
Dust fall—relation to concentration is very dependent on location, wind velocity, and collector design.	5	None	None	Settling and weighing
Acoustic counter—has been used primarily to count ice crystals as a sensor on ice nuclei counter.	5	100	1/L	Acoustic pulse from particle transit

TABLE 4.2 Major size-resolving methods used for measuring atmospheric aerosols.

Method or instrument	Effective size limit (μm)		Maximum number of size intervals practical	Lower concentration limit (μm)	Measurement principle
	Lower	Upper			
Cascade impactors—measures one-half to two-thirds of accumulation mode, all of coarse-particle mode; particle bounce is a serious problem in some applications.	0 (filter) 0.3 (last stage)	30	8	1 μg/m^3/stage	Inertial impaction
Dichotomous virtual impactors—one filter collects fine particles and one collects coarse particles; no bounce problem.	0 (filter) 2 (for cut on 2nd filter)	30	2	1 μg/m^3/stage	Virtual impaction
Crystal microbalance impactor—measures one-half of nuclei mode, all of accumulation mode and coarse-particle mode; subject to particle bounce on dry aerosols.	0 (filter) 0.06 (last stage)	30	10	0.02 μg/stage 1 μg/m^3/stage	Impaction, quartz crystal sensing
Spiral centrifuge—measures one-half of nuclei mode, all of accumulation mode, and part of coarse-particle mode; sensitivity depends on method of evaluation; mass determination is difficult.	0.06	10	20	10 μg/m^3	Centrifuge onto filter
Optical particle counters—single counter useful for only one decade of size; requires calibration; sensitive to shape and refractive index.	0.3 (commercial) 0.1 (research)	3 −100	>200 passible 20 useful	1 particle/L	Light scattering from single particles
Electric mobility—can measure nuclei and accumulation modes; can resolve σ_g of 1.4 without correction and 1.25 σ_g with correction.	0.006	1	15	1 μg/m^3	Diffusion charging and electric mobility measurement

1. High-volume air samplers

A high-volume sampler or a total suspended particulate (TSP) high-volume air sampler is used for the collection of TSP matter in ambient air with no preference to size selection. It is used to determine the concentration of TSPs, or it can be used to determine the identity of the particulates. It does not use a particle separator, which results in the collection of all ambient particulates.

The TSP high-volume air sampler collects particulates at a flow rate between 40 and 60 ft^3/min over a constant sampling period. The vacuum motors pull ambient air onto an 8 × 10 inch (1 inch = 2.54 cm) filter media (glass fiber, paper, quartz fiber filters) (Fig. 4.3). The filters are weighed pre- and postsample, and the weight is used to determine the TSP matter.

A TSP high-volume sampler can be composed of an anodized aluminum outdoor shelter with a gabled roof assembly. The sampler can also include a timing device to turn the instrument on and off, a filter holder to hold the filter media in place, a vacuum motor, a device to control the flow, a pressure recorder to record the flow rate, and an elapsed time indicator to count the sample time (Fig. 4.4).

2. Aerosol cascade impactors

Cascade impactors are instruments, which have been extensively used for sampling and separating airborne particles for determining the aerodynamic size classification of aerosol particles. There are three kinds of cascade impactors: inertial impactors, virtual impactors, and particle trap impactors. These are made by aluminum, 316 stainless steel, and titanium.

Inertial impactors have been used extensively to measure aerosol size distribution and to collect samples for further chemical analysis. It consists of an acceleration nozzle and a flat plate. In inertial impactors, particles larger than the cutoff diameter of the impactor will impact on the collection plate, whereas particles smaller than the cutoff diameter will follow the streamlines and not collected on the plate. Many researchers have investigated inertial impactors to collect and separate aerosol particles and found

inherent problems, which were particle bounce and reentrainment (Dzubay and Rickel, 1978; Markowski, 1984; Marple, 1970; Marple and Liu, 1974).

Virtual impactors have been designed to eliminate problems of bounce and reentrainment and to allow the collection of larger particles (Chen et al., 1986; Marple and Chein, 1980). In a virtual impactor, the intake air is typically divided into two air streams: the major and the minor flow. The major flow carries most of the fine particles smaller than the cutoff diameter, and the minor flow carries all the coarse particles above the cutoff diameter with a small fraction of the fine particles. Various studies on virtual impactors have been carried out for particle collection and concentration since the late 1980s. Meyer and Lee (1994) used a virtual impactor as a means for concentrating metal aerosol suspended in the air to enhance the performance of an inductively coupled plasma analyzer. Kim et al. (2000) designed and tested multinozzle virtual impactors for high-volume particle collection. Virtual impactors, however, have an inherent problem that a small fraction of the fine particles is collected with large particles.

A particle trap impactor (cup impactor) has been designed by Biswas and Flagan (1988), who intended to collect particles in the trap rather than to sample aerosol particles. Tsai and Cheng (1995) investigated the effect of solid-particle loading on the collection efficiency of an impactor with different impaction surface designs. The particle-trap impactor was applied to a sampling inlet with a cutoff diameter of 10 or 2.5 μm (Kim et al., 1998, 2003). Major advantages of the particle-trap impactors are their freedom from particle bounce-off and the problem of overload. The designs of particle trap impactors are based on those of inertial impactors and virtual impactors. The particle trap impactors are similar to inertial impactors in that they use inertial force and do not have a minor flow rate. Also, the particle-trap impactors are somewhat similar

to virtual impactors in that they have virtual space to collect the particles.

Even though inertial and virtual impactors have been widely used for aerosol collection and separation, particle-trap impactors have not been used extensively. Further studies on particle-trap impactors are needed. In addition, most of particle-trap impactors employ the design of inertial impactors for their design parameters, though actually the design of particle-trap impactors is different from that of inertial impactors. Therefore, there still remains the necessity for the study on the accurate design parameters of the particle-trap impactors.

The earliest and most fundamental work in inertial impactor theory was conducted in the early 1950s by Ranz and Wong (1952). In this work, they showed that the collection of a particle by an obstacle is a function of what is defined as the inertial impaction parameter:

$$K = \frac{C\rho_p U D_p^2}{18\mu D_c} \tag{4.1}$$

where U is the relative velocity, ρ_p is the particle density, D_p is the particle diameter, μ is the gas viscosity, D_c is the diameter of the round jet, and C is the Cunningham slip correction factor.

Data from inertial cascade impactors are normally presented as 50% effective cutoff diameters (ECDs). For the Andersen cascade impactors, containing round jets, and flat collection surfaces, the 50% ECD would yield a value of 0.14 for the inertial impaction parameter K. The Cunningham slip correction factor is equal to

$$C = 1 + 0.16x10^{-4}/Dp$$

for normal temperatures and pressures. This factor corrects for the fact that as particle diameters approach the mean free path length of the gas molecules, they tend to "slip" between gas molecules more easily and are therefore more easily able to cross the bulk flow streamlines. The collection efficiency is therefore slightly greater than that would be predicted by inertial impaction theory for particle diameters of the order of 1 or 2 μm. The overlapping of particle size between stages, which is naturally inherent in all cascade impaction devices, is minimized in Andersen's samplers by design. Ranz and Wong (1952) noted that as a particle passes through a jet, its nearness to the axis of the jet is one of the factors that determines whether or not the particle will reach the impaction surface. In contrast to competitive samplers, which have larger rectangular jets in each stage, the Andersen sampler has 400 small, round jets. Travel of the particle is thus confined near the axis of the jets. The average distance of the particles from the axis of the jets is very much less than in other cascade impactors. Ranz and Wong (1952) also observed that round jets have sharper cutoffs than rectangular jets. The Andersen sampler, therefore, on a theoretical basis, should have a sharper cutoff.

Another inherent advantage of the Andersen air samplers is that single circular orifice and multiple rectangular orifice impactors by design must operate with high orifice velocities. This results in more turbulent flow, greater reentrainment, and a skewing of the size distribution toward the lower end, i.e., the indicated size distribution being smaller than it really is.

The basic configuration shown in Fig. 4.5 (Mercer et al., 1970; Andersen, 1976; Marple and Willeke, 1979; Raabe, 1979) is simple. A jet of aerosol from a nozzle is directed at an impaction surface: the high inertia; large particles cross the air streamlines and strike the impaction plate, whereas the smaller particles with less inertia are not collected but remain airborne and pass onto a second nozzle-impactor plate arrangement. The second nozzle is of a smaller diameter than the first nozzle, which increases the velocity and inertia of all the remaining aerosol particles. The larger of the previously uncollected particles thus have sufficient inertia to be collected by the second stage. This process continues as the aerosol stream enters successive stages of the cascade impactor. The final element of a cascade

impactor is usually a filter, which collects all particles too small to be collected by the last impaction stage. The nozzles of each stage can be of any shape but are normally rectangular or round. The nozzles of each stage of the Andersen cascade impactors are round. Many cascade impactors have several nozzles of an identical size at a given stage with the aerosol jets from the nozzles impinging upon a common impaction surface.

The most important characteristic of an impactor stage is the collection efficiency curve, which gives the fraction of particles of a given size collected from the incident aerosol stream as a function of particle size. Ideally, an impactor would collect all particles larger than a certain size and none of the smaller ones, which would correspond to the sharp ideal cutoff illustrated in Fig. 4.6. The efficiency curve of a typical real impactor, also shown in Fig. 4.6, spans over a range of particle sizes but still has a good sharpness of cut. It has been shown (Marple and Liu, 1975) that ideal impactor behavior can be obtained, if the following two requirements are met:

1. In the region between the jet exit plane and the impaction plate, the Y-component of fluid velocity is a function of Y only (Y is parallel to the center line of the nozzle, Fig. 4.7).
2. The Y-component of the velocity of the particles as the jet exit plane is uniform across the jet.

These two requirements are reduced to only the first requirement, if the velocity of the particles is equal to the fluid velocity at the exit plane of the jet. Such requirements are nearly met in a real impactor, as can be seen by the velocity profiles in Fig. 4.7 for a rectangular impactor. It can be seen that the velocity component perpendicular to the jet exit plane, Vy, is independent of X over a major portion of the jet, where X is the distance from the jet center line. However, this criterion is not met in the boundary layer near the wall. Particles passing through this region are the cause for the nonideal cutoff characteristics at the larger efficiencies of the real impactor performance curve shown in Fig. 4.6. A schematic diagram of Andersen cascade impactor stages is shown in Fig. 4.8 (Marple and Willeke, 1979). This figure shows how impaction occurs at the orifice–collector interfaces. The use of an impactor with a single circular orifice for each jet provides a convenient method for determining the aerodynamic size distribution of an easily assayed aerosol such as of radioactive material (Raabe, 1979). Submicrometer aerosols, or condensation nuclei, in the diameter are most readily measured for number concentration and size distribution by diffusion batteries and CNCs (Sinclair et al., 1979).

The impaction characteristics of the cascade impactors are governed by the fluid's velocity flow field, which in turn is specified by the Navier-Stokes equations. A solution of the Navier-Stokes equations (Marple et al., 1974) reveals that the velocity flow field is a function of the physical configuration of the impactor and the Reynolds number, *Re*, of the flow passing through the nozzle. The Reynolds number is dimensionless and, based on the hydraulic diameter of the nozzle, is defined as

$$R_e = \frac{\rho V_0 W}{\mu} \tag{4.2}$$

For round cascade impactors, and

$$R_e = \frac{\rho V_0 2W}{\mu} \tag{4.3}$$

for rectangular cascade impactors, where r is the fluid density, in g/cm^3, V_0 is the mean velocity at the nozzle throat,

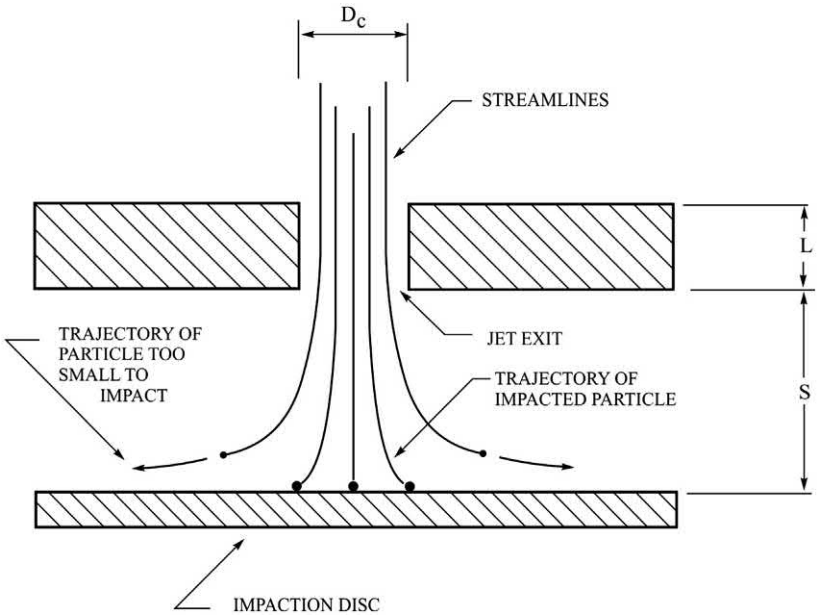

FIGURE 4.8 A schematic diagram of an aerosol cascade impactor stage. *From Tisch Environmental, Inc. (1999). Printed with permission from Tisch Environmental © 1999.*

in cm/s, W is the nozzle diameter or width, in cm, and μ is the fluid viscosity, in poise (g/cm s). Furthermore, the trajectory of the aerosol particles in the flow field, which determines whether or not the particles are collected, is found by solving the particles' equation of motion (Marple and Liu, 1974), the solution of which is a function of the particles' Stokes number and of the parameters that characterize the flow field. The Stokes number is defined as the ratio of the aerodynamic particle stopping distance to the radius, or half-width, of the impactor throat

$$Stk = \frac{\rho_p C V_0 D_p^2 \Big/ 18\mu}{W/2} \tag{4.4}$$

where ρ_p is the particle density, in g/cm^3, C is the Cunningham slip correction factor, and Dp is the particle diameter, in cm. The square root of the Stokes number, $(Stk)^{1/2}$, is a dimensionless particle size.

The collection efficiency of a cascade impactor is, therefore, a function of the Stokes number, the Reynolds number, and the physical configuration of the impactor. It has been found that the physical configuration for either a round or rectangular nozzle can be sufficiently specified by the value of nozzle's diameter or width, W, the nozzle-to-plate distance, S, and the nozzle throat length, T (Marple, 1970). Since the Stokes number and the Reynolds number are dimensionless, it is convenient to express the physical dimensions in dimensionless form by expressing all dimensions in units of the jet width, such as S/W and T/W.

The inertial cascade impactors are multistage cascade impactors. The Mercer-style cascade impactor is a seven-stage cascade impactor operating at low flow rate, e.g., 50−150 cm^3/min (Mercer et al., 1970; Raabe, 1979). Other inertial impactors are the Andersen cascade impactors, such as the 1 ACFM (actual cubic feet per minute) eight-stage cascade impactor operating at a flow rate of 28 L/min, which is described in the next paragraphs (Andersen, 1976), the Lundgren-type eight-stage cascade impactor operating at a flow rate of 1 L/min, with the samples at stages collected on Teflon, and the final stage being quartz (Lundgren, 1967; Marley et al., 2000), and the Berner-type nine-stage low-pressure cascade impactor (LPI) with a nominal volumetric flow rate of 28.9 L/min (1 ACFM), with the samples at stages collected on aluminum foil (Berner and Lurzer, 1980; Winkler et al., 1998). In this category also is classified the dichotomous sampler, which is used for air pollution studies and utilizes a virtual impactor with two emerging aerosol flows to separate the coarse and fine fractions of atmospheric aerosol particles and operates at 1 m^3/h (16 L/min) (Hinds, 1999).

The aerosols are collected on impaction substrates stamped from Teflon, aluminum foils, polycarbonate membranes from all stages of the cascade impactors of any type, and the smallest fraction on the backup glass fiber filter. After the end of collection, the collecting substrates are carefully removed from the impactor and are reweighed for evaluation of the size distribution, i.e., mass or volume distribution of the particles. Then, the substrates are folded and compressed to provide suitable geometry for measurement of the activity of radionuclides associated with aerosol particles with a high-resolution and high-efficiency low-background gamma ray spectrometric system linked

with a high-purity Ge detector for the determination of the activity size distribution of the radioactive aerosols.

Aerosol particulates in the atmosphere could be measured also by a standard gravimetric technique described by Qadir and Zaidi (2006).

Singh et al. (2010) developed a variable configuration cascade impactor (VCCI) comprised of seven normal-pressure and four low-pressure stages for aerosol size distribution measurements. In configuration 1, it operates as a low-pressure impactor with a sampling flow rate of 10 L/min and classifies the particles from 0.1 to 21 μm in 11 size classes. In configuration 2, it operates as a normal-pressure impactor, with a sampling flow rate of 45 L/min and classifies the particles from 0.53 to 10 μm in seven size classes.

a. Description

The Andersen 1 ACFM ambient aerosol sampler (Andersen, 1976) comprises the following:

Eight aluminum stages are held together by three spring clamps and gasketed with O-ring seals (Fig. 4.9). Each impactor stage contains multiple precision-drilled orifices. When air is drawn through the aerosol sampler, multiple jets of air in each stage direct any airborne particles toward the surface of the collection plate for that stage. The size of jets is constant for each stage but is smaller in each succeeding stage. Whether a particle is impacted on any stage depends on its aerodynamic dimension. The range of particle sizes collected on each stage depends on the jet velocity of the stage and the cutoff of the previous stage. Any particle not collected on the first stage follows the air stream around the edge of the plate to the next stage, where it is either impacted or passed onto the succeeding stage, and so on until the jet velocity is sufficient for impaction.

Stages 0–6 have integral air inlet sections that contain 400 orifices. Stage 7 contains 201 orifices. The inlet sections are approximately 3.125″ (inches) in diameter. The orifices are progressively smaller from top to bottom stages, ranging from 0.0625″ diameter in stage 0 to 0.0100″ diameter in stage 7. Each stage has a removable stainless steel or glass (3.25″ diameter) collection plate. The exhaust section of each stage is approximately 0.75″ larger in diameter than the collection plate, allowing unimpacted particles to go around the plate and into the next stage (Fig. 4.10).

A constant air sample flow of 1 ACFM aerosol cascade impactor, that is 28.316 L/min, is provided by a continuous duty vacuum pump. Flow rate is controlled by an adjustable valve on the pump, and periodic calibration is needed. Flow rate adjustments are also needed. The aerosol cascade impactor is supplied with a built-in backup filter, which will

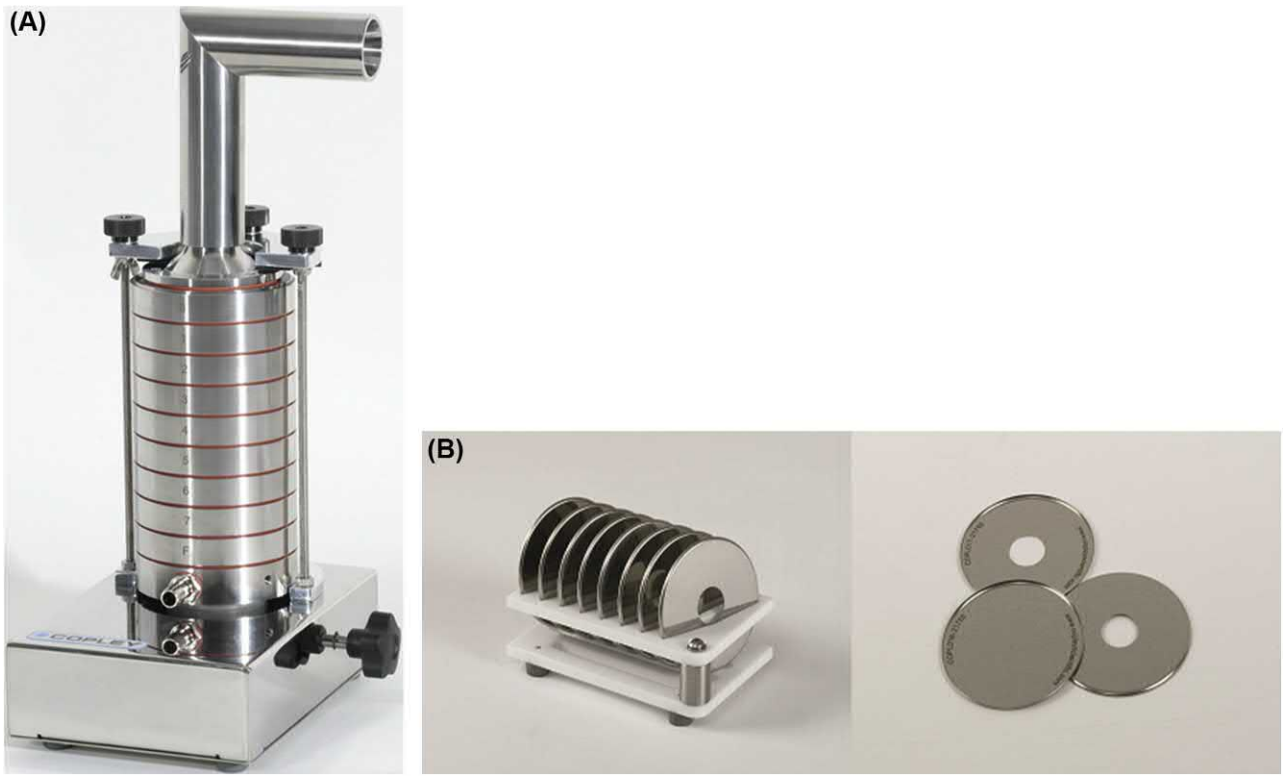

FIGURE 4.9 (A) Eight-stage nonviable Andersen cascade impactor (ACI) and (B) ACI collection plates. For the color version of the figure, the reader is referred to the online version of the book. *(B) From Copley Scientific. Printed with permission from Copley Scientific.*

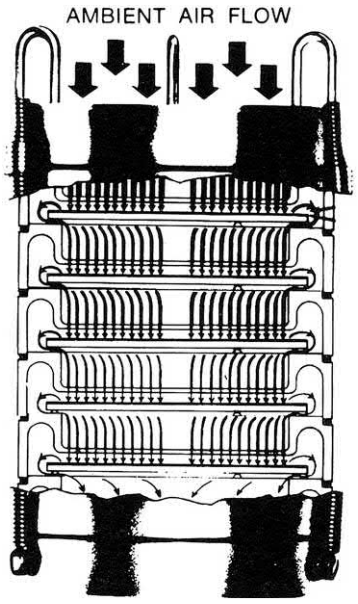

FIGURE 4.10 A schematic cross section view of the nonviable impactor stages. Progressively smaller orifices increase the orifice velocity in eight successive stages causing impaction of smaller aerosol particles onto the collection disks of each succeeding stage. *From Tisch Environmental, Inc. (1999). Printed with permission from TISCH Environmental Copyright 1999.*

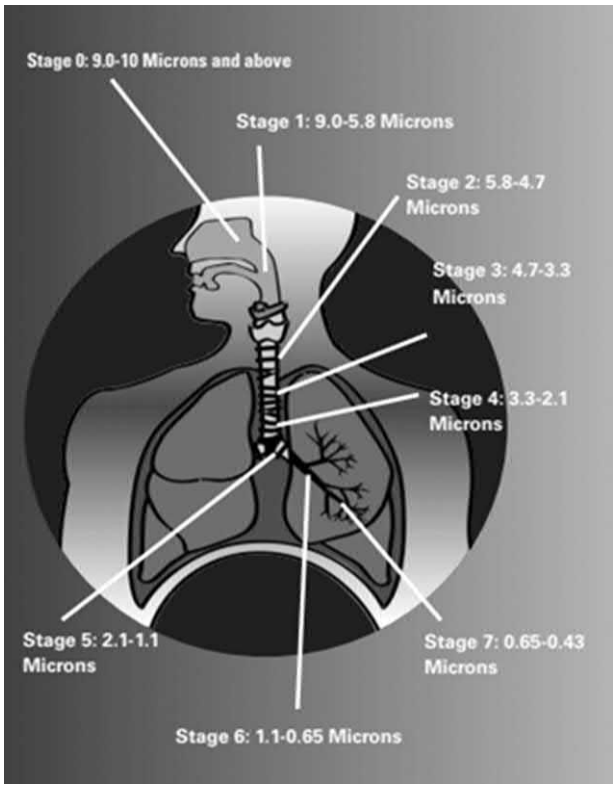

FIGURE 4.11 The 1 ACFM (actual cubic feet per minute) cascade impactor has been designed on the basis of the workings of the human respiratory system. *ThermoFisher Brochure. Printed with permission from ThermoFisher.*

accommodate an 81-μm filter disk. Normally, a binderless glass fiber filter medium is used because of its high collection efficiency for submicrometer aerosol particles. The 1 ACFM cascade impactor has been designed on the basis of the workings of the human respiratory system (Fig. 4.11)

The following are the ECDs for each stage of 1 ACFM cascade impactor (Table 4.3).

The Andersen LPI (Andersen, 1984) is really an adaptor assembly, which is used with stages 0−7 of an Andersen 1 ACFM ambient aerosol cascade impactor to extend the range of particle classification below 0.4 μm. Standard aerosol cascade impactors are normally used to classify particles down to approximately 0.4 μm aerodynamic diameter. However, many aerosols such as cigarette smoke and diesel exhaust are predominantly sub-0.4 μm in diameter. The 50% effective cutpoint of an impactor is given by

$$D_{p50} = \left(\frac{9\mu STK_{50}D_j}{\rho_p C V_j}\right)^{1\frac{1}{2}} \tag{4.5}$$

where μ is the gas viscosity, in poise (g/cm s); STK_{50} is the Stokes number (dimensionless); D_j is the jet diameter, in cm; ρ_p is the particle density, in g/cm^3; C is the Cunningham slip correction factor; and V_j is the jet velocity, in cm/s. For any given geometry, the gas viscosity, Stokes number, and particle density are fixed.

Therefore, to get a smaller cutpoint, the diameter of the jet can be reduced to increase the velocity through the jet or increase the Cunningham slip correction factor. Reducing the jet diameter to less than 0.0254 cm is difficult because the jet to collection surface spacing should be less than 10 jet diameters. Increasing the jet velocity causes unacceptable levels of particle bouncing. That leaves the Cunningham slip correction factor as the best variable.

The Cunningham slip correction factor is a measure of how easily a particle can slip in between gas molecules when crossing the bulk flow streams to reach the impaction surface. Reducing the gas pressure will increase the Cunningham slip correction factor. The Andersen LPI represents the state of the art for the particle sizing devices.

The low-pressure configuration includes eight atmospheric pressure stages and five low-pressure stages. The complete assembly consists of the following:

1. Brass hose barb connector for gas outlet
2. Base plate with three hold-down bolts
3. Stage LF—low-pressure filter stage
4. Stages L5, L4, L3, L2, and L1—low-pressure impactor stages

TABLE 4.3 Effective cutoff diameters (ECDs, in μm) of 1 ACFM (actual cubic feet per minute) Andersen-type cascade impactor stages.

Stage	ECD (μm)	Size range (μm)	Number of orifices
0	11.0	11.0 and above	400
1	7.0	7.0–11.0	400
2	4.7	4.7–7.0	400
3	3.3	3.3–4.7	400
4	2.1	2.1–3.3	400
5	1.1	1.1–2.1	400
6	0.7	0.7–1.1	400
7	0.4	0.4–0.7	201
F	0	0–0.4	Filter holder

5. Critical orifice stage with brass pressure tap and three hold-down springs for atmospheric-pressure stages
6. Three nuts and washers for tightening down low-pressure section to seal
7. Stages 0, 1, 2, 3, 4, 5, 6, 7—atmospheric-pressure stages
8. Inlet cone
9. Seven solid stainless steel collection plates
10. Seven stainless steel collection plates with open centers
11. Collection substrates, solid
12. Collection substrates with open centers
13. Vacuum pump
14. Pressure-measuring device (manometer)

The following are the ECDs for each stage of LPI (Table 4.4).

Ideally the pressure tap downstream of the critical orifice should be connected to a precision absolute pressure gauge, so the absolute pressure can be measured directly. Alternately, the pressure tap can be connected to a 16″-0-16″ U-tube mercury manometer and used in conjunction with a mercury barometer to determine the absolute pressure downstream of the critical orifice.

The pump should be switched on to initiate aerosol sampling. The "bleed valve" is then quickly adjusted to obtain an absolute pressure at the pressure tap of 114 mm Hg (0.15 ATM or 4.4″ Hg). Other absolute pressures can be used, but the cutpoints of the low-pressure stages will have to be recalculated. At least 400 mm Hg (16″ Hg) pressure drop should be maintained across the critical orifice to maintain the critical airflow rate of 3 L/min. This means that the critical airflow can be maintained at elevations where the atmospheric pressure is greater than approximately 525 mm Hg.

TABLE 4.4 Effective cutoff diameters (ECDs, in μm) of the Andersen-type low-pressure cascade impactor stages.

Stage	ECD (μm)
0	35.0
1	21.7
2	15.7
3	10.5
4	6.6
5	3.3
6	2.0
7	1.4
L1	0.90
L2	0.52
L3	0.23
L4	0.11
L5	0.08
LF	0

The sampling time should be selected so as to collect at least 1 mg of particulate per stage and not over 10 mg per stage. The lower limit is based on weighing accuracy, and the upper limit is based on preventing overloading. As a rule of thumb, the aerosol sampling time using the LPI will be approximately a multiple of 10 times the sampling time using the standard 1 ACFM aerosol cascade impactor since the airflow rate is approximately 1/10. To minimize the aerosol sampling time, collection substrates should be used

to minimize tare weights, and extra care should be taken with all weight measurements to minimize weighing errors.

b. Assembly

The complete assembly of an Andersen 1 ACFM aerosol cascade impactor consists of an inlet cone, nine stages, eight collection plates, and a backup filter. The stages are numbered 0, 1, 2, 3, 4, 5, 6, 7, and F. Stage 0 is an orifice stage only. Stage F contains the collection plate for stage 7 and the backup filter. Each stage contains an O-ring (neoprene-standard, Teflon-optional) for sealing. In addition, there is a large diameter O-ring inside stage F, which holds the backup filter in place.

The impactor assembly begins by placing stage F on the base plate stage, which is bolted to the base plate. A preweighted glass fiber backup filter is inserted into stage F and the large diameter O-ring placed into position around the periphery of the filter. Next, a preweighted collection plate 7 is placed onto stage F, so that the plate rests on the three raised, notched metal seats to prevent plate movement. There is no differentiation between top and bottom for the glass plates. The stainless steel plates should be placed with the curved lip down, so that a raised, smooth surface is exposed for particle impingement. This is followed by stage 7, collection plate 6, stage 6, and so on until cone is positioned last.

It should be noted that there are three metal pins extending from the base of each orifice stage. These pins hold the collection plates in place, so that the aerosol sampler can be used in any sampling orientation. In addition, special collection substrates are used other than the glass and stainless steel plates because of lighter tare weight and/or specific analytical requirements. These collection materials consist of glass fiber, cellulose aluminum foil, vinyl metricel, and other materials, which must be placed into the inverted stainless steel collection plate. The substrate surface must be leveled with the top of the curved stainless steel lip to maintain jet to collection surface spacing. In this orientation, the aerosol sampler should be used in an upright position at all times. After the aerosol sampler has been assembled, the outlet nipple on the base stage is connected to the pump intake port with the rubber tubing supplied with the aerosol sampler.

In the assembly of an Andersen low-pressure aerosol cascade impactor, the pump should be checked to be certain that it is operating properly and is capable of pulling 3 L/min at 27″ Hg pressure drop. The pump is designed for these conditions; however, continuous operation at pressure drops greater than 28″ Hg can burn out the pump motor.

All collection substrates should be preconditioned, if necessary, and greased. The substrates for the low-pressure stages should always be greased if at all possible. Good results have been reported at temperatures up to 200°C (392°F) (Lundgren and Balfour, 1980). This high-viscosity spray may be applied directly onto the collection disks (aluminum foil) by passing the spray over the foils two or three times with the spray can held at arms length from the substrate. The greased foils should then be preconditioned in an oven at approximately 100°C (212°F) for approximately 1 hour to drive off any volatiles in the grease. The substrates should then be desiccated and weighed to obtain the tare weight of the greased foil. Once the substrate and backup filter tare weights have been documented, the sampler is ready to be assembled for operation.

High-volume slotted cascade impactor The High-volume cascade impactors attached to any high-volume air sampler fractionate suspended particulates into as many as six different size fractions. The slotted impactor design separates particulates from larger than 7.2 μm to less than 0.49 μm while operating at a flow rate of 40 cfm. The cascade design of this impactor collects particles on small lightweight substrates that are analyzed for respirable particulate matter. There are several models available with 1, 4, 5, and 6 impactor stages allowing for ultimate flexibility. Their cutoff diameters according to their flow rate are given in Table 4.5.

The mechanism is the following: suspended particulates enter through the high-volume cascade impactor through the first set of parallel slots on the first stage. Particulates that are too large to travel to the next stage are impacted on the collection substrate, and the smaller particles remain in the air stream and travel to the next stage. The slots on each stage are the same width, but as the particulates continue through, the slots become successively smaller (Fig. 4.12) and most of the particulates will eventually become impacted on one of the collection substrates (e.g., slotted glass fiber-, quartz fiber-, and aluminum fiber substrates). After the last stage, the smallest particles will be collected on the backup filter, which will be weighed for particle size distribution.

c. Aerosol sampling—sampling artifacts

The problem of sampling aerosols from the ambient atmosphere has been considered from a theoretical point of view by Liu and Pui (1981). Following a review of the various aerosol samplers and inlets used in ambient aerosol sampling, the factors contributing to high sampling efficiency for large particles and the major mechanisms for particle loss in sampling inlets are impaction on external surfaces, and impaction, turbulent deposition, and sedimentation on internal surfaces. Therefore, an efficient inlet is one for which these losses are minimized.

When the aerosol sampler is ready to sample, the vacuum pump is turned on and a sample stream of 1 ACFM (one cubic foot per minute) air will flow through the aerosol sampler. Fig. 4.10 in fact shows how impaction occurs at the orifice-collector interfaces. Normally, there is no variation in flow rate throughout the sampling period since a constant pressure drop is maintained (no filtration occurs except at the backup filter, resulting in minimal pressure changes).

The particle-size range collected at each stage of the eight stages depends on the orifice velocity of the specific stage, the distance between the orifices and the collection surface, and the collection characteristics of the preceding stage. The combination of a constant flow rate and successively smaller diameter orifices increases the velocity of sampled air, as it cascades through the aerosol sampler, resulting in the impaction of progressively smaller particles in succeeding stages. At 1 ACFM aerosol cascade impactor, the particle fractionation ranges from 11.0 to 0.4 μm diameter according to a similar fractionation within the human respiratory system. Particles too small to be impacted on the last collection plate are collected in the backup filter, which is an optional, integral part of the aerosol sampler. Normal aerosol sampling periods vary from a few minutes to several hours, depending on the sensitivity of the analytical procedure. Ten mg of particulate matter on any one stage represents an approximate upper limit because of reentrainment problems. Overloading the aerosol sampler can be detected easily by visual inspection and is rarely encountered in industrial hygiene applications. Whenever oversampling occurs, rather than having well-defined, discrete piles of particulates, trails of particles can be seen leading from the sample deposits toward the periphery of the plate. This type of aerosol sample should be discarded.

After the aerosol sampling has been completed, the aerosol sampler is disassembled. The collection plates and backup filter are removed and replaced with fresh, preconditioned, preweighted collection media. After conditioning, the collection media can be weighed for net particulate accumulations, or the particulate matter can be analyzed radiologically or chemically for the various components of interest. Since airborne particulates have hygroscopic characteristics, all collection media used in the aerosol cascade impactor should be preconditioned prior to weighing, both before and after a sampling cycle, in a desiccator. Filter weighing should be made to an accuracy of $\pm$ 0.02 mg and a precision of $\pm$ 0.01 mg. It should be kept in mind that whenever an aerosol sample has been collected, the particle sizing has already been completed. To determine the nature of the radioactivity or mass size distribution, the required radiological and gravimetric and/or chemical analyses is performed.

d. Filter collection media

The analytical requirements determine the type of collection surface used. Normally, the stainless steel and glass plates are not used as the collection surfaces for gravimetric determinations because of the high tare weight-to-sample weight ratio. Glass fiber filters are normally used for these analyses because of their light weight and nonhygroscopic properties. However, other types of collection media are required for most radiological and chemical determinations because of the high and variable trace metal background levels in glass fiber. Stainless steel plates are used in many applications where the collected aerosol sample is washed off for subsequent radiological and chemical analyses. Glass plates are used rarely and only when there is a need to look at the collected aerosol particles optically. It is impossible to correlate aerodynamic dimensions with physical size because of the unknown particle density and shape characteristics. In addition, the aerosol particles might have scattered on impaction, which will not affect the aerodynamic sizing but would affect any optical sizing significantly.

For the radiological analysis, the plates of all stages and the glass fiber filter are measured by a high-purity, high-resolution, and high-efficiency Ge detector by the method of gamma spectrometry, and the measurement time is reduced in the mean time of the aerosol sampling, that is,

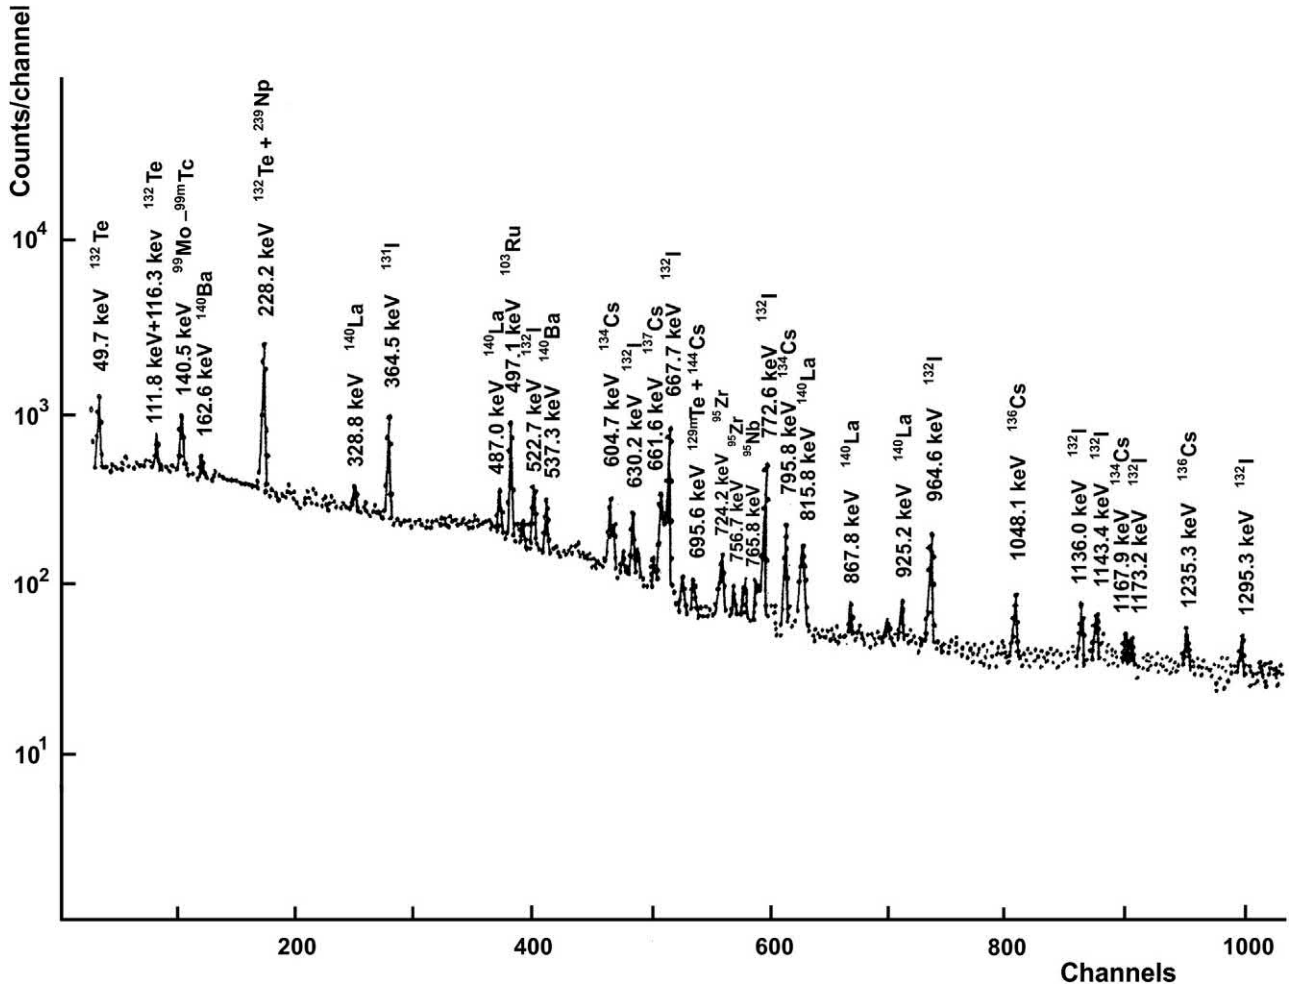

FIGURE 4.13 A typical γ-ray spectrum of the backup filter of an aerosol sampling measurement at Thessaloniki, Greece, obtained after the Chernobyl reactor accident (April 26, 1986). Printed with permission from Elsevier © 2012.

between the start time and the end time of the measurement, and a little earlier than the half-time. In Fig. 4.13, a typical gamma ray spectrum of the backup filter of an aerosol sampling measurement is presented and shows so many γ-photon peaks due to fission product radionuclides and neutron activation of various materials from the fallout due to the Chernobyl reactor accident (April 26, 1986).

By using the collected data of radioactivity of the plates and the backup filter, the activity size distribution of the radionuclides versus the aerodynamic particle diameter, D_p, is obtained; a typical plot for ^{7}Be is presented in Fig. 4.14. Finally, the activity median aerodynamic diameter (AMAD) is estimated for each radionuclide and the geometric standard deviation (σ_g).

e. Data interpretation

The steps that need to be made in any aerosol sampling are as follows:

1. Determination of the radioactive content of *i*th radionuclide in Bq of each plate of the stages and/or the change in weight in g for each stage in the aerosol cascade impactor, including the backup filter.
2. Add up all the amounts to obtain the total radioactivity in Bq and/or of the changes in weight (mass) to obtain the total particulate weight collected.
3. The amount collected on each stage to be divided by the total volume in m^3 collected to determine the percentage of the total Bq/m^3 collected in each size fraction (Table 4.5).
4. The particle density should be considered as 1.0 g/cm^3, the density of water, so that the particle sizes can be reported as equivalent aerodynamic diameters.
5. Selection of the lower size (smallest number) for each size range. This number represents the ECD for each stage. This ECD can also be obtained from Fig. 4.15.
6. Plotting the results on a log-probability graph with the ECD as the ordinate and the cumulative percent less

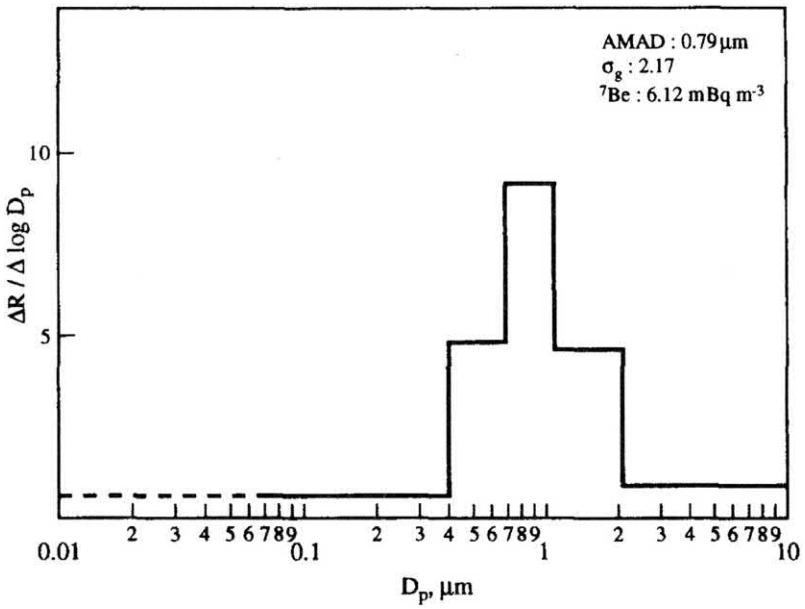

FIGURE 4.14 Aerodynamic size distribution of ^{7}Be ambient aerosols obtained in Thessaloniki, Greece (September 21, 1992). *AMAD*, activity median aerodynamic diameter. *From Papastefanou and Ioannidou (1995). Printed with permission from Elsevier © 1995.*

than the size range by weight as the abscissa (Fig. 4.16), or use a specific calculating program

7. Assuming a lognormal particle-size distribution, the particle-size geometric standard deviation, σ_g is given by

$$\sigma_g = \left(\frac{84.13\%\ \text{diameter}}{50\%\ \text{diameter}}\right) = \left(\frac{50\%\ \text{diameter}}{15.87\%\ \text{diameter}}\right) \quad (4.6)$$

Whenever these two geometric standard deviations are not equal (such as represented in a bimodal distribution), then the size distribution is not represented by a straight line (not really lognormal). A better method of presenting σ_g is

$$\sigma_g = \left(\frac{84.13\%\ \text{diameter}}{15.87\%\ \text{diameter}}\right)^{1/2} \quad (4.7)$$

Typically, the particle-size distribution is "lognormal." The spread of the particle-size distribution is characterized by the geometric standard deviation. The AMAD value of aerosol particles gives the diameter of aerosol particles, where above and below this diameter exists the 50% of the activity of radioactive nuclide. Generally, the particle-size information should be presented in graphical form rather than merely reporting the mass median aerodynamic diameter (MMAD) and σ_g. By plotting Fig. 4.16 Aerodynamic size distribution of ^{7}Be ambient aerosols obtained in Thessaloniki, Greece (September 21, 1992). From Papastefanou (2008)8, the ECD and cumulative percent on a log-probability graph and the particle concentration for any size range can be determined. Correspondingly, the AMAD and the corresponding σ_g are also determined.

8. From Table 4.6 and Fig. 4.16, it can be seen that approximately 98.2% of this aerosol sample is respirable (below 7.00 µm), and that the MMAD is 1.8 µm and σ_g is 1.94 µm for an aerosol sampling labeled as I, which is unimodal distribution, while for another aerosol sampling labeled as II, which is bimodal distribution, the MMAD is 2.1 µm and the σ_g is 6.09. The same procedure is followed for the determination of the AMAD, and the corresponding σ_g, in any aerosol sampling.

f. Calibration

Since the size fraction for each stage is determined by the orifice velocities, it is important that the aerosol sampler be operated at 1 ACFM airflow rate. For this reason, the unit should be periodically recalibrated, and whenever nonstandard temperatures and pressures are encountered, calibration should be performed at the aerosol sampling conditions. Rubber tubing of smaller diameter or length different from that supplied with the aerosol cascade impactor must not be used unless the airflow rate is readjusted.

The pump, which is used, is equipped with an adjustable valve. The lock nut must be tightened always on the adjustment valve after the airflow rate has been set. To adjust the airflow, the screw must be turned in to increase the airflow and out to decrease the airflow. The pump-impactor assembly is calibrated before use of the 1 ACFM airflow rate at ambient temperature and pressure

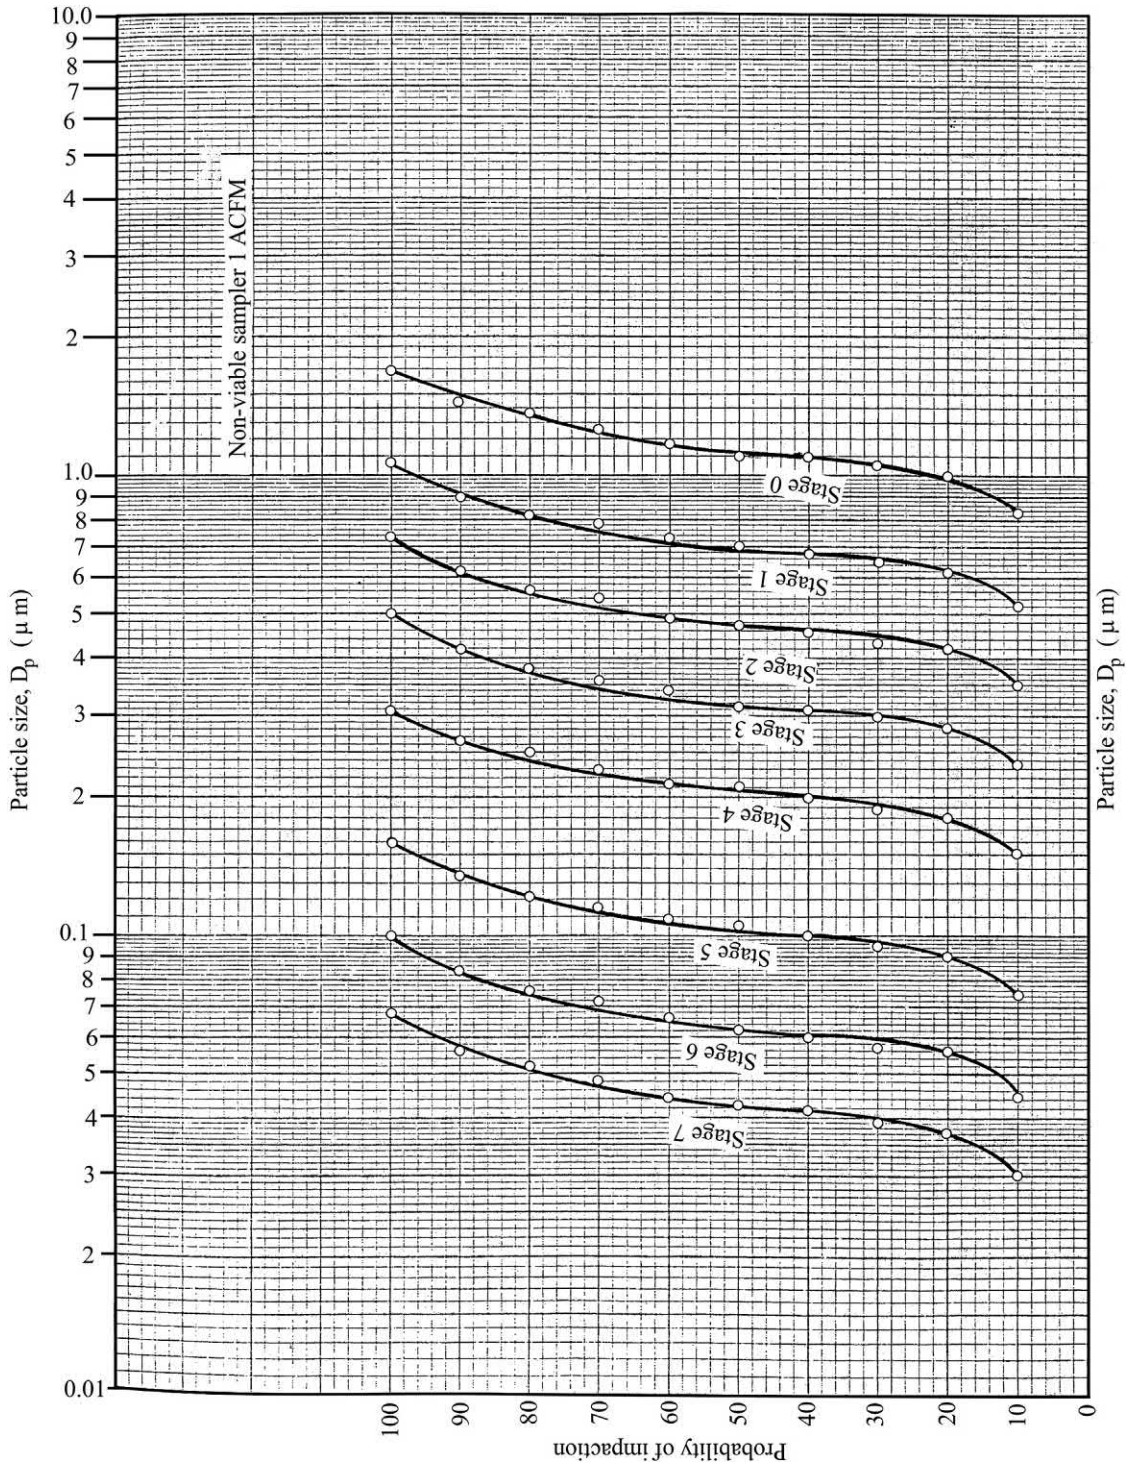

FIGURE 4.15 Probability of aerosol particle impaction at eight stages of a nonviable Andersen-type 1 ACFM (actual cubic feet per minute) cascade impactor versus particle diameter, *Dp*. Printed with permission from Elsevier.

levels. In order to recalibrate at any sampling environment, the following procedure must be conducted:

A calibrated dry gas meter must be placed upstream from the aerosol sampler. A short 100 interior diameter hose with approximately a ¼" wall must be attached to the inlet nozzle (cone) of the aerosol cascade impactor and the other end to the outlet of a dry gas meter. The pump valve must be adjusted until pulling 1 ACFM airflow rate over a

Particle size distribution data

3 minutes test time period as determined by an accurate stop watch. After maintaining 1 ACFM airflow rate for 3 minutes, the lock nut must be tightened on the adjustment valve.

Because of the 1.4 ACFM free airflow rating of the motor and pump, up to 50 feet of tubing can be used between the aerosol sampler and pump while still maintaining 1 ACFM airflow rate through the sampler. The pump and motor are guaranteed by the manufacturer and should not be disassembled for any reason. The pump and motor require no lubrication. The airflow rate of the 12 V DC pump will vary with voltage. One ACFM airflow rate can be drawn through the aerosol cascade impactor, provided the voltage of the pump is maintained near 12 V.

III. Radioactive aerosols in ambient air

A. Radon and thoron decay product aerosols

Radon (^{222}Rn) and thoron (^{220}Rn) are gases that formed as decay products of uranium and thorium in the uranium and thorium series in soil and rocks. They are emitted from the ground into the atmosphere, where they decay and form decay products, radioisotopes of polonium (Z = 84), bismuth (Z = 83), and lead (Z = 82), which either remain airborne until they decay or are deposited by rain and by diffusion to the ground. The decay of ^{222}Rn (radon) and ^{220}Rn (thoron) in the atmosphere produces low-vapor-pressure decay products, which coagulate with other freshly produced nuclei or condense on existing accumulation mode aerosols. These radioisotopes include ^{218}Po ($T_{1/2}$ = 3.05 minutes), ^{214}Pb ($T_{1/2}$ = 26.8 minutes), and ^{212}Pb ($T_{1/2}$ = 10.64 hours). A long-lived radioisotope in the ^{222}Rn decay chain, ^{210}Pb ($T_{1/2}$ = 22.3 y), is produced about an hour after attachment of ^{218}Po.

There is considerable information about radon decay product aerosols in ambient air (outdoors) and even in residences (indoors) (Mercer and Stowe, 1971; Kruger and Andrews, 1976; Porstendörfer and Mercer, 1978, 1979, 1980; Kruger and Nöthling, 1979; Porstendörfer et al., 1979; George and Breslin, 1980; Becker et al., 1984; George et al., 1984; Bondietti et al., 1987; Papastefanou and Bondietti, 1987; Porstendörfer, 1994; Grundel and Porstendörfer, 2004; Papastefanou, 2009a; Dlugosz et al., 2010).

The concentrations of radon (^{222}Rn) in ambient air are about 10 and 40 Bq/m^3 in indoor air, whereas the concentrations of thoron (^{220}Rn) in outdoor air are about 10 Bq/m^3 and approximately the same indoors (UNSCEAR, 1993, 2000). The concentrations of the radon (^{222}Rn) decay products in outdoor air are 19.05 Bq/m^3 for ^{218}Po, 3.88 Bq/m^3 for ^{214}Pb, 5.26 Bq/m^3 for ^{214}Bi, 0.5 mBq/m^3 for ^{210}Pb, and 0.050 mBq/m^3 for ^{210}Po, whereas the concentrations of thoron (^{220}Rn) decay products in outdoor air are 0.055 Bq/m^3 for ^{212}Pb and 0.575 Bq/m^3 for ^{212}Bi (UNSCEAR, 2000).

Study of the behavior of ^{222}Rn and ^{220}Rn decay products in air is important for assessing the natural background radiation exposures received by general populations through the inhalation route (Mishra et al., 2009). Among the several aspects of decay product behavior, deposition on surfaces is of special significance because of its prominent role in activity removal by plate out and consequent occurrence of decay product disequilibrium with the precursor gases. Due to their high diffusivities and ability to stick to surfaces, the freshly formed decay products soon attach to existing aerosol particles, thereby giving rise to a continuous activity size distribution. This distribution is broadly classified into two modes, namely, the fine fraction (2 nm diameter) and the coarse fraction (100 nm diameter). The activity size distribution, brought about by the attachment process, is governed by the concentration and distribution of atmospheric aerosols. The application of standard Jacobi (1972) model applies to dynamics of radon decay product aerosols.

Alpha decay carries away positive charge, and electrons are stripped from the precursor atom by its recoil. Therefore, the decay products are formed as positive

ions. Air is ionized by radiation from the naturally occurring radionuclides in the air and on the ground and by cosmic rays. Production of one ion pair requires 32.5 eV of ionization caused by fast electrons and 35.6 eV if by alpha particles. The total energy dissipated in air per decay of ^{222}Rn depends on the equilibrium ratio of radon decay products.

In the free atmosphere, the rate of production of small ions is in balance with the rate of neutralization by recombination and the rate of attachment to condensation nuclei. Condensation nuclei, otherwise called Aitken nuclei, are submicrometer particles mainly produced by combustion processes. In air containing water vapor, positive ions are mostly hydrated protons, H^+ $(H_2O)n$, where n may be any number between 1 and 8. Negative ions are mostly hydrated O^- or OH^-. The formation of clusters of water molecules around ions is very rapid, but in unpolluted air, the clusters do not grow beyond 1 nm diameter and remain as small ions until they become attached to condensation nuclei. They then become large ions.

Large ions themselves can be classified in two size ranges, the nuclei mode centered on 0.01 μm which is distinct from the accumulation mode and those centered on 0.1 μm (Whitby, 1978). In urban air, the number of particles in the nuclei mode is greater than the number of particles in surface area, which determines the probability of attachment of small ions to particles with diameters of the order of 0.1 μm or less. Thus, the large ions are mostly in the accumulation mode. The distinction between small and large ions is well established in atmospheric electricity. The existence of intermediate ions is in the size range 0.001−0.01 μm. If sulfates and nitrates are formed photochemically in air, molecules of acid will dissolve in the water clusters, and these will then grow into the intermediate ion range (Raes, 1985).

Reaction products can be created in air by radiolytic as well as photolytic processes. The radiolytic nuclei are initially uncharged, indicating that ions are not required for their formation. A possible mechanism for formation of radiolytic nuclei is radiolysis of water vapor, leading to formation of H_2O_2, which then oxidizes traces of SO_2 to give H_2SO_4. Increased formation of radiolytic nuclei occurs in air when SO_2 is added. Addition of O_3 to the air also increases nucleus production, whereas addition of NO, a well-known radical scavenger, inhibits it.

The radon decay product aerosols in the atmosphere are generated in two steps. After the formation from the radon isotope (^{222}Rn), the freshly generated decay product radionuclides react very fast (<1 seconds) with trace gases and air vapors, and become small particles, called clusters or unattached radionuclides with diameters ranging from 0.5 to 500 nm (Fig. 4.17A and B) (Porstendorfer, 1994; Porstendorfer et al., 2005). Besides the cluster formation, these radionuclides attach to the existing aerosol particles in the atmosphere within 1−100 seconds, forming the radon decay product aerosols (radioactive aerosols).

About 46% of the 46 low-pressure impactor measurements made over a 10-month period showed a radioactivity peak in the 0.11- to 0.23-μm region, whereas 39% showed a peak in the 0.23- to 0.52-μm region. The remaining 15% of the measurements resulted in activity size distributions, where ^{214}Pb and ^{212}Pb activities were highest in different size ranges in the same spectrum. On the average, about 76% of the ^{214}Pb activity and 67% of the ^{212}Pb activity were found to be associated with aerosol particles in the 0.08- to 1.4-μm size range. The activity associated with aerosol particles smaller than 0.08 μm can also be substantial. Lead-214 is generally enriched in the accumulation mode aerosol, particularly between 0.11 and 0.52 μm, where most of the surface area and mass occurs, whereas the Aitken nuclei fraction (below 0.08 μm) contained a higher percentage of ^{212}Pb activity compared with ^{214}Pb activity in 69.6% of the measurements (Bondietti et al., 1987; Papastefanou and Bondietti, 1987).

The radon decay products become associated with atmospheric aerosol particles by condensation or coagulation processes that are surface area related. The activity size distribution of ^{214}Pb aerosols showed a small shift to larger particle sizes relative to ^{212}Pb aerosols. The shift of ^{214}Pb to a slightly higher size distribution compared with ^{212}Pb was also found using 1 ACFM and high-volume cascade impactors. The higher flow rates of these impactors, as well as the ability to measure high-volume activity by gamma ray spectrometry, made us confident that this shift was real and not a data analysis artifact. The larger median size of ^{214}Pb aerosols was attributed to a-recoil depletion of smaller aerosol particles following the decay of the aerosol-associated ^{218}Po. Subsequent ^{214}Pb condensation on all particles effectively enriches larger-sized aerosols. Pb-212 does not undergo this recoil-driven redistribution. Even considering recoil following ^{214}Po α-decay, the average ^{210}Pb-labeled aerosol grows by a factor of 2 during its atmospheric lifetime. Early morning and afternoon measurements indicated that similar size associations of ^{214}Pb occur, despite humidity differences and the potential for fresh particle production in the afternoon.

The longer half-life of ^{212}Pb (10.64 hours) compared with ^{214}Pb (26.8 minutes) might favor the presence of larger aerosol associations of ^{212}Pb, if coagulation rates are fast relative to radioactive decay rates, although cascade impactor measurements may not be sensitive enough to record this effect. Instead, the measurements indicated that the shorter-lived chain (^{218}Po, ^{214}Pb, etc.) was more often associated with larger aerosol particle sizes than the longer-lived chain (^{216}Po, ^{212}Pb, etc.).

The ^{214}Pb shift might be explained by the fact that a significant fraction of the 3.05-min ^{218}Po atoms, precursor of ^{214}Pb, should themselves attach to an existing aerosol

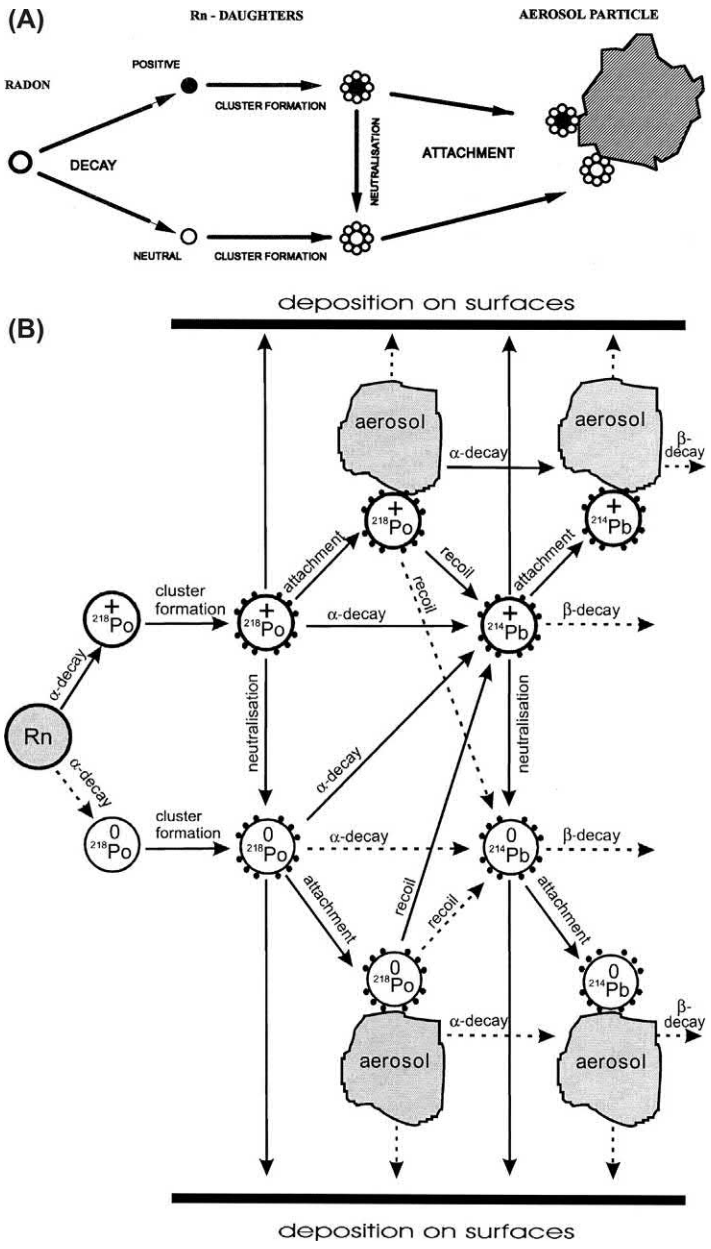

FIGURE 4.17 (A) Basic processes of radon decay product behavior in air defining "unattached" and "aerosol-attached" particle activities. (B) Processes of ^{218}Po and ^{214}Pb in air. *(A) From Porstendörfer (1994). Printed with permission from Elsevier Copyright (1994). (B) From Porstendörfer et al. (2005). Printed with permission from Oxford University Press Copyright (2005).*

particle or coagulate with other nuclei during their lifetime, as their mean attachment half-lives are of the order of a minute or less. When this attached ^{218}Po α-decays, the recoiling ^{214}Pb atom can escape the aerosol particles. Complete recoil loss would occur if the particle diameter, D_p, of the aerosol were smaller than the range of the recoiling nucleus. In water, this recoil range is 0.13 μm and should be somewhat less in the atmospheric aerosols that have a density closer to 1.5 g/cm^3. By contrast, very little of the 0.146 ms-^{216}Po would attach before decaying to ^{212}Pb, because of its short life relative to attachment times. A considerable fraction of the ^{214}Pb should undergo recoil detachment, particularly from aerosol particles with diameters smaller than 0.1 μm (diameter approximating the recoil range). The probability of loss would decrease with increasing particle radius. If the recondensing ^{214}Pb behaves like the original ^{214}Po, the net effect would be a shift of ^{214}Pb to a larger particle-size distribution.

Since the subsequent β-decays of ^{212}Pb and ^{214}Pb + ^{214}Bi do not result in significant recoil, the α-measurement

of ^{214}Po- and the ^{212}Pb-decay products is in reality tracing the aerosol size distribution of a ^{220}Rn-decay product atom (^{212}Pb), which has condensed only once and a ^{222}Rn-decay product atom (^{214}Pb) that has probably condensed more than once. This stability of the Pb isotopes is the basis for the generic reference to ^{212}Pb and ^{214}Pb size distributions.

The AMADs of ^{214}Pb aerosols determined with the low-pressure impactor data varied from 0.10 to 0.37 μm (average 0.16 μm) and for ^{212}Pb aerosols from 0.07 to 0.25 μm (average 0.12 μm). For the ^{210}Pb aerosols, the AMADs varied from 0.28 to 0.49 μm (average 0.37 μm). ^{210}Pb is produced by α-decay of ^{214}Po, the event used to quantify ^{214}Pb distributions on the LPIs. While the relationship between the aerodynamic sizes of ^{214}Pb and ^{210}Pb is complicated, because of the large differences in their atmospheric lifetimes, ^{210}Pb has always found to be associated with larger aerosols than ^{214}Pb. So, the AMADs of radon decay product aerosols are in the accumulation mode between 0.11 and 0.52 μm.

B. Radioactive aerosols associated with the cosmic ray–produced radionuclides

Relatively short-lived radionuclides with half-life about a few days, of cosmogenic origin, such as ^{7}Be ($T_{1/2} = 53.3$ d), ^{32}P (14.3 d), ^{33}P (25.3 d), and ^{35}S (87.4 d), occur permanently in the atmosphere. There is another category of long-lived radionuclides with half-life larger than a year, such as ^{3}H ($T_{1/2} = 12.5$ y), ^{10}Be (1.5×10^{6} y), ^{14}C (5730 y), ^{22}Na (2.6 y), ^{26}Al (7.3×10^{5} y), ^{32}Si (280 y), ^{36}Cl (3.01×10^{5} y), ^{39}Ar (269 y), and ^{81}Kr (2.1×10^{5} y), also occurring in the atmosphere. All the above-mentioned radionuclides are formed continuously by the interaction of cosmic ray particles with matter (atmosphere). Most of them are formed by spallation processes of light atmospheric nuclei, such as nitrogen ($Z = 7$), oxygen ($Z = 8$), and even carbon ($Z = 6$) or heavier atmospheric nuclei, such as sodium ($Z = 11$), phosphorus ($Z = 15$), sulfur ($Z = 16$), potassium ($Z = 19$), and calcium ($Z = 20$) (NCRP, 1987), when they absorb protons and even neutrons of cosmic origin. The production of ^{24}Na and ^{38}Cl by neutron activation of stable isotopes ^{23}Na and ^{37}Cl, respectively, is an exception.

Of the above radionuclides, ^{7}Be has a high isotope production rate in the atmosphere (8.1×10^{-2} atoms/cm^2 s), and as it is a gamma emitter (477.6 keV gammas, 11% yield), it can easily be detected and measured in the atmospheric air, in precipitation, and in vegetation as well. Its average concentrations in the tropospheric air are about 12.5 mBq/m^3 (UNSCEAR, 2000) and 700 Bq/m^3 in rainwater (UNSCEAR, 1982). Sodium-22 is also a positron and gamma emitter (511 keV gammas, annihilation peak), but its production rate in the atmosphere is too small (8.6×10^{-5} atoms/cm^2 s), and its concentration in the tropospheric air is 0.0021 mBq/m^3 (UNSCEAR, 2000). All the other referred radionuclides are mostly beta emitters with low production rates in the atmosphere and very low concentrations in the troposphere.

Beryllium-7 is a relatively short-lived ($T_{1/2} = 53.3$ d, $\tau = 1/\lambda = 77$ d) naturally occurring radionuclide of cosmogenic origin, which is formed by spallation processes of light atmospheric nuclei, such as carbon ($Z = 6$), nitrogen ($Z = 7$), and oxygen ($Z = 8$), when they absorb protons and even neutrons of the primary component of cosmic radiation (Bruninx, 1961, 1964; Rindi and Charalambous, 1967; Silberberg and Tsao, 1973; Ioannidou and Papastefanou, 1994; Papastefanou, 2009b), according to the following reactions:

$$^{12}_{6}\mathrm{C} + \mathrm{p} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{6}_{3}\mathrm{Li} \qquad {}^{12}_{6}\mathrm{C} + \mathrm{n} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{6}_{2}\mathrm{He}$$

$$^{14}_{7}\mathrm{N} + \mathrm{p} \rightarrow {}^{7}_{4}\mathrm{Be} + 2{}^{4}_{2}\mathrm{He} \qquad {}^{14}_{7}\mathrm{N} + \mathrm{n} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{8}_{3}\mathrm{Li}$$

$$^{16}_{8}\mathrm{O} + \mathrm{p} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{10}_{5}\mathrm{B} \qquad {}^{16}_{8}\mathrm{O} + \mathrm{n} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{10}_{4}\mathrm{Be}$$

$$^{16}_{8}\mathrm{O} + \mathrm{p} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{7}_{3}\mathrm{Li} + {}^{3}_{2}\mathrm{He}$$

$$^{16}_{8}\mathrm{O} + \mathrm{n} \rightarrow {}^{7}_{4}\mathrm{Be} + {}^{6}_{2}\mathrm{He} + {}^{4}_{2}\mathrm{He}.$$

Once ^{7}Be is formed in the troposphere, it rapidly associates primarily with submicron-sized aerosol particles (Bondietti et al., 1987). Beryllium-7 in these fine aerosols may subsequently enter the marine as well as the terrestrial environment and vegetation via wet or dry depositional events. Following deposition, ^{7}Be will tend to associate with particulate material (particle-reactive element).

Beryllium-7 has come to be recognized as a potential tool in studying environmental processes, such as aerosol transit and residence times in the troposphere (Martell, 1970), aerosol deposition velocities (Young and Silker, 1980), and aerosol trapping by above ground vegetation (Bondietti et al., 1984).

Beryllium-7 as well as other natural radionuclides like $^{212+210}$Pb, ^{22}Na, ^{35}S, and $^{32+33}$P participate in the formation and growth of the accumulation mode aerosols (0.07–2 μm diameter), which is a major reservoir of pollutants in the atmosphere. Following its production by gas-phase nuclear transformation, this isotope condenses on the aerosol population, growing by condensation of nonradioactive species (e.g., H_2SO_4 or organics), and the fate of ^{7}Be will become the fate of the carrier aerosols (Bondietti et al., 1988). On the behavior of ^{7}Be with atmospheric aerosols, it was concluded from early aerosol studies that considerable coagulation occurred during migration from the stratosphere and upper troposphere to ground level (Lockhart et al., 1965b; Gaziev et al., 1966).

Atmospheric aerosol size distribution appeared to follow a trimodal distribution expected for condensation-derived aerosols. This trimodal distribution of atmospheric aerosols showed the following mode ranges: the Aitken nuclei mode ranges from 0.003 to 0.07 μm (average 0.015 μm); the accumulation mode ranges from 0.07 to 2 μm (average 0.3 μm); and the coarse mode ranges from 2 to 36 μm (average larger than 10 μm) (NRC, 1979).

Young et al. (1975) reported that ^{7}Be is attached primarily to submicron-sized particles in the atmosphere. A histogram of the activity size distribution of ^{7}Be versus aerodynamic diameter (D_p) is represented in Fig. 4.18A. This distribution was selected by Papastefanou and Ioannidou (1995) from 11 atmospheric aerosol sampling measurements made over an almost 2-year period at Thessaloniki, Greece (40 degrees38′N, 22 degrees58′E) by using Andersen 1 ACFM cascade impactors at a flow rate of 1.7 m^3/h (28.3 L/min or 1 ft^3/min).

According to their observations, about 88% of ^{7}Be was found to be present as particles smaller than 1.1 μm in diameter, and less than 1% was found to be present as particles larger than 7 μm in diameter. This means that ^{7}Be aerosols are accumulation mode aerosols. This is also evident from the plot of Fig. 4.18A. The reported AMAD values varied from 0.76 to 1.18 μm (average 0.90 μm), and σ_g varied from 1.86 to 2.77 (average 2.24). The AMAD and (σ_g) calculations were made by plotting the cumulative distributions on log-normal probability graph. They also showed that 60% of the ^{7}Be activity was associated with particles with diameter smaller than 1.1 μm. Similar results are reported by Ioannidou (2012).

Beryllium-7 aerosol measurements carried out by Papastefanou and Ioannidou (1995) at sea level in a coastal area, at a hilly area, 250 m height, and on the top of a mountain, 1000 m height, showed that the ^{7}Be activity size distribution dominated a smaller size range of aerosol particles with an AMAD of 0.68 μm ($\sigma_g = 2.18$) at a height of 250 m and an AMAD of 0.68 μm ($\sigma_g = 2.24$) at a height of 1000 m, showing a dependency on height. In marine environments at sea level, the ^{7}Be activity size distribution dominated a higher size range of aerosol particles with an AMAD of 0.82 μm ($\sigma_g = 1.88$).

Bondietti et al. (1987) in 13 measurements in an almost 1-year period (June 1985−March 1986) at Oak Ridge, Tennessee, with temperate latitude (35 degrees58′N, 84 degrees30′W) and wet climate showed that the AMAD varied from 0.29 to 0.50 μm (average 0.35 μm) and that the fraction of ^{7}Be-associated aerosols above 1.4 μm was usually between 5% and 10%, i.e., analytically, 4.5% was found in the 1.4−2.1 μm size range, 1.1% in the 2.1−4.2 μm size range, and only 0.2% in sizes greater than 4.2 μm. They also concluded that cosmogenic radionuclides, such as ^{7}Be and ^{35}S, were associated with smaller aerosols and in respect of the longer-lived radionuclides, such as ^{210}Pb, a decay product of ^{222}Rn of terrestrial origin, which were associated with larger aerosols.

Röbig et al. (1980) reported that the distribution of the long-lived radionuclide ^{7}Be was shifted to large particle sizes due to large residence times of ^{7}Be in the atmosphere. An equivalent aerodynamic diameter of about 0.65 μm for ^{7}Be might have resulted from the plot of the activity size distribution of the ambient air obtained by a high-volume cascade impactor (flow rate 68 m^3/h) at Gottingen, Germany (51°32′N, 9°55′E). Shifts to large particle sizes were also observed when the RH increased during rainfalls. Much later, Grundel and Porstendorfer (2004) observed

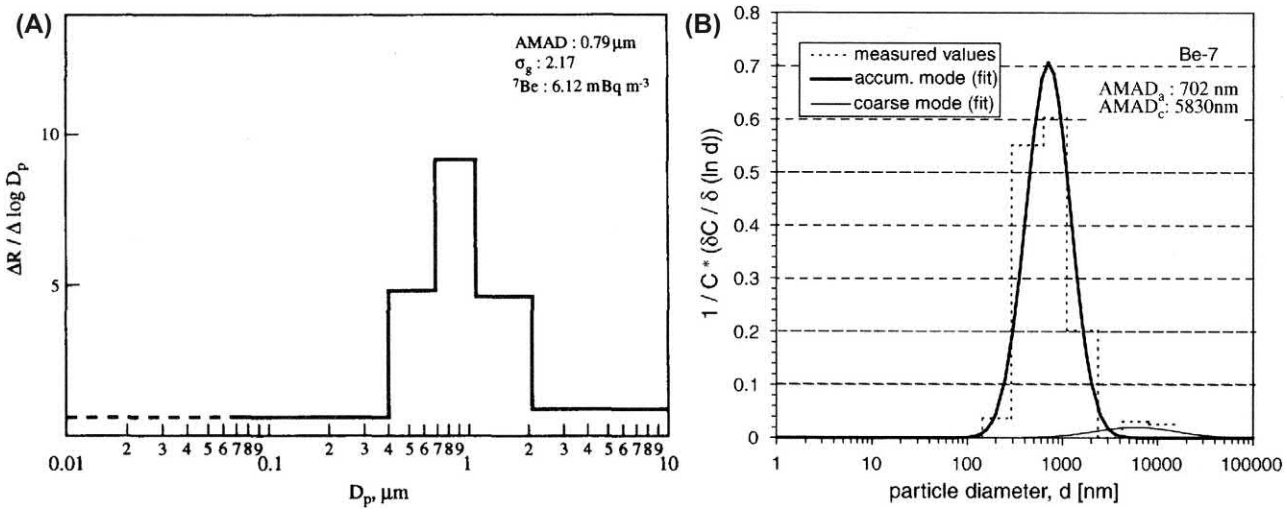

FIGURE 4.18 (A) Aerodynamic size distribution of ^{7}Be ambient aerosols. (B) Relative activity size distribution of ^{7}Be in outdoor air. *(A) From Papastefanou and Ioannidou (1995); reprinted with Permission from Elsevier Copyright (1995). (B) From Grundel and Porstendörfer (2004). Printed with permission from Elsevier Copyright (2004).*

that the results of the ^{7}Be measurements for a period of 4 weeks, carried out in outdoor air of a suburb area of the town of Göttingen, showed no activity fraction in the nucleation (Aitken nuclei) mode, but a small amount of the activity (5%) in the coarse mode size range (Fig. 4.18B). The accumulation mode of ^{7}Beaerosols with an activity fraction of 95% has an AMAD value of 702 nm.

Winkler et al. (1998) in 46 measurements in a period of $1^{1/3}$ years (December 1994−March 1996) at Munich-Neuherberg, Germany (48°13′N, 11°36′E) showed that the AMAD of ^{7}Be aerosols ranged from 0.44 to 0.74 μm (average 0.57 μm) and that seasonal effects during the period of high ^{7}Be air concentrations, i.e., in the summer period, when relatively low values of the AMAD (0.45−0.52 μm) have been observed. They also concluded that the AMADs, ranged between the MMADs, and the surface median aerodynamic diameters, SMADs, of the ambient aerosols, indicating that this radionuclide is involved in the transformation process of the tropospheric aerosols after formation in the stratosphere and upper troposphere.

Yu and Lee (2002) in 14 measurements at Hong Kong (22°18′N, 114°10′E) for a 3½ month's period (November 26, 2001−March 8, 2002) found that the AMAD of ^{7}Be-aerosols varied from 0.33 to 1.15 μm (average 0.67 μm). They concluded that the AMADs of ^{7}Be aerosols are anticorrelated to ^{7}Be concentrations in air and are correlated to RH and the mean cloud cover, whereas temperature does not affect the AMADs of ^{7}Be aerosols.

Apart from these, Lujaniene et al. (2001) reported larger ^{7}Be AMAD values varied from 1.12 to 2.06 μm (average 1.45 μm) in a northern latitude at Vilnius, Lithuania (54°41′N, 25°19′E). The investigated data rather indicate that the AMAD of ^{7}Be aerosols increases with increasing latitudes (latitudinal effect). As cosmic radiation increases with latitude, the number of ^{7}Be atoms and ions formed increases also with latitude, and so, there are more ^{7}Be atoms and ions available to form small aerosol particles in the nucleation (Aitken nuclei) mode, which then grow or become attached directly to the existing large particles in the accumulation and in the coarse-particle modes by increasing the AMAD of ^{7}Be aerosols.

Cho et al. (2007) reported that the mass size distribution of ^{7}Be aerosols in ambient air showed a bimodal distribution with a higher peak around 0.49 μm and a smaller peak between 3 and 7.2 μm. The AMAD decreased with increasing ambient ^{7}Be concentrations. The mean residence times by using a mean growth rate of 0.004 mm/h were estimated to be 2.5−6.4 days. The AMAD of the ^{7}Be aerosols has an increasing tendency with higher RH and increases with an increasing temperature, but the temperature dependency of AMAD should be explained with geological and meteorological conditions.

In the activity size distribution of ambient aerosols, ^{7}Be is shifted to large particle sizes in the presence of pollutants. Removal of small aerosol particles in the submicron size range of the activity size distribution, either by scavenging or by deposition of particles on any surface, may result in a depletion of small particles in the activity size distribution. Subsequent ^{7}Be condensation on all aerosols effectively enriches large particles in the activity size distribution. The radioactive aerosol is only generated by attachment, and there is no nucleation in contrast to the sulfate aerosol (nucleation + attachment) (Hopke, 1991). Freshly produced ^{7}Be should attach to an existing aerosol or coagulate with other nuclei during its lifetime, as mean attachment half-lives are of the order of a minute or less (Porstendörfer and Mercer, 1980).

Papastefanou and Ioannidou (1996) reported that sites where the AMAD of ^{7}Be aerosol was varied between 0.62 and 0.74 μm were located on lines with direction of wind blown (local wind). These streamlines of air masses are transferring pollutants from an industrial zone to the urban air and the marine environment over the sea surface. In the area influenced from the industrial zone, the AMAD of ^{7}Be aerosol was varied between 0.82 and 1.00 μm, which is higher than that observed out of the industrial zone.

Ioannidou (2011) measured the activity size distribution of ^{7}Be aerosols in association with trace metals in the urban environment and showed that the AMAD, ranged from 0.58 to 1.22 μm (averaging 0.80 μm), indicating post-condensation growth either in the upper atmosphere or after mixing in the boundary layer. It was shown that more than 80% of the ^{7}Be activity was associated with particles smaller than 1.3 μm. The AMAD values were anti-correlated with ^{7}Be activities, whereas they were correlated with RH, with high confidence ($R = 0.2$, $P < .00,813$). The composition of the associated particles was basically Ca, Si, and S. Among the heavy metals determined, Fe was the most abundant, followed by Cu. Minor amounts of Pb, Cr, and Ni were presented in coarse size ranges of the aerosol particles. The amount of Fe increased with decreasing particle size, displaying positive correlation with AMAD of ^{7}Be in the case of strong winds from NW direction and indicating the transport of polluted air from the industrial area of the city of Thessaloniki, Northern Greece (40°N).

Finally, Ioannidou et al. (2019) found that greatest ^{7}Be AMAD values observed at the most polluted areas, despite the season of the year, whereas lower AMAD observed in nonpolluted environments (of mountain Monte Rosa and lake Maggiore).

The activity size distribution of ^{7}Be aerosols depends probably on the location of formation. Most of ^{7}Be atoms and the ^{7}Be aerosols are generated in the upper region of the atmosphere, where other aerosol conditions exist than in the lower atmosphere.

Studies in Arctic environment have been conducted by Ioannidou and Paatero (2014) and Paatero et al. (2017). More specifically AMAD values of ^{7}Be aerosol were

determined by 12 measurements with a high volume cascade impactor in subarctic northern Finland. The ^{7}Be AMAD values ranged between 0.54 and 1.05 μm (average 0.83 μm), whereas a residence time of about 8 days applied to aerosols of 0.83 μm diameter, representing the residence of aerosol particles in arctic environment. The observed positive correlation between AMAD values and RH% explained by the fact that condensation during high relative humidity conditions becomes more intense, resulting in increased particle sizes of atmospheric aerosols. Greater aerosol particle sizes indicate a higher wet scavenging rate of aerosols, and as a result, lower activity concentration of ^{7}Be in the atmosphere, explaining the anticorrelation between the AMAD values and activity concentrations of ^{7}Be. But the aforementioned associated with possibly higher scavenging rates of aerosols does not necessarily alone explain the anticorrelation between the AMAD and the ^{7}Be activities. The air mass origin associated with synoptic scale weather phenomena may contribute to that too. The Flextra model was used to assess the transport pattern and to explain the deviation in radionuclide activity concentrations and AMAD values observed in the site of investigation.

In subarctic northern Finland, the activity size distribution of ^{210}Pb has been studied also in ambient aerosols, which were determined from high-volume cascade impactor samples collected. Most of the ^{210}Pb activity was incorporated in accumulation mode aerosol particles. The AMAD values of ^{210}Pb aerosol particles ranged from 0.53 to 0.98 μm, while the 38%–61% of ^{210}Pb activity was found to be associated with aerosol particles smaller than 0.69 μm. A slight descending tendency of ^{210}Pb activity median aerodynamic diameter was observed as a function of increasing ^{210}Pb activity concentration. This is related to the continental origin of airborne ^{210}Pb on one hand and various aerosol particle growth processes on the other hand. Also, a clear tendency toward a higher ^{7}Be/^{210}Pb activity ratio as a function of increasing aerosol particle diameter was observed. This, in turn, reflects the different origin of ^{210}Pb, exhalation of ^{222}Rn into the air, and ^{7}Be, formation via cosmic ray–induced spallation reactions in the upper troposphere and the stratosphere.

C. Radioactive aerosols in the workplace environment

The model of the respiratory tract produced by the International Commission on Radiological Protection (ICRP66, 1994) recommends default AMADs of 5 μm for occupational exposure and 1 μm for exposure of members of the public.

The distributions of measured AMADs for all workplaces and for different industries were well fitted by single lognormal functions characterized by their median and geometric standard deviation. Median values of AMAD for all workplaces, for the nuclear power industry and for fuel handling facilities, were 4–5 μm (Dorrian and Bailey, 1996). The median value for uranium mills was 7.3 μm. Doses for standard workers for a 5–11 μm AMAD are similar to those at 4 μm. For ^{234}U, doses for a 5 μm AMAD are at least 80% of those for a 7.3 μm AMAD. Therefore, the 5 μm default recommended by the International Commission on Radiological Protection (ICRP) provides realistic dose estimates for workers (Dorrian and Bailey, 1996).

The AMADs (in μm) and geometric standard deviations (σ_g), noted as GSDs, of the activity size distributions for aerosols collected in different work environments are given in Table 4.7.

1. Mine aerosols

Aerosols from mine sources have particle-size distributions that are determined by both the mining method and the source of the aerosol (Cantrell et al., 1987). A size distribution summarizing the physical characteristics of mine aerosols is shown in Fig. 4.19 (Willeke and Baron, 1993). The shape of the aerosol size distribution is influenced by the different sources contributing to the aerosol. This figure displays some of these sources and the physical mechanisms, such as condensation and coagulation that transfer aerosol mass from one size to another. It should be noted that these mechanisms and the general shape of the distribution are not unique to mine aerosols.

There are three distinct aerosol size ranges identifiable by features in measured mine aerosol size distributions:

1. The smallest of these from 0.001 to 0.08 μm is the Aitken nuclei range, which contains primary aerosols from combustion sources, such as diesel engines and secondary aerosols or chain aggregates formed by coagulation of primary aerosols.
2. The next size range from 0.08 to approximately 1.0 μm is termed the accumulation range. It contains emissions in this size range plus aerosols accumulated by mass transfer through coagulation and condensation processes from the Aitken nuclei range.
3. The last range from 1.0 to approximately 40 μm is termed the coarse-particle range. Aerosols within this size fraction generally result from mechanical processes such as rock fracture and bulk material handling. Mineral dust aerosol reentrained by mine haulage vehicles during the load-haul-dump cycle is an example of an in-mine emission that will contribute aerosols to this size range.

For convenience, the Aitken nuclei and the accumulation ranges are combined in a single fine-particle range. A division is usually made between this range and the coarse-

TABLE 4.7 Activity median aerodynamic diameters (AMADs, in μm) and geometric standard deviations (σ_g), noted as GSDs, of the activity size distributions for aerosols collected in different work environments.

		Coarse mode			Accumulation mode

particle range at 1.0 μm. This distinction is possible because sources of aerosols in the two ranges are usually different, and the coarse-particle range contains very little mass transferred from the accumulation range by coagulation. In each of the ranges mentioned, the size distribution of mine aerosols can exhibit a maximum or mode, which takes its name from the size range in which it occurs. Hence, the maximum in the accumulation range is termed the accumulation mode.

Radioactive isotopes, such as ^{238}U, ^{218}Po, ^{214}Pb-^{214}Bi, and ^{210}Pb-^{210}Po, characterized the mine aerosols.

D. Radioactive aerosols associated with the operation of high-energy particle accelerators

Particle accelerators and their surroundings are locations of residual radioactivity production that is induced by the interaction of high-energy particles with matter. In high-energy accelerators, nonradioactive aerosols are abundantly generated during machine operation. Radioactive atoms, which are produced through various nuclear reactions in the air of accelerator tunnels, attach to nonradioactive aerosols and form radioactive aerosols. These aerosol particles might be inhaled by workers who enter the tunnel just after the beam stop. Their particle size is very important information for estimation of internal exposure doses.

During accelerator operation, radioactive nuclides are produced by the interaction between the primary and secondary particles ($E \geq 30$ MeV) from the machine and the atmospheric air in the accelerator halls. Spallation reactions in solid machine parts can also lead to the formation of radioactive nuclides. If the air is confined in the accelerator hall, there will be no release of radioactive nuclides into the outside zones during operation of the machine. When the machine is stopped, an unexpected concentration of radioactive nuclides in the air may be present.

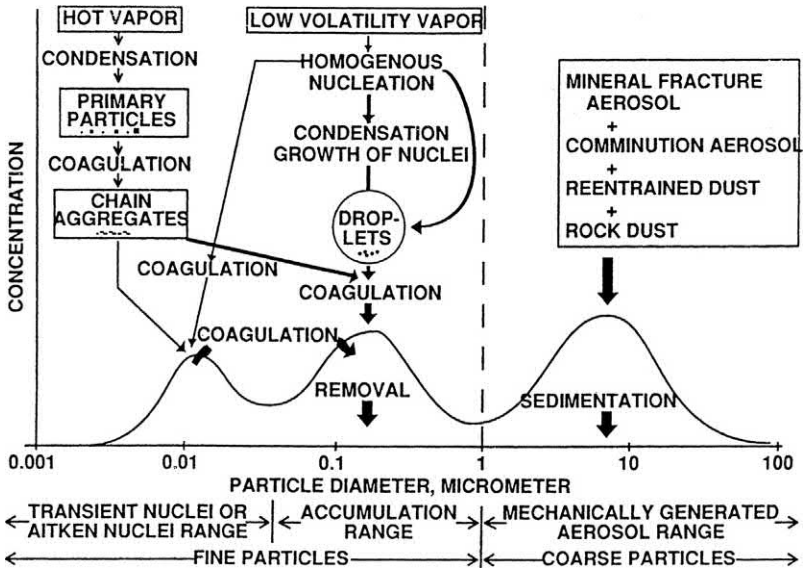

FIGURE 4.19 Idealization of an atmospheric surface area distribution showing the principle modes, sources of mass, and the processes involved in mass transfer and removal. *From Whitby (1978). Printed with permission from Elsevier Copyright (1978).*

Radioactive dust is produced from activated machine parts by normal erosion or mechanical wear. Dust in the accelerator halls is also activated when it is in suspension in the air or when it is deposited on the machine components. The principal radioisotopes found in dust are those produced from the constituents of the machine parts. Radioactive aerosols are produced from activated air in the accelerator hall (Charalambous and Rindi, 1967).

Thus far, little is known of the size distribution and the mechanisms of aerosol formation. Radioactive atoms are formed with high kinetic energy and/or charges and can interact with their surroundings as hot atoms. Subsequent reactions with ambient nonradioactive aerosols are considered to result in the formation of radioactive aerosols. It seems likely that the ^{7}Be aerosols are formed by the attachment of ^{7}Be to nonradioactive aerosols.

Oki et al. (2000) employed a screen-type diffusion battery for the aerosol size analysis. And they placed an aluminum chamber in the EP2 beam line of the 12-GeV proton synchrotron at the High Energy Accelerator Research Organization (KEK). They reported that the AMAD of ^{7}Be and ^{24}Na aerosol was between 0.01 and 0.04 μm and was always larger than the MMAD of the nonradioactive aerosols. The size for radioactive aerosols was much smaller than ordinary atmospheric aerosols.

Kondo et al. (1984) found that the particle size distributions of radioactive nuclides formed in accelerator beamline tunnels and measured by using a diffusion battery is lognormal had a geometric mean radius of about 28 nm. They used a parallel plate diffusion battery and a (CNC) for collecting aerosols at the KEK 12-GeV proton synchrotron in the National Laboratory for High Energy Physics at Tsukumba-gun, Ibaraki-ken, Japan (35°42′N, 139°46′E). They examined the aerosol size distribution of ^{7}Be produced by the spallation reaction of nitrogen, N, and/or oxygen, O, atoms in air in an integrated high-energy hadron flux around the sampling inlet about 5×10^{6} particles/cm^{2} s for particles with $E \geq 30$ MeV, which decreased with increasing energy. The mean geometric radius was $\sigma_g = 0.027 \pm 0.005$ μm and for the geometric standard deviation $\log \sigma_g = 0.36 \pm 0.02$ or $\sigma_g = 2.3$. They observed that naturally occurring radioactive aerosols of radon and/or thoron decay products also have a similar size distribution, but their mean geometric radii were slightly greater than the obtained values for the ^{7}Be aerosols. They also reported that the size distribution of radioactive aerosols of fission product radionuclides due to atomic bomb tests differs in the stratosphere and troposphere depending on the characteristics of ambient nonradioactive aerosols. For the nonradioactive aerosols, the size distribution was of a lognormal shape with a mean geometric radius $\sigma_g = 0.01$ μm and for the geometric standard deviation $\log \sigma_g = 0.3$ or $\sigma_g = 2.3$, whereas the aerosol concentration was $1.5 - 4.3 \times 10^{5}$/cm^{3}.

E. Fission product radionuclide aerosols

Following an accident at a nuclear power station, great amounts of radioactive aerosols are emitted into the troposphere because airborne fission product radionuclides interact with the environment and a carrier is responsible for their long-range transport and the atmospheric diffusion. Radioactive isotopes, such as ^{103}Ru, ^{131}I, ^{132}Te, and ^{137}Cs, characterized these aerosols. The particle size of a

fission product aerosol and the distribution of fission products between particulate and vapor phases depend on the mechanism of release to the atmosphere.

In a nuclear explosion, some physicochemical fractionation of radionuclides may occur, particularly if the explosion is near the ground. Everything in the vicinity is vaporized by the heat of the explosion, but within less than a minute, the fireball cools to a temperature in the range 1000−2000°C, and refractory materials, such as metal oxides and silicates, condense to form aerosol particles (Glasstone and Dolan, 1977). Refractory fission products and plutonium are incorporated into these aerosol particles. Less refractory fission products condense later onto the surfaces of the aerosol particles. Those with gaseous precursors, e.g., ^{90}Sr and ^{137}Cs, condense, as they are formed by the decay of their parent nuclides. The refractory fission products are distributed between particles according to their mass or volume (diameter cubed). The more volatile fission products and those with volatile parents are distributed according to a power of d_p between d_p and d_p^2. Per unit mass, there is then more activity in the smaller particles. The particle size depends on the volumetric concentration of condensing material and decreases as the fireball expands. The earlier a fission product condenses, the larger the particles in which it is incorporated, and the quicker it is lost by fallout to the ground.

At distances of about 100 km from ground zero of the explosion site, the aerosol particle size of fallout ranges from a few μm to a few 100 μm. Fission products with volatile precursors are enhanced by about a factor of 2 compared with refractory fission products. The greater the fractionation, the smaller the particles (Hicks, 1982).

The fireballs created in an explosion at high altitude are very large, but no ground-based material is incorporated. So, the condensation aerosol particles are very small, with 90% of the activity in particles less than 0.3 μm in diameter (Drevinsky and Pecci, 1965). Coagulation takes place with the natural stratospheric aerosol, which is thus labeled with fission products. In the troposphere, there is further coagulation, and near ground most activity is in the 0.3−1 μm size range (Lockhart et al., 1965a). Any fractionation of fission products in the explosions is evened out by the process of coagulation, and there is no evidence of fractionation in particles sampled near ground.

1. Nuclear bomb tests

The first nuclear test was carried out by the United States in July 1945, followed by the Soviet Union in 1949, the United Kingdom in 1952, France in 1960, and China in 1964 (CTBTO web site). At that time, there were no measurements regarding the radioactive aerosol size distribution. At the beginning, there were just total dose rate reports.

Prior to 1950, only limited consideration was given to the health impacts of worldwide dispersion of radioactivity from nuclear testing. Public protests in the 1950s and concerns about the radionuclide ^{90}Sr and its effect on mother's milk and babies' teeth were instrumental in the conclusion of the Partial Test Ban Treaty (PTBT) in 1963. The PTBT banned nuclear testing in the atmosphere, outer space, and under water, but not underground, and was signed by the United States, the Soviet Union, and the United Kingdom. However, France and China did not sign and conducted atmospheric tests until 1974 and 1980, respectively.

Although underground testing mitigated the problem of radiation doses from short-lived radionuclides such as ^{131}I, large amounts of plutonium, ^{129}I, and ^{135}Cs were released underground. In addition, exposure occurred beyond the test site if radioactive gases leaked or were vented.

The United States conducted 1032 nuclear tests between 1945 and 1992: mainly at the Nevada Test Site (NTS) and at various other sites. Between 1951 and 1958, around 100 nuclear weapons tests were conducted in the atmosphere at the NTS. The average yield for the atmospheric tests was 8.6 kilotons (kt). The fallout from the tests contained radionuclides and gases, which were transported thousands of miles away from the NTS by winds. As a result, people living in the United States during these years were exposed to varying levels of radiation.

Between 1946 and 1958, the United States carried out 67 nuclear weapons tests at Bikini and Enewetak atolls in the Marshall Islands in the Pacific Ocean. Following the detonation of the 15 Mt Castle Bravo test on March 1, 1954—the most powerful nuclear device ever detonated by the United States—the fallout caused contamination over an area of more than 11,000 square km, spreading traces of radioactive material as far as Australia, India, Japan, the United States, and parts of Europe. The fallout consisted of coral rock, soil, and other debris sucked up in the fireball and made intensively radioactive by the nuclear reaction.

Between 1949 and 1989, 456 atomic and thermonuclear devices were exploded at the Semipalatinsk Test Site (STS) in Russia under conditions of tight confidentiality. Explosions were conducted on the surface and in the atmosphere. Five of the surface tests were unsuccessful and resulted in the dispersion of plutonium into the environment, with the first test on August 29, 1949, unexpectedly contaminating villages to the northeast of the STS.

The approximate cumulative explosive yield of the tests conducted before 1963, when the Soviet Union signed the PTBT, was 6.4 Mt. More than 300 test explosions were conducted underground after 1961. Between October 1961 and October 1989, 224 tests were conducted there. The last test took place on February 12, 1989, and resulted in a leakage of large amounts of the radioactive noble gases xenon and krypton.

The United Kingdom conducted 12 atmospheric tests between 1952 and 1957 on Australian territory. From 1957 to 1958, nine atmospheric tests followed over Christmas Island (Kiritimati) and Malden Island in the central Pacific Ocean, some of which were considerably more powerful than the bombs dropped on Hiroshima and Nagasaki. The remaining 24 UK nuclear tests were conducted jointly with the United States at the NTS. A major nuclear test was detonated at Emu Field in the South Australian desert on October 15, 1953, sending a radioactive cloud known as the "Black Mist" over a 250 km^2 area.

France was the fourth nation to join the "Nuclear Club" when it successfully detonated a large nuclear device in Algeria in 1960. Over the next 5 years, France conducted 17 nuclear weapons tests at two locations in Algeria: 4 were atmospheric tests and 13 were detonated underground. The total amount of ^{239}Pu dispersed as a result of the 45 announced French atmospheric tests, including the 4 in Algeria, would be about 6750 Ci, assuming 150 Ci per test. On this basis, the amount of ^{137}Cs and ^{90}Sr dispersed into the atmosphere would have been 1.7 million curies and 1.1 million curies, respectively. About one half of the cesium and strontium remains in the atmosphere, on the ground, and in water bodies. French testing in the Pacific was the source of almost all the atmospheric fission product contamination, due to the much larger number of tests and the far greater yields of the French tests there than in Algeria.

After its first test on October 16, 1964, China exploded 45 nuclear bombs at the Lop Nor site, approximately 265 km southeast of Urumqi in the Xinjiang region in western China. The 23 atmospheric and 22 underground tests ranged in yield from about 1 kt to about 4 Mt. The total amount of ^{239}Pu released to the atmosphere as a result of the 23 atmospheric nuclear tests is estimated at 3300 Ci, approximately 48 kg in weight. One millionth of a gram of ^{239}Pu can cause cancer if inhaled. A further 2 million curies of ^{137}Cs and 1.3 million curies of ^{90}Sr were released into the atmosphere.

2. The comprehensive Test Ban Treaty

The Comprehensive Test Ban Treaty (CTBT) bans all nuclear explosions on earth whether for military or for peaceful purposes. The basic obligations of the Treaty are to prohibit States Parties from carrying out any nuclear explosion. It also prohibits any encouragement of or participation in the carrying out of any nuclear explosion. The technology that provides the means to identify and prove a possible violation of the Treaty is the radionuclide technology, which is of crucial importance to the entire verification effort. The 80-station "radionuclide monitoring" network enables a continuous worldwide observation of aerosol samples of radionuclides. The network is supported by 16 radionuclide laboratories hosting expertise in environmental monitoring and providing independent additional analysis of International Monitoring System (IMS) samples.

A radionuclide particulate monitoring station contains an air sampler, detection equipment, computers, and a communication setup. At the air sampler, air is forced through a filter, which retains more than 85% of all particles that reach it. Filters are replaced daily. The used filter is first cooled for a period of 24 hours and then measured for another 24 hours in the detection device at the monitoring station. The result is a gamma-ray spectrum, which is sent to the International Data Center for further analysis.

On an experimental basis, half of all radionuclide stations (i.e., 40) are equipped with the noble gas monitoring technology to test the measuring of radionuclide noble gases released by nuclear explosions. Radioactive noble gas isotopes—in particular xenon isotopes—are among the fission products generated in a nuclear explosion. Due to their property of being inert, these xenon isotopes will not attach to debris or dust to form larger particles. They remain in their gaseous state, and some of them will seep through layers of rock and sediment until they escape into the air. Exposed to prevailing winds, they are dispersed in the atmosphere and may, after a certain period of time, be detected thousands of kilometers away from the explosion site.

Ideal radionuclide monitoring sites are windy, exposed places where the passing air really hits the air sampler used to collect particulates transported by the wind. The objective of the CTBTO's radionuclide monitoring network is to detect this residual radiation in the form of radioactive particles or noble gas, even if only in miniscule amounts.

All systems in the International Noble Gas Experiment (INGE) project work in a similar way. Air is pumped into a charcoal-containing purification device where the noble gas xenon is isolated. Contaminants of different kinds, such as dust, water vapor, and other chemical elements, are eliminated. The resulting air contains higher concentrations of xenon, in its both stable and unstable (i.e., radioactive) form. The radioactivity of the isolated and concentrated xenon is measured, and the resulting spectrum is sent to the data center in Vienna for further analysis.

3. Chernobyl accident

After the Chernobyl accident, large and highly radioactive particles were found in at least 15 European countries (Pöllänen et al., 1997). Small particles are usually composed of volatile species, such as iodine and cesium, whereas most large particles, often referred to as "hot particles," have compositions similar to those of nuclear fuel.

According to Pöllänen et al. (1997), particles > 20 μm in aerodynamic diameter were transported hundreds of

kilometers from the plant, and they were sufficiently active (>100 kBq) to cause acute health hazards. Most particles found at a large distance (>500 km) from the plant were <1 μm in diameter although coarse particles up to tens of micrometers were also found. Near the plant, particles up to hundreds of micrometers in diameter were found (Cuddihy et al., 1989; Salbu et al., 1994; Krivokhatsky et al., 1991, as cited in Pöllänen et al., 1997). Radioactive materials from Chernobyl were transported throughout Europe during the 10-day release period. After April 26, the proportion of large particles in the release plume was much smaller than during the initial stages of the accident. Particles >20 μm in aerodynamic diameter, however, were found in Hungary, Romania, Bulgaria, and Greece. Trajectory analyses show that these countries were affected during the later periods of the accident (Fig. 4.20).

Mala et al. (2013) reported for the Czech Republic the activity size distribution of man-made radionuclides after the Chernobyl accident. These radionuclides fell into two categories: refractory radionuclides (^{140}Ba, ^{140}La ^{141}Ce, ^{144}Ce, ^{95}Zr, and ^{95}Nb) and volatile radionuclides (^{134}Cs, ^{137}Cs, ^{103}Ru, ^{106}Ru, ^{131}I, and ^{132}Te). The AMAD of the refractory radionuclides was approximately three times higher than the AMAD of the volatile radionuclides; nevertheless, the size distributions for volatile radionuclides having a mean AMAD value of 0.51 μm.

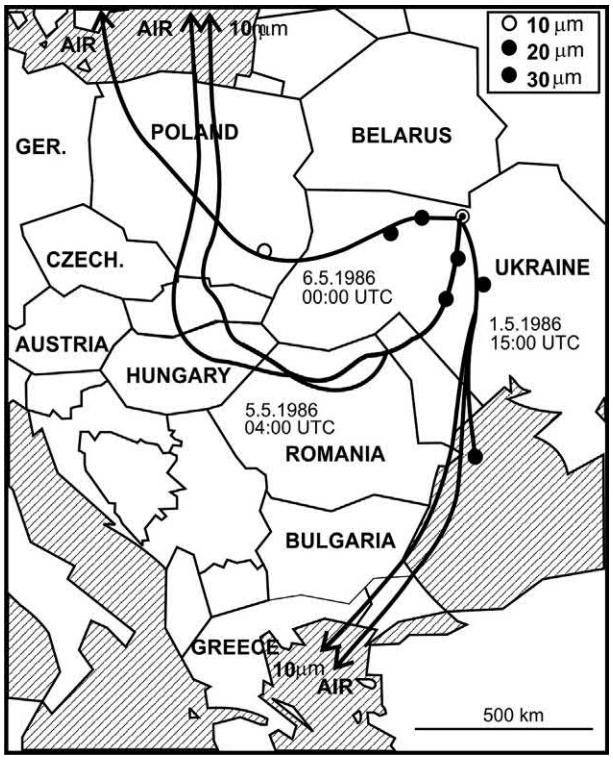

FIGURE 4.20 Route of air parcels and particles with aerodynamic diameters between 10 and 30 μm originating from Chernobyl on May 1 at 15:00 hours, May 5 at 06:00 hours, and May 6, 1986, at 00:00 hours UTC. Release height is 700 m. The trajectories for a particle 10 μm in diameter do not necessarily hit the ground due to large-scale vertical flows. The trajectories for particles 20 and 30 μm in aerodynamic diameter are terminated. *From Pöllänen et al. (1997). Printed with permission from Elsevier Copyright (1997).*

Jost et al. (1986) sampled aerosols with an Andersen impactor in Spiez, Switzerland (46°41′N, 7°39′E), from April 30 to May 13, 1986, and in Zurich, Switzerland (47°23′N, 8°32′E), from May 2 to 8, 1986, with a Berner impactor, soon after the accident. In the Spiez region, ^{131}I had a rather different activity size distribution from other fission product radionuclides, such as ^{103}Ru and ^{137}Cs. Most ^{131}I was found in the size fraction on the backup filter (<0.47 μm), whereas ^{103}Ru and ^{137}Cs showed a pronounced maximum at 0.93 μm (geometric mean diameter). In Zurich, a similar activity size distribution is shown with the maximum for ^{131}I at 0.35 μm and at 0.71 μm for ^{103}Ru, ^{132}Te, and ^{137}Cs. Different activity size distributions between the two regions were due to the different cutoff diameters of the aerosol sampling devices. The activity size distributions for ^{103}Ru, ^{132}Te, and ^{137}Cs are very similar to the concentration patterns of prominent ions, such as NH_4^-or SO_4^{2-} and NO_3^-, as determined by ion chromatography.

As iodine (^{131}I) was mainly (about 80%) present in the gas or vapor phase, the adsorption of gaseous species onto aerosol particles was strongly surface correlated (Papastefanou and Bondietti, 1987). These surface distributions for environmental aerosols usually peak at size fractions with particle diameters ≤0.4 μm (Seinfeld, 1986; Whitby et al., 1972). Therefore, it is concluded that the activity size distribution observed for ^{131}I does not reflect the primary particles released at Chernobyl but rather the surface distribution of the aerosols at the sampling sites. By contrast, ^{103}Ru, ^{131}Te, and ^{137}Cs were presumably ejected as particles or attached very early to aerosol particles and grew by coagulation with other particles during transport. It is therefore reasonable that their activity size distribution resembles that of the main inorganic ions (sulfate, nitrate, and ammonium), which may be transported also over long distances.

Bondietti and Brantley (1986) evaluated the aerodynamic sizes of the aerosol-associated fission product radionuclides from the Chernobyl accident in four aerosol samplings made during the period from May 7 to June 13, 1986, at Oak Ridge, Tennessee (35°58′N, 84°17′W), using Sierra high-volume cascade impactors and low-background intrinsic Ge coaxial and well-type detectors. The Chernobyl activity was shown to be mostly submicrometer in size, and the particle size increased significantly over the measurement period. They also observed that only a small fraction of the aerosol-associated ^{131}I was soluble in $CHCl_3$, whereas both ^{103}Ru and $^{134-137}$Cs were less soluble than natural radionuclides, indicating some association with

aerosols produced by the accident. They measured the aerosol-associated ^{131}I and its chemical composition by one cascade impactor operated from May 7 to 16, 1986 with a charcoal-impregnated final filter instead of the normal glass-fiber filter. Based on the ^{131}I activity size distributions on both charcoal-equipped and normal cascade impactors, they estimated that 40% of the airborne ^{131}I was aerosol-associated and that very little gas-to-aerosol transformation of ^{131}I occurred during its transit at long distances. The <0.41 μm aerosol ^{131}I fraction consisted of about 20% I_2, or I^- (or other $CHCl_3$-soluble species). No IO_3^- was detected. The 0.41–0.73 μm size fractions showed similar $CHCl_3$-soluble species.

Table 4.8 lists the activity mean aerodynamic diameter, AMAD, in μm, of fission product radionuclide aerosols of Chernobyl origin together with the ^7Be-associated aerosols of cosmogenic origin at Oak Ridge, Tennessee (35°58′N, 84°17′W). The particle sizes increased considerably during the measurement period. By contrast, cosmogenic ^7Be, which is initially associated with very small aerosol particles, was continually being added to the aerosol population. In the first two measurements, 2% of the fission product radionuclide aerosol particles were found to be larger than 2.1 μm, strongly suggesting the absence of any significant mechanical suspension of reactor material into the free troposphere. The behavior and sizes of the fission product radionuclides are consistent with the long-range transport of isotopes released by volatilization, which condensed on or with ambient or accident-produced aerosols. Zircon-95 or other rare-earth fission product radionuclides were not found in the aerosol samples. About 27% of the $^{134-137}Cs$ and 46% of the $^{103-106}Ru$ were not rapidly dissolved in cold 2 M HCl. This behavior was very different from what was observed for natural ^7Be, ^{210}Pb, or ^{212}Pb, which become associated with natural aerosols by surface condensation and are quite soluble. That poor solubility may indicate that some of the aerosol-associated fission product radionuclides were incorporated into reactor-derived materials, which condensed in the hot plume leaving the reactor core.

In contrast to the findings of Bondietti and Brantley (1986), Jost et al. (1986) found no increase of the AMAD, during the measurement period. They believed that this increase might not reflect the original release at Chernobyl but was due to transport effects. Apart from this, the size distribution in the fallout of nuclear weapons tests (Lockhart et al., 1965b), in contrast to the activity size distribution found in the stratosphere, is shifted toward smaller particles (Persson and Sisefsky, 1971).

Lujaniene et al. (1997) reported that the AMAD, of the soluble aerosols of ^{137}Cs of Chernobyl origin, varied in the range of 0.10–0.86 μm at Vilnius, Lithuania (54°41′N, 25°19′E), and the size of cesium radioisotopes stuck to insoluble aerosol particles in all the samples was similar (about 1 μm).

Kauppinen et al. (1986) also sampled ambient radioactive aerosols of Chernobyl origin at Helsinki, Finland (60°10′N, 24°58′E), during May 7–14, 1986, for the evaluation of the activity size distribution. They used 11-stage multijet compressible flow low-pressure Berner impactors (modified HAUKE 25/0.015 LPI) covering 0.03–0.16 μm aerodynamic diameter size range, AMAD. A Liu-type aerosol inlet was connected to the LPI inlet to minimize the effect of wind on the aspiration efficiency. Polycarbonate films of 10-μm thickness were used as impaction substrates. To prevent coarse-particle bounce, the films on the stages collecting particles greater than 1 μm were greased thinly with a uniform layer of Apiezon L-grease. The amount of grease on the film was 30–300 μg. The mass of collected particles was determined by weighing substrate films carefully before and after sampling with a microbalance. Before gravimetric analysis, the films were exposed to an ion stream generated by a polonium α-active source, to reduce the effect of electrical charge on the weighing results. Before the radioactivity analysis, the films (donut shaped, in the middle of which are the particle deposition spots) were cut into four equal pieces and laid above each other, to achieve better γ-counting geometry. As a result, the samples could be approximated with diskette geometry. The amount of radioactive isotopes in

the aerosol samples was determined by measuring their γ-spectra with a cylindrical Ge(Li) detector. During the measurements, the crystal was ventilated with aged pressurized air to reduce the iodine background.

In Fig. 4.21, the lognormal fits of ^{103}Ru, ^{131}I, ^{132}Te, and ^{137}Cs activity size distributions of four samples of Helsinki atmospheric aerosols are shown. All the activity size distributions are unimodal. The modal parameters, such as AMAD, σ_g, and the modal concentration for the accumulation mode mass and surface area size distributions (calculated from mass size distribution assuming unit density spherical particles) and for the activity size distributions, are given in Table 4.9. Iodine-131 activity size distributions differ clearly from the activity size distributions of ^{103}Ru, ^{132}Te, and ^{137}Cs. The AMAD of ^{131}I was smaller than that of ^{103}Ru, ^{132}Te, and ^{137}Cs. In two samples (samples 2 and 3), the AMAD was almost equal to the surface area mean aerodynamic diameter (SAMAD) of the accumulation mode, and in one sample (sample 4), the AMAD was equal to the MMAD, of the accumulation mode. The AMAD of ^{131}I seems to grow, whereas the AMAD of ^{103}Ru decreases, as the aerosol particles age.

Another case of radioactive aerosols associated with fission product radionuclides is that formed in the environment of nuclear power plants. Environments in the nuclear power plants are quite complex. Vaporization, condensation, fragmentation, and gas-to-particle conversion are all evolved in reactor vessels and containments.

TABLE 4.9 Geometric mean aerodynamic diameter* (DG_{ae}, in μm), geometric standard deviation (σ_g), noted as SG, and modal concentrations (*C*, in mBq/m^3) for the activity size distributions and for the accumulation mode mass and surface area sire distributions of chernobyl fission product radionuclide aerosols measured at Helsinki, Finland (60°N).

Practices such as sandblasting, grinding, and thermal arc cutting further complicate the situation of aerosol production and dispersion. These aerosols, however, may be grouped into several categories, e.g., the coarse mode and the accumulation mode. Coarse-mode particles with a diameter greater than about 1 μm are generally created by mechanical processes such as fragmentation. Finer particles, with a diameter <1 μm, are mostly derived from processes such as combustion and gas-to-particle conversion.

Analyses of such radioactive aerosols were performed by Yu et al. (1993) at the Chin-Shan Nuclear Power Plant, NPP, in Taiwan, consisting of a 636-MWe boiling water reactor that has been in operation since 1977. They used Andersen ambient cascade impactors (1 ACFM normal cascade impactors at an airflow rate of 28.3 L/min) with a preseparator to discriminate large particles with an aerodynamic diameter greater than 10 μm. For the segregation of smaller size aerosol particles in the accumulation mode, they applied a low-pressure adaptor to the Andersen cascade impactor. At an airflow rate of 3 L/min, the effective cutoff aerodynamic diameter of sampled aerosols by the Andersen LPI was between 0.08 and 35 μm. Fission products, including ^{131}I, ^{140}Ba, and ^{140}La, and the activation product, ^{60}Co, were the main radionuclides of the aerosols generated by sandblasting the steam turbine components. Long-lived activation products, ^{60}Co, ^{54}Mn, and ^{134}Cs, and the fission product, ^{137}Cs, constituted the major radionuclides in aerosols produced by the thermal-arc-cutting process on the waste concentration vapor body. Grinding activities on the heat-exchanger pipes produced aerosols containing mostly activated radionuclides, such as ^{60}Co and ^{54}Mn. Aerosols produced at the off-gas sump room contained mainly short-lived noble gas decay products, such as ^{88}Rb, ^{138}Cs, and ^{139}Ba.

A plot of the activity size distribution, which is a bimodal lognormal distribution for ^{137}Cs-bearing aerosols, is shown in Fig. 4.22. The AMAD of the accumulation mode is 0.29 μm and σ_g is 2.2, whereas the AMAD of the coarse mode is 3.2 μm and σ_g is 1.9. Cesium-137 could be produced directly from fission or as decay product of ^{137}Xe gaseous fission product radionuclide. The direct ^{137}Cs (fission product radionuclide) gives rise to aerosols in the coarse mode, whereas the coagulation of ^{137}Xe decay product (^{137}Cs) gives rise to aerosols in the accumulation mode. A plot of the activity size distribution for some major radionuclides associated with aerosols is shown in Fig. 4.23.

4. Fukushima accident

An earthquake of magnitude 9.0 occurred on March 11, 2011, on the Pacific Ocean side of northern Honshu, Japan, followed by a tsunami that struck the east coast of the Tohoku region and caused a serious nuclear accident at the Fukushima Daiichi Nuclear Power Plant. Emission of radioactive nuclides into the atmosphere started on March 12. The accidental releases from the Fukushima Daiichi NPP resulted in an increase in levels of artificial radioactivity in parts of the Japanese terrestrial environment and the marine environment to the east of Japan. The majority of the atmospheric releases occurred during the period from March 12 to 23, 2011 (Terada et al., 2012).

It is clear that a wide range of radionuclides are known to have been released to the atmosphere during the accident at the Fukushima Daiichi NPP (Table 4.10). Most have been detected by radiological measurements of environmental media. The fission noble gases ^{85}Kr and ^{133}Xe were released during the early phase of the accident. Nearly the entire inventories of these gases were released as a result of venting, explosions, and other events in Units 1, 2, and 3.

Very low levels of semi- and low-volatile elements were released. In particular, low-volatile gamma-emitting fission products, including isotopes of ruthenium, ^{140}Ba/^{140}La, and cerium, have not been detected at significant levels in the area around the Fukushima Daiichi NPP. During the accident, the release was mainly due to core overheating and fuel melting, without the presence of air; less volatile elements were therefore not released. Similarly, only very low levels of isotopes of strontium and the actinides, including plutonium, were released owing to the nature of the accident. This contrasts with the releases from the Chernobyl NPP, where there was an explosion at an operating reactor releasing fragments containing these less volatile elements.

Variations in the emission rates, in the physical and chemical properties of individual elements released from each of the three damaged reactors and in the changing meteorological conditions during this period, resulted in complex and heterogeneous dispersion of the radioactive material (Table 4.11). The spatial variation of deposition densities on land was further complicated by the influence of precipitation, topography, and land cover.

Following the events at the Fukushima Daiichi NPP in March 2011, the monitoring of radionuclides in the environment was increased throughout the Northern Hemisphere. The network of the CTBTO monitoring stations detected enhanced levels of isotopes of xenon, iodine, and cesium in the air. Some additional radionuclides—isotopes of tellurium, ^{140}Ba/^{140}La, ^{90}Mo/^{99m}Tc, ^{110m}Ag, and ^{111}Ag—were also detected in air samples collected across the United States and Europe. However, these measured activity concentrations were considerably (more than a thousand times) lower than the activity concentrations

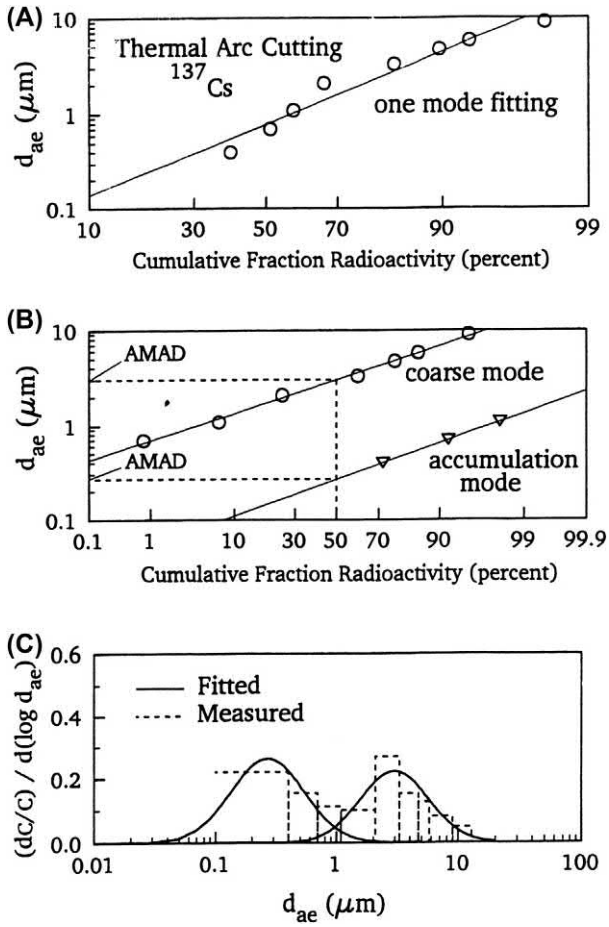

FIGURE 4.22 Activity size distribution of ^{137}Cs-bearing aerosols collected during the thermal-arc-cutting process, shown in terms of the following: (A) cumulative distribution with one mode fitting, (B) cumulative distribution with two modes fitting, and (C) differential distribution with two modes fitting solid curves are the fitting result using a lognormal function. *From Papastefanou (2008). observed in Japan. Radionuclides from the releases from the Fukushima Daiichi NPP were detected in most of the countries in the Northern Hemisphere, but, as expected, there was little activity detected in the southern hemisphere, owing to the low exchange of air masses across the equator (Thakur et al., 2013).

The contaminated air masses were transported across the Pacific toward the North American continent (Bowyer et al., 2011), toward Europe (Kritidis et al., 2012; Masson et al., 2011, 2013) and Central Asia, despite dispersion and washout along the trip. Radionuclides such as ^{131}I, ^{134}Cs, and ^{137}Cs were detected in different locations throughout Europe. The first European detection from Fukushima

fallout occurred between March 19 and March 20 in Iceland, between March 19 and March 21 in the northern part of Scandinavia, and between March 23 and 24 for most of the other European countries. Increasing levels were generally noticed during March 28 to March 30 in central Europe, whereas a second peak was also detected between April 3 and April 5 (Masson et al., 2011).

The observed air activity concentrations in Europe after the Fukushima accident are three to four orders of magnitude lower than activity levels encountered in Eastern Europe after the Chernobyl accident in April 1986 (Kritidis et al., 2012). In Europe, ^{134}Cs had not been measured in the atmosphere since the middle of the 1990s due to its fairly short half-life of 2.06 years, whereas ^{137}Cs was still measurable before the Fukushima accident at trace levels below 1 mBq/m^3 (Arctic Monitoring and Assessment Programme (AMAP), 2010; Masson et al., 2013). However, in soil samples, ^{137}Cs remaining from Chernobyl fallout accident and global fallout from past nuclear weapon tests is still detected.

There are numerous publications reporting the levels of contamination in various places all over the world; however, there are only few publications dealing with the size distribution of radioactive nuclides following the Fukushima accident.

There are some data on the size distribution of radioactive aerosols collected more than 1 month after the accident (Doi et al., 2013; Kaneyasu et al., 2012). Miyamoto et al. (2014) started collecting the radioactive aerosols 6 and 59 days after the accident with a low-volume cascade impactor at the JAEA-Tokai located 114 km south of the Fukushima Daiichi Nuclear Power Station. This may be the earliest size-fractionated sampling at a short distance from the site on record. Their first sampling was of 14.7 days and started on March 17, whereas the second one of 3.8 days started on May 9, 2011. They used an LPI (eight-stage with a backup filter, Tokyo Dylec, AN-200) with flow rate of 28.3 L/min, and the total sampling volume was 599 m^3 for the first sampling and 154 m^3 for the second one. The impactor was placed in a container house to avoid contamination of radioactivity in the environment. The cutoff value diameters were 11, 7.0, 4.7, 3.3, 2.1, 1.1, 0.65, and 0.43 μm. Wrapping film made of polyethylene and nylon of 14 μm in thickness was used as impaction substrates, and a glass-fiber filter (8.0 cm in diameter, T60A20, PALLFLEX Products, Co.) was used for collecting particles of <0.43 μm. For a typical aerosol of 0.3 μm in diameter, the filter collection efficiency is 96.40%.

The size distributions of ^{134}Cs, ^{136}Cs, ^{137}Cs, ^{129m}Te, ^{140}Ba, and ^{131}I in the first collection (March 2011) are presented in Fig. 4.24. The distributions of ^{134}Cs and ^{137}Cs in the second collection (May 2011) are also shown in the same figure. The AMADs of the three Cs nuclides in the first collection were the same, 1.5–1.6 μm, and there was a small peak at ~6 μm. In the second collection, the AMADs of ^{134}Cs and ^{137}Cs split into three peaks, at < 0.5 μm, 0.94 μm, and 7.8 μm. The change of diameter implies that the emission process or transportation mechanism of radioactive Cs may have changed between March and May. The AMAD of ^{131}I was 0.45 μm, and there was also a broad peak at 4 μm.

Doi et al. (2013) reported that the AMADs of ^{131}I, ^{134}Cs, and ^{137}Cs from dust samples collected at the beginning of April 2011 were 0.7 μm, 1.8 μm, and 1.5 μm, respectively. The diameter of ^{134}Cs and ^{137}Cs in their samples collected in the middle of April 2011 was 1.0 μm. Kaneyasu et al. (2012) reported the AMADs of ^{134}Cs and ^{137}Cs in dust samples collected in May 2011 were 0.54 and 0.53 μm, respectively. As noted by Kaneyasu et al. (2012), the carrier phase of radioactive Cs for the 0.5-μm size may consist of aerosols, including sulfates, whereas those for the 5- to 10-μm sizes may consist of soil particles and sea salts. Radioactive iodine including ^{131}I may be released as a gas phase and transported with fine particles of <0.5 μm in diameter, including sulfate aerosols and carbonaceous.

Masson et al. (2013) reported the size distribution of radioactive aerosol particles in many European countries (France, Austria, the Czech Republic, Poland, Germany, and Greece) immediately after the Fukushima accident. The AMAD ranged between 0.25 and 0.71 μm for ^{137}Cs, from 0.17 to 0.69 μm for ^{134}Cs, and from 0.30 to 0.53 μm for ^{131}I, thus, in the "accumulation mode" of the ambient aerosol (0.1–1 μm). The AMAD values did not show large differences from place to place compared with what was observed concerning bulk airborne levels registered on the European scale. They observed that when air masses arrived in Europe, AMADs for ^{131}I were about half those for cesium isotopes. Higher AMAD for cesium probably results from higher AMAD observed at the early stage of the accident in Japan. Lower AMAD for ^{131}I can be explained by the adsorption of gaseous iodine on particles of all sizes met during transport, especially for small particles. Additionally, weathering conditions (rain)

encountered during transport and in Europe in March and April contributed to the equilibrium of the gaseous to total ^{131}I ratio. AMAD slightly increased with time for ^{131}I, whereas a clear decreasing trend was observed with the AMADs for ^{137}Cs and ^{134}Cs. On average, the associated geometric standard deviation (GSD) appeared to be higher for iodine than for cesium isotopes. These statements also bear out a gaseous ^{131}I transfer on ambient particles of a broad size range during transport. Highest weighted activity levels were found on the 0.49−0.95 μm and on the 0.18−0.36 μm size ranges in France and in Poland, respectively. The contribution from resuspension of old deposited ^{137}Cs was assessed for the coarse particle fractions only for the first sampling week.

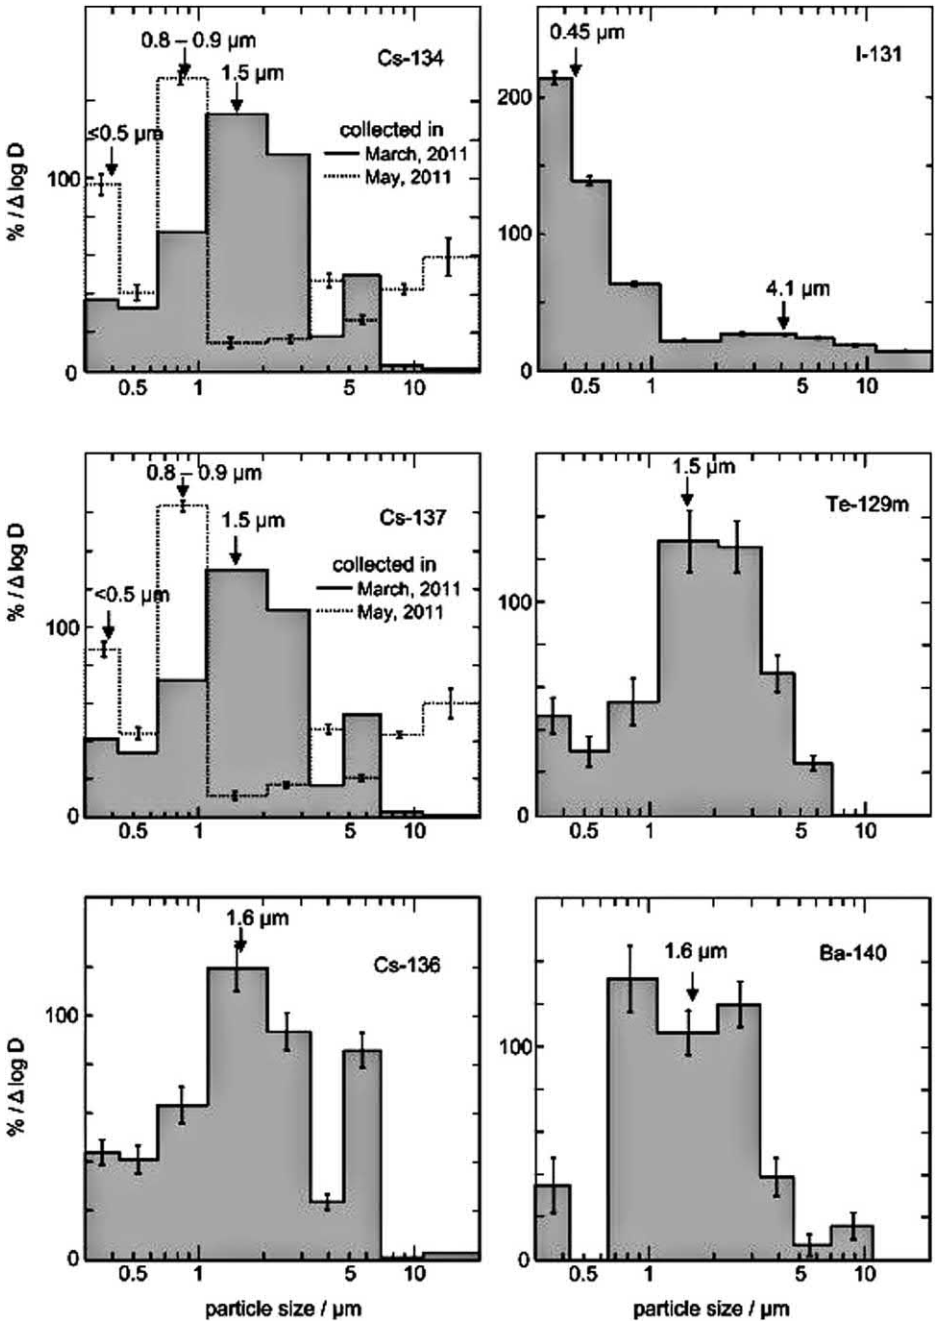

FIGURE 4.24 Activity size distribution of radionuclides. The solid lines show the distributions of the sample collected in the period of March 17−April 1, 2011, and the dotted lines show those collected in the period of May 9−13, 2011. The activity median aerodynamic diameter is also shown in each distribution. *From Miyamoto et al. (2014). Printed with permission from Elsevier Copyright (2014).*

Malá et al. (2013) reported for the Czech Republic the activity size distribution of man-made radionuclides ^{131}I, ^{134}Cs, ^{137}Cs, and natural ^{7}Be in five sets of samplings, after the Fukushima accident. All distributions were unimodal. The arithmetic means of the AMADs and GSDs of ^{131}I, ^{134}Cs, and ^{137}Cs from all sets of samplings were 0.43 μm and 3.6, respectively. The mean ^{7}Be AMAD value was 0.41 μm, and the mean GSD value was 3.0.

IV. Residence time of radioactive aerosols

The residence time of atmospheric aerosol particles in the lower atmosphere, assuming that the air in the troposphere is considered as a well-mixed reservoir (closed system), is a function of various removal processes, the most important being

1 dry deposition by impaction, diffusion, and sedimentation, and
2 wet deposition by rain drops (precipitation scavenging)

as a result of processes occurring both within and below the rain cloud. There could be variations in the removal rates at different continental locations of the globe (Lehmann and Sittkus, 1959), over the oceans (Koch et al., 1996), and at high altitudes of the atmosphere (Martell, 1970; Moore et al., 1973) due to changes in meteorological conditions. There is also a dependence of the tropospheric aerosol residence time on the latitude (Ehhalt, 1973; Balkanski et al., 1993; Koch et al., 1996).

The residence time of atmospheric aerosol particles can be estimated by means of radioactive nuclides as tracers, which become attached to aerosol particles and are removed with them as they are scavenged by precipitation or undergo dry fallout (Warneck, 1988). Several methods have been used for estimating the mean residence time of atmospheric aerosol particles. These include measurements of the activities and ratios of

(i) cosmic ray−produced radionuclides, such as ^{7}Be ($T_{1/2} = 53.3$ d) (Shapiro and Forbes-Resha, 1976; Winkler et al., 1998; Yu and Lee, 2002),
(ii) radioactive decay products of radon, ^{222}Rn, and thoron, ^{210}Rn, which emanate from continental surfaces into the atmosphere, such as ^{210}Pb ($T_{1/2} = 22.3$ y), ^{210}Bi ($T_{1/2} = 5.01$ d), and ^{210}Po ($T_{1/2} = 138.38$ d) (Francis et al., 1970; Poet et al., 1972; Lambert et al., 1982, 1983; Marley et al., 2000; Baskaran and Shaw, 2001), and
(iii) fission product radionuclides from man-made explosions from nuclear weapons testing or reactor accidents at nuclear facilities, such as ^{89}Sr ($T_{1/2} = 50.5$ d), ^{90}Sr ($T_{1/2} = 28.8$ y), and ^{140}Ba ($T_{1/2} = 12.79$ d) (Kuroda, 1982).

However, there is disagreement between the derived values of the residence times due to various processes, including the fact that they refer to different portions of the atmosphere, e.g., cosmic ray−produced radioisotopes refer to upper troposphere or lower stratosphere, such as ^{7}Be, and radon decay products, such as ^{210}Pb, ^{210}Bi, and ^{210}Po that refer to lower troposphere, and also due to the existence of different sources for some radioisotopes, such as ^{210}Po.

The collection of atmospheric aerosol particles is carried out with high-volume jet air samplers, type TFIA-2 of Staplex having glass-fiber filters type TFAGF 810 of Staplex, highly retentive for particulate material, 20.32 × 25.40 cm (8″ × 10″) in dimensions and 99.28% collection efficiency for submicron particles as small as 0.3 μm and over. The airflow rate of these samplers is regulated from 1.7 m^3/min (60 cfm) to 1.92 m^3/min (68 cfm) (average 1.84 m^3 $min^{=1}$ or 65 cfm). The length of each collection period is 24 hours. The size fractionation of atmospheric aerosol particles is carried out with aerosol cascade impactors, type Andersen 2000, as follows: (i) The 1-ACFM design is operated at an airflow rate of 28 L/min (1 ft^3/min). Its stages have ECD of 0.4, 0.7, 1.1, 2.1, 3.3, 4.7, 7.0, and 11.0 μm. (ii) The low-pressure modification, which alters the impactor's operation by increasing the resolution in the submicron region, involves a regulated airflow rate of 3 L/min, five low-pressure stages (114 mm Hg, which is the absolute pressure downstream of the critical orifice) for the submicron region, and eight atmospheric pressure stages for separating aerosol particles above 1.4 μm. The ECDs of the low-pressure stages are 0.08, 0.11, 0.23, 0.52, and 0.90 μm, whereas for the upper stages, they are 1.4, 2.0, 3.3, 6.6, 10.5, 15.7, 21.7, and 35.0 μm (iii) The high-volume cascade impactors have a regulated airflow rate either of about 0.57 m^3/min (20 cfm) or of 1.13 m^3/min (40 cfm), and the ECDs are 0.41, 0.73, 1.4, 2.1, 4.2, and 10.2 μm for the 20 cfm configuration or 0.49, 0.95, 1.5, 3.0, and 7.2 μm for the 40 cfm configuration at the standard temperature and pressure atmospheric conditions (25.0 and 760 mm Hg). The stainless steel plates supplied by the manufacturer are used for collection of the aerosol particles. Either polycarbonate or glass-fiber backup filters are used to collect all particles below the 0.08-μm collection plate for the LPIs, below the 0.4-μm collection plate for the 1 ACFM impactors, and below the 0.41-μm or 0.49-μm collection plate for the high-volume cascade impactors.

The length of each collection period varies from 1 to 24 hours for ^{7}Be, and ^{210}Pb, ^{210}Bi, and ^{210}Po, depending on impactor type and objective. The activity of ^{7}Be-associated aerosol particles is measured through its gamma-ray peak of 477.6 keV using a high-resolution (e.g., 1.9 keV at

1.33 MeV of ^{60}Co), high-efficiency (e.g., 42%), low-background HPGe detector. The uncertainty of the gamma-counting system for ^{7}Be measurements must be better than 8.5%. The activity of ^{210}Pb- and ^{210}Bi-associated aerosol particles is measured by a low-background phoswich scintillation detector system having a background of about 2 cpm and efficiency usually higher than 40% for counting beta radiation. This system is consisted of a thin CaF_2(Eu) primary crystal with a decay time of 0.23 ms. The samples are counted long enough to obtain a statistical accuracy better than 5%. It must be noted that ^{210}Pb and ^{210}Bi are chemically separated and measured for their activities. A detailed description of the analytical method and technique is established and analytically presented by Jaworowski (1963). The activity of lead-210 might also be measured by a surface barrier Ge detector through its gamma peak of 46.5 keV. The activity size distribution and the AMAD of the aerosol particles are determined upon the measurement of the activities of the aerosol-associated radioactive nuclides.

The activity aerodynamic size distribution of a sample of ^{7}Be atmospheric aerosol obtained by 1 ACFM cascade impactor is shown in Fig. 4.14 (Papastefanou and Ioannidou, 1995). The activity aerodynamic size distribution of a sample of ^{210}Pb-atmospheric aerosol obtained by a high-volume cascade impactor is shown in Fig. 4.25 (Bondietti et al., 1987).

A. Residence time of tropospheric aerosol particles associated with the cosmic ray–produced radionuclides

A method for estimating the residence time of tropospheric aerosol particles associated with the cosmic ray–produced radionuclides, such as ^{7}Be, is based on the aerosol particle growth rate, that is, the change of particle diameter with respect to time, which was estimated to be 0.004–0.005 μm/h (McMurry and Wilson, 1982), and the difference between the AMAD, of a radionuclide, e.g., ^{7}Be and the size of Aitken nuclei in the size distribution of aerosol particles, which is 0.015 μm (NRC, 1979). The AMAD of all radionuclides is in the accumulation mode of the size distribution of atmospheric aerosol particles, which ranges between 0.1 and 2.0 μm (NRC, 1979; Papastefanou and Bondietti, 1987).

Table 4.12 shows data for the AMAD, of atmospheric aerosol particles associated with ^{7}Be and ^{210}Pb atoms. Regarding the ^{7}Be-aerosols, the AMAD values varied from 0.33 to 1.18 μm (Bondietti and Brantley, 1986; Papastefanou and Ioannidou, 1995; Reineking and Porstendörfer, 1995; Winkler et al., 1998; Yu and Lee, 2002; Porstendörfer and Grundel, 2003; Papastefganou, 2009b), whereas for the ^{210}Pb aerosols, the AMAD values varied from 0.28 to 0.77 μm (Sanak et al., 1981; Reineking and Porstendörfer, 1995; Winkler et al., 1998;

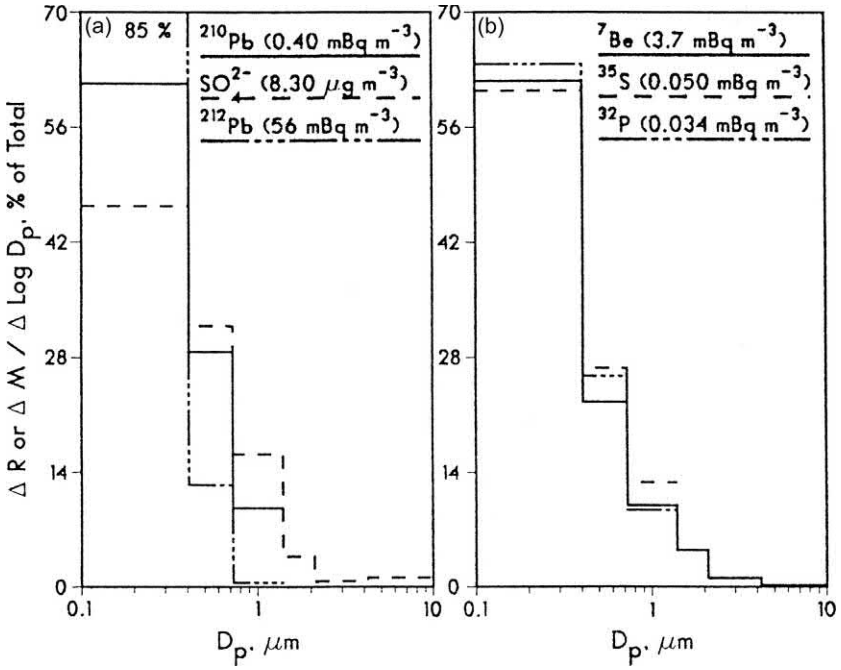

FIGURE 4.25 Aerodynamic size (Dp) distributions of radionuclides (*R*) and SO_4^- (M) derived from a 7-day aerosol sampling carried out using two high-volume cascade impactors. ^{212}Pb, ^{35}S, ^{32}P, and ^{210}Pb were only measured on three stages, < 1.4 μm. Lower D_p limits are arbitrary. *From Papastefanou (2008). Printed with permission from Elsevier Copyright (2008).*

Porstendörfer and Grundel, 2003). The residence time, τ_R, is described by a formula (Papastefanou and Ioannidou, 1995; Papastefganou, 2009b):

$$\tau_R = \mathrm{AMAD}_{\mathrm{mean}} - \frac{\mathrm{Size}_{\mathrm{Aitken\ nuclei}}}{\mathrm{Mean\ particle\ growth\ rate}} \qquad (4.8)$$

The residence time of atmospheric aerosol particles associated with ^{210}Pb, a decay product of soil emanated radon-222, could be determined, because ^{7}Be and ^{210}Pb have a common association with atmospheric aerosol particles (Dibb and Jaffrezo, 1993).

Residence times of tropospheric aerosols derived from ^{7}Be and ^{210}Pb concentrations in air are presented in Table 4.12. Papastefanou and Ioannidou (1995) estimated residence times for ^{7}Be aerosols varying between 7.4 and 8.9 days (average 8.0 days) with corresponding AMAD values of aerosol particles associated with ^{7}Be varying from 0.76 to 1.18 μm (average 0.90 μm) (Table 4.12) for 12 measurements of aerosol samplings carried out during a 1½-year period, thus included all seasons, at Thessaloniki region (48°38′N, 22°58′E), Northern Greece, with dry (precipitation-free) climate at temperate latitude.

Winkler et al. (1998) estimated residence times 5–6 days for ^{7}Be aerosols and 4–5 days for ^{210}Pb aerosols, in 46 measurements of aerosol samplings carried out during a 1¼-year period in ground level air at a semirural area at Neuherberg, Germany (48°13′N,11°36′E), 490 m above sea level.

Shapiro and Forbes-Resha (1976) much earlier estimated a mean tropospheric aerosol residence time for ^{7}Be-bearing aerosols of 35.4 days, significantly higher, i.e., more than four times higher, at Fullerton, California (33°52′N, 117°55′W), also at midlatitude for an almost 2-year period with relatively light precipitation.

Yu and Lee (2002) more recently estimated mean residence times for ^{7}Be-associated aerosols ranging from 2.6 to 4.8 days based on 14 measurements of aerosol samplings carried out during a 4-month period (November–March), 20 m above ground at Hong Kong (22°18′N, 114°10′E), including winter and spring measurements.

Balkanski et al. (1993) following a global three-dimensional model, which uses meteorological parameters, such as precipitation scavenging, computed residence times for ^{210}Pb aerosols in the tropospheric column of about 5 days at southern midlatitudes up to 80°S and 10–15 days in the tropics (30°S-30°N). Values at northern midlatitudes up to 80°N varied from about 5 days in winter to about 10 days in summer. The residence time of ^{210}Pb produced in the lowest 0.5 km of atmosphere is on the average four times shorter than that of ^{210}Pb produced in the upper atmosphere. They found that the tropospheric residence time is a function of latitude according to the following equation (Ehhalt, 1973):

$$\tau_R = C/\Phi \qquad (4.9)$$

where C is the tropospheric column of a radionuclide extending from the surface up to the model layer just below the tropopause, and Φ is the total depositional flux out of the column at a given latitude.

Koch et al. (1996) following a three-dimensional chemical tracer model as Balkanski et al. (1993) calculated tropospheric aerosol residence times of 9 days for ^{210}Pb aerosols at different latitudes from 80°S to 80°N. The respective residence times of ^{7}Be aerosols were 21 days reflecting the high-altitude versus low-altitude source regions of these two tracers. They also found that the tropospheric residence time is a function of latitude (Balkanski et al., 1993) according to Eq. (4.10).

The data of Table 4.13 admit residence times of tropospheric aerosols in the range 2.6–35.4 days, crowding these into two groups of values 2.6–15 days (average 8.8 days) and 21–35.4 days (average 28.2 days). The lower values are applicable only to the boundary layer near the earth's

TABLE 4.13 Residence times of tropospheric aerosols derived from ^{7}Be and ^{210}Pb activities in air (days).

surface, and the higher values are appropriate to the troposphere as a whole (Junge, 1963). Martell and Moore (1974) came to the opposite conclusion, namely, that the high values are due to the contribution of stratospheric aerosols, whereas the lower values represent the true tropospheric residence time essentially independent of altitude.

B. Residence time of tropospheric aerosol particles associated with the radon decay product radionuclides

A method for estimating the residence time of tropospheric aerosol particles associated with radon decay product radionuclides is based on the radioactivity of a pair of genetically related radioisotopes, such as ^{210}Pb, ^{210}Bi or ^{210}Pb, ^{210}Po according to the sequential disintegrations in the beta decay scheme, as

$$^{210}\mathrm{Pb} \xrightarrow{\beta^-,\ 22.3\ \mathrm{y}} {}^{210}\mathrm{Bi} \xrightarrow{\beta^-,\ 5.01\ \mathrm{d}} {}^{210}\mathrm{Po} \xrightarrow{\alpha,\ 138.38\ \mathrm{d}} {}^{206}\mathrm{Pb}\ (\mathrm{stable})$$

The residence time, τ_R, is described be the formulas (Papastefanou, 2009a)

$$\tau_R = {}^{1}/_{\lambda_{\mathrm{Bi}}} \cdot \frac{\lambda_{\mathrm{Bi}} N_{\mathrm{Bi}}/\lambda_{\mathrm{Pb}} N_{\mathrm{Pb}}}{1 - (\lambda_{\mathrm{Bi}} N_{\mathrm{Bi}}/\lambda_{\mathrm{Pb}} N_{\mathrm{Pb}})} \tag{4.10}$$

where $\lambda_{\mathrm{Bi}} \cdot N_{\mathrm{Bi}}$ is the activity of ^{210}Bi, $\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}$ is the activity of ^{210}Pb in air, and $\lambda_{\mathrm{Bi}} = 0.138\ \mathrm{d}^{-1}$ is the decay constant of ^{210}Bi. Eq. (4.10) is derived from the equation of the production and removal of radionuclides assuming steady-state equilibrium:

$$\frac{dN_{\mathrm{Bi}}}{dt} = \lambda_{\mathrm{Pb}} N_{\mathrm{Pb}} - (\lambda_{\mathrm{Bi}} + \lambda_{\mathrm{R}}) N_{\mathrm{Bi}} = 0 \tag{4.11}$$

where $\lambda_{\mathrm{R}} = 1/\tau_{\mathrm{R}}$ is the first-order rate constant for removal of aerosols from the atmosphere by all processes, that is, the inverse of residence time, τ_R. The ratio of the activities $\lambda_{\mathrm{Bi}} \cdot N_{\mathrm{Bi}}/\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}$ in Eq. (4.10) varied from 0.42 to 0.85 (Moore et al., 1972).

If the activity of ^{210}Po, $\lambda_{\mathrm{Po}} \cdot N_{\mathrm{Po}}$ is considered and $\lambda_{\mathrm{Po}} = 5.0\ 10^{-3}\ \mathrm{d}^{-1}$ is the decay constant of ^{210}Po, then the activity ratio of ^{210}Po and ^{210}Pb is given by the equation (Papastefanou, 2009a)

$$\frac{\lambda_{\mathrm{Po}} \cdot N_{\mathrm{Po}}}{\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}} = \frac{\tau_R^2}{(\tau_R + 1/\lambda_{\mathrm{Bi}}) \cdot (\tau_R + 1/\lambda_{\mathrm{Po}})} \tag{4.12}$$

from which the residence time, τ_R, is determined as

$$\tau_R = \frac{-b + (b^2 - 4ac)^{1/2}}{2a} \tag{4.13}$$

where

$$\begin{aligned} a &= \lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}} - \lambda_{\mathrm{Po}} \cdot N_{\mathrm{Po}} \\ b &= -\lambda_{\mathrm{Po}} \cdot N_{\mathrm{Po}} (1/\lambda_{\mathrm{Bi}} + 1/\lambda_{\mathrm{Po}}) \\ c &= -\lambda_{\mathrm{Po}} \cdot N_{\mathrm{Po}} \cdot \frac{1}{\lambda_{\mathrm{Bi}} \cdot \lambda_{\mathrm{Po}}} \end{aligned} \tag{4.14}$$

$$\lambda_{\mathrm{Bi}} = 0.138\ \mathrm{d}^{-1} \text{ and } \lambda_{\mathrm{Po}} = 5 \times 10^{-3}\ \mathrm{d}^{-1}$$

The ratio of the activity $\lambda_{\mathrm{Po}} \cdot N_{\mathrm{Po}}/\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}$ in Eq. (4.12) varied between 0.054 and 0.092 (Moore et al., 1972).

The residence time, τ_R, can also be determined through the ratio of activities of radon, ^{222}Rn, $\lambda_{\mathrm{Rn}} \cdot N_{\mathrm{Rn}}$ and ^{210}Pb, $\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}$ in air according to the sequential equation disintegrations in the alpha and beta decay scheme as:

$$^{222}\mathrm{Rb} \xrightarrow{\alpha,\ 3.824\ \mathrm{d}} {}^{218}\mathrm{Po} \xrightarrow{\alpha,\ 3.05\ \mathrm{m}} {}^{214}\mathrm{Pb} \xrightarrow{\beta^-,\ 26.8\ \mathrm{m}} {}^{214}\mathrm{Bi}$$

$$\xrightarrow{\beta^-,\ 19.7\mathrm{m}} {}^{214}\mathrm{Po} \xrightarrow{\alpha,\ 163\ \mu\mathrm{s}} {}^{210}\mathrm{Pb} \xrightarrow{\beta^-,\ 22.3\ \mathrm{y}}$$

and Eq. (4.11) by the formula (Papastefanou, 2009a)

$$\tau_R = \frac{1}{\lambda_{\mathrm{Pb}}} \cdot \frac{1}{\frac{\lambda_{\mathrm{Rn}} \cdot N_{\mathrm{Rn}}}{\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}} - 1} = \frac{1}{\lambda_{\mathrm{Pb}}} \cdot \frac{\lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}}{\lambda_{\mathrm{Rn}} \cdot N_{\mathrm{Rn}}} \tag{4.15}$$

where $\lambda_{\mathrm{Pb}} = 8.5 \times 10^{-5}\ \mathrm{d}^{-1}$ is the decay constant of ^{210}Pb and $\frac{\lambda_{Rn} \cdot N_{Rn}}{\lambda_{Pb} \cdot N_{Pb}} \gg 1$.

The ratio of the activities $\lambda_{\mathrm{Rn}} \cdot N_{\mathrm{Rn}} / \lambda_{\mathrm{Pb}} \cdot N_{\mathrm{Pb}}$ in Eq. (4.15) varied from 282 to 7700 (Moore et al., 1972).

Residence times of tropospheric aerosols derived from ^{210}Bi/^{210}Pb, ^{210}Po/^{210}Pb, and ^{222}Rn/^{210}Pb activity ratios in air are presented in Table 4.14.

Papastefanou and Bondietti (1991) estimated tropospheric aerosol residence times ranging from 4.8 to 15.3 days (average 8.2 days) based on the ^{210}Bi/^{210}Pb activity ratios for 21 measurements of aerosol samplings carried out during an annual period at Oak Ridge, Tennessee (35°58′ N, 84°17′ W), at temperate latitude with high precipitation (wet climate).

Poet et al. (1972) estimated tropospheric aerosol residence times ranging from 1.59 to 13 days (average 5.4 days) when based on the ^{210}Bi/^{210}Pb activity ratios and from 11 to 77 days (average 24 days) when based on the ^{210}Po/^{210}Pb activity ratios for 20 measurements of aerosol samplings carried out in surface air during a 4½-year period at Boulder, Colorado (40°01′N, 105°17′W). They concluded that a mean tropospheric residence time of about 4 days could be applied for aerosol particles in the lower troposphere and about a week for aerosol particles in precipitation. They also found that the mean aerosol residence time increases with altitude within the troposphere by a factor of less than 3 (Moore et al., 1973).

Francis et al. (1970) estimated a mean atmospheric residence time for ^{210}Pb of 9.6 days ± 20% based on the ^{210}Po/^{210}Pb activity ratios from the dust of filtrate (larger than 0.22 μm in diameter) collected during a 3-month period (May−August) at Madison, Wisconsin (43°05′N, 89°22′W).

Marley et al. (2000) estimated residence times for seven aerosol samples collected at Argonne, Illinois (41.7°N, 88.0°W) during a 2-year period, three aerosol samples collected at Phoenix, Arizona, one sample collected at Socorro, New Mexico, and five samples collected at Mexico City, Mexico. Based on the ^{210}Bi/^{210}Pb activity ratios, they resulted in residence times of 6−67 days, whereas the ^{210}Po/^{210}Pb activity ratios suggested residence times of 33−66 days for the aerosols below 2 μm in size.

Much earlier, Fry and Menon (1962) in 12 measurements carried out during a 7-month period (spring and summer) at Fayetteville, Arkansas (36°03′N, 78°54′W), indicated apparent aerosol residence times ranging from 2.4 to 25.6 days (average 8.5 days), based on the ^{210}Bi/^{210}Pb activity ratios in Arkansas rains. Gavini et al. (1974) also estimated residence times varied from 3 to 240 days (average 29 days) from ^{210}Bi/^{210}Pb activity ratios and from 2 to 320 days (average 40 days) from ^{210}Po/^{210}Pb activity ratios in Arkansas rains.

Baskaran and Shaw (2001) based on ^{210}Po/^{210}Pb activity ratios estimated residence times of arctic haze aerosols, from the upper atmosphere to the arctic atmosphere varied between 12 and 32 days from two measurements carried out during an 1½-year period (winter) at Poker Flat (65.1°N, I47.5°W) and between 0 and 39 days from eight measurements carried out during a 2-month period (winter) at Eagle (69.5°N, 141.2°W) in Alaska.

Very early, Lehmann and Sittkus (1959) estimated aerosol residence times of 20 days from ^{210}Po/^{210}Pb activity ratios in air at Freiburg, Germany (47°59′N, 7°51′E), whereas Peirson et al. (1966) estimated aerosol residence times of 40 days from ^{210}Po/^{210}Pb activity ratios in air at Milford Haven, Wales (51°40′N, 5°02′E).

Lambert et al. (1982) estimated aerosol residence times varied from 8.8 to 10.5 days based on the ^{210}Bi/^{210}Pb activity ratios in air, whereas later in another work, they estimated aerosol residence times varied from 7 to 9 days (average 8.58 days) based on the ^{210}Bi/^{210}Pb activity ratios in air, near the Paris area during a 6-year period (Lambert et al., 1983)

Gäggeler et al. (1995) during a 1-year period carried out measurements on the activities of ^{214}Pb, ^{210}Pb, and ^{212}Pb in air at high altitude in Jungfraujoch, Switzerland (46°32′N, 07°59′E) as high as 3450 m with an epiphaniometer. They estimated aerosol residence times varied between 1 and 12 days (average 6 days) from the ^{214}Pb/^{210}Pb activity ratios.

Rangarajan (1992), based on the ^{210}Bi/^{210}Pb activity ratios in air, estimated a mean residence time of the natural radioactive aerosols in the planetary boundary layer at Bombay, India (18°58′N, 72°50′E) around 8 days from 43 measurements carried out during the long dry period, October to May.

The data of Table 4.14 display residence times of lower values, as low as 1.59 days, and higher values, as high as 320 days. Mostly, the lower τ_R values were determined from the ^{210}Bi/^{210}Pb activity ratios and higher τ_R values from the ^{210}Po/^{210}Pb activity ratios. Low τ_R values were also determined from the ^{222}Rn/^{210}Pb activity ratios.

Poet et al. (1972) concluded that longer apparent residence time values for τ_R based on the ^{210}Po/^{210}Pb activity ratios than for τ_R based on the ^{210}Bi/^{210}Pb activity ratios. The difference may be explained by the presence of a mixture of aerosols of various apparent ages, of which older aerosols (those of greater age) contribute most of ^{210}Po. On

TABLE 4.14 Residence times of tropospheric aerosols derived from $^{210}Bi/^{210}Pb$, $^{210}Po/^{210}Pb$, $^{222}Rn/^{210}Pb$, $^{89}Sr/^{90}Sr$, and $^{140}Ba/^{90}Sr$ activity ratios in air (days).

the other hand, the solid products of radon-222 decay, that is ^{210}Pb, ^{210}Bi, and ^{210}Po, might arise from sources other than radioactive decay within the atmosphere. Poet et al. (1972) showed that up to 85% of ^{210}Po in the atmosphere is of terrestrial origin, and the vertical profile of ^{210}Po was found to differ appreciably from that expected from the decay of ^{222}Rn.

Lambert et al. (1979) indicated that volcanic gases are very rich in long-lived radon decay products, especially in ^{210}Po relative to ^{210}Pb. Soil particles are the most likely contributors, since a part of the tropospheric aerosols originates at the earth's surface. Coal burning and forest fires presumably are additional sources of radionuclides.

Dlugosz et al. (2010) calculated aerosol residence times from the ^{210}Po/^{210}Pb ratio ranging from 7 to 120 days in the urban air of Lodz, Poland.

C. Residence time of tropospheric aerosol particles associated with the fission product radionuclides

Apart from the activity ratios of the radon-222 decay product radionuclides, the residence time of tropospheric aerosols could be derived from the activity ratios of the fission product radionuclides released into the atmosphere during the explosions from nuclear weapons testing or nuclear reactor accidents, such as ^{89}Sr/^{90}Sr and ^{140}Ba/^{90}Sr. These isotopic ratios were considered as nuclear clocks. The applicability of the radioisotope ratios depends on the steady-state conditions held at the time and place of measurements and the kind of the sample whether they are surface air or precipitation (rain or snow) for the radioisotope activity determination.

Kuroda (1982) following the 22nd, 23rd, and 24th Chinese Weapons Tests at Lop Nor Desert (40°N, 90°E) of September 17, 1977, March 13, 1978, and December 14, 1978, respectively, calculated mean residence times of ^{90}Sr based on the ^{89}Sr/^{90}Sr and ^{140}Ba/^{90}Sr activity ratios in atmospheric precipitation in the corresponding period at Fayetteville, Arkansas (35°03′N, 78°54′W), where the nuclear debris passed over there for the second time, ranging from 5 to 12 days and 6 to 11 days. The difference in the mean residence times may be attributable to the difference in the average particle-size distributions of th`e debris, which passed over Fayetteville, Arkansas, for the first and second time. It is likely that large fallout particles were removed from the atmosphere more rapidly than smaller particles, and hence the nuclear debris that arrived at Fayetteville for the second time consisted of finer particles than that arrived earlier, and hence the mean residence time for the former was longer than for the latter.

Kristiansen et al. (2012) using a unique high-precision global measurement data set collected over several months after the accident at the Fukushima Dai-ichi nuclear power plant in March 2011 estimated the removal times of radioactive nuclides from the atmosphere. The noble gas ^{133}Xe released during the accident served as a passive tracer of air mass transport for determining the removal times of ^{137}Cs and ^{131}I via the decrease in the measured ratios ^{137}Cs/^{133}Xe and ^{131}I/^{133}Xe over time. After correction for radioactive decay, the ^{137}Cs/^{133}Xe ratios reflect the removal of aerosols by wet and dry deposition, whereas the ^{137}Cs/^{133}Xe ratios are also influenced by aerosol production from gaseous ^{131}I. The estimated removal times for ^{137}Cs were 10.0−13.9 days and for ^{131}I were 17.1−24.2 days, respectively, during April and May 2011. The removal time of ^{131}I is longer due to the aerosol production from gaseous ^{131}I; thus the removal time for ^{137}Cs serves as a better estimate for aerosol lifetime. The removal time of ^{131}I is of interest for semivolatile species.

The values of mean residence times based on the ^{210}Bi/^{210}Pb activity ratios, 2−78 days, and ^{210}Po/^{210}Pb activity ratios, 9−243 days (Table 4.14), are much greater than the values of the residence times obtained from the fission product radionuclide activity ratios. The differences are real and are attributable to the fact that, while the fresh fission product radionuclides were injected by the Chinese 22nd, 23rd, and 24th tests almost exclusively into the troposphere, the radon decay product radionuclides found in rain are mixtures of two different components: tropospheric and stratospheric. The radon decay products in the lower stratosphere are descending rapidly during the winter and mixing with the tropospheric component, whereas such a mixing process is occurring less frequently in summer and fall periods (Kuroda et al., 1978).

It is interesting to speculate on the following sequence of events: suppose that a large quantity of nuclear debris was injected into the stratosphere during the fall period. A large concentration of fission product radionuclides with an apparent "age" of several months will be located in the lower stratosphere during the early spring months of the following year. Now, suppose that these fission product radionuclides were brought down by a violent storm, which penetrated the tropopause (Dingle, 1965). If a mixture of radon decay product radionuclides, whose apparent "age" was also several months (Burton and Stewart, 1960), was located in the lower stratosphere together with the fission product radionuclides, approximately concordant residence times should be obtained from the ^{89}Sr/^{90}Sr and ^{210}Po/^{210}Pb activity ratios in rainwater at the ground level.

Konstantinos Eleftheriadis

Dr. Konstantinos Eleftheriadis is a **Director of Research at NCSR Demokritos**, Head of the Aerosol Group and the Environmental Radioactivity Laboratory at the Institute of Nuclear & Radiological Sciences & Technology, Energy & Safety. He has research expertise on Physicochemical aerosol characterization and nuclear analytical techniques with respect to climatic active aerosol species, nano-particle metrology, development of novel sampling and measurement techniques for aerosol particles, exposure of humans to aerosol contaminants, such as, heavy metals and radioactive pollutants, and retrieval of emission source impact, source apportionment and receptor modeling. Primary Investigator for Demokritos in several European Framework Programs (EU FP) and DG-ENV programmes, IAEA Regional projects & other National programmes. Dr. Konstantinos Eleftheriadis has established infrastructure, including the Athens GAW/ACTRIS Demokritos station, the Mt. Helmos Free Troposphere Aerosol and GHG station and the QA/QC physical aerosol properties lab facility. He has served as National Counterpart for Greece in Regional IAEA programmes. He has supervised 12 PhD thesis and 10 MSc project thesis; and has more than 150 publications in peer reviewed journals. Invited reviewer and evaluator for project proposals by a) EURAMET European Metrology Research, and the Czech Academy of Sciences Grant program. Dr. Konstantinos Eleftheriadis has carried out three expert missions for the IAEA in the Environment Program for Africa and the Middle East, and he is a Member of the National Emergency Action Plan "Xenokratis" and Founding Member and President of the Hellenic Association for Aerosol Research.

Alexandra Ioannidou

Alexandra Ioannidou is a professor at Aristotle University of Thessaloniki, Physics Department, Nuclear Physics Laboratory. She has research expertise on radiation physics and isotopes, radiation protection and environmental radioactivity—radioecology, environmental radioactivity from the Chernobyl and Fukushima accidents and effects of radioactive pollutants by their dispersion, contamination and decontamination, as well as on radioactive aerosols and their behavior in various environments, including the Arctic. Alexandra Ioannidou has steady interaction with the international scientific community through joint research projects, publications in international journals, conferences, meetings, and working in institutes abroad. Alexandra Ioannidou has supervised numerous thesis works by students for the PhD, MSc, and BSc degrees. She has more than 100 publications in peer-reviewed international journals and conferences, and she is a reviewer in more than 20 international scientific journals.

I. Introduction

Analyses of radionuclides in the marine environment and their applications in studying oceanographic processes have a long history. The first studies started in the late 1950s with investigations of ^{226}Ra in seawater (Koczy, 1958). Later, many other natural radionuclides (mainly U and Th isotopes and their decay products) found applications in marine sciences. After the introduction of anthropogenic radionuclides to the marine environment from atmospheric nuclear tests (e.g., ^{3}H, ^{14}C, ^{90}Sr, ^{137}Cs, Pu isotopes and others), it was recognized that these radionuclides represent powerful tools as tracers, which can be used effectively for the investigation of transport of water masses in oceans, in studying processes in the water column and in sediment, and mechanisms for the transfer of radionuclides to the marine biota (Broecker and Peng, 1982; IAEA, 1999, 2006; Livingston and Povinec, 2002; Povinec, 2004; Povinec and Sanchez-Cabeza, 2006; Povinec et al., 2013a). Another group of radionuclides utilized in marine studies is represented by the cosmogenic radionuclides (^{7}Be, ^{10}Be, ^{26}Al, ^{32}Si, ^{37}Ar, ^{39}Ar, ^{81}Kr, and others), produced by interaction of cosmic rays with atmospheric atoms (Lal, 1999).

Traditionally, marine radionuclide studies have always been limited by the techniques available for sampling (starting with a few hundred liters of seawater), as well as methods available for the analysis of radionuclides in the marine environment. The water sampling has developed from the reversing simple Nansen bottles into the present multibottle Rosette systems coupled with CTD detectors for measuring conductivity (C), temperature (T), and depth (D), combining thus water sampling and CTD measurements in one cast for the total water column. Robotic systems based on remotely operating vehicles and autonomous underwater vehicles, and other sophisticated sampling techniques, which use satellite views of sea areas for the optimization of sampling, are the examples of the present state-of-the-art technologies in marine sampling (Povinec and Sanchez-Cabeza, 2006; Povinec, 2008a, 2013; Povinec et al., 2013a).

Marine radionuclide activity measurements started with simple radiochemical separation methods and Geiger–Müller counters for activity measurements, which were later developed into the age of robotic radiochemical separation and purification technologies, sophisticated detectors working online with powerful computers (sometimes with satellite data transmission from continuous underwater radionuclide monitors), and coupled gas chromatography (GC) and mass spectrometry (MS) systems (Povinec et al., 2009).

An important breakthrough in marine radionuclide technologies was a change in the philosophy of radionuclide analysis. We shifted from the concept of waiting for radionuclide decays and subsequent counting of decay products (what has big disadvantages in the case of long-lived radionuclides), to the direct counting of radioactive atoms as if they would be stable, using highly sensitive mass spectrometers, working either with low-energy ions (e.g., thermal ionization mass spectrometry (TIMS), inductively coupled plasma mass spectrometry (ICPMS), resonance ionization mass spectrometry (RIMS)) or ions accelerated to levels of up to hundreds of MeV in accelerator mass spectrometry (AMS) (Povinec, 2004, 2008a, 2011, 2013).

This move from simple radioanalytical techniques to the present sophisticated state-of-the-art technologies has also been accompanied by a considerable change in the philosophy of oceanic studies (Livingston and Povinec, 2002; Povinec, 2004, 2011, 2013). It has been recognized that the world ocean cannot be investigated anymore in small institutional projects, typical of the time period from the 1960s to the 1970s, but large-scale global oceanic investigations carried out by international communities are necessary for a complex study of oceanic processes. Several such projects using radionuclides as tracers were carried out in the past, which contributed significantly to oceanic science, examples of which are the following:

- Geochemical Ocean Sections Program (GEOSECS)—a first global project on the distribution of ^{3}H, ^{14}C, ^{137}Cs, Pu isotopes in the world ocean;
- World Ocean Circulation Experiment (WOCE)—the largest worldwide project carried out till now with applications of radionuclides (^{3}H and ^{14}C);
- Worldwide Marine Radioactivity Studies (WOMARS)—the project carried out by the International Atomic

Energy Agency (IAEA) in cooperation with many marine and analytical laboratories, having the largest coverage of the world ocean with anthropogenic radionuclides (^{3}H, ^{14}C, ^{90}Sr, ^{129}I, ^{137}Cs, ^{241}Am, Pu isotopes) in the water column and sediment;
- Southern Hemisphere Oceans Tracer Studies (SHOTS)—a round-the-globe transect at 20 degrees S (^{3}H, ^{14}C, ^{90}Sr, ^{137}Cs, ^{241}Am, Pu isotopes) carried out by the Meteorological Research Institute (Tsukuba, Japan) and IAEA in collaboration with several marine and analytical laboratories; and
- GEOTRACES (www.geotraces.org)—the largest international worldwide project carried out at present on global marine biogeochemical cycles of trace elements and their isotopes.

In marine radioactivity studies, we have to deal with conflicting phenomena while planning and executing the sampling expeditions and the laboratory analyses. A sample size versus analysis determines the minimum size of samples required to accomplish the expected results with available laboratory techniques for radionuclide analyses. As the levels of anthropogenic radionuclides in the marine environment have been decreasing for the last 50 y after their main injection to the marine environment (Livingston and Povinec, 2002; Povinec, 2004; Povinec et al., 2013a; Hirose and Povinec, 2015), we have been forced to develop very highly sensitive radioanalytical technologies for minimizing the size of marine samples, especially seawater. On the other hand, with the increasing price of ship time we have been forced to minimize the sample size (and thus the sampling time). For example, seawater volumes usually sampled by the typical Rosette systems are 10−20 L, which is challenging for radiometric techniques (RMTs) (typical water volumes for ^{137}Cs and ^{239,240}Pu analysis in the water column are 200 and 400 L, respectively) currently in competition with mass spectrometry methods such as AMS and ICPMS (Povinec, 2005, 2010, 2011, 2013).

We shall review sampling, radiochemical, and measuring techniques for analysis of radionuclides in the marine environment with emphasis on recent developments in the field. In several cases, we shall illustrate the state of the art of the radioanalytical techniques together with recent developments and results obtained in the International Atomic Energy Agency's Environment Laboratories (IAEA-EL) in Monaco.

II. Sampling techniques

Generally, four types of samples—water, sediment, biota, and particulate matter—are used for the investigation of radionuclides in the marine environment. Therefore, we shall deal with each group of samples separately. A sampling strategy should be designed well in advance of real sampling in the marine environment (Scott and Dixon, 2008; Macášek, 2008).

A. Seawater sampling

The sensitivity of analytical methods often demands the analysis of large samples (e.g., hundreds of liters of seawater) in order to obtain meaningful results, especially in the case of radiometric methods (e.g., alpha-, beta-, and gamma-ray spectrometry). Therefore, a reduction in the volume of water sampled would be a great advantage, as this would be reflected also in the reduction in the time needed for sampling. This has important implications on financial budgets of cruises, as the ship time is very expensive (around 50 k€ per day for open ocean sampling). Therefore, more sensitive methods of radionuclide analysis than those offered by traditional RMTs are needed. As will be discussed later, if AMS, ICPMS, or TIMS are used, only small-volume samples are needed for the analysis of several long-lived radionuclides in the water column. For example, ^{14}C or ^{129}I analysis by AMS requires only 0.5 L of water. The ^{239}Pu or ^{240}Pu analysis by AMS or TIMS requires only around 10 L of water. For other radionuclides analyzed by γ-ray spectrometry (e.g., ^{137}Cs) or β-ray spectrometry (e.g., ^{90}Sr), measurements in low-background underground laboratories would seem to be the solution for decreasing sample volumes to about 10 L (Aoyama and Hirose, 2008; Povinec et al., 2008a, 2013a).

Two kinds of water samples are collected during oceanographic cruises. Small-volume samples, e.g., separate samples each of 0.5 L, are required for ^{3}H analysis (by a light isotope mass spectrometer, which analyzes the decay product of ^{3}H (i.e., ^{3}He) and for ^{129}I and ^{14}C analyses by AMS (^{14}C sample is usually poisoned with mercury chloride to prevent any biological activity). These samples are filtered only (by a 0.45-μm membrane filter) on board the ship, and then carefully bottled to prevent any exchange of air with water. All the preparation chemistry is then carried out in the home laboratory.

Water sampling for traditional radionuclide analysis by RMTs requires collection of large-volume samples (100−500 L). This is very laborious and time consuming, especially if water has to be raised onto the ship deck from several kilometer depths (Povinec et al., 2003a). The operation with large-volume (around 100 L, 200 L, 500 L) samplers (e.g., of the Gerard−Ewing type) usually made from glass fiber reinforced plastic (Fig. 5.1) is very difficult and time consuming. After collection, the water is filtered (0.45 μm) and transferred by a pump to precipitation tanks for pretreatment.

The need for accurate and timely radiochemical measurements is the driving force behind the search for rapid methods with high selectivity, excellent purification

FIGURE 5.1 Large-volume seawater samplers of Gerard Ewing type (270 L), and deployment of the sampler. For the color version of the figure, the reader is referred to the online version of the book.

FIGURE 5.2 Rosette/CTD multibottle seawater sampling system. For the color version of the figure, the reader is referred to the online version of the book.

factors, and good chemical recoveries. Large-volume samples are too large to be transported to the laboratory; therefore, preconcentration should be carried out on shipboard. Consequently, the most important development in seawater sampling has been the introduction of the CTD/Rosette multibottle samplers (CTD/RMS) illustrated in Fig. 5.2. They have been employed for the collection of both small- and medium-volume samples by using one bottle per depth layer, or several bottles at the same depth. The volume and number of Niskin bottles used in a CTD/RMS sampler vary from type to type. Further advantages of the CTD/RMS sampler are online monitoring of oceanographic parameters, e.g., pressure, temperature, conductivity/salinity, dissolved oxygen, and sound velocity. Twenty-four sets of CTD data can be collected every second. The CTD/RMS system is submerged during operation at a vertical speed of 1−1.5 m/s, and the CTD data are monitored in real time in a dry laboratory on shipboard. The data obtained during downcast are usually used as the CTD profile data; seawater samples are collected during the upcast. In general, two casts, one shallow (up to about 1000 m) and one deep, are enough for deepwater sampling. In this way, the whole water column can be sampled more accurately and with only two casts (Povinec et al., 2004a, 2004b, 2004c).

B. Sediment sampling

Box corers or multiple corers, illustrated in Fig. 5.3, are usually used for sediment sampling down to a sediment depth of around 60 cm, although shallow samples can be obtained by hand sampling (Lee et al., 2017). Both types of corers have their advantages and disadvantages. Box corers allow subsampling of cores by the insertion of a plastic tube into the recovered sediment. They are easier to control and show relatively large undisturbed sediment surfaces. Simple grab corers (Fig. 5.3) have been used only for bulk surface sediment sampling, when radionuclide distribution with depth is not required for the study. A pinger fixed around 50 m above the corer is used for reading the relative distance of the box core from the seafloor, which is registered by an echo-sounder on the shipboard. The last 50−60 m from the bottom are recorded by a deep-sea echo sounder (DSES), and the winch cable is slowly lowered until the corer hits the bottom. The changes in cable tension are continuously recorded on an X−Y chart recorder. After successful retrieval of a box core, plastic tubes may be used to subcore sediments by slow penetration into the collected sediment (Fig. 5.3). Special care must be taken not to compress the sediment column by modifying the force while maintaining equal sediment surface levels inside and outside the wall of the plastic tube. When sediments are too cohesive, a vacuum pump should be used to ease the core liner into the sediment. The tubes containing sediment are capped on the top and plugged at the bottom with a plastic stopper with silicone O-rings to make the plugging water tight. After X-ray investigations for studying micro- and macrosediment structures (which can also be done later in the home laboratory on an extra collected tube), the tubes are sliced

FIGURE 5.3 Preparation of the box corer (left), multicorer (center), and a simple grab corer (right) for the bottom sediment sampling, and subsectioning of the box core. For the color version of the figure, the reader is referred to the online version of the book.

into predetermined sections (usually 0.5−1 cm thick) in the wet laboratory on the shipboard. Each sediment section is placed in a preweighted plastic container and kept at 4°C until the appropriate conditions for wet weighing are encountered. The samples are freeze-dried in the home laboratory and weighed again, thus determining the total sediment weight. This information is used to determine water content, bulk density, porosity, and the mass depth of the sediment column sampled, which are the sediment parameters needed for the correct interpretation of radionuclide results. The sediment remaining in the box after subsampling, usually from 0 to 5 cm, is squeezed to obtain pore water. The pore water is then filtered through a 0.45-μm filter and stored at 4°C in small bottles for subsequent analyses in the home laboratory.

A Kullenberg corer (Fig. 5.4) was used for the sampling of sediment columns a few meters in length (Povinec et al., 1999). As surface layers of sediment are usually compressed during sampling, this type of corer, which acts as a gravity corer, is not suitable for sampling surface sediment layers.

C. Biota sampling

Plankton invertebrates are collected using plankton nets generally of four different mesh sizes (1000, 500, 250, and 100 μm) with a ring aperture of around 1 m and a length of a few meters (Fig. 5.5). The nets are towed horizontally or rarely vertically. When towing horizontally at a depth of 10−20 m, it is possible to use nets with different meshes simultaneously (except for 100 μm nets which are very fragile and with which special precautions must be taken). The ship's speed is maintained at about 1 knot to avoid damaging both the nets and the animals collected. The sampling period is usually a few hours. The total volume of water, which passes through the nets, is estimated by a fixed current meter centered at the opening of one of the plankton nets. Upon retrieval of the net from the water, the collected animals are placed in labeled plastic containers and studied. Finally, they are frozen in plastic bags and cooled in a box cooler containing dry ice during transportation to the home laboratory.

FIGURE 5.4 Deployment of the Kullenberg corer in the Mururoa lagoon (left), radiation contamination checks of the sediment core in the plastic tube (center), and two sections of the sediment core (right). For the color version of the figure, the reader is referred to the online version of the book.

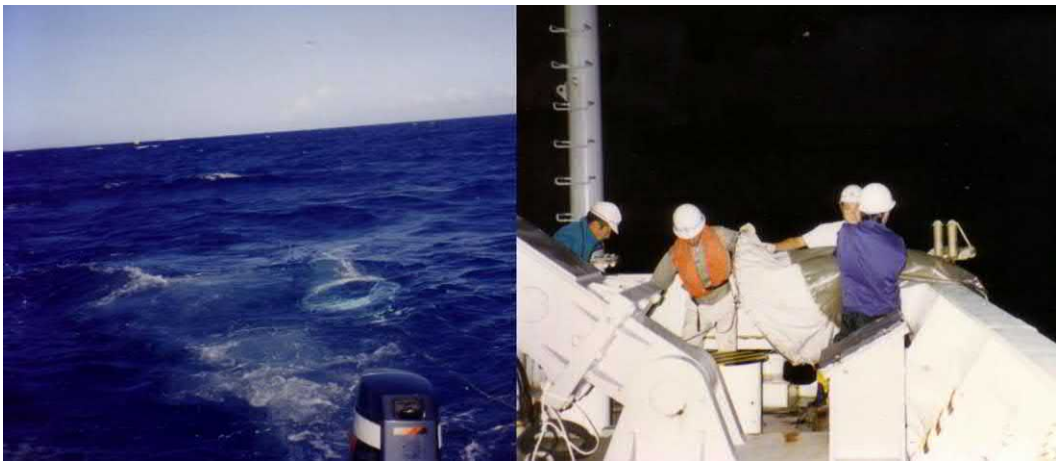

FIGURE 5.5 Plankton sampling with a net in the Mururoa lagoon (left) and recuperation of the net after plankton sampling (right). For the color version of the figure, the reader is referred to the online version of the book.

Samples of fresh algae are usually collected on plastic foils moored in the water column (Fig. 5.6). Fish, shellfish, and seaweeds are collected in a traditional way.

D. Sampling of particulate matter

A sediment trap consists of an upward-facing funnel that directs sinking particulate organic and inorganic material toward a mechanism for their collection and preservation (Fig. 5.7). The traps may be arranged as free floating or moored systems remaining in the water column for periods of months, thus enabling seasonal and annual changes in particle fluxes to be recorded. These studies have broadened our knowledge of ocean particulate dynamics and their links with the ocean carbon cycle (Fowler et al., 2000). Traps are often moored at a specific depth in the water column (usually below the mixed layer) in a particular location, but some are so-called Lagrangian traps that drift with the surrounding ocean currents (though they may remain at a fixed depth). The most important development

FIGURE 5.6 Recuperation of a plastic foil with algae after its exposition in the Mururoa lagoon. For the color version of the figure, the reader is referred to the online version of the book.

in the sediment trap sampling technique is the microprocessor-controlled sampling using sediment traps with sampling bottles changed according to pre-programmed time intervals, thus enabling the development of a continuous time series over a number of years. A formaldehyde solution in the bottles prevents the deterioration of sampled particulate matter throughout the sampling period.

III. Underwater gamma-ray spectrometry

A complimentary detection method to a traditional sampling and laboratory analysis is a direct, in situ analysis of radionuclides, e.g., in the air, soil, water, or sediment. We shall focus in this chapter only on underwater γ-ray spectrometry and applications in the aquatic environments. Such a novel approach can have several advantages, as complicated and laborious sampling, preconcentration and separation techniques, and long-term measurements are not necessary. On the other hand, mapping of γ-emitters in large surface areas is possible, which otherwise would require long-term sampling and measurement periods (Noakes et al., 1999; Jones, 2001; Osvath et al., 1999a; Osvath and Povinec, 2001; Povinec et al., 2001a). Further advantages include the screening of sunken or dumped radioactive objects (Osvath et al., 1999b), a continuous analysis of radionuclides in water replacing a sporadic short-term sampling and analysis, a real-time reporting of data, observation of temporal changes, and the development of a time series of data collected (Soukissian et al., 1999; Wedekind et al., 2000; Povinec, 2004; Van Put et al., 2004; Osvath et al., 2005; Povinec et al., 2006a, 2006b; 2008a, 2008b, 2008c; Tsabaris et al., 2012).

The systems most commonly used for the underwater γ-ray spectrometry are based on NaI(Tl) or BGO (bismuth germanate) detectors. The advantages of NaI(Tl)-based systems are firstly related to the high detection efficiency of NaI(Tl) crystals at much lower cost than equivalent HPGe crystals. Moreover, NaI(Tl)-based systems can be built sufficiently robust and are adequate for long-term underwater deployment. In addition, polycrystalline NaI(Tl) materials can be obtained with identical optical characteristics and far better thermal and mechanical strength than single crystals, thus further improving the shock resistance and thermal stability of the system. The drawbacks of NaI(Tl)-based systems are the high power consumption required for the operation of the photomultiplier tube and a relatively poor energy resolution of the detector (with peaks tens of times wider than those in spectra recorded with HPGe detectors). HPGe-based systems on the other hand have the advantage of good energy resolution and hence excellent radionuclide identification capability (Povinec et al., 1996, 2008a; Osvath et al., 1999a, 1999b). An HPGe (20% relative efficiency) underwater γ-ray spectrometer utilizes liquid propane cooling (Povinec et al., 1996). Because of the special cooling required for the working regime (the detector after its exposition in water should be cooled again down to the liquid propane temperature), the detector could operate underwater only for about 10 hours. The system was tested in the Irish Sea (Povinec et al., 1996), and the resultant spectra represent the first set of high-resolution seawater/seabed γ-ray spectra ever recorded in situ. Fig. 5.8 illustrates, as an example, a γ-spectrum obtained with the underwater HPGe detector in the Stepovoy Bay of the Novaya Zemlya island (the Kara Sea) where dumping of radioactive wastes was carried out in the past (Povinec et al., 1997; Osvath et al., 1999b).

Electrically cooled HPGe γ-ray detectors using Stirling cycle refrigerators have also been developed. The size of such a detector assembly is small and its power consumption is only ∼1 W (Kobayashi et al., 1998). Other available types of detectors, such as CsI crystals (pure or doped with Tl or Na), fluorides (e.g., CsF and BaF_2), or semiconductor detectors which do not require external cooling (e.g., CdTe, CdZnTe, HgI_2, and GaAs), have not become competitive

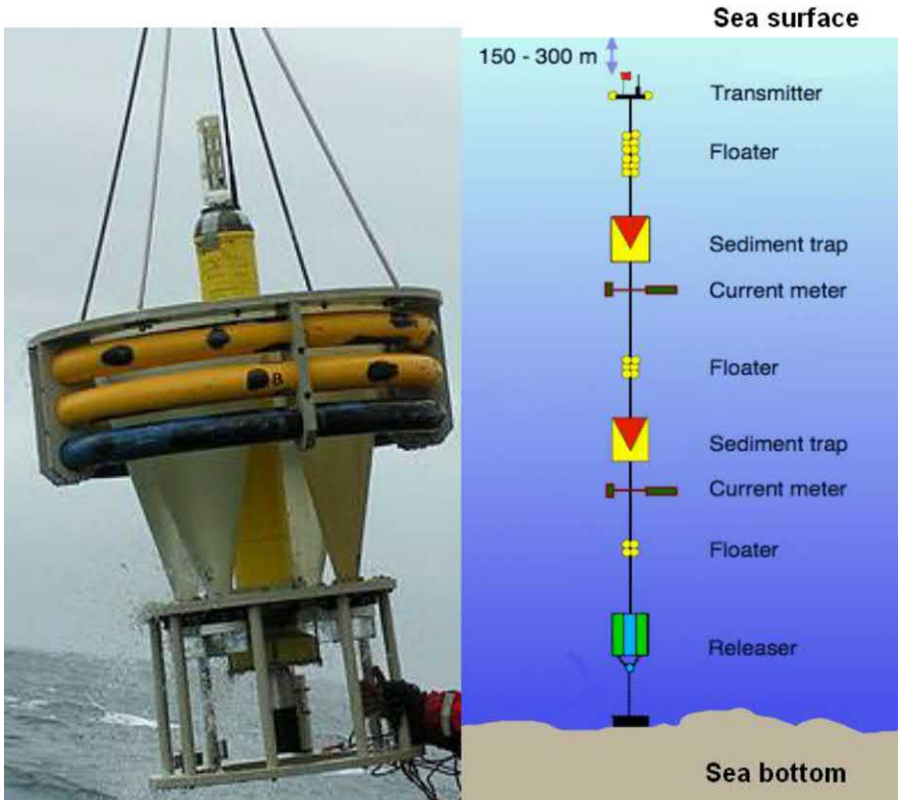

FIGURE 5.7 Recuperation of a sediment trap for the sampling of sinking particulate organic and inorganic material in the ocean (left), and mooring system for deployment of sediment traps (right). For the color version of the figure, the reader is referred to the online version of the book.

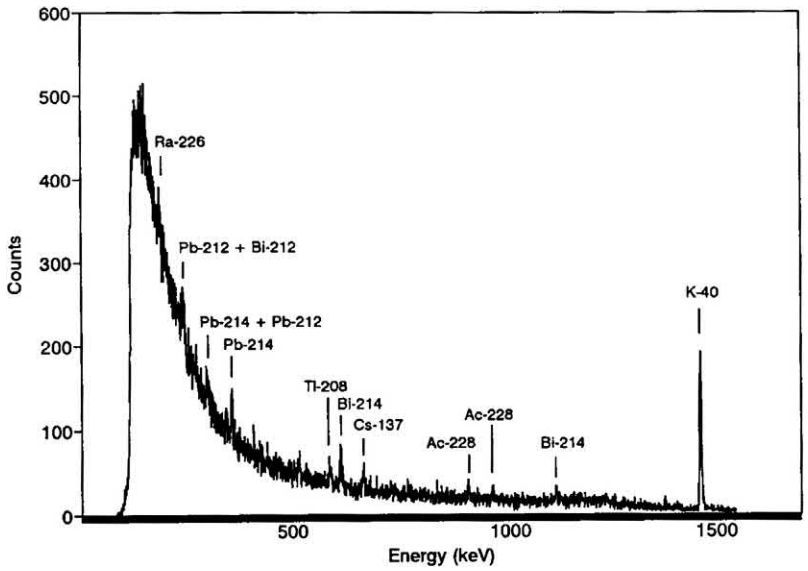

FIGURE 5.8 The γ-spectrum obtained with the underwater HPGe detector in the Stepovoy Bay of the Novaya Zemlya island (the Kara Sea) where dumping of radioactive wastes was carried out in the past. *Modified after Osvath et al. (1999a). Printed with permission © Elsevier 1999.*

with NaI(Tl) and HPGe detectors mainly because of their lower efficiency for the detection of γ-rays in the energy interval 30−3000 keV. Higher-energy *β-ray* emitters, such as ^{90}Sr, could be monitored in water either via Cherenkov radiation and/or via bremsstrahlung (Chernayev et al., 1999).

A. Towed detector systems

We shall describe, as an example, an in situ γ-spectrometric system consisting of a NaI(Tl) probe operating with a shipboard computer, a power supply, and data acquisition electronics (Osvath and Povinec, 2001). A stainless steel tubular probe casing houses a 152 × 51 mm NaI(Tl) ruggedized crystal; a high gain photomultiplier tube; pressure, temperature, and seabed roughness sensors; and electronic circuit boards, which provide power to the sensors and process the signals (Fig. 5.9). Data are transferred from the probe to the logging computer every second and can be sequentially stored. A generated 300-channel spectrum covers the energy range from 100 to 3000 keV. The logging program on the computer allows the monitoring of the spectrum recording and of the total count rate, bottom ruggedness, pressure, and temperature. The energy calibration of the γ-ray spectrometer was carried out using ^{137}Cs and ^{60}Co radioactive sources. The energy resolution for 662 keV (^{137}Cs) γ-rays was 6.5%. The efficiency calibration was done using a ^{137}Cs source dispersed in a polyethylene tank 1 m in diameter and 1 m high, filled with freshwater. The tank was later filled with seawater with natural concentration of ^{40}K (1462 keV), ^{226}Ra, and ^{222}Rn and its daughter products. Background measurements were carried out with the detector immersed in the tank filled with freshwater without any additional tracers (Povinec et al., 2006a, 2006b).

Another example of the state-of-the-art technology is a mobile underwater γ-spectrometer developed by the Japan Atomic Energy Research Institute (JAERI, 2005). The ROV-based system is equipped with γ-detectors (NaI(Tl) and HPGe), CTD, water and sediment sampling devices, cameras, etc., as illustrated in Fig. 5.10. The system has been used for seawater monitoring and sea-bottom prospection in coastal waters of Japan (JAERI, 2005).

B. Stationary detector systems

The NEMO (Nautic Environment Marine Observatory), a stationary underwater monitoring system, based on a NaI(Tl) detector (Fig. 5.11), is another type of in situ γ-ray spectrometer (Osvath et al., 2005). It records γ-ray spectra in water together with a suite of environmental parameters including seawater temperature, conductivity, current speed, and its direction. These data may be transmitted via a satellite link to a base station. The monitor's capabilities can be further expanded by adding sensors for meteorological (wind speed and direction, air temperature, and pressure) and oceanographic measurements (wave height, direction and period, water temperature and salinity profiles, light attenuation, chlorophyll-A, and hydrocarbon content measurements). The water current speed and its direction are measured with a three-axis ultrasonic transducer, with ranges of 0−300 cm/s and 0−360 degrees and uncertainties of 3% and 2%, respectively. The temperature sensor has an operational range of −5°C to +45°C with an uncertainty of 0.1°C. Salinity is determined from conductivity measurements performed with an electrodeless induction type cell. The sensors are suspended 4 m underwater on a structure attached to a floating buoy.

The NaI(Tl) detector, 76 mm in diameter and 76 mm in length, made of ruggedized crystal, has a 7% resolution for

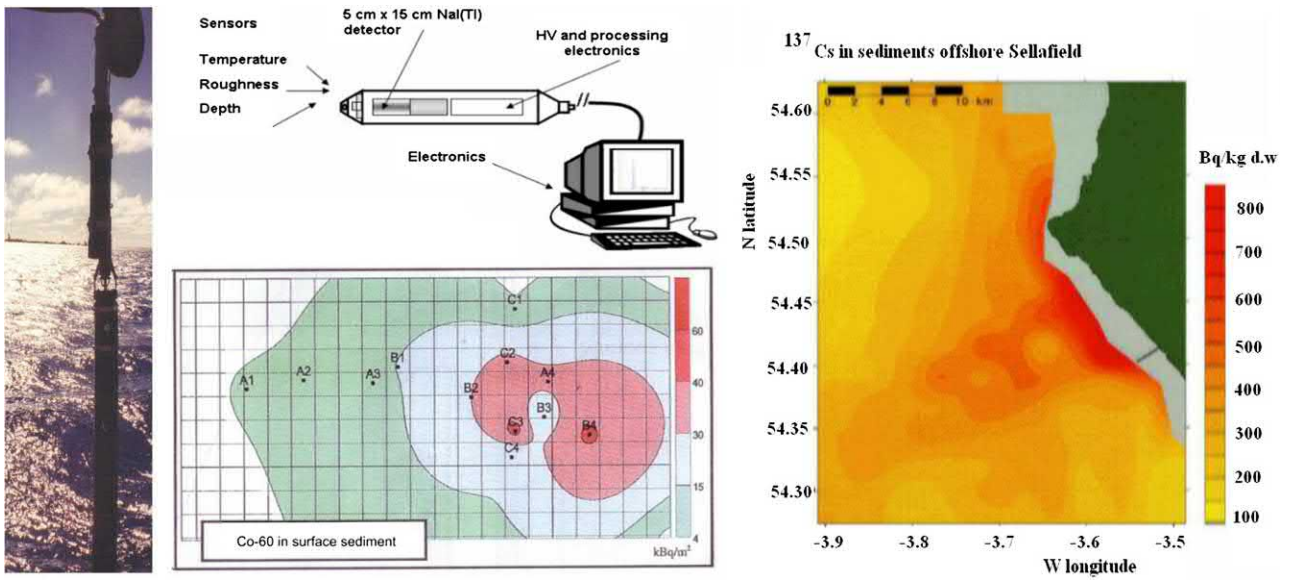

FIGURE 5.9 Underwater γ-ray spectrometer (top); its deployment in the Mururoa lagoon with a camera (left); ^{60}Co in Fangataufa lagoon sediments (bottom); and ^{137}Cs in sediments offshore Sellafield (right). 662-keV γ-rays (^{137}Cs). The calibration of the NaI(Tl) detector was carried out in a tank filled with seawater spiked with ^{137}Cs. The efficiency was estimated to be 2.1×10^{-4} s^{-1}/(Bq/m^3) under the ^{137}Cs photopeak. The limit of detection for ^{137}Cs in water is 19 Bq/m^3 for a 24-h spectrum integration time or 4 Bq/m^3 for a 30-day integration time. The buoy is equipped with signal processing electronics, including a microcomputer and a marine transceiver, as well as with a set of batteries. An integrated GPS receiver continuously records the buoy position. The instruments and batteries are maintained in a nitrogen atmosphere in an air- and water-tight container. The NEMO's autonomy is supported by a set of solar panels installed on the instrument container. The satellite antenna and visual signal devices are mounted on the top deck, about 4 m above water level. The NEMO observatory was deployed in the Irish Sea with satellite data transmission to the IAEA-EL, Monaco (Osvath et al., 2005; Povinec et al., 2008a).

C. Applications of underwater gamma-ray spectrometry

1. Mururoa and Fangataufa lagoons

A survey of Mururoa and Fangataufa lagoons in the French Polynesia (the South Pacific Ocean) was carried out with the aim to assess their radioactive contamination (water, sediment, and biota) after nuclear weapons testing (Povinec et al., 1999). ^{60}Co and ^{137}Cs were the main γ-ray emitters present in lagoon sediment. The in situ sediment measurements were used to guide the sediment sampling campaign in the most contaminated areas of the lagoons where surface tests of nuclear weapons had taken place. A distribution of ^{60}Co in the Fangataufa lagoon sediment (Fig. 5.9) showed activities up to 60 kBq m^{-2}. A good correlation ($R^2 = 0.8$) found between ^{60}Co and ^{239,240}Pu concentrations (^{239,240}Pu is the radionuclide of the main interest in lagoon sediments) enabled the estimation of ^{239,240}Pu inventories on the basis of ^{60}Co mapping and

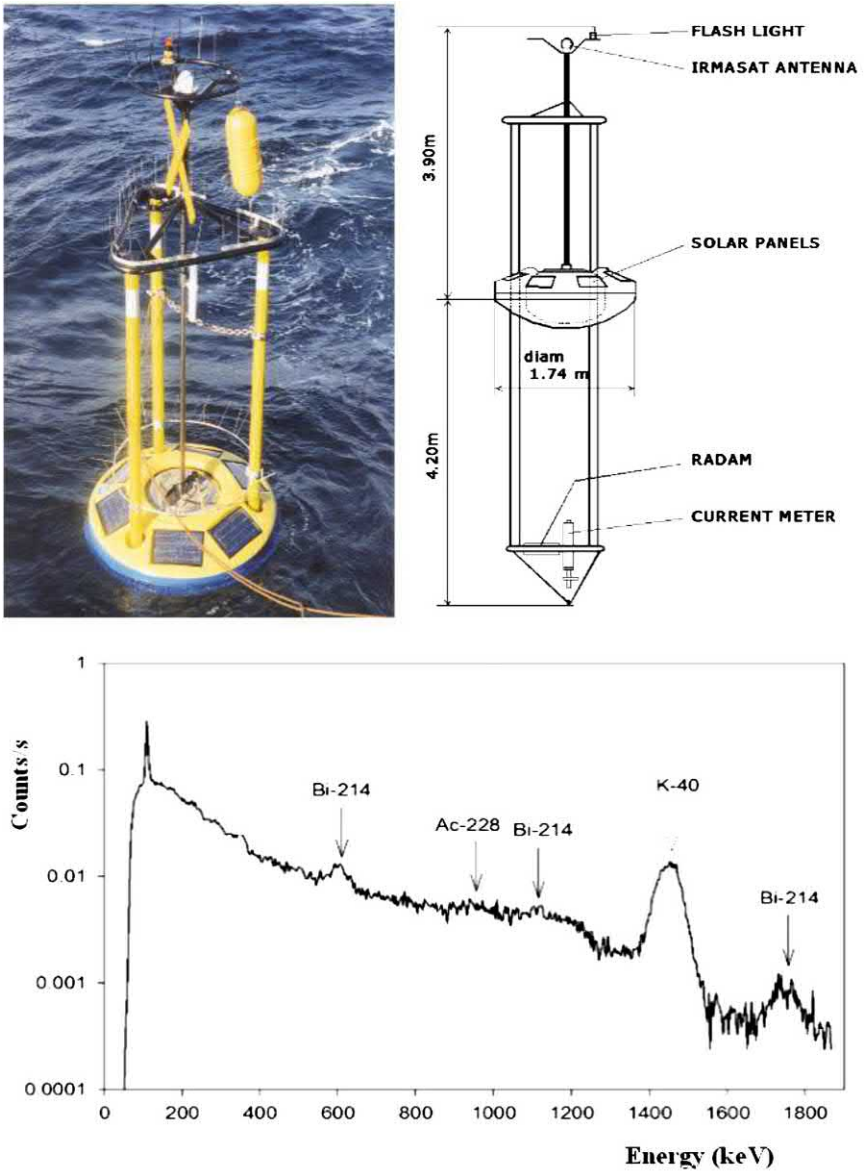

FIGURE 5.11 The NEMO (Nautic Environment Marine Observatory), a stationary underwater monitoring system, based on a NaI(Tl) detector (top), and a γ-spectrum of seawater (bottom) measured in the Irish Sea during a heavy rain when the ^{137}Cs peak (662 keV) was masked by the ^{214}Bi peak (609 keV) as a result of washout of radon decay products from the air. *Modified after Osvath et al. (2005). Printed with permission, Springer Science + Business Media Copyright, 2005.*

laboratory analysis of ^{239,240}Pu in sediments (Osvath et al., 1999a; Povinec et al., 1999).

2. Novaya Zemlya bays

Novaya Zemlya bays in the Kara Sea were visited with the aim to assess radioactive contamination of water and sediment after the dumping of radioactive wastes (Povinec et al., 1997). Fig. 5.8 shows a γ-spectrum measured with the underwater HPGe detector with propane cryogenic cooling at one of the stations in Stepovoy Bay. The far superior resolution of the HPGe detector has enabled observation of a low ^{137}Cs concentrations, which were not visible in the NaI(Tl) γ-spectrum. The ^{137}Cs sediment contamination close to dumped radioactive containers was up to 10 kBq/kg dry weight (Osvath et al., 1999b).

3. Mapping of coastal sediments in the Irish Sea

Seabed γ-mapping of radionuclides (mainly ^{137}Cs) was carried out in the Irish Sea close to the Sellafield nuclear reprocessing facility. Fig. 5.9 shows the distribution of ^{137}Cs in surface sediments close to the outlet of liquid

discharges from the Sellafield reprocessing facility. The measured ^{137}Cs levels in the sediment were up to 1 kBq/kg dry weight. They were lower by 40%–70% than the results obtained 10 years ago, documenting that a remobilization of ^{137}Cs in sediment of the Irish Sea has been effective (Osvath and Povinec, 2001; Osvath et al., 2001).

4. Monitoring of ^{137}Cs in Irish Seawaters

In situ stationary γ-monitoring of radionuclides in seawater in the NW Irish Sea with satellite data transmission to IAEA-EL, Monaco, was carried out using the NEMO system with the objective of searching for resuspension of ^{137}Cs from sediment and studying possible changes in its concentration in surface water associated with releases from the Sellafield reprocessing facility. The second aim was to search for changes in circulation patterns of the western Irish Sea gyre during the summer months. The obtained results indicate that at the time scale of months, no significant changes were detectable in ^{137}Cs concentration in seawater. Fluctuations of ^{137}Cs levels over shorter time scales were within the range of uncertainty (Osvath et al., 2005). Fig. 5.11 shows a γ-ray spectrum of water (at 4-m water depth) taken with the NEMO observatory in the Irish Sea during a heavy rain when the ^{137}Cs peak (662 keV) was completely masked by the ^{214}Bi peak (609 keV) as a result of washout of radon decay products from the air. The dominant peak in the spectrum is due to ^{40}K.

5. Submarine groundwater discharge studies

The in situ, fully automatic γ-spectrometers for continuous monitoring of radionuclides in the aquatic environment were also applied to the monitoring of natural radionuclides such as ^{40}K, ^{228}Ra, and radon decay products, which are commonly used as tracers for studying marine and coastal processes. A frequently studied coastal process is submarine groundwater discharge (SGD) because of its potential importance in the management of freshwater resources in coastal areas (Burnett et al., 2006; Povinec et al., 2006a, 2006b, 2008a, 2008b, 2008c, 2012). New technologies developed in recent years have been used to carry out temporal and spatial monitoring of SGD via the analysis of radon and its decay products emitting γ-rays. Radon is a conservative tracer in groundwater–seawater systems, and because its concentration in groundwater is much higher than in seawater, it is an ideal tracer for studying groundwater–seawater interactions (Burnett et al., 2006). ^{222}Rn is a decay product of ^{226}Ra (half-life 1600 y) in the ^{238}U natural decay chain, and due to its short half-life (3.82 d), it is a suitable tracer for studying dynamic systems that are usually found in coastal regions. ^{222}Rn daughters are short-lived radionuclides such as ^{214}Pb and ^{214}Bi, which undergo alpha- and beta-decays to medium-lived ^{210}Pb (22.2 y) and ^{210}Po (138 d), and finally to the stable ^{206}Pb. In the ^{232}Th natural decay chain, there is another radon isotope, ^{220}Rn (also called thoron), with a shorter half-life (55.6 s). ^{220}Rn is a decay product of ^{224}Ra (half-life 3.66 d) which further decays to several short-lived daughter products, including ^{208}Tl (half-life 183 s), and finally to stable ^{208}Pb.

As short-lived daughter products of both radon isotopes, ^{222}Rn and ^{220}Rn, emit γ-rays, in situ γ-spectrometry would be a suitable nondestructive technique of their analysis in seawater, replacing time-consuming analysis of ^{222}Rn in the marine environment (Povinec et al., 2006b, 2006c). In situ γ-spectrometry has the advantage that it also can analyze simultaneously other radionuclides, e.g., ^{40}K, ^{228}Ra (via its daughter ^{228}Ac), ^{234}Th–^{234}Pa, and others. The best-visible γ-lines in the γ-ray spectrum of seawater are due to ^{214}Bi (609, 1120, and 1765 keV) for ^{222}Rn daughters, and due to ^{212}Pb (239 keV) and ^{208}Tl (583 and 2615 keV) for ^{220}Rn decay products. Fig. 5.12 compares γ-spectra of groundwater and seawater measured by the NaI(Tl) detector presented in Fig. 5.9. The main differences between groundwater and seawater are well visible—groundwater shows higher concentrations of ^{222}Rn decay products and absence of ^{40}K.

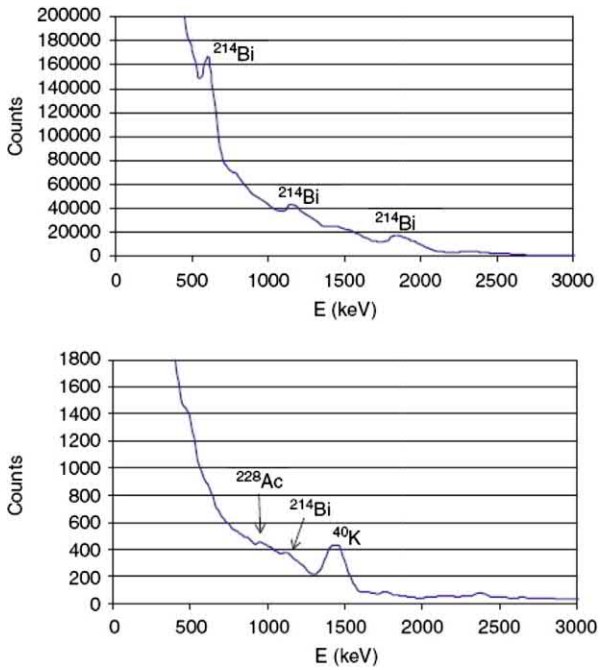

FIGURE 5.12 A comparison of γ-spectra of groundwater (top) and seawater (bottom) measured by the NaI(Tl) detector (Fig. 5.9) in the Donnalucata intercomparison. The main difference is the higher concentrations of ^{222}Rn decay products and absence of ^{40}K in groundwater. *Modified after Povinec et al. (2006c). Printed with permission © Elsevier 2006.*

a. Sicily/Italy SGD site

Time series data of ^{222}Rn in seawater, salinity, and tide were recorded with the small NaI(Tl) submersible detector (Fig. 5.9) at a site close to the coast in the southeastern Sicily (near Donnalucata town). Results presented in Fig. 5.13 document that, after the maximum tide, the ^{222}Rn activity concentration of seawater was at a minimum (down to 2.3 kBq/m^3), and after the minimum tide, the ^{222}Rn activity concentration was at maximum (up to 4.8 kBq/m^3) with a delay of about 1 hour. A shift of approximately 2 hours was observed between the maximum tide and the salinity maximum. It is interesting to see that even small changes in the water level, observed, e.g., during March 21 and 22, made corresponding changes in ^{222}Rn activity concentrations (Povinec et al., 2006a, 2006b).

b. Brazil SGD site

Continuous underwater γ-spectrometry measurements were carried out in several bays along the Ubatuba coast (Povinec et al., 2008b, 2008c, 2008d). The ^{222}Rn activity concentration in seawater during time-series measurements varied between 1.0 and 5.2 kBq/m^3, while the tide varied between 4.4 and 5.6 m, and generally, the salinity record followed the tide record. The calculated SGD fluxes from radon measurements showed similar patterns with time as the ^{222}Rn concentrations (Fig. 5.13). The SGD fluxes obtained from ^{222}Rn measurements varied between 8 and 35 cm/d (the unit is cm^3/cm^2 per day), with an average value of 21 ± 10 cm/d, and they were in reasonable agreement with those obtained from seepage measurements (Povinec et al., 2008b). The spatial ^{222}Rn activity concentrations observed at eight stations varied between 50 and 200 Bq/m^3 (Povinec et al., 2008c). Fortunately, due to elevated concentrations of ^{232}Th in the region, it was possible to measure for the first time nondestructively ^{228}Ra in seawater (via its daughter gamma-ray emitter ^{228}Ac) as well as ^{220}Rn (via its daughter product ^{208}Tl). ^{228}Ra and ^{220}Rn activity concentrations measured in Flamengo and Picinguaba bays varied between 1.6 and 3.3 Bq/m^3. They

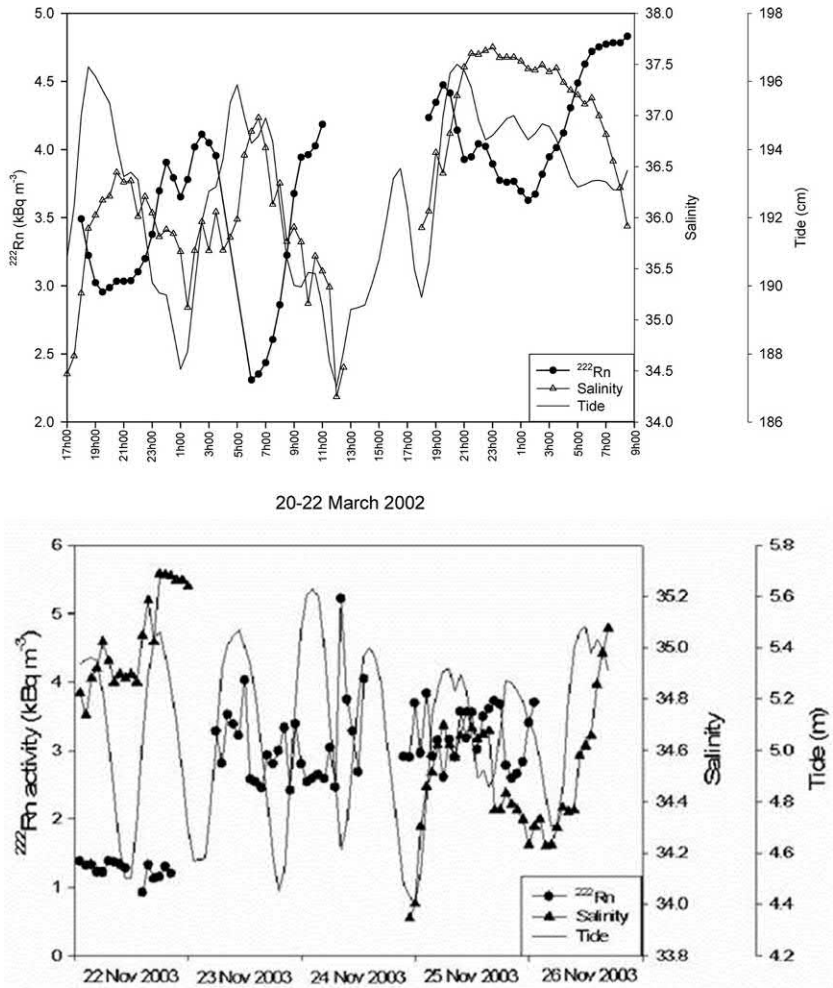

FIGURE 5.13 Time series of ^{222}Rn (^{214}Bi) concentrations in seawater offshore Donnalucata, Sicily/Italy (top), and Ubatuba, Brazil (bottom), versus salinity and tide. *Modified after Povinec et al. (2006b, 2008c). Printed with permission © Elsevier 2006, 2008.*

were following the ^{222}Rn concentrations measured at the same stations (Povinec et al., 2008c).

IV. Analysis of natural radionuclides

The natural radioactive thorium–uranium decay series (Fig. 5.14) provides a natural clock for several transport and reaction processes in the marine environment. Relatively soluble radionuclides (e.g., U, Ra, and Ac) besides insoluble radionuclides (e.g., Th, Pa, and Pb) cause daughter/parent disequilibria in certain compartments of the marine environment, which can be utilized to derive times scales of oceanic processes (Cochran and Krishnaswami, 2008). We can distinguish between radionuclides which are highly particle reactive in seawater and which are produced by the decay of soluble parent radionuclides, e.g., Th/U, Pa/U, and Pb/Ra (Rutgers van der Loeff and Moore, 1999). Such radionuclides are particularly useful for various studies of the marine environment including:

- Estimation of particle fluxes in the water column (^{234}Th/^{238}U and ^{210}Po/^{210}Pb) (Coale and Bruland, 1985; Eppley, 1989; Nozaki et al., 1991; Rutgers van der Loeff et al., 2006).
- Determination of sediment accumulation rates (^{230}Th/^{234}U, ^{210}Pb) (Allen et al., 1993; Appleby, 2013; Bacon, 1984; Baskaran and Naidu, 1995; Scholten et al., 1994).
- High-precision age dating of corals for the reconstruction of past climate changes (^{230}Th/^{234}U, ^{231}Pa/^{235}U) (Edwards et al., 2003; Stirling and Andersen, 2009; van Calsteren and Thomas, 2006).
- Determination of water mass circulation in the geological past (^{231}Pa/^{230}Th) (Hayes et al., 2015; Moran et al., 2002; Vogler et al., 1998; Yu et al., 1996).
- Calibration of sediment trapping efficiency (^{234}Th/^{234}U, ^{230}Th) (Buesseler, 1991; Buesseler et al., 2006; Scholten et al., 2001).
- Quantification of particle flux caused by resuspension of sediments (^{234}Th/^{238}U) (Bacon and Rutgers van der Loeff, 1989; Rutgers van der Loeff et al., 2002).

Soluble daughter radionuclides such as ^{228}Ra, ^{226}Ra, ^{224}Ra, ^{223}Ra, and ^{227}Ac which are produced by the decay of insoluble parents as well as ^{222}Rn and the cosmogenic ^{7}Be are particularly useful for studies of water mass mixing, upwelling, as well as the determination of eddy diffusion coefficients (Berelson et al., 1982; Burnett and Dulaiova, 2003; Geibert et al., 2002; Kadko, 2009, 2017; Ku and Luo, 2008; Moore, 2000).

We will describe the techniques most frequently used to analyze the radionuclides in marine studies, i.e., thorium isotopes, ^{231}Pa, uranium isotopes, radium isotopes, ^{210}Pb, ^{210}Po, ^{222}Rn, and ^{7}Be. In general, the type of analytical technique applied to the measurement of these radioisotopes will depend on the available instrumentation (e.g., mass spectrometry and/or radiometric methods) and the environment studied. We will describe here the most common procedures but will also give references to alternative methods where deemed appropriate. For latest developments in sampling protocols and analytical techniques, the reader is referred to the program "International Study on Marine Biogeochemical Cycling of Trace Elements and their Isotopes (GEOTRACES)" (www.geotraces.org).

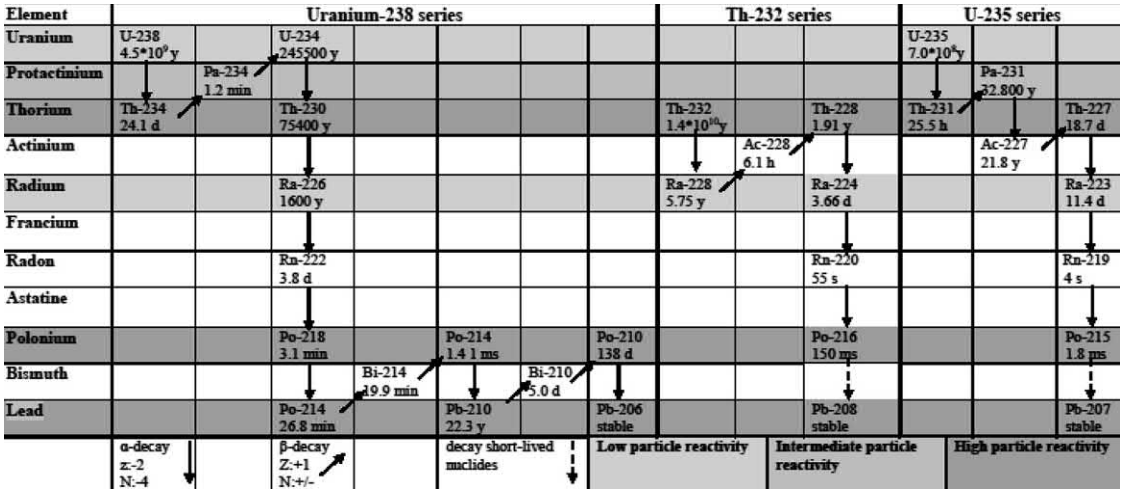

FIGURE 5.14 The uranium–thorium decay series with half-lives of the radioisotopes.

A. Thorium, protactinium, and uranium isotopes

1. Sampling of seawater

Due to the low concentrations of ^{230}Th and ^{231}Pa in seawater (~0.1−50 fg/L), previous investigations used in situ filtration pumps (McLane, Challenger) to determine these radioisotopes by means of α-spectrometry (Rutgers van der Loeff and Moore, 1999). The pumps are equipped with particle filters and in-line MnO_2 impregnated cartridges which adsorb the dissolved radionuclides. This technique permits the determination of particulate and dissolved matter from the same volume of water. However, due to advances in analytical measurement techniques, the preferred method for the determination of ^{230}Th and ^{231}Pa in seawater is now mass spectrometry (TIMS, ICPMS, multi-collector ICPMS (MC-ICPMS)) (Anderson et al., 2012). This technique combines smaller sample sizes with much higher precision of the measurements. About 2−5 L (for ^{230}Th) and 10−20 L (for ^{231}Pa) of seawater (filtered or unfiltered) are filled in acid-clean bottles or cubi-containers. After collection, the samples are acidified with concentrated HCl to pH ≤ 2. Further processing of the samples at sea has the advantage of avoiding transport of large water volumes but requires a determination of the exact sample volumes and the possibility for handling of radioactive yield tracers on ships. As tracers, ^{229}Th ($T_{½}$ = 1700 y; note that the tracer solution should have a ^{229}Th/^{230}Th ~ >1 × 10^4) and ^{233}Pa ($T_{½}$ = 27 days) are used. The ^{233}Pa tracer solution is obtained by milking ^{237}Np (Shen et al., 2003) or by neutron activation of ^{232}Th (Bourdon et al., 1999). After adding appropriate amounts of spikes, the sample is stored for ~24 hours to allow for chemical equilibration. Further preconcentration can be achieved by adsorption of Th and Pa on Fe-hydroxides, Mg-hydroxides, or Mn-hydroxides. For Fe-precipitation, 0.05 mL $FeCl_3$ (50 mg Fe/mL; cleaned by extraction in isopropyl) per liter is added and, after allowing for equilibration (~24 hours), ammonium is added to increase the pH ~7−8. The Fe-precipitates are allowed to settle, and the supernatant is siphoned off. For preconcentration using Mg-hydroxides, NH_4OH (ultraclean) is added until white precipitates form, which are allowed to settle, and the supernatant is siphoned off (Scholten et al., 2008). In order to reduce the amount of precipitates, HNO_3 is carefully added. Samples have to be shaken after each acid addition, and after centrifugation, the supernatant is siphoned off. For preconcentration using Mn-hydroxides, a few drops of ultraclean concentrated ammonium hydroxide are added together with 0.75 mg/L $KMnO_4$ and 2 mg/L $MnCl_2$ (Rutgers van der Loeff et al., 2006). After 24 hours, the MnO_2 precipitates are filtered on 1-μm filters.

Due to a high concentration of uranium (~3 ng/L = ~2.4 dpm/L) only ~10 mL of seawater is needed for mass spectrometric measurements of uranium. If α-spectrometry is the method of choice, about 2 L of seawater are required. The first preconcentration step is via Fe-hydroxide precipitation, as described above. As the yield tracer, a double ^{233}U−^{236}U spike for mass spectrometric measurements or a single ^{236}U (^{232}U for α-spectrometry) spike may be used.

2. Sampling of particulate matter and sediments

Determination of ^{230}Th and ^{231}Pa on suspended particulate matter using MC-ICPMS requires seawater volumes of about 10−20 L for ^{230}Th and 100−200 L for ^{231}Pa. Such volumes from deep waters can be obtained using in situ filtration pumps equipped with membrane/polycarbonate filters (0.4 μm or 1 μm pore size).

The relatively high ^{230}Th, ^{231}Pa, and uranium concentrations in sediments allow their determination using conventional α-spectrometry. The amount of sediment needed normally varies between 0.05 and 0.25 g depending on the origin and composition of the sediments.

3. Dissolving of particulate matter and sediments

The determination of ^{230}Th, ^{231}Pa, and uranium in suspended particles and in sediments requires digesting of the sample matrix in the presence of ^{229}Th, ^{233}Pa, and uranium yield tracers. The ^{233}Pa contains trace amounts of ^{232}Th which may bias thorium measurements, especially when, e.g., suspended particles with low thorium concentrations are analyzed. For such samples, it is recommended that the spikes be added after dissolving the particle filter and separating the solution (gravimetrically) into a thorium fraction (~10% of the total solution) and into a protactinium fraction (Scholten et al., 2008).

Particles on membrane and/or polycarbonate filters can be dissolved in a microwave oven in a mixture of 2 mL conc. HF and 4−6 mL conc. HNO_3 (Negre et al., 2009). Thereafter, the solution is evaporated down to near dryness on a hot plate and taken up in conc. HNO_3 (note that working with HF in open vessels requires special fume hoods, i.e., with water rinsing of the outlet channels). This step is repeated twice in order to remove any fluorides. Thereafter, the sample is dissolved in 2 M HCl and 1 μL $FeCl_3$ (50 mg Fe/mL; cleaned by extraction in isopropyl alcohol) is added followed by precipitation of Fe-hydroxides by adding appropriate amounts of conc. NH_3. This step removes alkali and alkali earth metals. The precipitates are centrifuged down, and the supernatant is

siphoned off. The precipitate is washed three times with Milli-Q water. If no microwave is available, filters can be leached following the procedure described by (Landing and Lewis, 1991): The filters are placed for 4 hours in a Teflon beaker on a hot plate in a mixture containing 1 mL conc. HF and ~20 mL "aqua regia" (mixture of conc. HNO_3 and conc. HCl). The filters are then removed from the solution and rinsed with 6 M HCl. The solution is evaporated down to near dryness on a hot plate. The sample is taken up in a few mL of conc. HNO_3 and is evaporated down to near dryness; this step is repeated twice. Finally, the sample is taken up in diluted HCl, and 1 μL $FeCl_3$ is added followed by Fe-hydroxide precipitation caused by adjusting the pH to 7–8 using conc. NH_3. The precipitates are centrifuged down and washed three times with Milli-Q water.

Total dissolution of marine sediments is best achieved by using a microwave (Gupta and Bertrand, 1995; Kuss, 1992; Negre et al., 2009). About 50–200 mg of homogenized freeze-dried sediment is placed in the Teflon beakers of the microwave, and appropriate amounts of ^{229}Th, ^{233}Pa, and ^{236}U spikes are added. Then a mixture of 10 mL conc. HNO_3, 4 mL conc. HCl, and 6 mL of conc. HF is added. It is advisable to wait for carbonate dissolution before processing the samples in the microwave to avoid overpressure. Thereafter the solution is evaporated to near dryness. Negre et al. (2009) report a better chemical recovery for protactinium, if an additional step with 9 mL of reverse aqua regia (6 mL HNO_3 + 3 mL HCl) is added. The solution is evaporated down to near dryness and taken up in 6 mL conc. HNO_3. This step is repeated twice. A further step to remove alkaline and alkaline earth metals by Fe-hydroxide precipitation (as described above) may facilitate subsequent ion-exchange procedures.

The dissolution of sediments may also be achieved by conventional digestion techniques using open vessels or Teflon bombs applying hot-plate heating with a mixture of HNO_3/HF (3 mL/2 mL) followed by evaporation to near dryness. Thereafter a few mL of conc. $HClO_4$ are added and fumed at ~190°C. Complete dissolution may be hampered due to the presence of minerals such as zircon and barite which are difficult to dissolve; the above procedure may have to be applied multiple times. In a final step, the sample is taken up in diluted HCl; ~1 μL $FeCl_3$ is added followed by the addition of NH_3 to precipitate Fe-hydroxides which are centrifuged. The precipitate is further washed and centrifuged with Milli-Q water three times.

4. Ion-exchange separation

Both mass spectrometry and α-spectrometry measurements of thorium, protactinium, and uranium require further purification in order to remove interferences in masses and in the α-energy spectrum. These purifications are achieved by chromatographic resins which can extract certain elements from solutions. The most commonly used resins are the anion-exchange resins (e.g., Bio-Rad AG1-X8, Dowex AG1-X8; Eichrom 1-X8; see e.g., Anderson and Fleer, 1982; Auro et al., 2012; Edwards et al., 1986/87; Rutgers van der Loeff and Moore, 1999), UTEVA resin (Kretschmer et al., 2010; Rodriguez y Baena et al., 2006) and TRUE resin (Bourdon et al., 1999; Goldstein and Stirling, 2003; Luo et al., 1997).

The anion-exchange resin AG1-X8 (e.g., from Bio-Rad, Eichrome), which is most commonly used for α-spectrometric measurements of thorium, protactinium, and uranium in sediments, require several column separations (Anderson and Fleer, 1982). First, the column (depending on the size of the sample up to 13 cm long and of a diameter up to 13 mm) is conditioned with 9 M HCl. The sample is dissolved in 9 M HCl and poured over the column, washed three times the column volume (cv) with 9 M HCl. This step elutes all the Th (as well as alkali and earth alkali elements). Thereafter the column is rinsed 3× cv with 9 M HCl + 0.13 M HF to remove Pa, and in the final step U together with Fe is eluted with 3 cv 0.1 M HNO_3. The three fractions are evaporated to near dryness (forming of precipitates should be avoided), and 8 M HNO_3 is added. The Th and U fractions are poured over separate AG1-X8 columns conditioned with 8 M HNO_3. The columns are rinsed with 3 cv 8 M HNO_3 to remove Ca (Th fraction) and Fe (U fraction). Th and U are eluted with 3 cv 9 M HCl and 3 cv 0.1 M HNO_3, respectively. After evaporating to dryness, a tiny yellow or brown spot should remain. Large reddish or white material will result in poor electroplating. The Pa fraction is evaporated down to near dryness in the presence of 8 M HNO_3 at least twice to remove all fluoride. The Pa fraction is dissolved in 9 M HCl and poured over AG1-X8 column conditioned with 9 M HCl, and Pa is eluted with 3 cv 9 M HCl + 0.13 M HF. This last step removes any remaining thorium and uranium. After evaporating down three times in the presence of 8 M HNO_3, the Pa sample is ready for electroplating. Recently, poor Th recovery and an increase in procedure blanks were reported for Th seawater analyses when using Bio-Rad columns filled with AG1-X8 resin (Auro et al., 2012). These authors modify the method for Th and Pa seawater analyses described above by using Eichrom anion exchange resin (100–200 μm mesh) and Eichrom Environmental Express columns together with higher acid concentrations.

In extraction chromatography using TRUE resin (Goldstein and Stirling, 2003; Luo et al., 1997), about 2–10 mL (depending on sample sizes) of TRU resin is conditioned with 6 cv 0.01 M HCl and 4 cv 10 M HCl. The sample is dissolved in 10 M HCl, and an equal volume of 10 M HCl plus saturated H_3BO_3 (to complex HF) is added. The sample is loaded on the column and washed with 1× cv 9 M HCl (note that the elution contains the radium

fraction). Thorium is eluted by adding 1 cv of 4 M HCl and then 10 cv of 1.2 M HCl. Uranium and protactinium are washed from the column by adding 10 cv 0.1 M HCl +0.05 M HF. In a further AG1-8X column conditioned with 9 M HCl, Pa is separated from U and remaining Th. Other authors use slightly different acid concentrations for the Th, Pa, and U separations (e.g., Bourdon et al., 1999; Luo et al., 1997).

In extraction chromatography using UTEVA, the sample is loaded in 4 M HNO_3 on a column conditioned with 4 M HNO_3. In order to increase the recovery of Th, it is recommended that chemical analogs such as Ti^{4+} and Zr^{4+} (~1 mg) be added when conditioning the UTEVA columns (Rodriguez y Baena et al., 2006). This is especially important for samples with little matrix such as seawater samples. Di- and trivalent ions (e.g., Mn, Fe, Ca, Pb, Bi, Ra and Ac) are washed from the column by 3 cv 4 M HNO_3, whereas hexavalent U and tetravalent Th ions are not (Horwitz et al., 1993). Th is eluted with 3 cv 6 M HCl, U, and Pa by 3 cv of 0.02 M HCl + 0.02 M HF. Pa is further purified using AG1-8X column as described above.

5. Electrodeposition of Th, U, and Pa

We describe here the procedure of Rutgers van der Loeff and Moore (1999) which is based on a previously published paper of Krishnaswami and Sarin (1976). This method is suitable for electroplating of Th, U, and Pa. The sample in a beaker is taken up in 1 mL 0.01 M HNO_3 and transferred into an electroplating Teflon cell equipped with cleaned silver or stainless steel disks on its base. The beaker is rinsed twice with 1 mL NH_4Cl buffer (pH = 2) followed by a 1 mL rinse of saturated ammonium oxalate. A transfer pipette may be used to remove the solution quantitatively from the beaker. The plating cell is placed on a magnetic stirrer in the fume hood and connected to the power supply, which should be current-limited at 0.8 A. Agitating the solution in the Teflon cell prevent blocking of the electrode surface by bubbles. After about 20–30 minutes the resistance will increase so that the power supply will increase up to 6 V. After about 50–60 minutes when the current drops to ~0.2 A, plating can be terminated by adding 1–2 mL of conc. NH_3. The plating cell is disconnected from the power supply and the disk is washed with Milli-Q and ethanol.

A Th platting may also be performed by NdF_3 precipitation (Rodriguez y Baena et al., 2006). To the Th fraction (in 9 M HCl) 100 µL of 1 mg Nd^{3+}/mL (as $NdCl_3$ in 1 M HCl) and 5 mL of concentrated HF is added and mixed. Th is co-precipitated with the NdF_3. The solution is allowed to stand for 0.5–2 hours, and then the NdF_3(Th) suspension is filtered through a polypropylene membrane filter (0.1 µm porosity, 25 mm diameter). The precipitate is washed three times with 2 mL of diluted (ca. 4%) HF followed by two washes with 1.5–2 mL of 80% ethanol solution. The NdF_3(Th)-loaded filter is allowed to dry for at least 15 minutes.

The activity of the sample can be calculated as

$$A = A_{Tracer} \cdot \frac{counts_A}{counts_{Tracer}} \cdot \frac{1}{weight} \quad (5.1)$$

where A (in Bq/g) is the activity of isotope of interest, A_{Tracer} is the activity of the yield tracer, $counts_A$ are the counts/s of the isotope of interest determined via α-spectrometry, $counts_{Tracer}$ are the counts/s of the yield tracer determined via α-spectrometry, and weight is the amount of sample (in g) used for the analyses.

B. Thorium-234

1. Sediments

The determination of ^{234}Th in sediments can be done using γ-spectrometry of about 100 g of dried and grounded sediment which is filled in the appropriate geometry. Better detection limits are achieved if ^{234}Th is measured by β-counting (Turnewitsch et al., 2000). About 10 g of dry sediment is leached for about 4–5 hours in 100 mL of near boiling 6 M HCl in the presence of a yield tracer. Thereafter the particles are centrifuged off (DeMaster et al., 1991). Further purification is achieved by Fe-hydroxide precipitation followed by chemical purification as described in Section IV.A.4.

2. Seawater

The technique for sampling of ^{234}Th in the water column depends on the environment and the objective of the study. A detailed discussion on the various methods and their methodological protocols can be found in Cochran and Masque (2003), Rutgers van der Loeff and Moore (1999), and Rodriguez y Baena et al. (2006). A decision chart which assists in finding the appropriate method was published by Rutgers van der Loeff et al. (2006). The two main sampling techniques are large-volume sampling using in situ filtration pumps and small-volume sampling.

Large-volume sampling is conducted using *in situ* filtration pumps equipped with particle filters and two in-line MnO_2 impregnated cartridges. Measurements of particulate ^{234}Th can be performed directly by β-counting or γ-spectrometry (Buesseler et al., 1992), or by dissolving the particulate filter followed by chemical separation for thorium as described above. The cartridges containing the dissolved ^{234}Th can be prepared for γ-spectrometry measurements either by ashing in a muffle furnace (Buesseler et al., 1992) or melting/crushing (Buesseler et al., 1995), and putting them into a standard geometry. Care should be taken for precise calibration of β- and γ-detectors for the different sample sizes and geometries of particulate filters (Rutgers van der Loeff et al., 2006). Alternatively,

cartridges may also be leached in acid (>3N HCl) solutions in a recirculating system followed by chemical purification as further outlined below Rutgers van der Loeff and Moore (1999). The activity of ^{234}Th is then calculated as

$$Th_{Activity} = \frac{A}{1 - \frac{B}{A}} \tag{5.2}$$

where A and B are the activities of the first and second cartridges, respectively (Livingston and Cochran, 1987).

Calculation of ^{234}Th activities using Eq. (5.2) requires the extraction efficiencies of cartridges A and B to be the same. Various field studies observed, however, extracting efficiencies ranging from 65% to ~100% (Rutgers van der Loeff et al., 2006 and references therein). Applying constant extraction efficiency may cause both random and systematic errors in calculated ^{234}Th activities that are highest when the extraction efficiency is lowest.

If high precision and accuracy are required, a small-volume sampling (2–20 L) is the method of choice for ^{234}Th determination. From a volume of seawater, ^{234}Th may be preconcentrated using Fe-hydroxide precipitation in the presence of a ^{230}Th yield tracer (Rutgers van der Loeff and Moore, 1999). As U is coprecipitated with Fe-hydroxides, rapid chemical chromatographic separation is required in order to minimize the in-growth correction for ^{234}Th from the decay of ^{238}U. A further complication arises from the fact that the amount of U coprecipitated with Fe-hydroxides must be precisely known to perform the in-growth correction (Smith et al., 2004). Therefore, a ^{236}U yield tracer must be added prior to the preconcentration with Fe-hydroxides, and after chemical purification uranium is measured via α-spectrometry or MC-ICPMS.

The ^{234}Th protocol using MnO_2 as the preconcentration step for ^{234}Th avoids the complication of ^{234}Th in-growth correction as the amount of U which coprecipitates with MnO_2 is negligible. The MnO_2 precipitates from large sample (~20 L) can be measured directly by β-counting and no yield tracer is necessary, as the recovery for ^{234}Th is considered as nearly quantitative (Rutgers van der Loeff et al., 2006). Most recent studies use sample volumes of 2–5 L due to ease in sample collection, processing, and low overall analytical blank. This procedure needs only ~10% of the reagents used for the 20 L MnO_2 precipitation method (Buesseler et al., 2001). Due to the difficulty to maintain reproducibility especially when many samples are processed, it is recommended to use yield tracers. Pike et al. (2005) and Rodriguez y Baena et al. (2006) developed a two-spike method in which the first spike ^{230}Th accounts for losses during MnO_2 precipitation, and the second spike (^{229}Th or ^{228}Th) for the loss of ^{230}Th during the chemical separation process. After β-counting for ^{234}Th, the filters are dissolved in the presence of the appropriate yield tracers followed by chemical purification. Depending on the availability of instrumentation, the tracers are measured by α-spectrometry and/or MC-ICPMS. A comparison of the one- and two-spike methods is shown in Fig. 5.15.

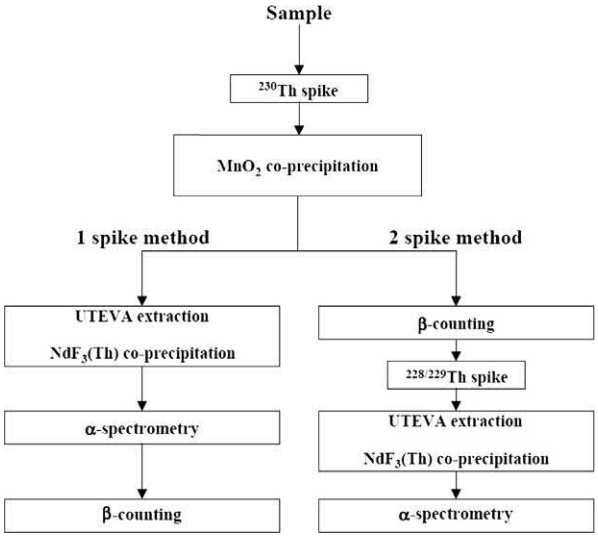

FIGURE 5.15 Flowchart of ^{234}Th measurement procedures using one and two spikes. *From Rodriguez y Baena et al. (2006). Printed with permission from Elsevier © 2006.*

The ^{234}Th activity at the time of sampling ($^{234}Th_{to}$) in Bq is calculated using the following equation, which combines data on the ^{234}Th net count rate, chemical recovery of the MnO_2 co-precipitation, efficiency of the β-detectors, and in-growth from ^{238}U activity in the sample:

$$^{234}Th_{to} = \frac{^{234}Th_{net}}{^{234}Th_{yielded}} \cdot (\beta - \text{efficiency})^{-1} \cdot \left(e^{-\lambda t}\right)^{-1} \cdot {}^{238}U \cdot \left(1 - \left(e^{-\lambda t}\right)\right) \tag{5.3}$$

where $^{234}Th_{net}$ is the net ^{234}Th count rate in cps at the time of MnO_2/FeOOH coprecipitation as determined by β-counting, $^{234}Th_{yield}$ is the recovery of ^{234}Th as determined by α-spectrometry of ^{228}Th (or ^{230}Th), (β-efficiency) is the efficiency of the β-counting, λ is the decay constant of ^{234}Th, t is the time between sampling and MnO_2/FeOOH precipitation, and ^{238}U is the activity of ^{238}U in Bq at the time of sampling.

C. Polonium-210 and Lead-210

1. Seawater

In seawater, ^{210}Po ($T_{½} = 138$ days) and ^{210}Pb ($T_{½} = 22.3$ y) are normally in radioactive disequilibrium. In order to measure both isotopes by means of α-spectrometry, two analytical steps are required (Baskaran and Swarzenski, 2007; Masqué et al., 2002; Rigaud et al., 2013; Rutgers van der Loeff and Moore, 1999). In a first step, the so-called *in situ* ^{210}Po is measured. In a second step, after

storing the sample for a minimum of ~½ year, the ^{210}Po is determined which was produced by the decay of ^{210}Pb. Thus, this measurement provides the data on ^{210}Pb. In seawater, the measurements of ^{210}Po and ^{210}Pb are usually done in the same sample (Fleer and Bacon, 1984). An approximately 20–50 L sample of water is filtered through a 0.45-μm membrane/nuclepore filter (or 0.7 μm GFF). For the determination of particulate ^{210}Po/^{210}Pb in the open ocean, at least 30 L are necessary. The filtrate is collected in 20 L containers, and the weight is determined. The filtrate is acidified to pH < 2 using conc. HCl, and 10 mg of stable Pb plus the ^{209}Po yield tracer are added. Depending on the preconcentration method, 100 mg Fe or 20 mL of saturated $KMnO_4$ solution are added, homogenized, and stored overnight for isotope equilibration.

For Fe-precipitation, the filtrate is neutralized with NH_4OH solution to pH 8–8.5 and the precipitate is allowed to settle overnight. Thereafter, the clear solution is siphoned off with a water jet pump and the precipitates are transferred to 250 mL Nalgene bottles for transport to the home lab. Here the precipitate is centrifuged down and then washed three times with Milli-Q water and centrifuged again.

For Mn-precipitation, NaOH is dissolved in Milli-Q water and added to the sample while stirring; the pH is ~9. Then 20 mL of 0.5 M $MnCl_2$ are added so that MnO_2 gets precipitated. After a few minutes the pH is controlled and adjusted to pH 8, if necessary. The solution is stirred for 5 minutes, and the precipitate is allowed to settle. The supernatant is siphoned off with a water jet pump. For the transport to the home lab, the precipitate is stored in 500 mL bottles. Here the precipitates are centrifuged and washed three times.

2. Digestion of filters and sediments

A microwave digestion is the most convenient way for dissolving filters and sediments (50–500 mg). A preweighted ^{209}Po spike (~1–5 dpm), stable Pb (~10 mg), 5 mL conc. HNO_3, 2 mL conc. HCl, 3 mL HF 40%, and 10 mL Milli-Q water are added to the sample in the microwave reactor. After the total dissolution of the sample, 1.1 g of H_3BO_3 is added followed by further heating in the microwave. The solution is quantitatively transferred to 50 mL Teflon beakers, evaporated to almost dryness, and 2 mL of concentrated HCl are added. This last step is repeated three times in order to assure complete removal of HNO_3 traces. The sample is then diluted to an appropriate volume of 0.5/0.6 M HCl, and it is ready for Po electroplating. Note that ^{210}Po and ^{210}Pb in sediments are usually in equilibrium. Thus, the addition of stable Pb is not required and only one plating step is performed (as described below).

3. Plating of ^{210}Po

We describe here the technique used at the IAEA Environment Laboratories in Monaco (I), and the one described by Rutgers van de Loeff and Moore (1999) (II).

a. Technique I

The precipitate is dissolved in 0.5 M HCl. It may be necessary to add a few drops of conc. HCl to completely dissolve the precipitate. Then the solution is transferred quantitatively into 30 mL HDPE Nalgene bottles and some ascorbic acid powder is added until yellow color disappears. This step should complex Fe which otherwise would prohibit the spontaneous electroplating of Po. High amounts of ascorbic acid may be necessary (i.e., 1 mol $C_6H_8O_6$ per 2 mol Fe(III) or ~150 mg $C_6H_8O_6$ per 100 mg Fe(III)). A silver disk followed by a support disk (a stainless steel disk) is placed on the mouth of the Nalgene bottle, and closed with the plastic cap after having made a hole in the center of the cap. The bottle is turned upside down and, after making a little hole into the Nalgene bottle to allow excess pressure to escape, it is set on a hot plate at a temperature of 70–80°C for 5 hours plating. Afterward the silver disk is removed, and the remaining solution is poured in a 50-mL Teflon beaker. A piece of silver foil/scrap about 2 × 2 cm in size is placed into the Teflon beaker for about 24 hours in order to remove any Po traces which eventually may have remained in the solution. Thereafter, the silver foil is removed. A 5-mL aliquot from the solution is obtained for further Pb-recovery check using atomic adsorption or ICP-MS. The solution is spiked again with ^{209}Po and stored for at least 6 months to allow for the in-growth of ^{210}Po from ^{210}Pb. Thereafter Po is replated again from the solution after the addition of 1 mL of the ascorbic acid solution.

b. Technique II

The precipitate is dissolved in 0.5 M HCl, transferred quantitatively into 50 mL Teflon beakers and a magnetic stirring ball is added. Ascorbic acid powder is added until the yellow color disappears. In order to prevent adding too much ascorbic acid, it is recommended to wait after each addition since the solution of the powder and complexation of Fe is slow. A silver disk (which is covered on one side with plastic) is placed using plastic tweezers on the bottom of the beaker. The hot plate is set to a temperature of 80–90°C (a temperature probe in a Teflon beaker filled with water may be used as a temperature control) and slowly stirred. The plating proceeds for 4 hours. Note: Regularly check the color; if the solution is yellow, more ascorbic acid has to be added. If the color remains, there is probably an excess of ascorbic acid being broken down. If the silver disk gets a dark coating, the plating should be

terminated. After 4 hours the disk is removed with plastic tweezers, it is rinsed with 2 mol/L HCl, then with Milli-Q, and then with ethanol. The solution is stored at least for one night with scrap silver so that any remaining Po is removed. Thereafter about 3 mL of conc. HNO_3 is added, and the solution is evaporated to dryness. The beaker is rinsed with 2 M HCl, evaporated again, and taken up in ~0.5 M HCl for storage for a minimum of half a year to allow ingrowths of ^{210}Po from ^{210}Pb. Thereafter an appropriate amount of ^{209}Po is added (the spike should have twice the expected activity of ^{210}Po) and then Po is electroplated as described above. The plating solution is diluted to 500 mL, and stable Pb is measured by means of flame atomic adsorption.

The activities of ^{210}Po and ^{210}Pb are calculated using the following equations (García-Orellana and García-León, 2002):

$$^{210}\mathrm{Po} = \frac{P_1 - {}^{210}\mathrm{Pb}\cdot\gamma(t_1 - t_0)}{e^{-\lambda_{\mathrm{Po}}(t_1 - t_0)}} \tag{5.4}$$

$$^{210}\mathrm{Pb} = \left(\frac{\left(P_2 - P_1\cdot e^{-\lambda_{\mathrm{Po}}(t_2 - t_1)}\right)}{\gamma(t_2 - t_1)}\right)\cdot e^{-\lambda_{\mathrm{Pb}}(t_1 - t_0)} \tag{5.5}$$

where P_1 and P_2 are the activities measured at time t_1 and t_2, respectively, λ_{Po} and λ_{Pb} are the decay constants of ^{210}Po and ^{210}Pb, respectively, and $\gamma(t_2{-}t_1) = {}^{210}\mathrm{Po}_{(t)}/{}^{210}\mathrm{Pb}(t_0)$ is the function given by Batman's equation for the three related radionuclides (^{210}Po, ^{210}Bi, and ^{210}Pb) assuming that at time t_0 there is a certain activity of the parent nuclide ^{210}Pb and none of the daughters are present. A more complex calculation of ^{210}Po and ^{210}Pb activities including uncertainties is presented in Rigaud et al. (2013).

D. Radium isotopes

The sampling and measurement techniques for radium isotopes, i.e., ^{223}Ra ($T_{½} = 11.4$ days), ^{224}Ra ($T_{½} = 3.7$ days), ^{228}Ra ($T_{½} = 5.75$ y), ^{226}Ra ($T_{½} = 1600$ y) in seawater, depend on the objective of the investigation, the isotopes of interest, and the availability of analytical instrumentation (Charette et al., 2012). In most cases, large-sample volumes >20 L are required so that applications of preconcentration procedures are necessary (Henderson et al., 2013). Radium can be extracted from seawater by $BaSO_4$ precipitation (Li et al., 1980; Rutgers van der Loeff and Moore, 1999). A barium chloride solution is added slowly to 30–60 L of seawater while stirring the sample for 1–2 hours. The precipitate is allowed to settle, and the supernatant is siphoned off. The precipitate is dried and weighed to determine the recovery using the $BaSO_4$:$BaCl_3$ mass ratio of 1.883. Another radium preconcentration method uses Empore Rad Disks in the presence of a ^{225}Ra (= ^{229}Th) yield tracer (Purkl and Eisenhauer, 2003b). The most convenient method to extract radium from large seawater volumes is by passing the water through a column containing MnO_2-coated fiber (Mn-fiber) (Moore et al., 1985). For the preparation of Mn-fiber, see Rutgers van der Loeff and Moore (1999). This extraction method removes radium nearly quantitatively (97 ± 3%), if the water flow rate is < 1 L/min (Moore, 2007). The Mn-fiber can be used for the determination of all radium isotopes.

1. Measurement of ^{223}Ra and ^{224}Ra

Although the measurements of ^{223}Ra and ^{224}Ra are possible by means of α-spectrometry (Hancock and Martin, 1991; Purkl and Eisenhauer, 2003a), this method is not frequently applied due to lengthy chemical procedures. The method of choice for the analysis of the short-lived radium isotopes ^{223}Ra and ^{224}Ra is the delayed coincidence technique of Moore and Arnold (1996). The Mn-fiber is placed in a closed-loop circulation system, and a helium stream sweeps off the ^{219}Rn and ^{220}Rn produced by the decay of ^{223}Ra and ^{224}Ra, respectively. Radon circulates in a Lukas cell where α-particles from the decay of Rn and daughters are recorded. For more details on the measurement technique, see Garcia-Solsona et al. (2008), Moore (2008), Scholten et al. (2010) and Moore and Cai (2013). Kim et al. (2001) describe a method in which ^{224}Ra on the Mn-fiber is measured using a commercially available radon-in-air monitor (RAD 7, Durridge) to count ^{220}Rn released from the Mn-fiber. Other methods use ultralow-level γ-spectrometry for ^{223}Ra and ^{224}Ra determination after having ashed or leached the Mn-fiber (Elsinger et al., 1982; Van Beek et al., 2010).

2. Measurement of ^{228}Ra and ^{226}Ra

The first determinations of ^{226}Ra in seawater were performed by measuring the daughter ^{222}Rn, which was extracted from 20 L of seawater and measured in scintillation cells (Key et al., 1979b; Mathieu et al., 1988) (see Section E). Other studies use a delayed coincidence counting technique (as described above), radon-in-air monitors (see Section E) and liquid scintillation counting for ^{226}Ra determinations (Peterson et al., 2009; Purkl and Eisenhauer, 2004; Sanchez-Cabeza et al., 2010; Waska et al., 2008). Recent advances in mass spectrometry (MC-ICPMS and TIMS) allow the determination of ^{226}Ra in sample volumes < 0.5 L (Bourquin et al., 2011; Foster et al., 2004; Hsieh and Henderson, 2011; Sharabi et al., 2010). For high-activity estuarine or coastal samples, γ-spectrometry offers an easy method of measuring ^{226}Ra and ^{228}Ra via ^{214}Bi and ^{214}Pb (^{226}Ra daughters) and ^{228}Ac (^{228}Ra daughter) as described by Reyss et al. (1995) and Schmidt and Reyss (1996). The Mn-fibers can be prepared for γ-measurements by ashing the fibers at 820°C for 16 hours and placing the ash in a sealed vial (Charette et al., 2001). The vial is stored for 3–4 weeks to allow

^{222}Rn and daughters to equilibrate with ^{226}Ra. Alternatively, the Mn-fiber can be leached in a Soxhlet extraction apparatus (Rutgers van der Loeff and Moore, 1999) or leached in a beaker in a mixture of hot hydroxylamine hydrochloride and 20% HCl. After the fiber is bleached and washed three times with 20% HCl, the solution is filtrated and 10 mL of saturated $BaCl_2$ is added. Then, while steering and heating to near boiling, 25 mL 7 M H_2SO_4 is added slowly. The precipitate is allowed to settle down and the supernatant is siphoned off. The precipitate is washed with Milli-Q water and placed in a gamma counting vial (note that due to the high density of $BaSO_4$, the emanation of ^{222}Rn is <2% (Michel et al., 1981; Scholten et al., 2013). Compressing the Mn-fiber after mixing with an adhesive (e.g., powdered sugar) is a less laborious method for the preparation of Mn-fibers for gamma measurements (Schubert et al., 2018).

Due to low ^{228}Ra content in the open ocean and due to the relatively high detection limits of γ-spectrometry, a determination of ^{228}Ra via ^{228}Th in-growth may be necessary. Following the procedure described in Moore et al. (1985) and Rutgers van der Loeff and Moore (1999), the Ba(Ra)SO_4 precipitated is converted to Ba(Ra)CO_3 by fusing it with a mixture of K_2CO_3 and Na_2CO_3. In order to remove any traces of thorium, a few μL of $FeCl_2$ solution is added and thorium is precipitated with the Fe-hydroxides after adjusting the pH to 7−8 using concentrated NH_3. Then Ba and Ra are coprecipitated with K_2CO_3 solution, and the precipitate is stored for 5−20 months to allow ^{228}Th to partially equilibrate. The Ba(Ra)CO_3 precipitate is dissolved in HCl, followed by the addition of Fe and ^{230}Th yield tracer. Thorium is concentrated by Fe-hydroxide precipitation, and the remaining supernatant containing ^{226}Ra is quantitatively recovered and measured as described above. The Fe-hydroxide precipitate is dissolved in 9 M HCl followed by chromatographic purification and electroplating as already described. The ^{228}Th/^{230}Th activity ratio is determined by α-spectrometry, and ^{228}Th is calculated from the activity of the spike. The initial ^{228}Ra activity of the sample is calculated by multiplying the measured ^{228}Th activity by the reciprocal of the fraction of ^{228}Th/^{228}Ra equilibrium. The result is decay-corrected for the time elapsed from sample collection to the initial purification and precipitation of Ba(Ra)CO_3.

E. Radon-222

^{222}Rn concentration in seawater are usually low (~1mBq/L), thus large (>20 L) seawater volumes are required for ^{222}Rn determinations. ^{222}Rn can be measured using alpha spectrometry (Key et al., 1979a; Mathieu et al., 1988; Schlosser et al., 1984): It is extracted from a water sample with a carrier gas (nitrogen, helium) which is bubbled through the water sample. The gas flows over a stainless steel trap cooled with liquid nitrogen or a charcoal-filled trap cooled with dry ice where ^{222}Rn adsorbs. After the water sample is completely degassed the traps are heated and ^{222}Rn is transferred to evacuated scintillation cells ("Lukas cell"). The sample is stored for about 1−2 hours to allow ingrowth of ^{222}Rn daughters (^{218}Po, ^{214}Po). For the calculation of the ^{222}Rn activity a decay correction from the time of sampling, the efficiency of the counter, the background of the detector and well as the blank (note that glass containers may be a source of ^{222}Rn) must be taken into account.

For spatial mapping of ^{222}Rn concentrations in coastal waters, radon-in-air monitors (e.g., RAD-7 (Durridge); AlphaGuard (Saphymo)) are appropriate methods (Burnett and Dulaiova, 2003; Burnett et al., 2001). Seawater is constantly pumped through an air−water exchanger (RAD-Aqua (Durridge) or MiniModule (Membrana)) that strips ^{222}Rn from the water to a closed air loop connected to a radon-in-air monitor (Schmidt et al., 2008). The radon-in-air concentration is converted to the final ^{222}Rn-in-water concentration using the water/air partitioning coefficient which is calculated based on the salinity and the temperature of the sampled seawater (Schubert et al., 2012).

F. Beryllium-7

Due to low particle reactivity, ^{7}Be is present in seawater predominantly in the dissolved phase. The short half-life ($T_{1/2} = 53.3$d) and the low concentrations in seawater require large water volumes for ^{7}Be determinations. About ~100−700 L of seawater is pumped into barrels and a stable Be-9 yield tracer (500 ml of a 1000ppm Be atomic adsorption standard solution) is added (Kadko, 2009). The water is pumped (10 L/min) over iron-impregnated acrylic fibers (Krishnaswami et al., 1972) which adsorb beryllium. An aliquot of the effluent that passes the fiber is taken for Be-9 determinations by atomic adsorption or ICPMS. From the Be-9 concentration measured, the Be extraction efficiency is determined. The fibers are dried and ashed; the ash is then pressed in pellets which are placed on a low-level germanium detector where ^{7}Be is detected by the gamma peak at 478 keV.

V. Analysis of anthropogenic radionuclides

A. Preparation of samples for radionuclide analysis

As sampling of marine materials such as seawater, sediment, and biological material including sediment trap samples is difficult and expensive, it is desirable to analyze as many radionuclides as possible on a minimum single sample aliquot. Numerous methods have been published

for the determination of anthropogenic radionuclides in marine samples, including precipitation methods, use of ion-exchange resins, extraction chromatography, liquid–liquid solvent extraction, etc. (La Rosa et al., 2001, 2005; Lee et al., 2001, 2005a; 2010; Povinec, 2004; Levy et al., 2011). Radionuclide separation using liquid–liquid solvent extractions is time consuming and generates substantial volumes of organic wastes. One of the most popular methods, a separation using ion-exchange resins, is effective for large samples and reasonable in cost relative to extraction chromatography resins such as TEVA, UTEVA, and TRU (Eichrom Industries). However, the process requires the use of many chemicals, it is time consuming and produces large amounts of chemical wastes. Extraction chromatography reduces the number of chemicals needed, as well as the processing time. Nevertheless, large samples still need preconcentration techniques such as coprecipitation to reduce the amount of matrix before extraction chromatography can be applied. On the basis of the advantages of anion-exchange resins and extraction chromatography methods, sequential separation procedures were developed by the IAEA-EL for the analysis of radionuclides in marine samples.

The preparation chemistry for three of the most frequently analyzed radionuclides (^{90}Sr, ^{137}Cs, and Pu isotopes) will be described in detail using the methods adopted at the IAEA-EL in order to demonstrate the present state-of-the-art techniques (La Rosa et al., 2001, 2005; Lee et al., 2001, 2005a; Povinec, 2004; Levy et al., 2011).

B. Shipboard chemistry for seawater samples

1. Transuranics

Transuranics, cesium and strontium, are usually preconcentrated on the shipboard in precipitation tanks (Fig. 5.16) in three steps. Samples of about 400 L of filtered (0.45 μm cutoff) seawater are transferred into precipitation tanks and acidified by 250 mL of concentrated HCl followed by the addition of tracers (e.g., ^{85}Sr, ^{134}Cs, ^{242}Pu, and ^{243}Am) and carriers (Fig. 5.17). Then 125 mL of saturated $KMnO_4$ is added and mixed by bubbling air for 15 minutes. This is followed by the addition of 250 mL of 0.5 M $MnCl_2$ and subsequently 150 g of NaOH is added to adjust the pH to 6–7. Finally, 2–3 mL of H_2O_2 is added to transform the $Mn(OH)_2$ to MnO_2 ($Mn(OH)_2 + H_2O_2 \geq MnO_2 + 2H_2O$), which is then stirred for 30 minutes. The sample is then left to stand for 4–5 hours to enable the separation of the precipitate from the sample solution. The supernatant is then transferred to a different plastic tank for preconcentration of cesium with ammonium molybdophosphate (AMP). The precipitate is transferred to a plastic container for further separation and determination of transuranics in the home laboratory.

FIGURE 5.16 Precipitation tanks (400 L) for seawater on the shipboard. For the color version of the figure, the reader is referred to the online version of the book.

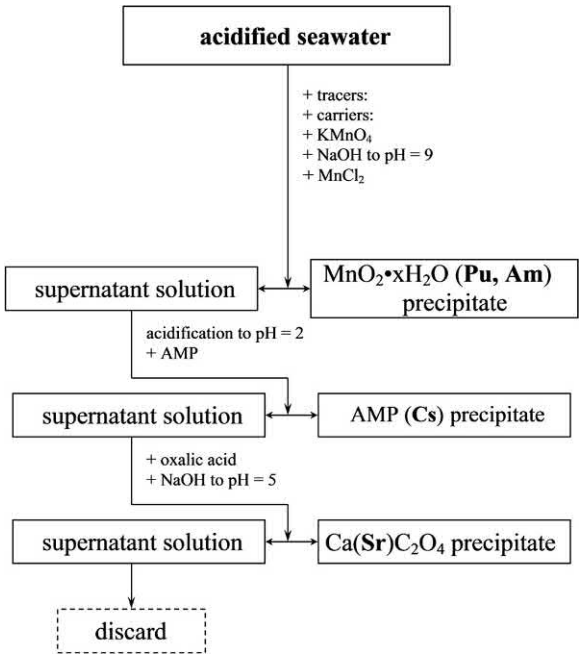

FIGURE 5.17 Preconcentration procedures for transuranics, ^{137}Cs and ^{90}Sr, carried out on the shipboard. *Modified after Povinec (2004). Printed with permission © Elsevier 2005.*

2. Cesium

The supernate from the previous step is acidified (pH 1.5–2.0) with 350 mL of concentrated HCl, and mixed by bubbling air for 15 minutes. Two mL of H_2O_2 is then added to dissolve traces of MnO_2 solids. Then 30 g of AMP, slurred in 100 mL of demineralized water, is added, and the sample bubbled for 30 minutes, and left to stand for 4–5 hours to allow the precipitate to settle. The solution is then transferred to another plastic tank to separate strontium by oxalate coprecipitation. The AMP precipitate is

transferred to a plastic container for further separation and determination of cesium in the home laboratory.

3. Strontium

Oxalic acid (500 g), dissolved in 1 L of boiling demineralized water, is added to the supernate, which is stirred by bubbling air for 15 minutes. 400 g of NaOH is then added to adjust the pH to 6−7, resulting in white oxalate precipitate. The sample is stirred for 30 minutes and left to stand for 4−5 hours to allow the precipitate to settle. The supernate sample is then discarded and the oxalate precipitate collected and stored for further separation and determination of strontium in the home laboratory.

C. Laboratory chemistry for seawater samples

1. Transuranics

Manganese dioxide containing Pu and Am isotopes obtained from shipboard preconcentration is prepared from the suspension in the home laboratory (after checking pH of the liquid) using a combination of settling, decantation/siphoning of the supernatant liquid, and centrifugation. The procedure is described in Fig. 5.18. Further separation of Pu and Am from the iron matrix is carried out by the separation of Pu (IV) using an anion-exchange resin column from 8 M HNO_3 followed by the recovery of Am from the column eluate. An alternative method has been developed by Burnett et al. (1997) using the Eichrom UTEVA + TRU double column. The flowchart for the method as adapted for mass spectrometry measurements of small-volume water samples (<20 L) is shown in Fig. 5.19 (Lee et al., 2001, 2005a; La Rosa et al., 2001, 2005; Levy et al., 2011). With the traditional method, the typical chemical recoveries of Pu and Am from several hundred liters of seawater are in the range of 40−60% and 60−80%, respectively. The resulting α-ray spectra of Pu and Am electrodeposited sources show good radiochemical purity and well-resolved peaks. With the extraction chromatography double-column method, the Am and Pu sources have

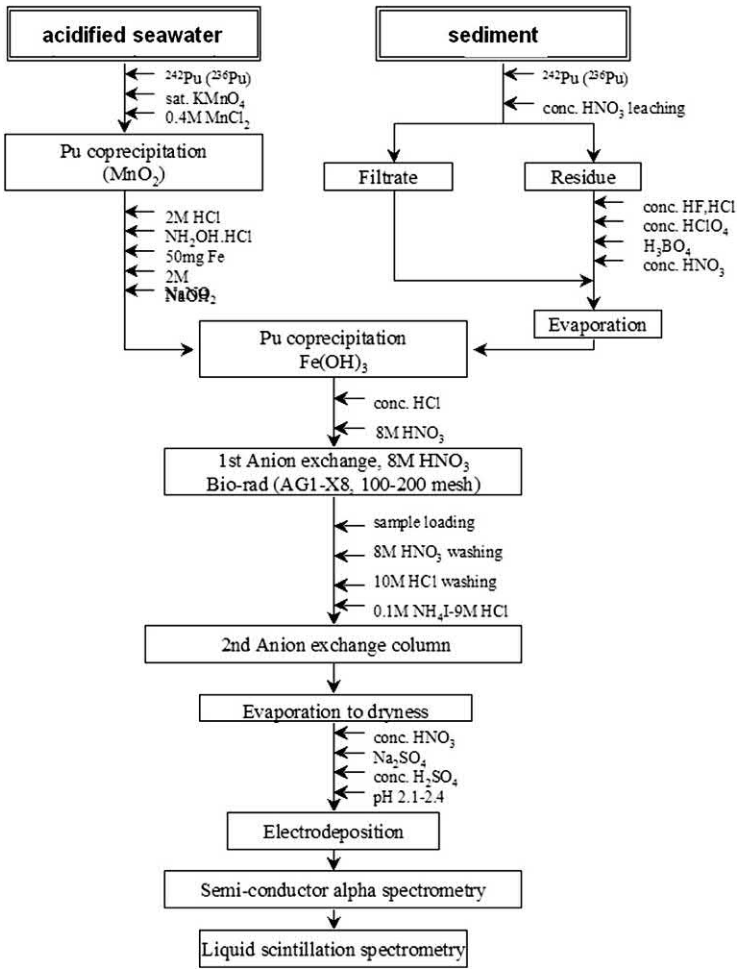

FIGURE 5.18 Plutonium separation from seawater and sediment samples. *Modified after Povinec (2004). Printed with permission © Elsevier 2004.*

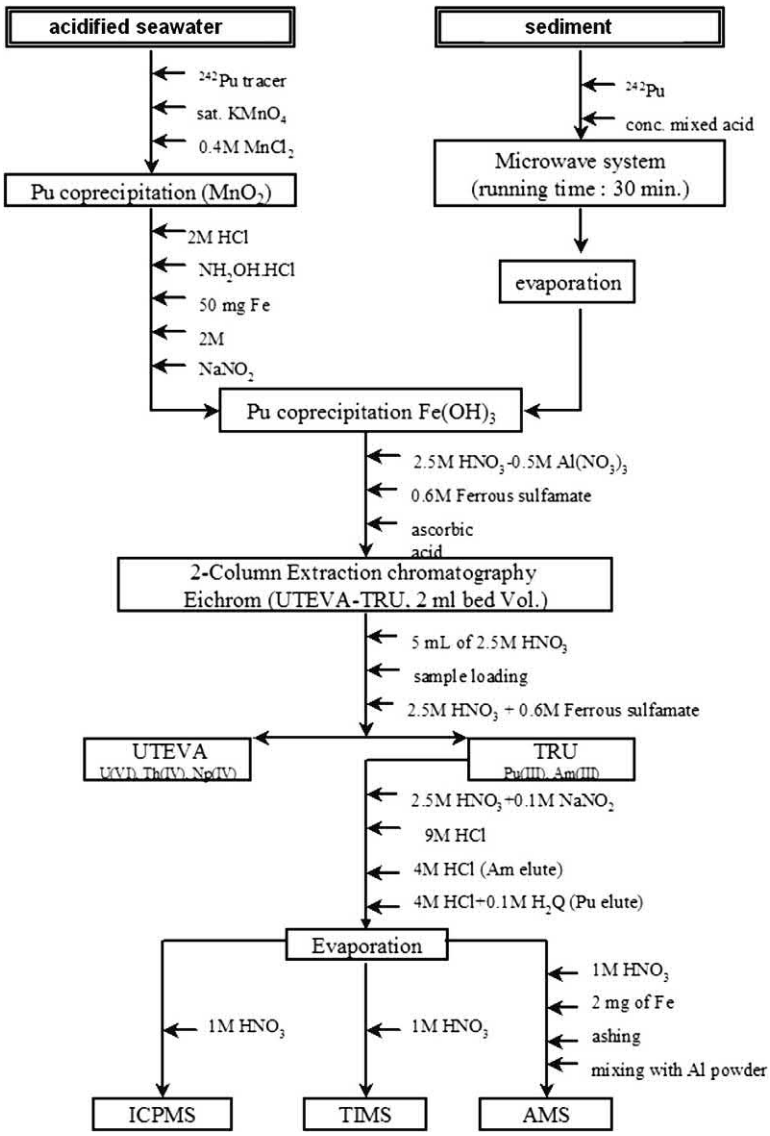

FIGURE 5.19 Plutonium separation for mass spectrometry analysis. *Modified after Povinec (2004). Printed with permission © Elsevier 2004.*

high chemical recoveries (~90% in each case), and the excellent-quality α-spectra shows no visible foreign peaks. In large-volume seawater samples, it is expected that additional purification of the Pu and Am fractions from the TRU column would be necessary; however, small working volumes permit easy and fast chemical operations with less time spent on evaporation steps. In particular, Pu and Am may be retained together on the same TRU column (unlike the traditional method). Small-volume water samples suitable for ICP-MS or AMS measurements of Pu isotopes show very good results. In Am separation and purification, sources produced by both methods show good chemical recoveries, purity, and spectral resolution. In the reprocessing of Am electrodeposition onto disks, one cycle of TEVA + TRU columns gives excellent decontamination from Po with very little loss of Am.

2. Cesium

The AMP suspension (10–20 L) is allowed to settle, and the supernatant solution is decanted or siphoned away. The remaining suspension is centrifuged, and the remaining AMP solid is washed with water and acidified to pH 2. The flowchart for cesium procedures is given in Fig. 5.20. A

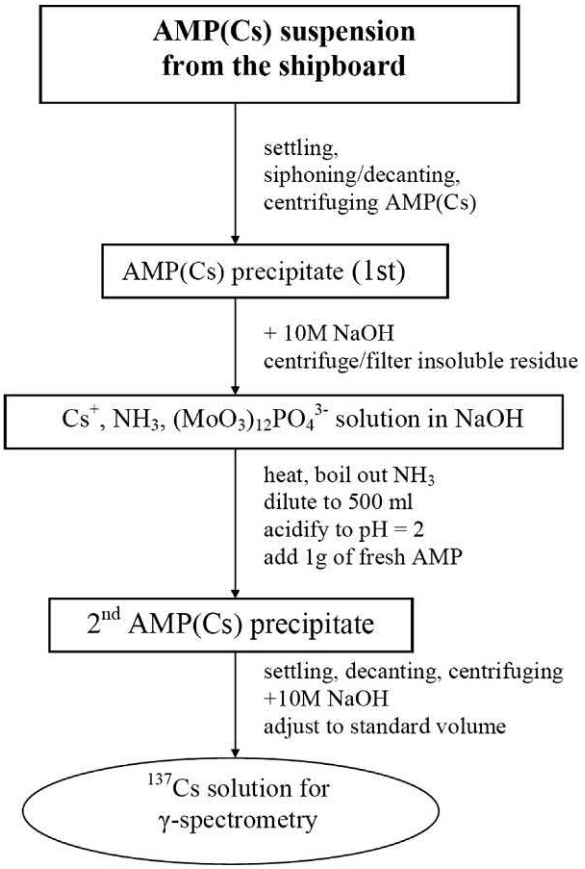

FIGURE 5.20 Cesium separation for γ-spectrometry measurements. *Modified after Povinec (2004). Printed with permission © Elsevier 2004.*

comparison of two sorbents for the collection of cesium (ferric-potassium hexacyanoferrate on a cellulose carrier—ANFEZH, and potassium cobalt ferrocyanide—KCFC) with the AMP was made (La Rosa et al., 2001). It shows that AMP and KCFC quantitatively collect Cs tracer in 20 minutes, whereas ANFEZH does so more slowly and incompletely after 180 minutes. Experimentally derived Cs capacities of the sorbents show that AMP has the highest capacity for Cs sorption and ANFEZH the lowest.

3. Strontium

The strontium chemical separation and purification procedure is illustrated in Fig. 5.21. The calcium oxalate suspension is transferred to a large beaker and allowed to settle. The supernatant solution is siphoned off, and the precipitate washed several times with water to remove the seawater. It is then dried and ashed at 600°C to convert the oxalate to carbonate. After separation, ^{90}Sr is measured by liquid scintillation spectrometry (LSS) (chemical recovery 67%, ^{90}Sr counting efficiency 92%, and background 1.2/min (Liong Wee Kwong et al. (2001)) or by milking ^{90}Y from the purified strontium fraction followed by ^{90}Y counting in a gas flow β-counter or by LSS. Typical

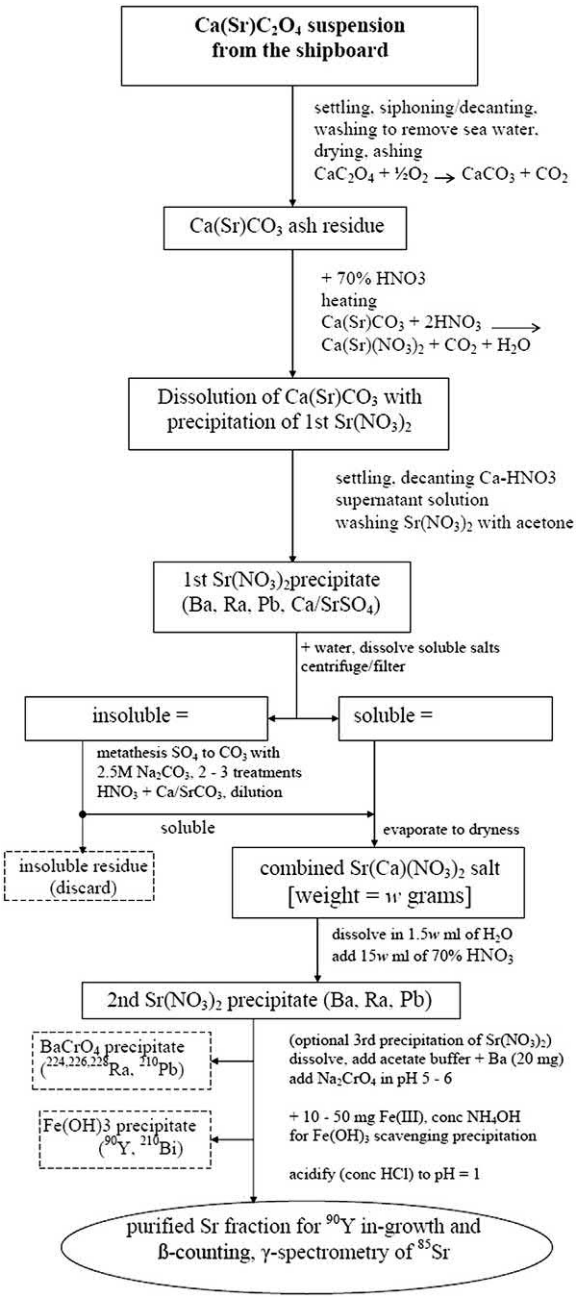

FIGURE 5.21 Strontium separation for β-counting. *Modified after Povinec (2004). Printed with permission © Elsevier 2004.*

parameters are 50% Sr chemical recovery, 90% Y chemical recovery, 48% ^{90}Y counting efficiency, 0.1/min for the gas counter-background, and the detection limit of 3 mBq.

D. Laboratory chemistry for sediment and biota samples

A suitable quantity of a dry, ground solid sample is weighed into a porcelain crucible and ignited at 550°C in an electric furnace to avoid production of refractory

plutonium compounds (e.g., PuO_2) which could be formed at higher temperatures. All or part of the remaining ash is transferred to a PTFE beaker and slurred with 2 M HNO_3. Known amounts (typically 10–20 mBq) of radiochemical yield determinants (e.g., ^{242}Pu and ^{243}Am) are added to the suspension, which is heated for several hours to preclude possible vigorous reactions and evaporated to a conveniently small volume. Either an acid leaching method (8 M HNO_3) or an aggressive dissolution method (using concentrated HNO_3, HCl, and HF) is used for the extraction of actinides from the samples. Especially, the acid leaching method for anthropogenic radionuclides (e.g., Pu, Am, Cs, and Sr) have been widely adopted by a number of laboratories to accommodate large sample sizes. Alternatively, the dissolution method using a combination of HNO_3, HCl, and HF, or a high-temperature, molten salt fusion method can replace the acid leaching method. However, these total dissolution methods can be more time consuming, costly (in terms of amounts of reagents and equipment such as Pt crucibles), and hazardous. Both methods were applied on sea sediments and biological materials, focusing on the global fallout radionuclides, and no remarkable differences were found between the acid leaching (8 M HNO_3) and total dissolution method using the combination of HNO_3, HCl, and HF. This suggests that the leaching method is generally acceptable to analyze the anthropogenic radionuclides in marine samples.

Further, the sediment and biota samples could be treated in a similar way as seawater samples for the separation of radionuclides by anion-exchange resin, or separation and purification by extraction chromatography (e.g., TRU, TEVA, and UTEVA resins). Anion exchange has proved to be a strong tool to treat large-volume samples, and extraction chromatography shows an excellent selectivity and reduction of the amounts of acids. The best results have been obtained by the application of the combined procedure using anion-exchange resin and extraction chromatography. The combined method allows the treatment of large sample sizes and provides excellent selectivity, high chemical recoveries, and reduction of the amounts of acids. A disadvantage of the extraction chromatography method is an increase in price per analysis of one sample (Lee et al., 2001, 2005a; Povinec, 2004). The prepared samples can be then measured either by radiometric (α-spectrometry, β-spectrometry) or by mass spectrometry methods (ICP-MS, AMS, etc.).

VI. Activity measurement techniques

A. Radiometric methods

1. Low-level alpha-spectrometry

Semiconductor α-spectrometry (SAS) has been widely used for the analysis of α-emitters (mainly actinides) in marine samples (e.g., Bowen et al., 1980; Livingston et al., 2001). Other techniques, such as ionization chambers and track detectors, have not been used in the analysis of marine samples, mainly because of poorer energy resolution. Therefore, the most important developments in SAS have been in the radiochemistry sector, as previously discussed. However, one development we would like to mention here, as the major disadvantage of high-resolution SAS compared to mass spectrometry techniques, is the difficulty in resolving ^{239}Pu and ^{240}Pu peaks. Large surface ($\sim$10 mm in diameter) silicon detectors frequently used in SAS cannot resolve this duplet. However, by using high-resolution silicon detectors and special deconvolution software, this problem can be solved (Leon Vintro et al., 1996). The disadvantage here is that due to the smaller detector surface, sensitivity is lower and only samples with relatively higher concentrations of α-emitters can be analyzed. This is one of the reasons why mass spectrometry techniques are more and more widely used for the analysis of Pu and Am isotopes in the marine environment (Baxter, 1993; Buesseler, 1997; Kelley et al., 1999; Fifield, 2008; Hou and Ross, 2008; Povinec et al., 2008a).

2. Low-level beta-spectrometry

Several anthropogenic radionuclides (e.g., ^{3}H, ^{85}Kr, ^{90}Sr, and ^{241}Pu) are found in the marine environment, which are still analyzed by β-counting or β-spectrometry, mainly because their half-lives are too short to be analyzed by mass spectrometers. For some *β-ray* emitters, such as ^{14}C and ^{129}I, which were previously analyzed by β-spectrometry, AMS is at present the most widely used technique. Other radionuclides, such as ^{99}Tc, are still analyzed by β-spectrometry, although ICP-MS (and AMS) have been successfully applied as well, and in the future, mass spectrometry techniques will prevail for these radionuclides (Hou and Ross, 2008). The most important breakthrough in β-spectrometry was the introduction of low background LSS, which are now mainly used for the analysis of short-lived *β-ray* emitters in the marine environment (Povinec et al., 2008a). The advantage of low-level LSS over low-level gas counting is the higher detection efficiency of LSS and its capability as a β-spectrometer, registering only those β-electrons with energies inside the *β-ray* spectrum, and not all β-electrons registered by e.g., Geiger–Müller counters. We shall illustrate the possibilities of LSS techniques using a few examples—^{3}H (maximum energy of β-electrons 18.6 keV; $T_{1/2} = 12.3$ y) and ^{241}Pu (maximum energy of β-electrons 20.8 keV; $T_{1/2} = 14.4$ y). ^{3}H analysis by LSS without enrichment has a detection limit of about 2 TU (1 tritium unit (TU) is the ratio of 1 atom of ^{3}H to 10^{18} atoms of ^{1}H). Operation of the LSS underground can improve the detection limit by about a factor of two (Povinec et al., 2008a). Electrolytic enrichment can further

lower the detection limit to 0.02 TU (Taylor, 1977; Groening et al., 2009; Morgenstern and Taylor, 2009), which is similar to the value obtained by ^{3}He in-growth mass spectrometry (Clarke et al., 1976). For ^{3}H analysis of surface waters contaminated by radioactive discharges, simple LSS is the best solution. The Quantulus liquid scintillation spectrometer (formerly produced by Wallac Oy and now by PerkinElmer, Inc.), which benefits from the low background achieved with the use of an anti-coincidence shielding of the counting vial, can reach a background of 0.4/min, detection efficiency of 20%, and detection limit of ~1 TU (10 mL distilled water sample is directly mixed with 10 mL of the scintillation cocktail) (Liong Wee Kwong et al., 2001). Similar counting parameters are obtained with the Packard LSS (now produced by PerkinElmer, Inc.), which uses the pulse shape discrimination method for decreasing the spectrometer's background. Recently, an electrolysis apparatus utilizing solid polymer electrolyte has been developed (which greatly simplifies the enrichment procedure), and with LSS ^{3}H concentrations in water down to 0.02 TU can be measured (Saito et al., 2000).

Another good example of the advantageous use of LSS is in the analysis of ^{241}Pu. As it is a pure β-emitter, it cannot be analyzed simultaneously with other plutonium isotopes using α-spectrometry. However, the disk with electrodeposited Pu after α-spectrometry measurement can be placed in a polyethylene vial containing a liquid scintillator (e.g., Insta-Gel cocktail produced by PerkinElmer). Using the pulse shape analysis method, α-rays can be separated from *β-rays* registered by LSS (see Chapter 6, Volume 1 and Chapter 2, Volume 2 of this book). Typical counting parameters are 5 mL of cocktail, 12% efficiency, 0.3 min^{-1} background, and detection limit of 0.03 Bq (Liong Wee Kwong et al., 2004a). Although ^{241}Pu has the highest activity concentrations in environmental samples compared to other Pu isotopes, the direct counting is not sufficiently sensitive for many applications. Therefore, the more preferable method is leaching plutonium from the stainless steel disk after α-spectrometry (or to separate a portion of Pu sample before its electrodeposition on the disk), and dissolving the sample in the counting vial, enabling 4π geometry measurements, thus increasing the detection efficiency by a factor of two (Liong Wee Kwong et al., 2004a).

3. Low-level gamma-spectrometry

The most important development in the radiometrics sector was the utilization of large-efficiency HPGe detectors in underground laboratories (Povinec et al., 2004a, 2008a, 2010; Aoyama and Hirose, 2008; Levy et al., 2011). Low-level γ-spectrometry with HPGe detectors is an effective tool in the study of marine radioactivity, which exhibits the following advantages:

- an excellent energy resolution that permits the analysis of various radionuclides in composite samples selectively and very often nondestructively (e.g., in sediments);
- the high efficiency of recently produced HPGe detectors (up to 200% relative to a 76 mm diameter × 76 mm NaI(Tl) crystal).

Although the most effective way of increasing the sensitivity of a spectrometer is to increase its counting efficiency and the amount of analyzed sample, frequently the only possible way is to decrease its background (Michel, 2001). The background components in a typical low-level HPGe detector, not situated deep underground, are cosmic radiation (cosmic muons, neutrons, and material activation), environmental radioactivity, radioactivity of construction materials, radioactivity of the detector, radon, and its progenies (Heusser, 1995). For present day, carefully designed low-level HPGe γ-spectrometers, operating not deep underground, the dominating background component is cosmic rays, mainly cosmic muons (Heusser, 1995; Vojtyla and Povinec, 2000, 2006; Povinec et al., 2008a; Breier and Povinec, 2009, 2010). However, in the majority of marine applications, a simple γ-spectrometer with an HPGe detector of about 100% efficiency (especially if the sample size permits the use of a well detector) is the usual choice (Aoyama and Hirose, 2008).

In single HPGe spectrometers, there is no protection against cosmic ray muons; therefore, a spectrometer with an anticosmic shielding will provide a better sensitivity. The anti-Compton spectrometer is a powerful technique for reducing the detector's background because it combines both the anticosmic and the anti-Compton suppression of background (Cooper and Perkins, 1972; Debertin and Helmer, 1998; Reidel et al., 2000) in which the scattered photons escaping from the principal detector volume can be detected by a sufficiently large NaI(Tl) or BGO crystal surrounding the detector. The simplest anti-Compton spectrometer can be made using a Ge detector and an NaI(Tl) crystal with a well. Using a Ge detector in a large NaI(Tl) crystal (about 30 cm diameter × 30 cm), the Compton suppression factor should reach values above 10 (for $E\gamma \leq 1.5$ MeV), and thereby decreasing detection limits more than threefold (Zvara et al., 1994). Usually, a well-designed anti-Compton spectrometer can be used simultaneously as a coincidence and anti-Compton spectrometer. Although the detection efficiency is reduced in coincidence spectrometers, a considerable decrease in background (by about two orders of magnitude) makes these spectrometers superior for very low-level γ-spectrometry (Sýkora et al., 2008). The most sophisticated spectrometric system is, however, the multidimensional γ-spectrometer (Cooper and Perkins, 1971b; Povinec, 1981) in which signals from the analyzing detectors create

three-dimensional spectra (volumetric peaks) which can contain both coincidence and noncoincidence peaks. Analyzing electronics, if two HPGe detectors are used, require 8000 × 8000 channels, which, with present state-of-the-art computer electronics, is not difficult. The background can be reduced more than two orders of magnitude.

4. Underground laboratories

In low-level γ-spectrometry, muon-induced background becomes dominant for large-volume HPGe detectors, as the most prominent peaks observed (i.e., the annihilation peak and neutron activation peaks) are due to cosmic ray interactions (Povinec et al., 2008a; Povinec, 2012). Monte Carlo simulations of background spectra of detectors are possible to carry out prior to the construction of a low-level spectrometry system and thus predict its characteristics and parameters (Vojtyla and Povinec, 2000; Povinec et al., 2008a). The simulation tools based on the GEANT code, developed by CERN, proved to be capable of modeling background characteristics of detectors and thus enable the optimization of the design of low-level γ-spectrometric installations. Computing power is no longer a problem, as desktop computers of sufficient speed and power are available. Therefore, the influence of various parameters on the detector background can be studied well in advance, and the cosmic muon−induced background can be estimated before a low-level detector system is constructed. Simulations of the characteristics of HPGe detectors placed inside a lead shield without and with anti-Compton shielding in surface or shallow underground laboratories revealed useful trends in design of such systems. Given the detector setup, its background spectra induced by cosmic ray muons can be scaled down by a factor corresponding to the shielding depth (Breier and Povinec, 2009, 2010; Breier et al., 2016, 2017, 2018).

Simulations with various shields showed that the background depends mainly on the thickness, dimensions, and lining of the shield (Vojtyla and Povinec, 2000, 2006). The shape of the shield (cylindrical or rectangular) has almost no effect on the background provided that the inner dimensions are similar. The best results were obtained for the smallest shields with the low-Z materials in the lining. The background characteristics most affected are the maximum of the background continuum with a count rate of 450 d^{-1} keV^{-1} in a shield lined with 1 cm of copper compared to the count rate of 190 d^{-1} keV^{-1} in a lead-only shield. The use of shields with removable linings is recommended for applications where lead X-rays do not have a disturbing effect. It is inadvisable to build an unnecessarily large shield. In a medium-size shield, the integral background count rate (0−1500 keV) is expected to reach count rates of about 85 $minute^{-1}$, and the count rate in the annihilation peak is estimated to be about 4400 d^{-1} keV^{-1}, whereas the maximum count rate in the background continuum should be approximately 210 d^{-1} keV^{-1} (at sea level). A well-type detector intended for the counting of small samples inside the well should be placed into a tight shield without lining. In this case, the integral background count rate can be as low as 50 $minute^{-1}$, the count rate in the annihilation peak can be reduced to 900 d^{-1} keV^{-1}, and the maximum counting rate in the background continuum can be minimized to only about 100 d^{-1} keV^{-1}. Simulations at 20 m.w.e. (meters of water equivalent) underground showed that the features simulated background spectra remain unchanged, except that all the count rates scaled down by a factor of about 3 (Breier and Povinec, 2010).

The nucleonic component of cosmic rays (mainly neutrons) is attenuated at 10 m.w.e. by three orders of magnitude; however, the muonic component remains at this shielding layer without notable reduction (by a factor of 2 only; Povinec et al., 2008a). To decrease the muonic component by a factor of 10, shielding over 50 m.w.e. is needed. At 1000 hg/cm^2 depth, the reduction in muon flux can be as high as 10^6 (Povinec et al., 2008a). Therefore, muon-induced background can be lowered significantly either by operating the detector deep underground or by using an anticosmic detector located above the HPGe crystal which operates as a veto detector. The use of anticosmic shielding is advantageous also in shallow underground laboratories operating at depths only down to several hundred meters of water equivalent (Povinec et al., 2008a).

Backgrounds of HPGe detectors in CELLAR (Collaboration of European Low-level Underground Laboratories) laboratories (Laubenstein et al., 2004) are compared in Fig. 5.22. Although the IAEA-EL laboratory in Monaco is

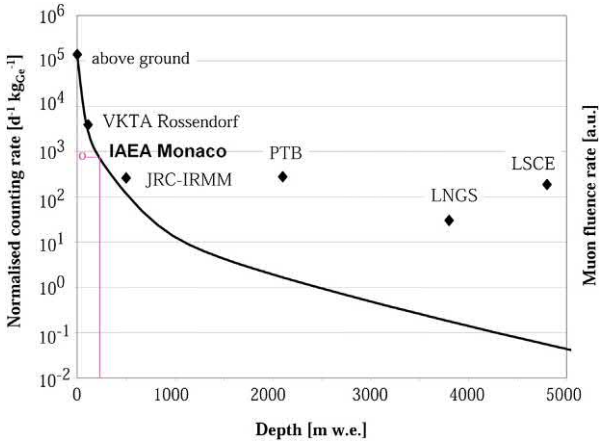

FIGURE 5.22 A comparison of backgrounds of HPGe detectors operating in CELLAR underground laboratories. The background of the HPGe detector with anticosmic shielding operating in the IAEA Monaco laboratory (35 m w.e.) is similar to that operating at 250 m w.e. *Modified after Laubenstein et al. (2004). Printed with permission © Elsevier 2006.*

operating at 35 m.w.e. only, thanks to the anticosmic veto shielding, its background is comparable with laboratories operating at depths of around 250 m.w.e. The CAVE (**C**ounting l**A**boratory for en**V**ironmental radionuclid**E**s) laboratory in Monaco (Povinec, 2004; Povinec et al., 2004a, 2005a, 2006d,e) is equipped with a common lead shield housing four large-volume HPGe detectors (Fig. 5.23). An anticosmic veto shielding was made of plastic scintillation detectors surrounding the lead shield which protect the HPGe detectors against cosmic radiation. Such a novel design, supported by Monte Carlo simulations, when several HPGe detectors are shielded against cosmic rays by a common guard detection system, has been used for the first time in low-level γ-spectrometry. The CAVE also houses an anti-Compton γ-spectrometer, comprising an n-type HPGe detector and NaI(Tl) anticoincidence shielding placed in a lead shield, and a liquid scintillation β-spectrometer. The HPGe detectors, housed in the common lead shield surrounded by the anticosmic guard, are the following (Povinec et al., 2008e; Levy et al., 2011):

a. 100% relative efficiency coaxial detector (CANBERRA) with cryostat made of electrolytic copper with carbon window;
b. 150% relative efficiency well-type detector (CANBERRA) with cryostat made of electrolytic copper (well dimensions: 32.5 mm diameter, depth 73 mm); well walls made of thin copper;
c. 170% relative efficiency coaxial detector (EURISYS) with cryostat and window made of pure aluminum;
d. 200% relative efficiency well-type detector (CANBERRA) with cryostat made of electrolytic copper (well dimensions—25 mm diameter, 60 mm depth); well walls made of thin copper.

FIGURE 5.23 The CAVE (Counting lAboratory for enVironmental radionuclidEs) laboratory in the IAEA-EL, Monaco, houses four large-volume HPGe detectors placed in a common lead shield protected against cosmic rays with anticosmic veto shielding made of plastic scintillators. *Modified after Povinec et al. (2008a). Copyright Institute of Physics. Slovak Academy of Sciences. All rights reserved.*

ORTEC modular electronics have been used for signal processing and data acquisition. During all measurements, radon is expelled from the detector chambers by the evaporation of nitrogen from the detector's Dewar containers, thus keeping background during measurements stable. It should be stressed that this detection system is used only for the analysis of low-activity samples. The measured background of HPGe detectors with anticosmic veto shielding is compared by Povinec et al. (2008e). As the volumes of the detectors differ significantly, it is necessary to compare their background characteristics per kg of Ge. The total detector background per kg of Ge in the energy window 40−2000 keV decreases with increasing detector volume, i.e., from 290 h^{-1} kg^{-1} Ge for the 100% efficiency detector to 205 h^{-1} kg^{-1} Ge for the 200% efficiency detector. However, the background with the anticosmic veto shielding does not follow this rule, but clearly shows a larger contribution of radioactive contamination of the detector materials to its background. The lowest total background with the anticosmic veto shielding was obtained for the 150% efficiency detector (27 h^{-1} kg^{-1} Ge), the highest for the 170% efficiency detector (59 h^{-1} kg^{-1} Ge). The 170% efficiency detector has the cryostat made of "pure" aluminum; however, this has been clearly contaminated by U and Th (and their decay products), as well as by ^{40}K. Generally, aluminum is, from the point of view of radioactive contamination, not a suitable construction material.

It is important that construction materials be carefully tested by the manufacturing companies for the presence of radionuclides before the detector construction, especially for the detector's cryostat and its window (Laubenstein, 2017). Monte Carlo simulations of background characteristics of HPGe detectors operating in Gran Sasso (Breier et al., 2017) and Modane (Breier et al., 2018) showed that measured background was due to radioactive contamination of construction parts of the detectors and surroundings by two and three orders of magnitude higher than the predicted cosmic ray contribution. Therefore radiopurity of construction materials is playing a dominant role in obtaining low background, not only for applications in marine radioactivity studies, but generally for rare nuclear physics investigations (Povinec, 2017, 2018a,b; Palušová et al., 2018; Povinec et al., 2018).

However, it has also been a surprise that three detectors with copper cryostats, ordered as low background detectors for an underground laboratory from the same company (CANBERRA), had very different background characteristics.

The background γ-ray spectra of HPGe detectors operating in the Monaco laboratory are shown in Fig. 5.24. The highest background reduction with the anticosmic veto shielding was obtained for the 150% efficiency detector (factor 9) and the lowest for the 170% efficiency detector

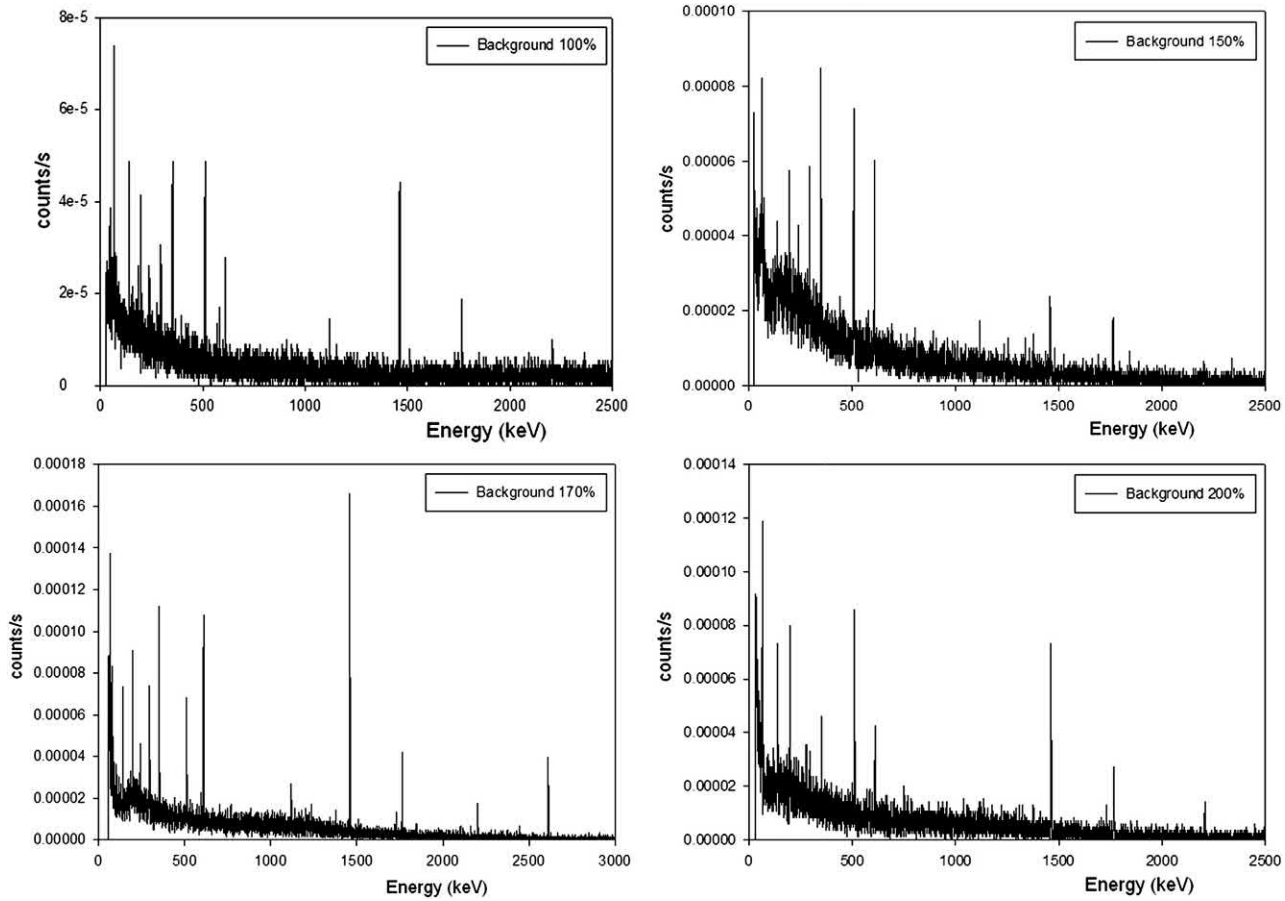

FIGURE 5.24 Background γ-spectra of HPGe detectors operating in the CAVE laboratory (35 m w.e.) with 12.5 cm lead shield and anticosmic veto shielding. *Modified from Levy et al. (2011). Printed with permission © Elsevier 2011.*

(factor 4). The 100% and 200% efficiency detectors have the reduction factors within these limits (factors 7 and 6, respectively). The important finding is that the annihilation peak at 511 keV is still dominant in all background spectra. This peak is produced by annihilation of electrons and positrons in the shield and in the detector, which are products of the interaction of secondary cosmic rays with materials surrounding the detector. The second important finding is a large background continuum, which has a maximum at around 200 keV. This background continuum is produced by the interactions of cosmic muons with the lead shield, as previously discussed. Both observations indicate that it would be advantageous to operate the detectors in a deeper underground laboratory.

The underground counting laboratory with anticosmic shielding of detectors effectively decreases the background of large-volume HPGe detectors, especially when operating in anticosmic, anti-Compton, or coincidence modes. The anticosmic shielding has proved to be a valuable investment, as the background of HPGe detectors operating at shallow depths is comparable with underground laboratories operating at moderate depths of about 250 m.w.e.

The new underground technology with anticosmic shielding enabled the analysis of ^{137}Cs in small-volume (around 10 L) seawater samples from the Atlantic and Indian oceans, what was not possible earlier. It has been possible to decrease the sample volume by about a factor of 10, which greatly reduces sampling time, and the same seawater volumes could be used for γ-spectrometry as well as for mass spectrometry measurements (Povinec, 2004; Povinec et al., 2008a; Levy et al., 2011).

B. Mass spectrometry methods

Several mass spectrometric techniques have been successfully applied in the past for the analysis of isotopes in the marine environment. These techniques have entailed the use of traditional isotope mass spectrometers (White and Wood, 1988), like those used for the analysis of light isotopes such as ^{2}H, ^{3}He, ^{4}He, ^{13}C, ^{15}N, and ^{18}O. The traditional isotopic technique has not been successful in the analysis of radioactive isotopes in marine samples, mainly because of problems with high background. ^{3}He, which is a decay product of ^{3}H, has been successfully analyzed for the

determination of very low concentrations of tritium. ICP-MS and TIMS have been used for the analysis of several long-lived radionuclides, along with RIMS (Michel, 2001; Povinec, 2004; Ross, 2008; Erdmann et al., 2008; Povinec et al., 2008a). AMS has increased the number of radionuclides from ^{14}C to transuranics, and because the background of the system is significantly reduced by accelerating analyzed ions up to several tens of MeV (Kutschera et al., 2000), AMS has become the most sensitive technique at present for the analysis of long-lived radionuclides in the environment (Kutschera, 2005, 2010; Jull et al., 2008; Fifield, 2008; Povinec et al., 2008a).

1. ^{3}He in-growth spectrometry for ^{3}H analysis

The ^{3}H decay product, ^{3}He, is very rare, so its analysis is most suitable for measuring ^{3}H concentrations down to 0.01 TU (Clarke et al., 1976; Palcsu et al., 2010). At present, this is the most sensitive method of isotopic analysis as isotopic ratios of $^{3}H/^{1}H$ can be measured down to 10^{-20}, which represents the lowest isotopic ratio analyzed in the environment. The only disadvantage of the ^{3}He method is the long waiting period (about 6 months) for in-growth of ^{3}He in a water sample hermetically sealed in a glass flask. On the other hand, if appropriate sampling techniques and containers are used for water sampling, it is possible to analyze ^{3}He and ^{4}He gases in the water column simultaneously. The helium isotopes can give additional information on the water age ($^{3}H-^{3}He$ method) and on circulation of water masses in the ocean (^{4}He). If a given water parcel in the sea is not subject to mixing with water of different ages, the relation between its ^{3}He content becomes the time (age) elapsed since the last contact with the atmosphere (Schlosser et al., 1999).

2. Inductively coupled plasma mass spectrometry

With the introduction of the present state-of-the-art high-resolution ICP-MS machines, this technique has been dominating in the analysis of long-lived radionuclides in the marine environment (Sturup et al., 1998; Chiappini et al., 1999; Wyse et al., 2001; Ross, 2008; Hou and Ross, 2008). The principal advantages of ICP-MS are its capacity to determine long-lived radioisotopes of metallic elements down to fg levels, to analyze aqueous samples directly and rapidly (in a few minutes), to keep a low cost per analysis, and to analyze small samples. However, ICP-MS is not free of matrix and isotopic effects, and the formation of chlorides and oxides requires extra careful purification procedures, e.g., extraction chromatography. A steady increase over the past decade in radioanalytical applications using ICP-MS has resulted in a decrease in both the price of instruments and detection limits. New-generation sector field instruments with double-focusing and even multicollector systems have improved sensitivity (by about an order of magnitude) and precision over traditional quadrupole machines (Wyse et al., 2001; Ross, 2008; Hou and Ross, 2008; Povinec et al., 2008a; Nisi et al., 2009). ICP-MS has been used in both higher-resolution and lower-resolution modes. The higher-resolution mode has the advantage of addressing polyatomic interferences, although it cannot solve all the problems with isobaric interferences, which may be caused by incomplete separation chemistry. On the other hand, maximum sensitivity can be reached in the lower-resolution mode. Thus, a combination of the two modes appears to be the best compromise for reaching maximum sensitivity and controlling interferences. The higher count rates under lower-resolution mode give better analytical peaks with lower uncertainties and optimal data quality. Analytes with a relatively strong probability of polyatomic interferences (e.g., ^{238}U which produces a hydride peak that would interfere with ^{239}Pu) should always be scanned. Even so, there are problems with the relatively poor abundance sensitivity of sector field ICP-MS in the measurement of isotopes with one mass below an abundance peak (e.g., ^{237}Np in the presence of high ^{238}U) and two mass units below (e.g., ^{230}Th in the presence of ^{232}Th or ^{236}U in the presence of high ^{238}U content). Even when sample matrices are reasonably clean, and care has been taken to minimize oxides during tuning, measurements made near the detection limit are sensitive to overestimation due to polyatomic interferences. The use of chromatographic resins (Lee et al., 2001, 2005a, 2008, 2009a) has been found to be a suitable technique for processing small volumes, removing possible interferences by additional cleaning, as well as for cleaning leached plutonium samples electrodeposited on stainless steel disks, previously analyzed by SAS.

Production and certification of reference materials have also gained from the introduction of ICP-MS, as this has been used as an effective method for the certification of concentrations of Th, U, and Pu isotopes in various reference materials—seawater, sediment, and biota (Lee et al., 2001, 2005a, 2005b; 2008, 2009a; Inn et al., 2001; Pham et al., 2006a, 2006b; 2008, 2010a; 2010b, 2011; Povinec et al., 2007).

Although molecular, isobaric, and isotopic interferences remain crucial for successful operation of ICP-MS, this technique has a large potential for automation by direct coupling with the new generation of chromatography instruments. ICP-MS has been widely applied, e.g., on the analysis of long-lived radioisotopes of actinides in seawater, sediment, and biota, such as Th, U, Np, and Pu isotopes (Chiappini et al., 1999; La Rosa et al., 2001, 2005; Lee et al., 2001, 2005a; 2008, 2009a; Ross, 2008; Hou and Ross, 2008). Long-lived fission radionuclides, such as ^{99}Tc and ^{129}I, have been studied in seawater and seaweeds (Hou et al., 2009). Usually solution neutralization has been

applied for liquid samples with detection limits below pg. The ETV (electrothermal vaporization) technique has also been used for determining U and Pu isotopes in seawater and ^{129}I in seaweeds (Hou and Ross, 2008).

3. Thermal ionization mass spectrometry

Until the introduction of ICP-MS, TIMS was the most widely used technique for ultralow analysis of long-lived radionuclides (especially actinides) in the marine environment. TIMS has proved to be a highly sophisticated analytical method providing the most precise isotope ratio determinations with precision down to a few ppm (White and Wood, 1988). With TIMS, positive ions are produced in the spectrometer's ion source by evaporating a sample from a heated metal surface. Source filaments are usually chosen from metals with relatively high work functions, high melting points, and the necessary purity and mechanical properties (e.g., platinum, rhenium, tantalum, or tungsten). After heavy separation chemistry, samples are loaded as highly purified solutions onto the filament or by electrodeposition. By adding a known quantity of yield tracer to the sample, isotope dilution analysis is used to measure concentrations below the fg scale (Inkret et al., 1998). Interferences from isobars and mass discrimination between isotopes of a given element need to be carefully evaluated and excluded by chemical purification and control of ionization conditions. Nevertheless, the problem of interferences with TIMS is not as great as in ICP-MS. This problem has been solved when using the total sample evaporation method, as the sample is completely evaporated from the filament. The final results are given in averaged isotopic mean values when measurement has been completed and no measurable amount of sample is left on the filament. Thus, the limiting factor of TIMS in environmental analysis is very often the purity of the sample, as improvements and innovations in mass spectrometer hardware have augmented analytical precision. The new state-of-the-art TIMS machines with multicollector arrays have considerably improved operation in multidynamic mode, producing a sensitivity of around 10^5 atoms for ^{239}Pu, which is comparable to AMS. When using measurement techniques with the extreme sensitivity of TIMS at levels below 10^{-15} g per sample, it is very important to minimize the effects of airborne dust particles, reagents, glassware, etc. which can all contribute significantly to the sample blank and, as a result, to analytical detection limits which are actually defined by the contamination of the blank sample. For this reason, successful TIMS requires more careful sampling, very clean chemical processing, and a higher level of instrumental expertise than any other method. The main advantage of TIMS is its high sensitivity for actinides (more than an order of magnitude higher than for SAS), as well as the possibility of measuring ^{240}Pu/^{239}Pu ratios in low-level samples and identifying the origin of plutonium in marine samples (Buesseler and Scholkovitz, 1987; Lewis et al., 2001). A wide range of ^{240}Pu/^{239}Pu atom ratios have been found in the marine environment: from 0.05 in Mururoa lagoon sediment, through global fallout ratio (0.186) to discharges of plutonium from reprocessing plants (e.g., 0.24 for Irish seawater or 0.20 for Irish Sea sediment) (Kershaw et al., 1999), to 0.30 in Bikini lagoon sediment (Muramatsu et al., 2001). It has been found (Buesseler, 1997) that plutonium delivered as stratospheric fallout appears to be relatively soluble and has a longer residence time in seawater than plutonium from close-in fallout, which is more rapidly removed from the water column to deep-ocean sediments. Highly sensitive TIMS has been used for size-fractionated plutonium isotope studies in the coastal environment (Dai et al., 2001).

4. Resonance ionization mass spectrometry

RIMS is based on highly efficient and selective ionization of elements by tunable lasers and subsequent analysis of ions by a mass spectrometer (Baxter, 1993; Wendt et al., 2000; Becker, 2007). It has been found to be a powerful technique with the main advantages in almost complete isotopic suppression, high ionization efficiency, low background, and high isotopic selectivity, resulting in an overall sensitivity of detection limits down to the fg scale (Erdmann et al., 2008). As only atoms of the desired element (or isotope) are excited and ionized by laser, undesired ions in the mass spectrometer can be suppressed to a significant extent. Therefore, of the various applications of RIMS, ultralow-level determination of long-lived radionuclides in the environment has been the most widely acknowledged (Erdmann et al., 2008). As ICP-MS is very often limited by molecular effects which very often create isobaric interferences (as occasionally occurs with TIMS as well), RIMS together with AMS is currently the most selective technique with minimum interferences for the analysis of long-lived radionuclides in the marine environment at very low levels. However, compared to the more widely used ICP-MS or TIMS, RIMS is yet a very complicated technique requiring a lot of skill and strong technical support. It would seem that RIMS will remain an alternative technique to AMS whenever AMS cannot be used effectively because of insufficient or no production of negative ions (e.g., in the case of ^{81}Kr), strong isobaric interferences or other sources of background. RIMS has been applied successfully in the analysis of several long-lived radionuclides in the environment such as, ^{81}Kr, ^{90}Sr, and ^{99}Tc (Kramer et al., 1986; Wendt et al., 2000) with a detection limit for ^{239}Pu down to 10^6 atoms (Erdmann et al., 2008). Especially, ultratrace isotope detection of noble gases (^{39}Ar and ^{81}Kr) are still a challenging task which has recently been addressed also by AMS, as well as by optical spectroscopy using a magneto-

optical trap and collinear laser photon burst spectroscopy (Kutschera et al., 2000; Bailey et al., 2000). Although the application of RIMS in environmental radionuclide studies has been very limited, its great potential could be in speciation studies, especially when it is coupled to chromatographic systems. As an alternate mass spectrometry technique, it may also play an important role in certification of reference materials.

5. Accelerator mass spectrometry

The first successful attempts to analyze isotopes using accelerated ions were made by Alvarez and Cornog (1939); however, the technique was forgotten for almost 40 y. Attempts were made to use cyclotrons (Muller, 1977, 1978), as well as tandem accelerators (Bennett et al., 1978; Nelson et al., 1977) for acceleration of ions, but the problems with current stability in cyclotrons led latter to the widespread of tandem accelerators in AMS.

The real breakthrough was the development of dedicated tandem accelerators for AMS, firstly for ^{14}C and then for other radionuclides as well, such as ^{10}Be, ^{26}Al, and ^{129}I (Donahue et al., 1990; Kilius et al., 1987; Tuniz et al., 1998). The AMS consists of three main parts—the ion source, the accelerator, and the mass spectrometer illustrated in Fig. 5.25 (see also Chapter 8 Volume 1 of this book). As in tandem accelerators, only negative ions can be used for acceleration, therefore AMS technique can only be applied for those elements (the great majority) forming negative ions. For elements which only form positive ions (e.g., noble gases), cyclotrons can be used, e.g., for the analysis of ^{39}Ar and ^{81}Kr (Kutschera et al., 2000). Very promising AMS systems use a combination of AMS and IBA (Ion Beam Analysis) for better identification of elements of interest in the samples (e.g., Povinec et al., 2015a,b,c, 2016b). The AMS technologies have been extensively reviewed by Kutschera et al. (2000, 2005), Fifield (2000, 2008), Becker (2007), Jull et al. (2008), and Povinec et al. (2008a), including their applications for analysis, e.g., ^{3}H, ^{14}C, ^{10}Be, ^{26}Al, ^{32}Si, ^{39}Ar, ^{99}Tc, ^{129}I, U, Pu isotopes in environmental studies (Kutschera et al., 2005, 2016; McHargue et al., 2000; Kobayashi et al., 2000; Lawson et al., 2000). Some other long-lived radionuclides have been successfully analyzed by AMS (or are under development) with possible applications in marine sciences, including ^{32}Si (Treacy et al., 2000), ^{36}Cl (Hatori et al., 2000; Jacobsen et al., 2000), ^{53}Mn (Knie et al., 2000), ^{135}Cs (Zhao et al., 1999), and ^{237}Np (Fifield, 2000).

The most important development in the AMS sector has been the small "desktop" AMS systems with 0.2 MV accelerator voltage (Suter et al., 2000; Skog, 2007; Synal et al., 2007), which eliminated the need for pressure tanks. This interesting design has been a new competitor to larger AMS machines for ^{14}C analysis, having important impact on environmental and archeological research. In general, however, as the operating terminal voltage used for AMS decreases, the technical engineering difficulties increase, as below 200 kV stripping efficiencies are too low. These small AMS machines have also considerable potential for applications to the analysis of ^{10}Be, ^{129}I, and actinides (Synal et al., 2007; Fifield et al., 2008; Suter et al., 2010).

a. Examples of radionuclide analyses with AMS

Tritium ($T_{1/2} = 12.23$ y): The AMS prototypes (Roberts et al., 2000), based on a radio frequency quadruple linac, can measure $^{3}H/^{1}H$ ratios down to 10^{-13} only (and with further improvement probably down to 10^{-15}) in milligram-sized samples, which makes its application possible only in biological research dealing with ^{3}H-labeled compounds. Another possibility, of course, would be to analyze ^{3}He (the daughter product of ^{3}H decay as it was done originally by Alvarez and Cornog, 1939) in the same way as in isotope mass spectrometry, but this would require the use of an ion source with positive ions.

Carbon-14 ($T_{1/2} = 5730$ y): This is the most frequently analyzed radionuclide by AMS (Povinec et al., 2009). Fig. 5.25 shows how great developments have been done during the last 50 years in measuring environmental radiocarbon (Povinec et al., 2009). Radiocarbon has been analyzed by AMS in seawater samples as a worldwide tracer of water mass movement in the WOCE (World Ocean Circulation Experiment) program (Key, 1996; Key et al., 2002, 2004; McNichol et al., 2000) as well as in several other works (e.g., Key et al., 1996, 2002; Povinec et al., 2000, 2004a, 2004b, 2004c; 2010; Aramaki et al., 2001; Bhushan et al., 2003; Kumamoto et al., 2011). It has also been used for the investigation of sediment dynamics (Somayajulu et al., 1999), dating of deep-sea sediments (Brown et al., 2000), as well as in studies of ^{14}C in marine biota (Yoneda et al., 2000) and in corals, also in connection with the El Nino phenomenon (Guilderson and Schrag, 1998; Key et al., 2004; Kilbourne et al., 2010).

A typical schema of the ^{14}C line used for the preparation of graphite samples is shown in Fig. 5.26 (the line is used at the Comenius University of Bratislava, Povinec et al., 2015a)). Usually only dissolved inorganic carbon is extracted from the water sample by acidification of the water sample to pH 3, and the carbon dioxide released in a flow of high-purity oxygen (or nitrogen) is collected in traps cooled with liquid nitrogen (in other applications dissolved organic carbon can be extracted from larger samples using a different technique). After purification, the CO_2 is converted to graphite over, e.g., an Fe catalyst (Liong Wee Kwong et al., 2004b; Jeskovsky et al., 2015; Kontuľ et al., 2017; Kaizer et al., 2018a). The graphite

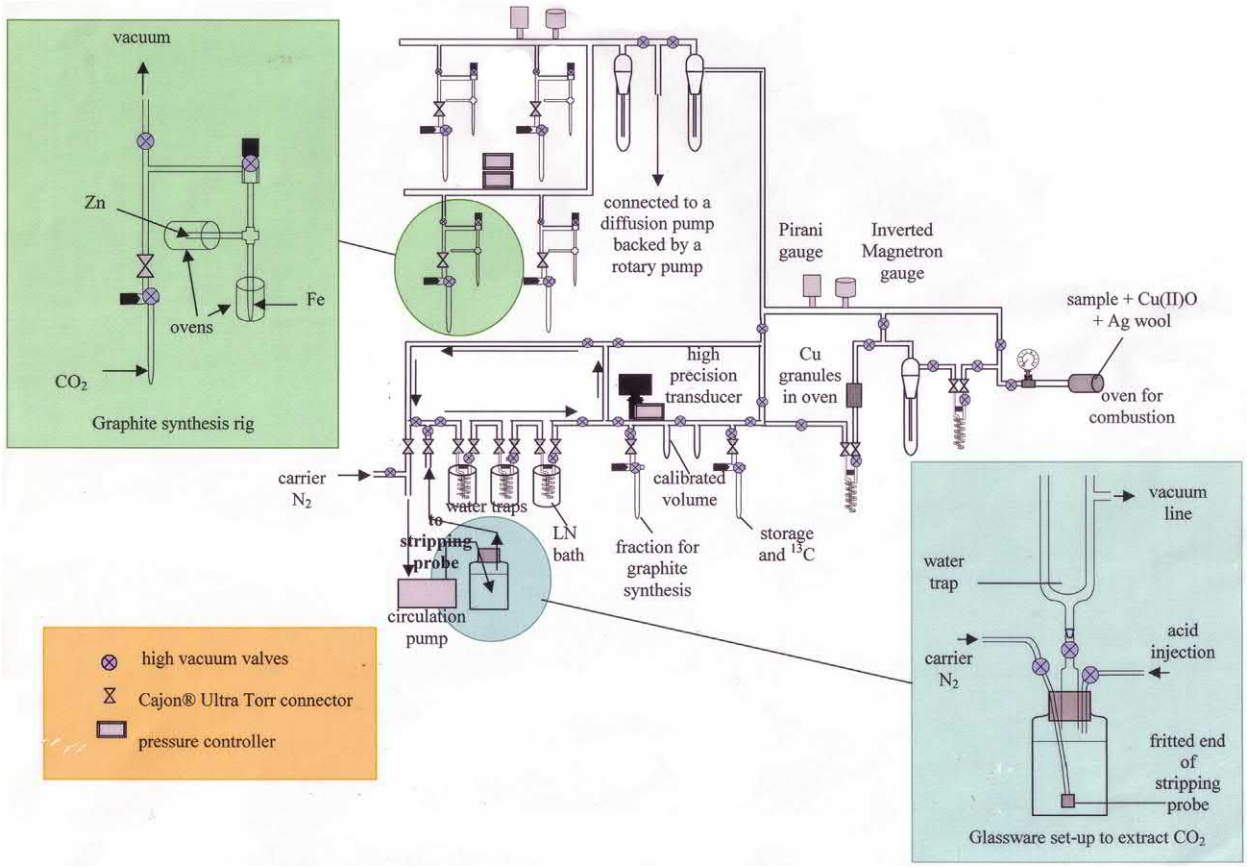

FIGURE 5.26 A schema of a ^{14}C line used at the Comenius University of Bratislava for the preparation of graphite targets for AMS. AMS, accelerator mass spectrometry.

sample is inserted in a sample holder and fixed in the carousel of the ion source. Carbon ions liberated from the graphite sample are accelerated to energies of a few MeV/nucleon and further analyzed by magnetic and electrostatic spectrometers. The precision of AMS measurements is typically below ±5‰.

Technetium-99 ($T_{1/2} = 2.13 \times 10^5$ y): It has been widely distributed in the marine environment through global fallout and releases from nuclear reprocessing plants. It was determined in the past by RMTs as well by TIMS, ICPMS, and RIMS and applied in oceanic water studies (Beasley and Lorz, 1986; Kershaw et al., 1999; Bergquist et al., 2000; Hou and Ross, 2008).

Iodine-129 ($T_{1/2} = 15.7 \times 10^6$ y): It has been widely used as an oceanic tracer to study water transport (Beasley and Lorz, 1986; Raisbeck and Yiou, 1999; Fehn and Snyder, 2000; Povinec et al., 2000, 2010, 2011, 2013b; Hou et al., 2013). Half-liter seawater samples collected and stored without additives are treated in the laboratory following the schema given in Fig. 5.27. A NaI carrier (10 mg) is added to the sample, and after several preparation steps, the AgI sample produced is used as a target for AMS analysis. The results of ^{129}I analysis in seawater samples can be expressed either as activity concentrations (Bq/m^3), as a concentration (^{129}I atoms/L), or as an ^{129}I/^{127}I ratio (Povinec et al., 2000; Santschi and Schwehr, 2004). AMS measurements should be normalized with respect to a reference material. No background subtraction is necessary as the AMS background is very low. Nonetheless, subtraction of a blank sample, processed in a similar way to the real samples, is usually necessary (Povinec et al., 2010).

Uranium isotopes: In the uranium isotopic sector, the most interesting development was the AMS ability to analyze ^{236}U in environmental samples (Hotchkis et al., 2000; Berkovits et al., 2000). This isotope has been a challenge for AMS, as it is embedded in a matrix of ^{235}U and ^{238}U which are potentially sources of background (Lee et al., 2008). The principal applications could be in the area of safeguards, as the ^{236}U/^{238}U ratio clearly shows the reactor origin of uranium. Recently, the ^{236}U/^{238}U ratio has been used as an indicator of the use of depleted uranium in military munitions (Danesi et al., 2003). Because of the long half-life of ^{236}U, it has also been used as oceanographic tracer (e.g., Sakaguchi et al., 2012; Castrilejjo et al., 2017).

Plutonium isotopes: AMS has also been used for the analysis of Pu isotopes (^{239}Pu, ^{240}Pu, and ^{242}Pu) in marine samples (e.g., Oughton et al., 2001; Lee et al., 2001, 2008, 2009a; Povinec, 2004, 2005, 2008, 2010; Lujanienė et al., 2015, 2016, 2017). The samples were prepared either by leaching electrodeposited plutonium from stainless steel disks previously analyzed by SAS or by direct preparation of small-volume samples using Eichrom resins (Fig. 5.19). In the final stage of sample preparation for AMS, the plutonium is dispersed in an iron oxide matrix, adjusted to the atom ratios of ^{242}Pu/Fe from 10^{-10} to 10^{-9}, evaporated to dryness, and baked at 550°C to obtain Fe_2O_3. The resulting sample is then mixed with Al powder (in the proportion of 4:1 by weight), which acts as an electrical and thermal conductor. Finally, the sample is pressed into the sample holders, fixed in the carousel, and analyzed by AMS. The activities of Pu isotopes in a sample are calculated on the basis of the isotopic dilution technique using either ^{236}Pu (if ^{242}Pu is to be analyzed) or ^{242}Pu as tracers. In general, a good agreement was found in Pu analysis using the different techniques. The ICP-MS results were very often slightly higher (up to 10%) than the SAS results (for combined ^{239,240}Pu data) and the AMS results (Povinec et al., 2008a, 2010; Lee et al., 2009a). These discrepancies may have been caused by experimental errors contributing to the total uncertainty. It has often been seen with ICP-MS analyses of Pu isotopes that some matrix or interference effects (such as a contribution of ^{238}U, polyatomic chlorides and oxides, and different forms of hydrates) could contribute to the final results. However, for the ^{240}Pu/^{239}Pu atom ratios, AMS and ICP-MS results were in very good agreement. The relative precision of ^{239,240}Pu results obtained to date by SAS, AMS, and ICP-MS was around 5% (Povinec et al., 2010).

6. Laser-based ^{14}C spectroscopy

The recent development in the mass spectrometry technologies is represented by a laser ^{14}C spectroscopy

(Murnick et al., 2007, 2008). The system is based on the specificity of narrow laser resonances coupled with the sensitivity provided by standing waves in an optical cavity, and detection via impedance variations. The technique combines the optogalvanic effect with laser-assisted isotope ratio analysis, which is a technique based on the existence of large isotope shifts in molecular spectra. The analyzer uses a unique resonance between a specific molecular transition in the molecule $^{14}CO_2$ and the narrow-band output of a laser based on the same molecular transition. The laser spectroscopy has been extended from its current use for the precision analysis of $^{13}CO_2$ to analysis of $^{14}CO_2$. Calibration experiments with a 15-W CO_2 laser demonstrated detection limits for the $^{14}C/^{12}C$ ratio near 10^{-15}. The laser ^{14}C spectroscopy represents an alternative ^{14}C measurement technique, suitable for routine laboratory use. Possible applications may include biomedical and pharmacological studies using radiocarbon as a tracer at global fallout concentrations, thus enabling direct therapeutic tests of drug metabolism on people. It is expected that the method can also be applied for the detection of other trace radionuclides.

7. Positive-ion mass spectrometry

It has been recognized from the beginning of the AMS era that an advantage of the tandem accelerator–based AMS using negative ions for acceleration (e.g., isobaric suppression of ^{14}N vs. ^{14}C as ^{14}N does not form negative ions) may be a disadvantage when using sputter ion sources with solid targets instead of plasma ion sources (RF plasma source or Electron Cyclotron Resonance (ECR) ion source), which are more efficient and capable of greater current outputs. Although with the introduction of a direct ^{14}C analysis using CO_2 gas ion sources simplified the sample preparation, however, the output currents have been very low requiring thus long counting times.

The most important recent development in ^{14}C mass spectrometry analysis has been therefore an introduction of the positive-ion mass spectrometry (PIMS), a new approach in "desktop" ^{14}C systems that would compete with single-stage AMS systems (Wilcken et al., 2010; Freeman et al., 2015; NEC, 2018). The PIMS uses an ECR ion source to produce carbon beams directly from CO_2. The positive carbon beams are accelerated from the ion source to a differentially pumped charge exchange gas cell. Interfering nitrogen and hydrocarbon molecules are then eliminated during the charge exchange process. The ECR source is intrinsically capable of very large ion beam production, it is self-cleaning, and has no memory effects. The PIMS should be therefore more efficient and much faster than AMS. First results indicate that a ^{14}C age limit of about 50,000 years is feasible (Freeman et al., 2015).

TABLE 5.1 Detection limits (in Bq).

Method	^{14}C	^{129}I	^{236}U	^{240}U
Radiometrics	10^{-4}	10^{-2}	10^{-3}	10^{-5}[a]
ICP-MS	–	10^{-3}	5×10^{-8}	5×10^{-6}
TIMS	–	10^{-8}	10^{-10}	5×10^{-7}
RIMS	–	–	–	10^{-6}
AMS	10^{-7}	10^{-10}	10^{-10}	2×10^{-7}

[a] *For $^{239,240}Pu$.*

Moreover, the PIMS may not be restricted to ^{14}C measurements only. Modifying the ECR ion source to accept solid samples, it has been demonstrated that large aluminum positive ion beams could be produced with a plasma ion source as well (Shanks and Freeman, 2015).

8. Comparison of detection limits

A comparison of detection limits for a number of long-lived radionuclides measured by the radiometrics, ICP-MS, TIMS, and AMS, is given in Table 5.1. It can be seen that the most sensitive technique is AMS, which gives the lowest detection limits (three to eight orders of magnitude lower than those obtained by the radiometric methods).

Further development and more frequent use of mass spectrometry techniques (TIMS, ICP-MS, AMS, and RIMS) for ultralow-level analysis of long-lived radionuclides are expected. The AMS will be used more widely as "desktop" machines operating at 250–500 kV voltages. Accelerators working with positive ions (e.g., for ^{39}Ar and ^{81}Kr analysis) will be further developed and applied in marine studies. Direct coupling of ICP-MS (liquid sources) and AMS (gas sources) with the new generation of chromatographs (e.g., GC/MS-AMS systems) will be further developed and applied in marine studies. Other long-lived radionuclides analyzed with mass spectrometry methods, such as ^{135}Cs, ^{237}Np, and others, will enlarge the group of radionuclides used in oceanic tracer studies.

VII. Analysis of radioactive particles

A. Radioactive particle studies

Radioactive substances and their concentrations are usually assumed to be homogeneously distributed within the sample, and also to some degree in the environment. Sample protocols have been developed with geo-statistical methods in order to gain a representative sample for further analysis and, from the sample results, the activity concentrations are calculated, and extrapolations of the concentrations are made to the area where the samples were taken. However,

in some cases these protocols cannot be used due to a heterogeneous radioactive contamination pattern. This is especially true where the radioactivity is bound to discrete particles leading to a very heterogeneous activity distribution. Usually this is the case when the contamination is due to explosions or fire of nuclear material. In such events, the material is pulverized and the particle-size distribution of the debris is so-called log-normal; the effect of such contamination can be seen in the hypothetical example given in Fig. 5.28. A log-normal size distribution also means that the activity/mass distribution of the particles is log-normal, and a consequence of such distributions is that relatively few particles bear the main activity/mass released in the event (Eriksson, 2002). This fact makes them very important to be considered in radiological studies. The IAEA has defined radioactive particles as: "aggregation of radioactive atoms that give rise to an inhomogeneous distribution of radionuclides significantly different from that of the matrix background" (IAEA, 2011). A recent interest of such particles, also sometimes called "hot particles," can be seen in the number of PhD thesis and publications published since the end of 1990s. However, a lack of research in the field is clear, in order to get a full understanding of the environmental behaviors of such particles (Salbu et al., 2018). The number of recent published articles is still small compared to more classical radiological studies. One explanation of this may be that particle studies can be more difficult to conduct as many advanced microanalytical techniques usually are required, not normally present in laboratories conducting a radiological program. It can also be difficult to interpret and extrapolate results gained from particles, as usually they are site specific and similar particles cannot be found elsewhere in the environment.

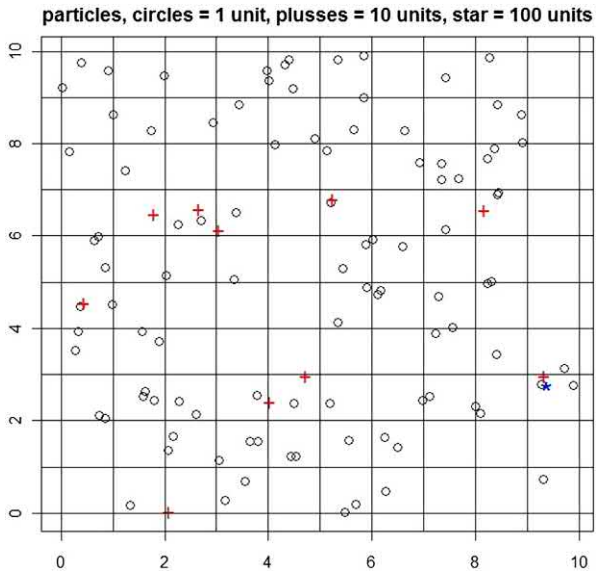

FIGURE 5.28 Hypothetical example of a spatial heterogeneous contamination with the activity associated to particles belonging to a log-normal size distribution. It can be observed that about 30% of the squares (that may represent a typical sample size) have no particles, and only about 10% of the cells have the expected average value of 3 units per cell; thus, the inventory in the particles contaminated area has a higher probability to be underestimated and much care must be taken to design an adequate sampling strategy in order to gain a correct inventory. For the color version of the figure, the reader is referred to the online version of the book.

Radioactive particles are mainly studied in three different areas for their radiochemical, chemical, and physical characterization, namely, (1) nuclear safeguard work, (2) radiological studies, and also to some extent (3) geo-chemical behavior studies. In this chapter, the analytical methods developed for particle analysis will be highlighted; however, it will rather be an overview than a review on the subject. For more extensive information on the specific techniques, that will be mentioned, the reader should refer to text books. It will be shown that in the three areas named above, many of the analytical techniques applied in the particle studies are complementary and are necessary for a proper characterization of the particles. It is important to note that the more conventional methods routinely used for homogeneous samples may produce erroneous results if they are carelessly applied to radioactive particles.

1. Safeguards applications

As a result of the increased demands for nuclear inspections in relation to the nonproliferation treaty (NPT) following the discovery of the Iraq nuclear program in 1991, it was realized that there is a need to improve the method used for detecting nuclear activities (Doyle, 2008). One of these improvements that was adopted in the IAEA safeguards program was the so-called "environmental monitoring" for the analysis of isotopic fingerprints of nuclear material. In the "environmental monitoring" method, samples are taken inside and in the vicinity of nuclear facilities (Donohue, 1998, 2002; Axelsson et al., 2009). In these samples, the nuclear and isotopic fingerprints are determined in order to reveal uranium isotopic enrichment, fuel fabrication, or reactor operation. Typically, these samples are collected with a piece of cloth that swipes surfaces and collects microscopic-sized particles. These particles are then later analyzed either as single particles or as a bulk sample (the whole piece of cloth containing many particles) for the nuclear and isotopic fingerprint.

2. Radiological impact studies

In radiological impact studies, radioactive (hot) particles have gotten into focus in the last 15 years or so. The interest has mainly increased as more advanced analytical techniques have become available resulting in a deeper understanding of the particles, in combination with the findings

of several studies, which have shown that in some cases the radioactive particles are extremely important to consider. It has been shown that in accidents and incidents releasing nuclear material after fire and/or explosions, most of the released nuclear material is associated with few large-sized radioactive particles (Eriksson, 2002; Shevchenko, 2004; Kaltofen and Gundersen, 2017). This is the effect of a so-called log-normal size distribution, where the few large-sized objects carry most of the released mass/activity. In sites contaminated in this way, the radioactivity distribution is extremely heterogeneous, making representative sampling very difficult. One should keep this in mind, as most radiological sampling strategies are based on the assumption that the radioactivity is homogenously distributed in an area or within the subsamples from the area. As radionuclide inventory estimates are essential in determining the source terms, one must take these few large-sized particles into account; however, usually one has a "needle in a haystack problem." Fig. 5.28 illustrates this problematic situation. Several studies have focused on these particles, examples are given later, to reveal the source term of the accident. It has also been shown that the radioactive particles must be taken into account in radiation dosimetry estimates (e.g., Jaeschke and Bradshaw, 2015). In the case of respiratory-available particles (aerodynamic diameters less than 10 μm), which are attached to the skin, highly localized absorbed equivalent doses can be achieved. This may result in biological and medical consequences for the exposed person. In radiological studies with a focus on the radioactivity uptake and transfer in food webs, it is important to note the difference between particle-associated radioactivity compared to the normally assumed homogenously distributed activity. Most of the experiments conducted to measure transfer factors and Kd's use a different chemical form (ionic tracer solution added to the system) from particles where the radioactive elements are in a solid phase. It is very important to take into account a chemical speciation in such investigations. Several studies have now been conducted on solid-state speciation of radionuclides attached to particles.

3. Geo-chemical behavior studies of radionuclides

The third thematic area where particles are important is in geo-chemical behavior studies of radionuclides. As mentioned above, the chemical speciation of the radioactive elements will determine their solubility and mobility in the ecosystem. In order to fully assess the long-term consequences of a radioactive contaminated area involving particles, like nuclear accident sites as well as in nuclear fuel facilities and uranium mine tailings, it is essential to perform speciation studies. These studies involve both laboratory and field conditions and include sequential extraction experiments, physical speciation using synchrotron radiation-based techniques, and dissolution/leaching studies in selected solutions. It has been shown that radiological assessments based on the assumption of homogenous activity distribution (average bulk mass or surface activity) will be biased in the case of contamination of radioactivity bound to particles. The dissolution/weathering of some type of radioactive particles will increase over time. Further, it was shown that weathering rates will depend on the particle composition, structural changes occurring during the release scenario (e.g., transformation from UO_2 to U_3O_8), and on local chemical conditions and transformation processes occurring after deposition (e.g., pH, redox conditions, and bioerosion) (Kashparov et al., 2004).

In the following section, an overview of the most common techniques applied to radioactive particle studies is presented. A schematic view summarizing these techniques is presented in Fig. 5.29. It is not possible to give in this chapter an extensive review of all applied techniques with all references. More detailed information can be found in PhD theses (Eriksson, 2002; Pöllänen, 2002; Jernström, 2006; Lind, 2006; Ranebo, 2009; Gostic, 2010; IAEA, 2011) and in the NATO Science for Peace and Security Series (Oughton and Kashparov, 2009).

B. Protocols for studying radioactive particles

There has been a lack of standard analytical techniques and protocols on the collection, isolation, and further analysis of radioactive particles. In addition, no certified reference materials exist for the validation of their analysis, even though potential material has been produced (Erdmann et al., 2000; Ranebo et al., 2010a). In 2000, the IAEA initiated a coordinated research project with the aim to fill these gaps and to develop standardized methodologies. The

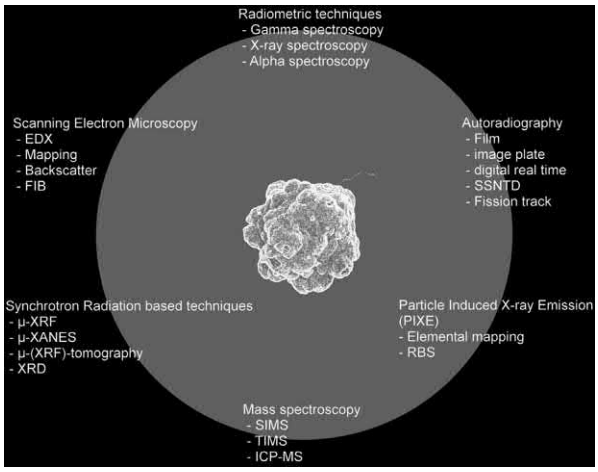

FIGURE 5.29 The most common radioanalytical techniques applied in studies of radioactive particles.

participants of this project produced a useful IAEA publication summarizing all the activities (IAEA, 2011).

The protocol for studying radioactive particles highly depends on the application and on which questions the analyses are assumed to answer. However, commonly to all applications are that the studies start with the nondestructive analysis (e.g., radiometric measurements) followed by the semidestructive analysis (e.g., SIMS) and finally with the destructive particle analysis (e.g., particle dissolution and ICP-MS).

Before any analysis can be performed, the particles must be identified and separated from the bulk sample (e.g., sediment, soil, and wipe sample). The preferable technique to use in this process depends highly on the radioactive particle decay mode and its activity.

For particles consisting of high-activity gamma-emitting radionuclides, a so-called sample splitting technique using a gamma spectrometer can be used. This is an effective separation method in the case of a large sample, as after about 20 splittings only a few grains remain, if the starting bulk mass sample is of about 150 g (Eriksson et al., 2005a). In the case of a search for actinide particles, this separation method can be enough in order to identify the particle with a simple loupe. Actinide particles with a size above 100 μm can be seen with a loupe magnifying, e.g., eight times, and usually these particles can be distinguished from the bulk SiO_2 particles. In the loupe, the actinide particles have a dark greenish color and the SiO_2 particles have a lighter brown-yellow color. Potential particles may exist which could be separated with a pipette and a drop of distilled water. The drop is placed on the top of the actinide particle and then everything (water drop + particle) is sucked up into the pipette again. The particle in the pipette can then be placed on a detector for verification and then further placed on a sample support. An alternative to this is to place the remaining particles on a new support where they are fixed, e.g., on double adhesive carbon tape of a graphite planchet fixed with isopropanol alcohol. The particles can then be identified on the support either in a SEM/EDX system or with autoradiography techniques (Fig. 5.30). Another effective technique for the identification of actinide particles from a large bulk sample is the use of high-resolution X-ray computed tomography (CT) instrumentation (Gostic, 2010). This technique was used to identify and separate high-radioactive particles from the contaminated soil in the BOMARC missile site in New Jersey, USA. The high-resolution X-ray CT was used to identify potential particles in soil cores, assuming that actinide particles have a much higher density than the bulk soil. From the CT images, the depths in the cores were determined, and the core slices with the particles were checked with a NaI(Tl)γ-detector.

The above-mentioned techniques cannot be used in the case of radioactive particles containing alpha- and beta-decaying elements of a low activity (<0.1 Bq). In the case of such particles, autoradiography technique is the alternative. However, if the particles consist of fissile material, also the fission track techniques can be used. Several different autoradiography techniques exist which work differently. The solid-state nuclear track detection (SSNTD) technique has been widely used for identifying radioactive particles (e.g., Jernström, 2006). A detailed description of SSNTD can be found in this book, Chapter 3, Volume 1 (see also Ilić and Durrani, 2003). The SSNTD technique is based on the principle that ionizing particles emitted in the nuclear disintegrations process, which hit a detector, form microscopic tracks in the detector material. The detectors can be of various materials, such as plastic, mineral, or glass. After the exposure, the detectors must be treated by etching them with alkaline solution to enlarge the tracks so that they can be visible with an optical microscope. A commonly used detector is the cellulose nitrate films, which are sensitive in the detection of alpha and heavy ion rays. The radioactive particles are recognized from where tracks have formed clusters, star-shaped patterns, on the film. Image plates are also commonly used techniques which are based on the principle that the ionizing radiation emitted by the radioactive particle interacts with the plate, and deposits its energy, which is "stored" in the detector. This information (the absorbed radiation dose) is, after exposure, read out by using laser light to achieve a de-excitation process of the trapped electrons, and the fluorescence signal is proportional to the energy deposited in the detector. Real-time digital autoradiography techniques also exist. They have the advantage because they are fast and do not require any posttreatment (e.g., etching or readout) as an image is given directly on

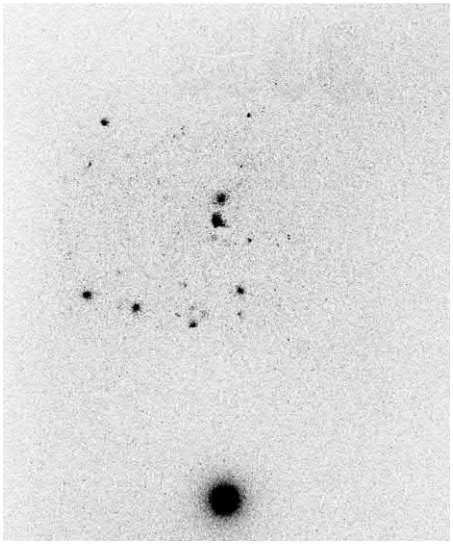

FIGURE 5.30 An autoradiograph of a sediment sample containing radioactive particles emitting alpha-, beta-, and X-rays from the decay of Pu-, U-isotopes. *The film is a tritium image plate from Fuji.*

the computer screen. These techniques are described in detail elsewhere (Eriksson et al., 2002; Zeissler, 1997; Ljunggren, 2003) and in Chapter 9, Volume 2 of this book.

1. Nondestructive analysis

After the particles have been separated from the bulk matrix, depending on the aim of the studies, they are usually subjected to multiple analyses. In order to achieve as much information as possible, the first set of analysis would be the so-called nondestructive analysis, i.e., gamma-ray, X-ray, and direct alpha-spectrometry and charge particle and X-ray-based scanning techniques such as scanning electron microscopy and X-ray fluorescence (XRF) for surface analysis and elemental distribution mapping (Betti et al., 2008). Some systems have an integrated approach making several nondestructive analyses simultaneously such as the system known as PANDA (particles and nondestructive analysis) (Turunen et al., 2009). The PANDA has detectors for gamma ray, X-ray, and alpha ray detection, to determine the radionuclide activities and ratios besides determining the particles location on the sample support simultaneously.

a. Gamma ray, X-ray, and alpha spectrometry on particles

Radioactive particles can contain both actinide elements and short-lived fission and/or activation radionuclides. In the latter, the main bulk material of the particle is usually a nuclear fission material (i.e., nuclear fuel or bomb fragments) containing uranium and/or plutonium. This signifies that the photon energy range is from the X-ray energy range (10−25 keV for the characteristic *L* X-rays of, e.g., U and Pu) to the MeV region for radionuclides such as ^{137}Cs and ^{60}Co. An alternative to using two different detectors, such as an X-ray detector (e.g., Si(Li)) and an HPGe detector, one can use a broad energy germanium (BEGe) detector to detect photons in this large energy range with a high efficiency. The energy resolution of the BEGe is not as good as an X-ray detector; however, it has a high detection efficiency to detect photons in the range of ∼10 keV to a few MeV.

The activity determination of particles containing radionuclides emitting high-energy gamma rays is fairly straightforward (Pöllänen et al., 1999). The particles can be considered as a point source, and for photons with energy higher than a few hundred keV, the self-attenuation in the particles is not a problem and the efficiency calibration is easily achieved. In the low-energy region, it is much more problematic as self-attenuation in the particles can be high leading to difficulties in obtaining a good efficiency calibration. The L X-rays, emitted following the ejection of a conversion electron in the internal conversion disintegration process, of the ^{238,239,240}Pu and ^{241}Am occurring in the radioactive particles, have been measured in several studies, as illustrated in the left spectra in Fig. 5.31. From these measurements, the activities and the isotopic and radionuclide ratios have been determined (Jernström et al., 2006; Komura et al., 1984; Eriksson et al., 2005a; Mitchell et al., 1997). The efficiency calibration has been carried out generally by determining the ^{241}Am efficiency from a point source and assuming a neglectable self-absorption in this source. It is theoretically possible to determine the Pu isotopic ratios using this technique by solving a linear equation system (Eriksson et al., 2005a). However, in practice this is very difficult, especially for particles with low activity (less than few Bq). In order to solve the linear

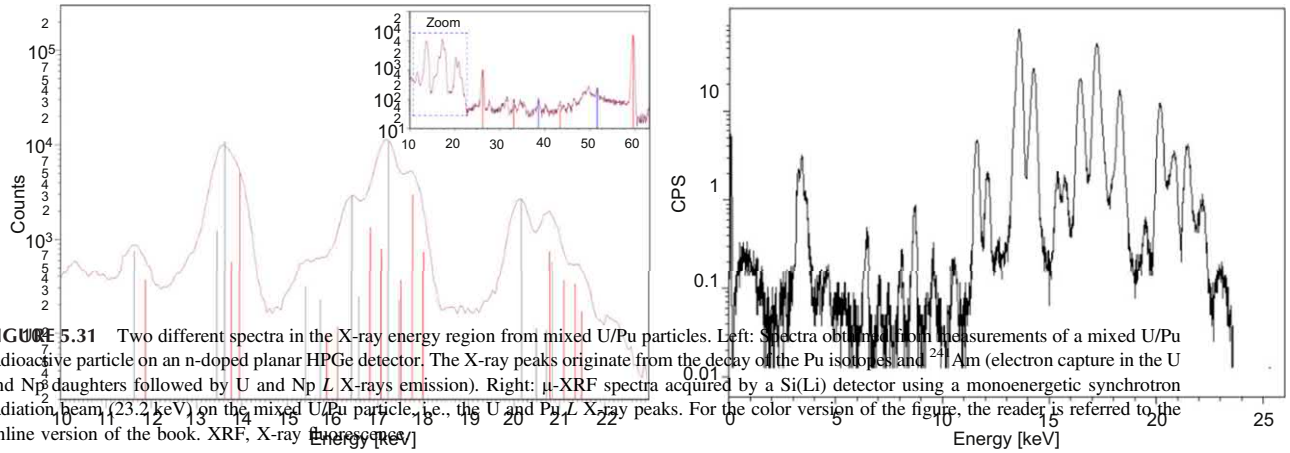

FIGURE 5.31 Two different spectra in the X-ray energy region from mixed U/Pu particles. Left: Spectra obtained from measurements of a mixed U/Pu radioactive particle on an n-doped planar HPGe detector. The X-ray peaks originate from the decay of the Pu isotopes and ^{241}Am (electron capture in the U and Np daughters followed by U and Np *L* X-rays emission). Right: μ-XRF spectra acquired by a Si(Li) detector using a monoenergetic synchrotron radiation beam (23.2 keV) on the mixed U/Pu particle, i.e., the U and Pu *L* X-ray peaks. For the color version of the figure, the reader is referred to the online version of the book. XRF, X-ray fluorescence.

equation system and obtain results with low uncertainty (or acceptable uncertainties), long acquisition times would be required for the measurements in a system with very low background, as the muon continuum and multiple scattering from other gamma rays will be pronounced in the X-ray region of the full gamma-ray spectra. In addition, the differences in the emission probabilities for the different Pu isotopes are small and the data for these emissions have relative large uncertainties. The abovementioned problems often result in nonexisting solutions to the linear equation systems, i.e., negative activity for one or more nuclides. However, if the particle is simultaneously measured with an alpha and a gamma spectrometer, such as the PANDA system, and the spectra are acquired in an event mode (also called list mode or time-stamp mode), one can simplify the spectra by only acquiring the events that are associated with α-rays originating from the ^{239,240}Pu decay (Peräjärvi et al., 2011). By this gating, X-ray spectra can be constructed exclusively from the two radionuclides, without any multiple scattering photon background or any continuum from cosmic muons. For radioactive particles containing higher activity (>100 Bq of ^{239,240}Pu), the isotopic ratios can be determined directly from the gamma ray lines associated with the ^{239}Pu and ^{240}Pu decays (Jernström et al., 2006; Gostic, 2010).

A Finnish research group at the Radiation and Nuclear Safety Authority (STUK) has been working extensively on high-resolution direct alpha-spectrometry on radioactive particles. They have produced software, an advanced alpha-spectrometric simulation (AASI), for simulating energy spectra in alpha-spectrometry (Siiskonen and Pöllänen, 2004). In AASI, the geometrical detection efficiency and energy loss of the alpha rays in the source and in the material between the source and detector can be simulated. In addition, it is possible to specify characteristics of the radioactive particles and of the alpha detector, which are taken into account in the simulations. Several radioactive particle applications have been demonstrated using this program as well as activity ratios and density estimates for the particles (Ranebo et al., 2010b).

b. Scanning electron microscopy coupled with X-ray detectors

In radioactive particle studies, the nondestructive scanning electron microscopy (SEM) technique is essential. With the use of SEM, multiple information is gained. In the case of many particles on a sample support (e.g., a safeguard sample), particle-size distribution can be determined. In addition, SEM provides information on morphology, the surface, and subsurface structure, and identifies and localizes high-density (high-atomic number) particles. The SEM images are also used as guiding "maps" when the particles should be relocated for analysis by another technique, e.g., in the XRF and SIMS experiments described below (Fig. 5.32). Compared to the conventional optical microscope, an SEM offers advantages including high magnification, large depth of focus (providing a sharp high-resolution image on a large part of the particle, size range for radioactive particles from sub-micrometers up to millimeters), high-resolution and elemental surface composition when coupled with an X-ray detector system.

The principle of SEM imaging is summarized as follows: The sample or specimen surface is irradiated with a scanned (rastered) electron beam emitted from a filament (electron gun). The impinging electrons undergo scattering interactions with the surface and subsurface atoms, either by elastic or by inelastic interactions. Each interaction will result in one or more electrons (secondary electrons) leaving the interaction point. The secondary electrons can in turn undergo scattering interactions in the sample, leading to many events throughout a volume determined by the electron beam energy and the cross section for each element in the irradiated point.

The two different electron scattering processes are used in SEM for imaging. The backscatter (BS) imaging utilizes the elastic scattered electrons (more than 90° from the

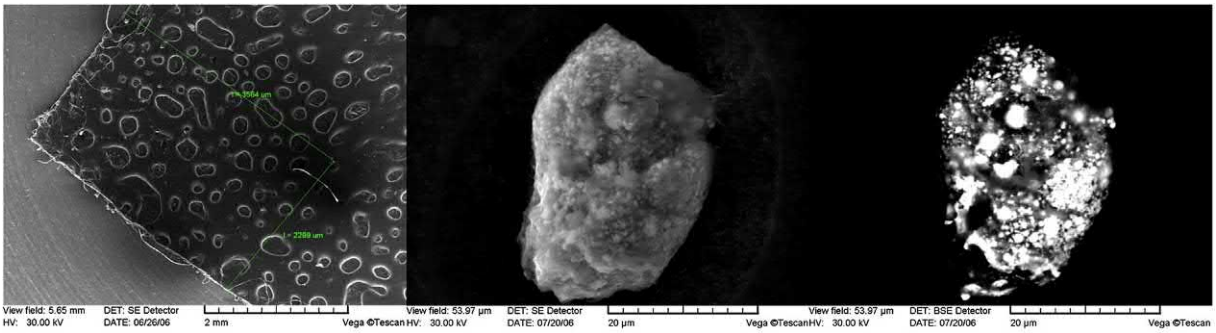

FIGURE 5.32 SEM images of a radioactive particle originating from the Thule accident on its sample support. Left: guiding map of the particle position on the sample support to relocate particle in other systems. Middle: Secondary electron (SE) image providing the dimensions and morphology. Right: Backscatter (BS) image showing the regions with the high Z element uranium and plutonium.

impinging beam direction, called backscattered electrons) that are reemitted away from the surface toward a PIPS detector. The elastic scattering cross section for backscattered electrons increases with the atomic number (Z). This is used in the BS imaging to distinguish, e.g., uranium particles from bulk soil particles mostly consisting of SiO_2, as illustrated in Fig. 5.32 (Ranebo et al., 2007). In the inelastic scattering, the impinging electron energy is delivered to the sample atoms and may result in excitations/ionizations from which secondary electrons are emitted. Most of the secondary electrons will be absorbed in the sample and therefore do not escape the sample surface or reach the detector. The secondary electrons generated at a shallow depth in the sample will be able to reach the detector. As a consequence of this, they are very sensitive to the sample topography and are used for high-magnification SEM images (Fig. 5.32) in the so-called secondary electron (SE) mode. In the inelastic scattering interactions, some of the atoms in the excited state will radiate a characteristic X-ray or Auger electrons. As the X-ray is characteristic for each element, elemental information of the specimen is gained. Two types of X-ray detector systems are used generally and coupled to the SEM, namely, energy-dispersive X-ray (EDX) or wavelength-dispersive X-ray (WDX) analyzers. In order to perform quantitative elemental analysis from the X-ray spectra, several interaction cross sections must be known in combination with liner attenuation coefficients for the sample material as well as the energy spectra of the impinging energy beam (Garratt-Reed and Bell, 2003). In theory, the radioactive particle X-ray spectra are compared with a set of standards in order to estimate the elemental composition. Some EDX/WDX systems have good analytical programs to process the spectra and evaluate the elemental composition. However, very few include the option to analyze the actinide elements. The National Institute of Standards and Technology (NIST) provides free software (Desktop Spectrum Analyzer, DTSA) with some options for the analysis of SEM-generated X-ray spectra including the actinide elements (Newbury and Myklebust, 2005; NIST, 2011).

c. Microbeam X-ray fluorescence techniques applied to particles

In this section, an overview of the nondestructive XRF techniques applied to radioactive particle studies will be given. We will focus on the applications rather than the theories behind the techniques. Common to these techniques is that they have very little to do with radioactivity, as these are atomic-sensitive techniques that give information on elements and the chemical environment of the atoms rather than the decay processes in the nucleus. It is justified to discuss these techniques in this book, as many studies related to radioactive particles apply these techniques as a part of the particle characterization and for information on the source term description. The most utilized technique in this sense is the synchrotron radiation-based micro-X-ray fluorescence (μ-XRF). This technique has been shown to be a powerful tool for obtaining elemental compositions and their distribution in radioactive particles (Lind et al., 2005; Lind, 2006; Eriksson et al., 2005a). The use of X-ray tube-based μ-XRF systems (Wegrzynek et al., 2005) has been applied as well to the particle-induced X-ray emission with nuclear microprobe technique (μ-PIXE) for the study of radioactive (Jiménez-Ramos et al., 2012). The abovementioned techniques are applied commonly to studies on particles containing a bulk mass of uranium and/or plutonium. The detection limits of the techniques do not allow the mapping of short-lived radionuclides at the amounts at which they are present in the particles. The shortest-lived radionuclide that has been mapped by this technique, to the authors knowledge, is the ^{241}Am (432 y) in particles originating from the BOMARC accident in 1960 (Gostic, 2010).

d. Synchrotron radiation–based XRF

The intensity of the characteristic X-rays is proportional to the elemental concentration in the particle as well as the excitation beam intensity. The use of synchrotron radiation (SR) as a source for the excitation beam has several advantages compared to the use of, e.g., an X-ray tube. First, a tunable monochromatic beam with a high and known photon flux is used, simplifying the elemental characteristic X-ray intensity calculation to concentrations. Second, the beam can be focused and scanned over different areas enabling two-dimensional (2D) and three-dimensional (3D) elemental mapping of the particles. In addition, the density fluctuation in the particles can be determined from the X-ray transmission measurements of the SR-beam. With recent developments in X-ray optics, improved spatial resolution in the images has been achieved. The earlier focusing devices were of capillary type, and the SR-beam could be focused from 1 mm size down to a focus spot of around 20 μm in diameter. With the use of so-called compound refractive lenses (CRLs), a focus of less than 1 μm can be achieved (Simon et al., 2006). This makes the CRL optics superior to the capillary optics in the study of radioactive particles, as typically the size range of the particles is from 1 up to $\sim$500 μm. Early studies of SR μ-XRF using capillary optics made erroneous conclusions of the homogeneity of the U/Pu distribution in radioactive particles (Eriksson et al., 2005a). The reason for this was that the μ-XRF focus on the particle was more or less in the same order as the particles, making the analysis more like an average bulk elemental analysis. When the particles were analyzed with a tenfold smaller focus using CRL, heterogeneities could be observed in the U/Pu distribution.

However, the μ-XRF elemental maps are still a 2D projection of a 3D object, meaning that information is smeared out in the SR-beam direction. A full understanding of the 3D elemental distribution cannot be gained from the 2D scans. In order to gain the full-volume elemental distribution in particles, the SR μ-XRF experimental setup was modified by assembling an X-ray lens in front of the X-ray detector, forming a so-called confocal μ-XRF setup. Confocal μ-XRF enables 3D scans and gains the elemental distributions within the studied sample. Another great advantage of the confocal μ-XRF setup is that "low"-density volumes can be analyzed within the radioactive particle. This is important if it is expected that the particles have been leached and started to dissolve the surface rime of the particle, as it then probably has a lower density than the inner core. In classical μ-XRF, this is not possible to study, as the fully exited volume of the primary beam impinging on the particle is analyzed. If heterogeneities exist in the density/concentrations of the different elements in this exited volume, most of the fluorescence photons will come from the areas with highest density/concentration of the element biasing the elemental ratio evaluation. The difference between the approaches has been demonstrated by comparing U/Pu mass ratios derived from the summed confocal μ-XRF spectra (bulk information) measured in the full-particle volume with the measured mean U/Pu mass ratio derived in all confocal measured volumes (Jimenez-Ramos et al., 2010). In the calculated mean elemental ratio in the confocal μ-XRF scan, volumes with low density/concentration have equal weight in affecting the mean ratio as volumes with high density/concentration. The ratio in the high-density volumes can be considered as representative for the bulk of the particles. If one expects that leaching/corrosion processes have been affecting the particles leading to depletion and lower density (concentration) of elements on the surface, the confocal μ-XRF technique is ideal for the analysis of such surfaces, where classical μ-XRF would fail. By this important analysis, an understanding can be developed on the geo-chemical behavior that these particles have in the environment.

High-resolution μ-tomography (absorption μ-CT) has been demonstrated on radioactive particles showing internal structures as well as density distributions in the submicrometer scale (Salbu et al., 2001). Combined X-ray absorption and fluorescence microtomography have been used to obtain the 3D elemental distribution in radioactive particles (Wegrzynek et al., 2005; Eriksson et al., 2005a). The combined technique first reconstructs the absorption tomogram and uses this for the photon attenuation correction of the characteristic X-ray elements in the particle. The reconstruction is based on the radon transform referred to as the filtered back-projection. An example of the combined X-ray absorption and fluorescence microtomography is shown in Fig. 5.33.

e. X-ray absorption spectroscopy

The binding energies of atomic core electrons are dependent on the oxidation state of the atom as well as the surrounding chemical environment (chemical binding to neighbor atoms). The chemical form of the radionuclides will determine the leach ability and solubility in the environment of the elements bound to the particle. The oxidation state can also be used to predict the formation of the particle, as demonstrated for radioactive particles discharged from the Chernobyl accident in 1986 (Salbu et al., 2001, 2005). Oxidation states can be studied with the use of a highly chromatized, tunable monoenergetic synchrotron radiation light in X-ray absorption spectroscopy (XAF) studies. In radioactive particle studies, the microfocused X-ray absorption near edge structure (μ-XANES) has been used for the determination of U and Pu oxidation state distributions in particles. One example of uranium L_{III} μ-XANES can be seen in Fig. 5.34. Confocal μ-XANES (Bielewski et al., 2009) as well as tomographic XANES

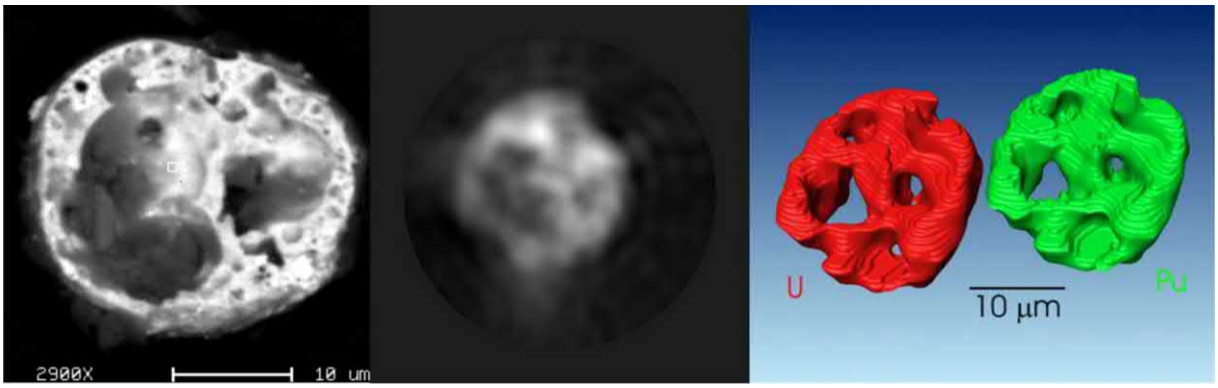

FIGURE 5.33 SEM image of a mixed U/Pu particle originating from Thule (left); a tomographic reconstruction of the density distribution in one section of the particle (middle); and the full 3D reconstruction of both U and Pu in the particle derived by combined SR X-ray absorption and fluorescence microtomography (right). For the color version of the figure, the reader is referred to the online version of the book.

(Lechelle et al., 2004) have been used to get the 3D information of the oxidation states (electron-binding energies) in the particles. Usually oxidation-state standards are measured and used to "translate" binding energies to the oxidation state distributions in the particle. It should be mentioned that the high X-ray dose given to the particles during the measurements may be of a problem. For example, one type of Pu oxidation state standard crystal (Pu(+4)-oxylate) shows a rapid reduction in the oxidation state from Pu+4 to Pu+3 (Eriksson et al., 2005b). This finding shows an effect that may occur also in radioactive particles under study, and this effect has not been considered in the solid-state oxidation state determinations by μ-XANES analysis of actinide particles.

Synchrotron radiation–based micro-X-ray diffraction (μ-XRD) can be used as a complement to the XAF determination of the chemical species of the elements present in particles (Salbu et al., 2004; Lind et al., 2009).

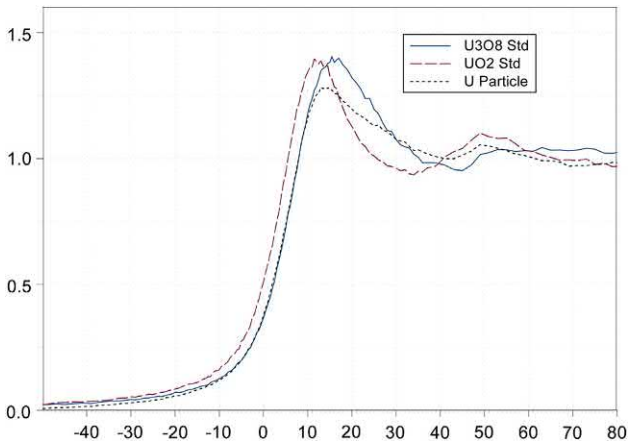

FIGURE 5.34 Uranium L_{III} μ-XANES on a radioactive particle and two spectra from particles with known uranium molecular formula (UO_2 and U_3O_8) used as oxidation state standards.

2. Semi-destructive analysis of particles

Secondary ion mass spectrometry (SIMS) has successfully been applied to the characterization of radioactive particles and the nuclear fingerprint. One of the advantages, compared to the ICP-MS, is that the particle does not need to be dissolved and no radiochemical separation is required that could bias the fingerprint signals. This is especially important when the uranium isotopic ratios are to be determined. As an example, a radioactive particle with the size of ~50 μm originating from the Thule accident typically contains 10–100 ng of the uranium isotopes. As natural uranium is present almost everywhere in our environment and laboratories, cross-contamination is a potential risk and may bias the ICP-MS results (Eriksson et al., 2008). SIMS can be operated in several different modes and provide information of the most superficial layers of the particles as well as deeper layers when conducting depth profiling. Besides serving as a mass analyzer, it is also an ion microscope, providing mass images of the sample. In the SIMS analysis, a primary ion beam is focused onto the sample surface, sputtering the surface atoms that generate secondary ions from the target area, which are then accelerated into a mass analyzer (Vickerman, 1989, see also Chapter 8, Volume 1 of this book). The production of secondary ions has different efficiency for different elements which also depends on the matrix. As the mass spectra contain masses (isotopes) from different elements of the particle, important corrections must be made to correctly interpret the elemental isotopic composition (Ranebo et al., 2007, 2009; Simons, 1986).

Fig. 5.35 illustrates, as an example, an SEM image of a radioactive particle with a crater on the top, produced by

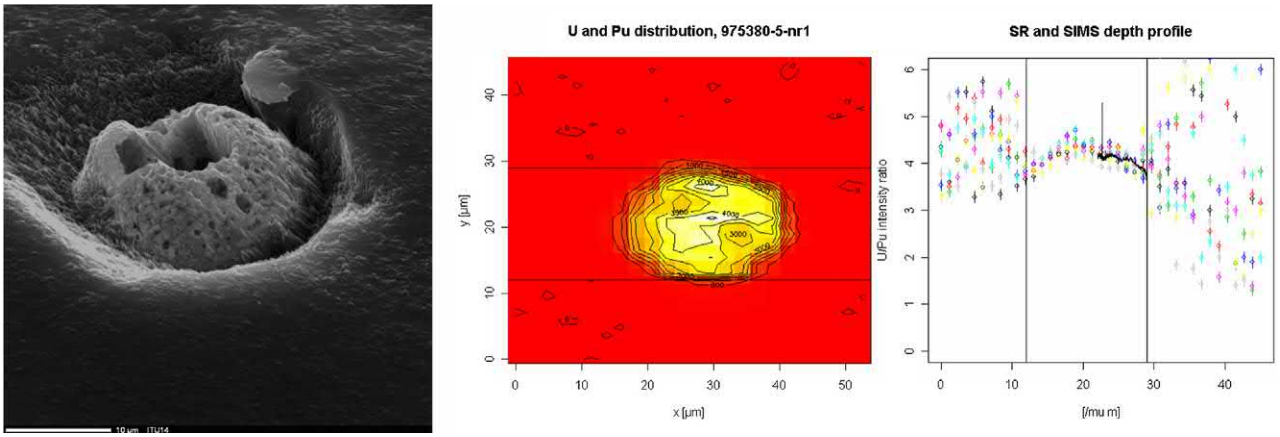

FIGURE 5.35 SEM image of a radioactive particle with a crater on the top produced by SIMS in the depth profile analysis (left); confocal SR m-XRF derived Pu and U distributions in one section of the particle (middle); the SR-derived U/Pu ratio line scans and superimposed the total SIMS-derived U/Pu mass ratio (black line) (right). SIMS during the depth profile analysis. Confocal SR m-XRF derived Pu and U distributions in one section of the particle, together with the SR-derived U/Pu ratio line scans, and the total SIMS-derived U/Pu mass ratio.

3. Destructive analysis on particles

In order to analyze the nuclear fingerprint with, e.g., ICP-MS or high-resolution alpha-spectrometry for the determination of isotopic ratios, the radioactive particles must first be totally dissolved, and a radiochemical separation of the dissolved particle should be conducted. Radiochemical separations are described elsewhere in this book; however, some specific notes concerning actinide particles should be mentioned.

Dissolution of (U, Pu)O_2 hot particles is notoriously difficult requiring mineral acids (Keller, 1971; Eriksson, 2002). It is very important to check that complete dissolution of the particles had occurred in the dissolution process. This can be done by comparing the ^{241}Am gamma activity, measured by, e.g., an HPGe detector on the whole particle, with the activity of ^{241}Am determined after dissolution and chemical separation with, e.g., alpha spectrometry.

Two efficient (U, Pu)O_2 particle dissolution methods have been described (Eriksson et al., 2008), where the full-particle matrix was dissolved. In this method, the particles were dissolved in a small amount of a mixed solution of hydrofluoric and nitric acids (ratio 1:3) in high-pressure Teflon cells. The closed Teflon cells were then placed on a hot plate, which maintained that the mixture was under pressure for 24 hours. The solution was then evaporated to dryness. In addition, the use of microwave digestion using a mixture with 7 mL of HF, 7 mL of HNO_3, and 1.5 mL of HCl was proved to be effective in totally dissolving the particles. The microwave Teflon cell was heated for 20 minutes at a maximum pressure of 250 psi (17.2 bar) and a maximum temperature of 200°C. In order to break the Pu-fluoride complexes formed in the dissolution process, 25 mL of saturated boric acid was added, and the mixture was heated for another 20 minutes in the microwave oven. The solutions from both dissolution methods with the totally dissolved particles were evaporated to dryness, and 0.3 mL of HNO_3 was added and evaporated to dryness, which was repeated three times. This was done to ensure that all the Pu-fluoride complexes were destroyed, which would cause problems in the ICP-MS measurements.

In addition, one of the challenges of working with hot particles is the determination of the U isotopic composition, as these particles typically contain a 10th of ng of uranium, and these amounts are typically equivalent to procedure blank values of U found in normal laboratories; thus, the radiochemistry must be conducted under ultrapure conditions, preferably in clean laboratories in order to not bias the U isotopic signature of the particles.

VIII. Management of data quality

The production of good-quality data is an important prerequisite for any environmental investigations if meaningful results should be obtained. Quality assurance (QA) as a system of activities and actions (Garfield, 1992) has two main components:

1. Quality assessment—a mechanism to verify that the system is operating within acceptable limits;
2. Quality control (QC)—a mechanism to control data quality (errors).

The objectives of the QA program include maintaining a continuous assessment and control of data quality, identifying proper analytical methods, providing permanent records of the performance of instruments, standardizing analytical procedures, ensuring sample integrity, improving sample recording, and identifying training needs. The common aim of all these objectives is to provide high-quality data. The QA functions include the development (or selection) of proper methods of sampling, sample preservation, sample pretreatment, sample analysis and methods for evaluation and reporting of results. Furthermore, they include intralaboratory and interlaboratory methods of validation and evaluation, establishing quality control guidelines and maintaining quality control sample programs. A laboratory without a proper QA program cannot operate successfully. This is especially important when the laboratory produces series of data that are of interest in regional or worldwide programs (Povinec et al., 2005b).

A QA program (including good laboratory practices) should be described in one of the most important laboratory documents—the QA manual. It should contain QA policy and objectives, staff responsibilities, description of sampling/analytical methods, field measurements, sample handling protocols, data reduction, data evaluation (including uncertainty budget, e.g., Dovlete and Povinec, 1999), description of materials and standards used, QA procedures, results of interlaboratory comparisons, and the recording database. The QA manual should be regularly updated with any new developments in the laboratory.

A. Laboratory Information Management system

Accurate and precise determinations of radionuclide concentrations in marine samples are important aspects of the assessment of the marine environment and the use of radionuclides in studies of oceanographic processes. Data credibility is becoming essential in regional and worldwide programs to which laboratories with different practices contribute, especially if the resulting data are input into regional and global radionuclide databases.

In order to deal with an increasing number of incoming samples and/or to follow more closely their life cycle

within an analytical laboratory, a computerized system is generally used to increase track ability and to support good laboratory practice (Nakagawa, 1994). Additional reasons for the development of the Laboratory Information Management System (LIMS) rest in sharing methods, results, and reports (including sample history) within the laboratory members in a very flexible way. The impacts of LIMS implementation may be expected in the altering and improving of working habits of individual laboratory members, and in changes of laboratory management practices. The main objectives of the LIMS may be summarized in three points:

- Improved laboratory management with workload monitoring, resource allocation, and computerized instrumental control;
- Improved data management with easy retrieval and security of data, improved data accuracy, improved data consistency, and improved track ability;
- Increased laboratory throughput with improved performance, efficiency, and capabilities.

The System for Laboratory Information Management (SLIM) which is used at the IAEA-EL Monaco is a computerized system designed to suit the sample processing and analytical operations specific to a marine environment laboratory running a wide range of projects involving the measurement of radioactive and nonradioactive contaminants and tracers and global-scale support to analytical quality (Bartocci et al., 2006). The system is custom-tailored to the laboratory needs, but it is flexible enough to be adaptable for use in other environmental analytical labs.

The design of the SLIM database structure was the first step of the system development. While no changes are needed foreseeably in the developed backbone structure, the database implementation can evolve with software, hardware, and communication-related options, one key area being that of analytical instrument—computer interface. The structure of the SLIM database can be divided into three distinct parts:

1. Collection of information—a database where information is organized in tables allowing fast and easy retrieval.
2. Sample tracking—to report the status of samples (progress reporting), and their history. This allows a systematic traceability and controls the flow of the operational steps.
3. Reporting of results—the data reporting and validation of results.

Different programs and protocols can be used depending on needs, which provide an enhancement of data accuracy and consistency.

B. Intercomparison exercises

The International Atomic Energy Agency's Environment Laboratories in Monaco have been assisting marine laboratories in quality assurance and control for over 40 years (Parr et al., 1998; Povinec et al., 1999; Povinec and Pham, 2001; Pham et al., 2006a; Sanchez-Cabeza et al., 2008). This has been done through the IAEA's Analytical Quality Control Services (AQCS) by organizing intercomparison exercises and proficiency tests for the analysis of radionuclides in the marine environment, by establishing QA programs in the participating laboratories, by providing examples of QA manuals, and by QA training and QA missions. Both worldwide and regional intercomparison exercises are the most important part of a laboratory's QA program. These exercises have helped considerably laboratories in their assessment of their performance, supplied them with reference materials and enabled them to gather information on their performance. Although there has been remarkable growth both in the number of participating laboratories (from 40 to more than 150) and in the quality of data, the performance of all participating laboratories in these exercises is not yet satisfactory.

We shall illustrate recent developments in the performance of laboratories in four intercomparison exercises organized by the IAEA-EL, namely IAEA-385 (Irish Sea sediment), IAEA-414 (Irish Sea and North Sea fish flesh), IAEA-437 (mussel sample from the Mediterranean Sea), and IAEA-443 (seawater from the Irish Sea), by comparing the results obtained for the analysis of ^{239,240}Pu (Fig. 5.36). This radionuclide belongs to the group of radionuclides where improvements in analytical performance have been made recently, thanks to the introduction of ICP-MS and AMS techniques. It can be seen that generally a good agreement has been reached among the laboratories using different radioanalytical techniques (except for the IAEA-414 where several laboratories reported outliers).

Following the ISO (1997) recommendations for the assessment of laboratory performance, Z-score methodology has been introduced in the evaluation of intercomparison results, namely

$$Z = (x_i - x_a)/s_b \tag{5.6}$$

where x_i is the robust mean of the reported values of massic activity in the sample, x_a is the assigned value (a mean value of accepted results), and s_b is the target standard deviation (Cofino and Wells, 1994). The performance of a laboratory is considered acceptable if the difference between the robust mean of the laboratory and the assigned value (in s_b units) is less than or equal to two. The analysis is regarded as being out of control when $|Z| > 3$. The Z-score evaluation represents a simple method which gives

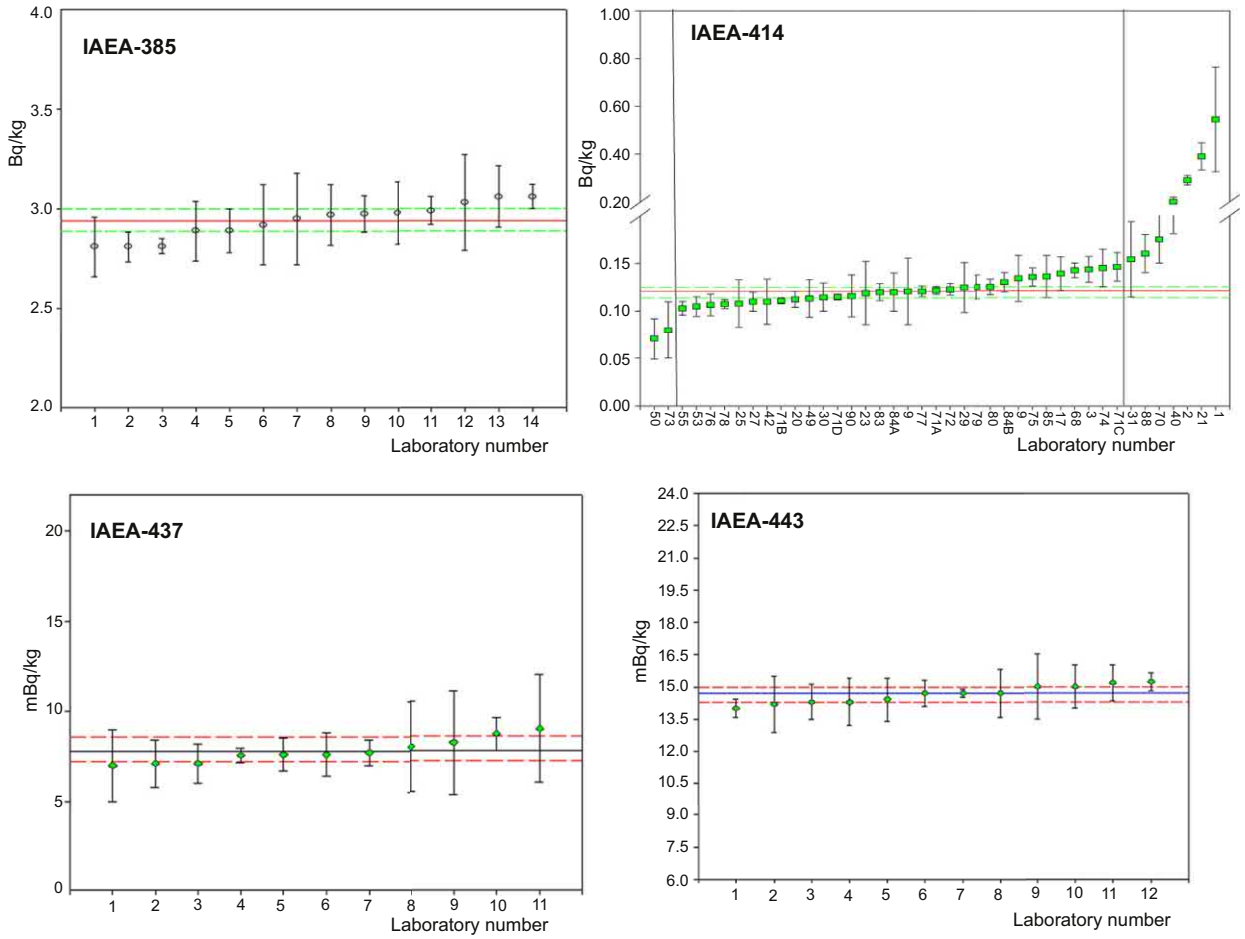

FIGURE 5.36 Results of $^{239+240}$Pu analysis in intercomparison exercises recently organized by the IAEA-EL. The full horizontal lines represent the medians, the broken lines represent the confidence intervals (95% level), and the results on the sides of the vertical lines are outliers.

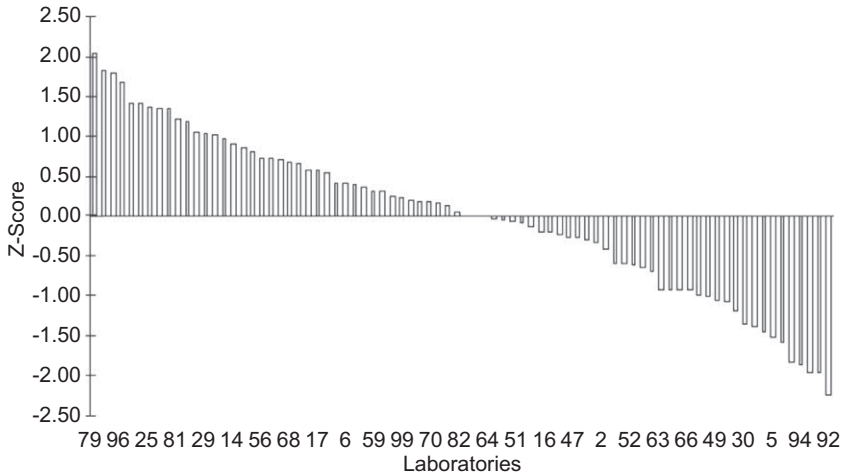

FIGURE 5.37 Z-score analysis of ^{137}Cs data reported for the reference material IAEA-385 (Irish Sea sediment). *Modified after Pham et al. (2008). Reprinted with permission © Elsevier 2008.*

participating laboratories a normalized performance score for bias. As an example, Fig. 5.37 illustrates a Z-score distribution for ^{137}Cs in the reference material IAEA-385 (Irish Sea sediment). The performance of laboratories in this instance was very good.

C. Reference materials

Reference materials (RMs) represent samples of well-established properties used for the assessment of analytical methods. More rigorous materials—certified reference materials (CRMs) or standard reference materials (SRMs), issued by the National Institute of Standards and Technology—NIST, USA (Inn et al., 2001; Outola et al., 2006), have property values certified by technically valid procedures (at least with two independent methods) traceable to SI units (ISO, 1996, 1997). RMs and CRMs have great impact on the development of methods of known accuracy. They represent important benchmarks in QA, identifying weaknesses in methodologies, detecting training needs, upgrading the quality of laboratories' performances, and assessing the validity of analytical methods. The reference methods can only be accepted on the basis of interlaboratory tests performed on selected CRMs. The CRMs should be available for the different environmental matrices, e.g., water, sediment, and biota, as well as for technical materials (Povinec et al., 2016a). The required long-term availability of CRMs (over 10 y) necessitates their long-term stability and the collection and preparation of large-volume samples (over 100 kg). The relative precision of all reported data should be better than 5%. This would require highly homogenized samples thoroughly tested for any inhomogeneities of major elements. The principal analyses should be accompanied by supporting characterization, e.g., for multielemental composition, mineralogy, particle-size distribution, and radionuclide speciation studies. At least two independent analytical methods should be used for reporting certified values. This may not be a major problem in the case of radionuclides, where different methods are available (e.g., RMT, ICP-MS, TIMS, and AMS). In this respect, neutron activation analysis techniques play an important role as really undependable methods for radionuclide analyses. The specific needs for the production of CRMs for mass spectrometric methods (e.g., AMS, ICP-MS, and TIMS), where usually small samples with very low radionuclide concentrations are necessary and which require special treatment, should be addressed. Table 5.2 lists RMs for the analysis of anthropogenic and natural radionuclides in marine sediments, seawater, and biota, which are either available or under production.

TABLE 5.2 Reference materials for radionuclides in the marine environment produced by the IAEA-EL.

Code	Origin matrix	Reference
IAEA-381	Irish Sea seawater	Povinec et al. (2002)
IAEA-384	Fangataufa lagoon sediment	Povinec et al. (2007)

IX. Marine radioactivity databases

The IAEA's Environment Laboratories in Monaco have been developing in its Radiometrics Laboratory a database called Marine Information System (MARIS) (Povinec et al., 2006f). The input database for the MARIS has been the Global Marine Radioactivity Database (GLOMARD) on the distribution of radionuclides in the marine environment (Povinec et al., 2004b). The block scheme of the database is shown in Fig. 5.38.

The IAEA's Marine Information System is a relational database, which is based on the GIS (Geographical Information System), covering the distribution of radioactive and stable isotopes, and in the near future also other tracers (organic compounds and tracer metals) in the marine environment, as well as supporting oceanographic parameters such as seawater temperature, salinity, and sea bathymetry (www.maris.iaea.org).

The main objective of MARIS is to provide information on radioactive contamination of the marine environment by grouping and storing available data on the most important radionuclides in the world oceans and seas (in the open sea as well as in coastal zones), specifically in seawater, particulate matter, biota, and sediment (Povinec et al., 2004b,

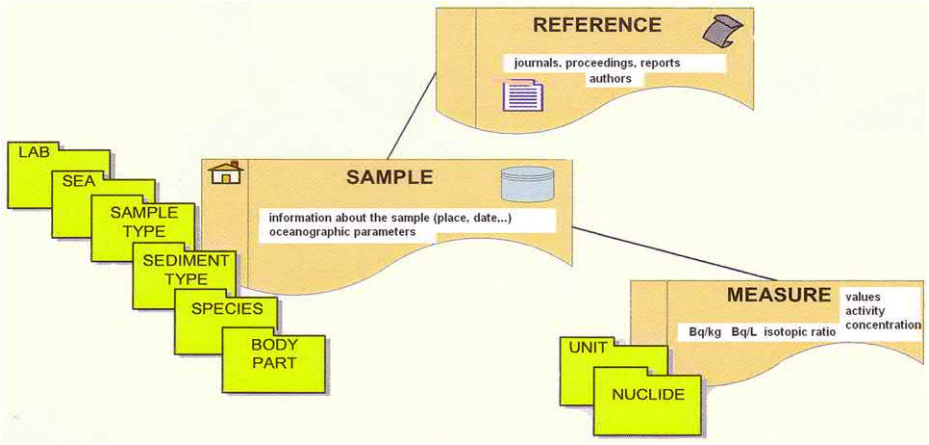

FIGURE 5.38 Organization of the MARIS database. For the color version of this figure, the reader is referred to the electronic version of this book.

2005b). Quantification of the sources of radionuclides in the world's oceans and seas, computer modeling of the dispersion of radionuclides, and radiological assessment studies require that marine laboratories should be provided with information on the past and present levels of radionuclides in the marine environment. The IAEA has been acting as a clearing house for information on radioactive contaminants in the marine environment. It provides data on marine radionuclide levels to laboratories for future assessment studies and the evaluation of trends in the contamination of the marine environment. The collection, synthesis, and interpretation of data on marine radioactivity in the world ocean have been carried out with the following objectives:

1. to provide immediate and up-to-date information on radionuclide levels and inventories in the seas and oceans;
2. to provide a snapshot of radionuclide levels at any time in any location;
3. to investigate changes with time in radionuclide levels and inventories;
4. to provide data for validation of computer models on the dispersion of radionuclides in the marine environment;
5. to provide bases for assessments of radiation doses to local, regional, and global human populations and to marine biota;
6. to identify gaps in available information.

The data provided by MARIS have been used as the international reference source on radionuclide contamination of the marine environment so that any further contributions from nuclear industry, radioactive waste disposal sites, nuclear weapons test sites, and possible nuclear accidents can be identified.

The second main objective of MARIS is to provide information on the distribution of radioactive isotopes (and

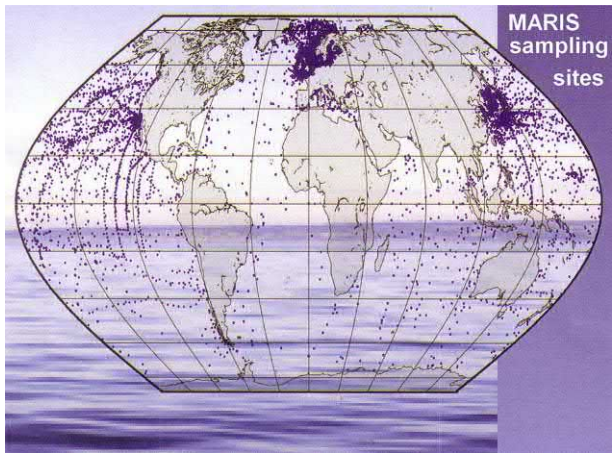

FIGURE 5.39 Sampling sites included in the MARIS database. For the color version of the figure, the reader is referred to the online version of the book.

in future also stable isotopes, tracer metals, and organic compounds) in the world oceans and seas, which could be used as tracers for the investigation of marine processes. This part of the database will grow substantially in the near future, so that data on all important oceanic tracers will be available to laboratories for oceanographic investigations. Fig. 5.39 shows that the MARIS is covering all oceanic basins. The data stored in MARIS could be used for water and sediment dynamics studies, investigation of processes in the water column, seawater–sediment interactions, seawater–groundwater interactions, etc., as well as validation of models used in climate change studies. Data on supporting oceanographic parameters such as seawater temperature, salinity, and sea bathymetry are mainly available to laboratories from Internet sources.

Fig. 5.40 shows, as an example, the distribution of ^{137}Cs in surface waters in the North European Seas, as extracted from the MARIS database. The figure documents the impact of ^{137}Cs discharges from the Sellafield and La

Hague reprocessing facilities, as well as the impact of the Chernobyl accident on surface waters of the North European Seas (Kershaw et al., 1999; Livingston and Povinec, 2000). Global fallout radionuclides and those discharged from nuclear reprocessing plants at Sellafield and La Hague, which have been transported to the Arctic Ocean and adjacent seas, represent a substantial new tracer signal in the Arctic following on the heels of the global fallout. The distinctive time and composition signatures of these two signals are of great value in studies on the circulation and ventilation of the deep waters.

A similar extraction from the MARIS database is presented in Fig. 5.41 for the distribution of ^{137}Cs in surface waters of the northwest Pacific Ocean (Povinec et al., 2003a), information which has been crucial for studying the impact of the Fukushima accident on waters of the North Pacific Ocean.

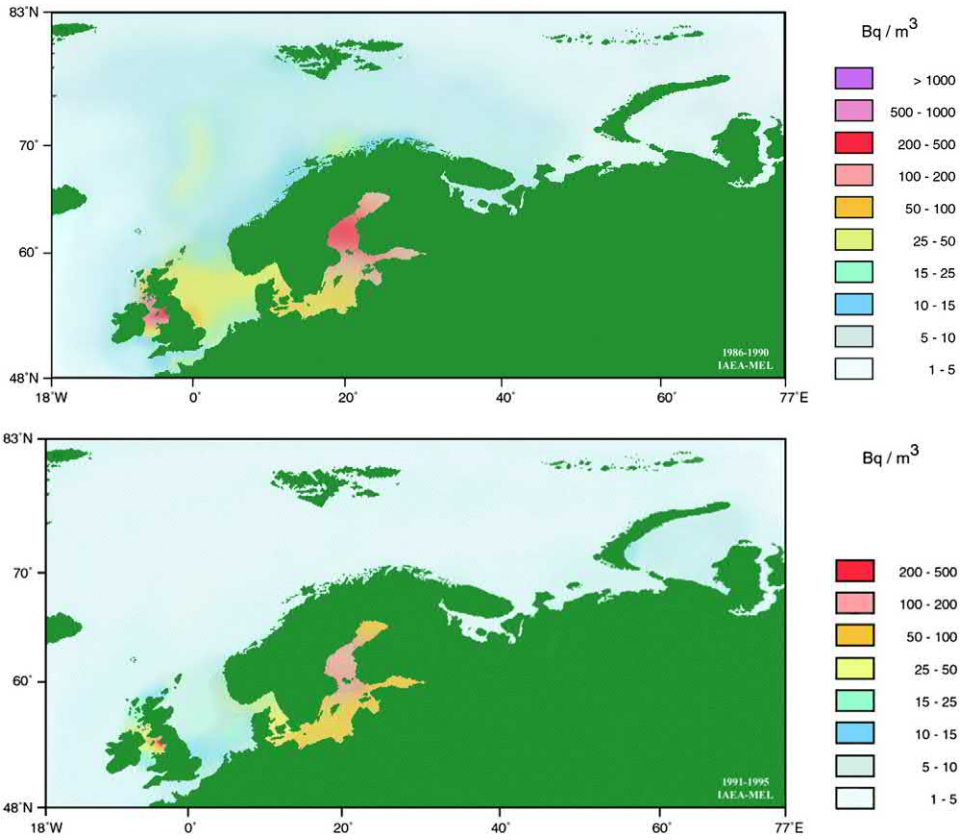

FIGURE 5.40 Distribution of ^{137}Cs in surface waters of the North European Seas after releases from the Sellafield and La Hague reprocessing facility, and after the Chernobyl accident, as extracted from the MARIS database. *Modified after Povinec et al. (2003a). For the color version of the figure, the reader is referred to the online version of the book.*

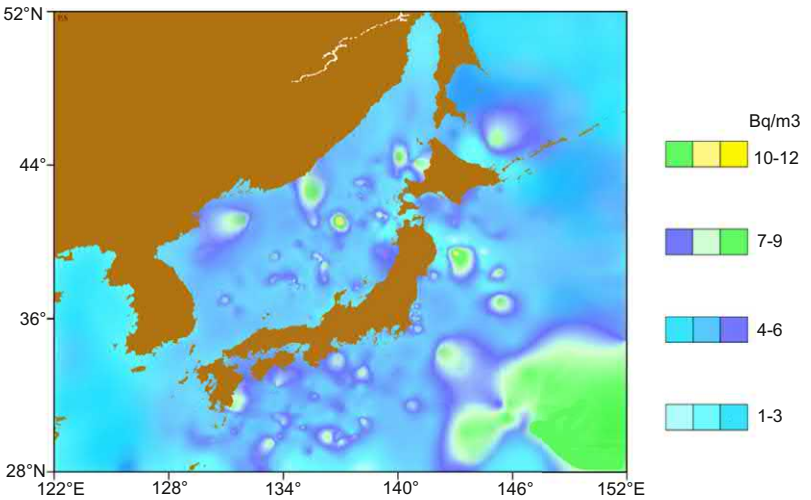

FIGURE 5.41 Distribution of ^{137}Cs in surface waters of the northwest Pacific Ocean as extracted from the MARIS database. For the color version of the figure, the reader is referred to the online version of the book.

The Meteorological Research Institute in Tsukuba (Japan) developed a HAM database which contains data on the distribution of ^{137}Cs in seawater of the world ocean (Aoyama and Hirose, 2004). The database has been used for the investigations of a time series of this radionuclide in surface waters, as well as for water profile studies (Aoyama et al., 2006, 2011; Inomata et al., 2009).

X. Examples of marine radioactivity studies

A. Worldwide marine radioactivity studies

We shall illustrate applications of radionuclides as tracers of oceanic processes on results obtained in the framework of the IAEA international project Worldwide Marine Radioactivity Studies (WOMARS) carried out between 1996 and 2002 in collaboration with several marine and analytical laboratories (Povinec et al., 2005b; IAEA, 2005). Some of the WOMARS results were published in the special issue of *Deep-Sea Research* II, **50**, 17–21, 2003 (Povinec et al., 2003a, 2003b; 2003c, 2003d; Bhushan et al., 2003; Ito et al., 2003; Lee et al., 2003a, 2003b; Moon et al., 2003; Mulsow et al., 2003).

The aim of the WOMARS project was to identify major sources of anthropogenic radionuclides in the world's oceans, to develop the knowledge of the distribution of key radionuclides in the water column and in sediment, and to study the development with time of radionuclide concentrations in water and sediment (Livingston et al., 2001; Povinec et al., 2003a, 2005b; IAEA, 2005). Three anthropogenic radionuclides, ^{90}Sr, ^{137}Cs, and ^{239,240}Pu, were chosen as the most important and radiologically typical of each class of marine radioactivity (beta, gamma, and alpha emitters). They are the most abundant anthropogenic radionuclides present in the marine environment and could lead to the highest radiation doses to humans and marine biota (Aarkrog et al., 1997). The WOMARS results confirmed that the dominant source of anthropogenic radionuclides in the marine environment is global fallout. The total ^{137}Cs input from global fallout was estimated to be 311 PBq for the Pacific Ocean, 201 PBq for the Atlantic Ocean, 84 PBq for the Indian Ocean, and 7.4 PBq for the Arctic Ocean. For comparison, about 40 PBq of ^{137}Cs was released to the marine environment from Sellafield and La Hague reprocessing plants. The Chernobyl accident contributed about 16 PBq of ^{137}Cs into seas, mainly the Baltic and Black Seas (Povinec et al., 2005b; IAEA, 2005).

For studying the distribution of radionuclides and their time series, the world ocean was divided into latitudinal belts/boxes, for which average radionuclide concentrations were estimated. In addition, where available, time trends in radionuclide concentrations in surface waters were studied and mean effective residence times/half-lives of radionuclides in these areas, as well as in the world ocean were estimated.

The Atlantic and Arctic Oceans, together with their marginal seas, were divided into boxes 18–30. The main boxes include the Arctic (18–20), the north (25,28), and the south (29,30) Atlantic Ocean. The rest has been reserved for the marginal seas (IAEA, 2005). The Pacific Ocean with marginal seas was divided into latitudinal boxes 1–13 (Fig. 5.42) on the basis of known ocean current systems, the location of nuclear test sites, the availability of recent data, and the probability of a relatively uniform distribution of radionuclides. Twelve boxes have been delineated in the Pacific Ocean and one box has been attributed to the Southern Ocean. The Sea of Japan has been given a separate box because of its oceanographic specificity and importance in marine radioactivity studies. Box 1 (north of 40 degrees N) is the subarctic Pacific Ocean, where the largest fallout rates of ^{137}Cs and ^{90}Sr over the Pacific Ocean were observed in the 1960s (Aoyama et al., 2001a, 2001b, 2006). Boxes 2 and 3 (25°–40 degrees N) are upstream and downstream of the Kuroshio Extension, respectively, where the water masses of the Kuroshio and Oyashio Currents mix (this box will contain most of radionuclides released to the sea after the Fukusfima accident). Boxes 4 and 5 (5–25 degrees N) are downstream and upstream of the North Equatorial Current, a typical oligotrophic ocean current corresponding to the subtropical gyre (Box 5 also includes the California Current). These boxes include the Pacific Proving Grounds nuclear weapons tests sites (Bikini, Enewetak, Johnston Atolls, and others), especially important for plutonium. The subtropical region of the northwestern Pacific was affected by local fallout as opposed to the subtropical region of the northeastern Pacific. Boxes 6 and 7 (5 degrees S–5° N) are downstream and upstream of the South Equatorial Current, respectively. The boundary between Boxes 4, 5 and 6, 7 is approximately at the Equatorial Counter-Current. Box 7 includes the Equatorial upwelling region. Boxes 8 and 9 (5°–25 degrees S) are downstream and upstream of the South Equatorial Current, respectively. The boundary between boxes 6, 7 and 8, 9 approximately corresponds to the South Equatorial Counter-Current. Box 9 includes the French nuclear weapons test sites (Mururoa and Fangataufa). Box 10 (25 degrees–40 degrees S) corresponds to the Tasman Sea. Box 11 (25 degrees–40 degrees S) is the midlatitude region of the South Pacific. Boxes 12 (40 degrees–60 degrees S) and 13 (below 60 degrees S) include the Southern Ocean and the Antarctic Circumpolar Current.

The Indian Ocean was divided into three boxes—box 15 covers the north and central part, box 16 includes the Indian Ocean Subtropical gyre, and box 17 covers the South Indian Ocean.

1. The ^{137}Cs time series in the Atlantic Ocean

Data used for the calculation of effective half-lives of ^{137}Cs in some of the boxes of the Atlantic Ocean are shown in Fig. 5.43. ^{90}Sr and ^{137}Cs showed similar effective half-lives of 16 ± 4 and 19 ± 4 y, respectively, for the North

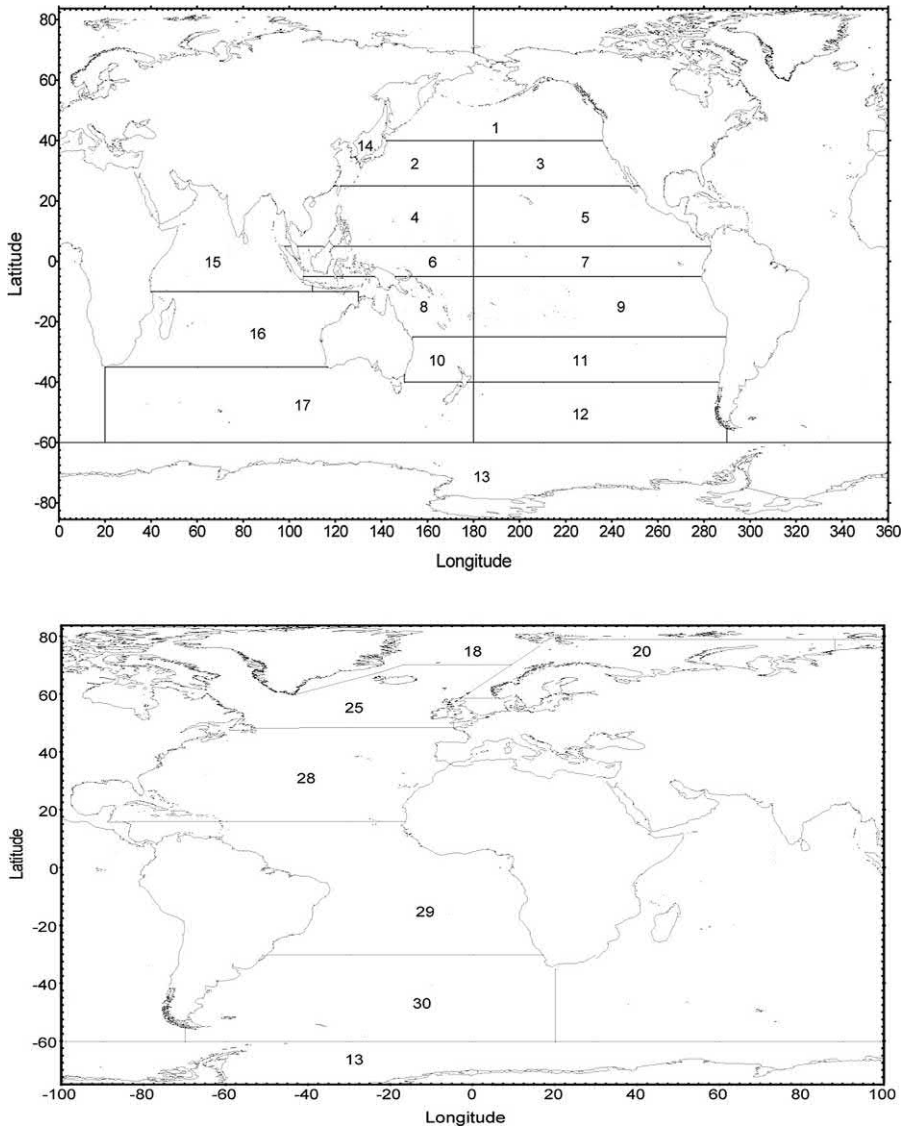

FIGURE 5.42 Latitudinal belts in the Pacific, Indian, and Atlantic Oceans. *Modified after Povinec et al. (2005b).*

Atlantic, 24 ± 2 and 24 ± 6 y for the central Atlantic, and 17 ± 9 and 20 ± 6 y for the South Atlantic Ocean. The average of all Atlantic data is 22 ± 2 and 20 ± 3 y, for ^{90}Sr and ^{137}Cs, respectively. The ^{239,240}Pu data gave an average value for all the Atlantic Ocean of 9 ± 1 y.

A specific situation is in the Irish Sea (box 23) where the discharges from the reprocessing plant at Sellafield dominated the radionuclide source term. The maximum discharge of ^{137}Cs and other β-emitting nuclides from the Sellafield reprocessing facility occurred in 1975 (5.2 PBq). Afterward, the discharges have been decreasing down to the TBq levels (UNSCEAR, 2000). As the distribution of ^{90}Sr, ^{137}Cs, and ^{239,240}Pu in the Irish Sea has been controlled by discharges, effective half-lives were not calculated (Fig. 5.43). The North Sea (Box 22) has been receiving contamination from the reprocessing plants at Sellafield and Cap de la Hague by the prevailing residual currents from the Irish Sea and the English Channel. Consequently, the concentrations of ^{137}Cs, ^{90}Sr, and other radionuclides follow with delay the temporal trends of the discharges.

Due to significantly decreasing discharges in recent years, the concentrations of ^{137}Cs, ^{90}Sr, and transuranics are presently only slightly above the global fallout levels for North Atlantic surface water. Remobilization of ^{137}Cs from highly contaminated sediment in the Irish Sea is now the dominant source also for water contamination of the North Sea.

The accident at Chernobyl deposited large quantities of radionuclides over the northern part of the Baltic Sea (Box 21). The levels of ^{137}Cs in the Baltic Sea were

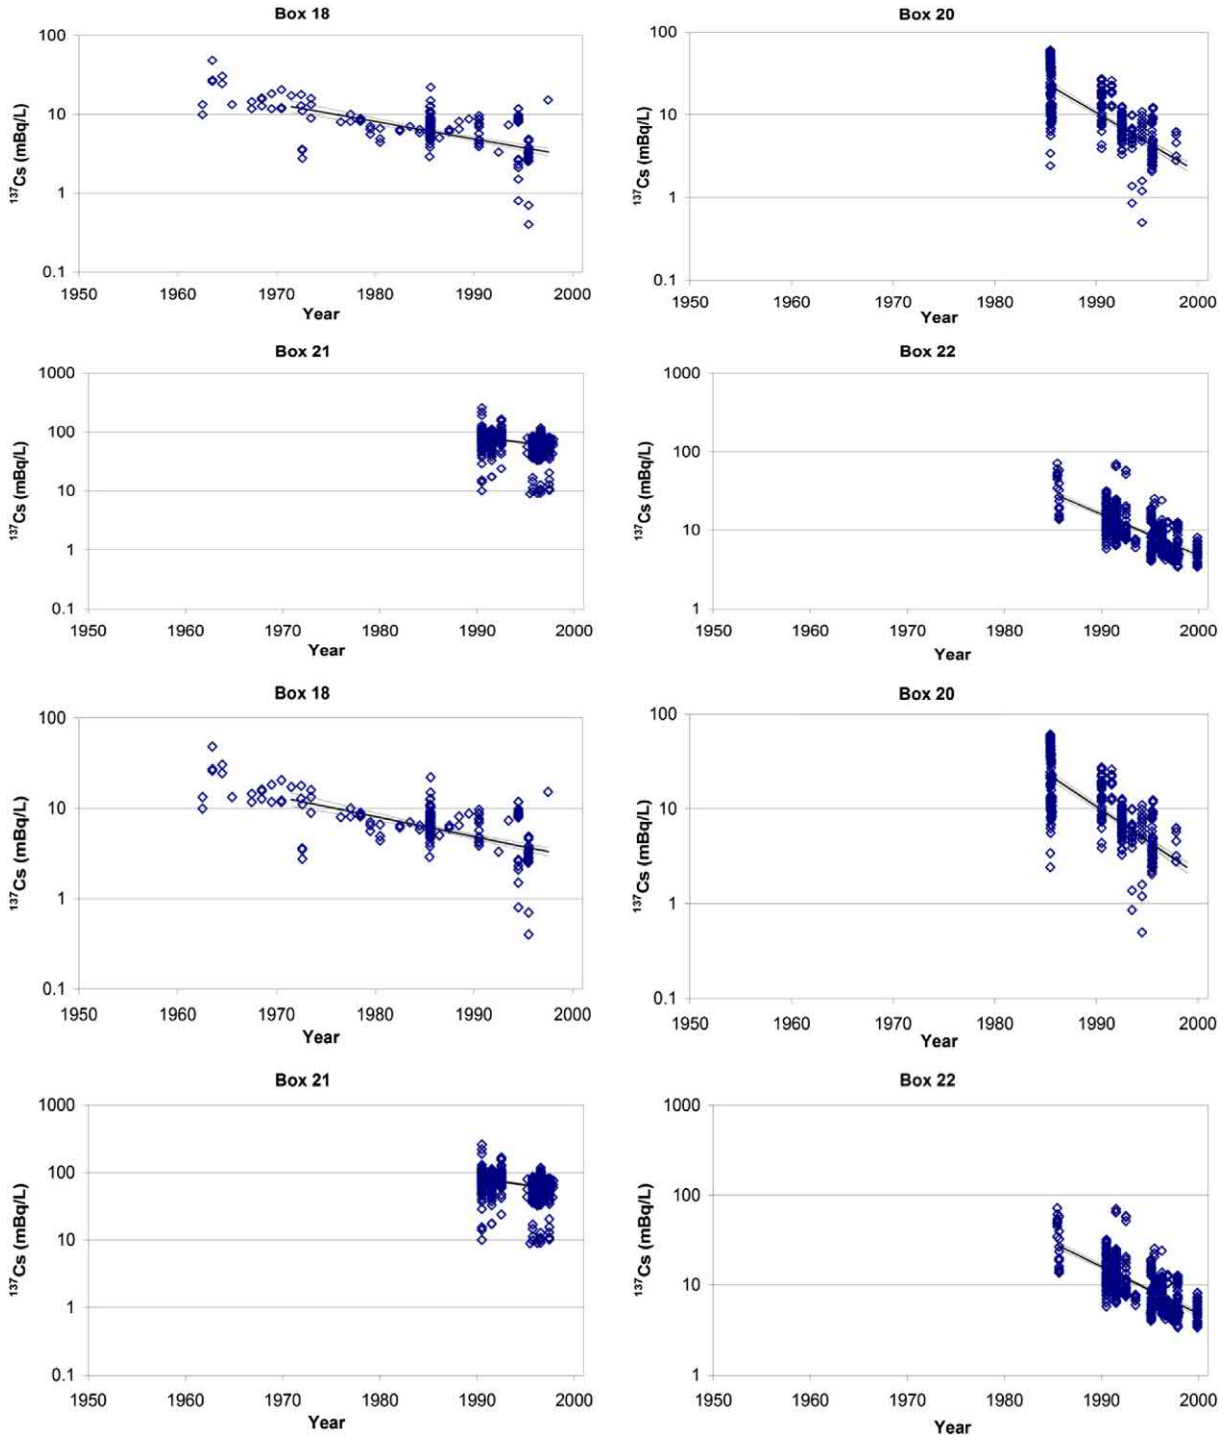

FIGURE 5.43 The ^{137}Cs surface water time series in some of the boxes of the Atlantic Ocean.

dominated by this fallout from 1986 onward. Before 1986, ^{137}Cs was due to global fallout and the inflow of North Seawater through the Danish Straits. The ^{137}Cs surface water time series are given in Fig. 5.43. The calculated effective half-lives for ^{90}Sr, ^{137}Cs, and ^{239,240}Pu in the Baltic Sea are 12 ± 2, 14 ± 2, and 5 ± 1 y, respectively.

Combining all available data for ^{90}Sr, ^{137}Cs, and ^{239,240}Pu in the Atlantic Ocean, the effective half-lives could be calculated (keeping in mind that they could have been affected by releases from reprocessing plants and the Chernobyl accident). The effective half-lives for ^{90}Sr, ^{137}Cs, and ^{239,240}Pu are 22 ± 2, 20 ± 3, and 9 ± 1 y, respectively.

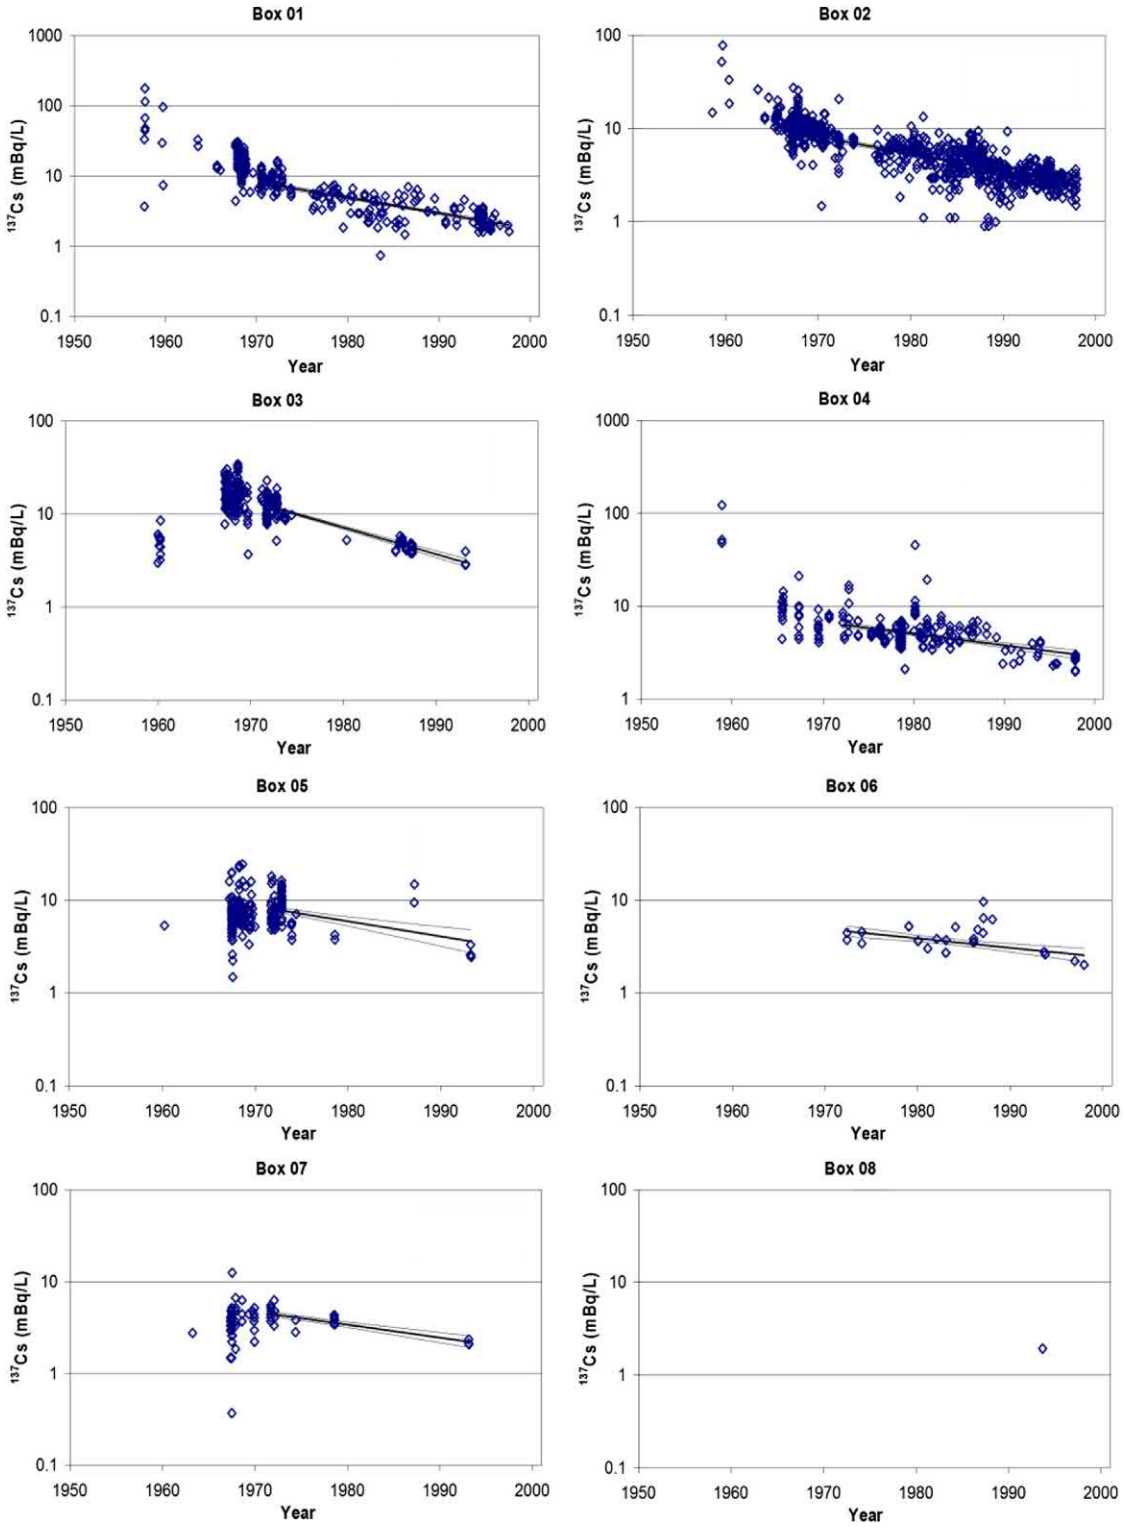

FIGURE 5.44 The ^{137}Cs surface water time series in some of the boxes of the Pacific Ocean.

2. The ^{137}Cs time series in the Pacific Ocean

The surface water ^{137}Cs time series for some selected boxes in the Pacific Ocean are presented in Fig. 5.44. The effective half-life of ^{137}Cs in surface water in each box ranged from 11 to about 30 y. The shortest effective half-life of ^{137}Cs is observed in the midlatitude of the eastern North Pacific (Box 3). The longest effective half-life of ^{137}Cs is found in the Equatorial Pacific (Boxes 6 and 7) and in the eastern subtropical South Pacific (Box 9).

The effective half-life of ^{90}Sr in surface water in each box ranged from 10 to 21 y. The shortest effective half-life of ^{90}Sr is observed in the eastern North Pacific (Box 3). The longest effective half-life of ^{90}Sr occurs in the Equatorial Pacific (Boxes 6 and 7), which is the same area as for ^{137}Cs. The effective half-life of ^{90}Sr seems to be a little less than that of ^{137}Cs; however, the data are not precise enough to confirm this.

The effective half-life of ^{239,240}Pu in surface water in each box ranged from 5 to about 15 y. The shortest effective half-life of ^{239,240}Pu is observed in the midlatitude region of the northeastern Pacific (Box 3), similarly as for ^{137}Cs. These findings suggest that the midlatitude region of the northeastern Pacific is a sink of anthropogenic radionuclides. The surface water mass in the midlatitude region of the northeastern Pacific is penetrated under the surface layer of the subtropical gyre. The longest effective half-life of ^{239,240}Pu is found in the eastern Equatorial Pacific (Box 7), as is the case for ^{137}Cs and ^{90}Sr. At present, the eastern Equatorial Pacific seems to behave as a source of anthropogenic radionuclides. The effective half-life of ^{239,240}Pu is generally shorter than that of ^{137}Cs in each box. Plutonium is a particle-reactive radionuclide as opposed to ^{137}Cs and ^{90}Sr, i.e., plutonium reacts with biogenic particles in surface water, sinks with attached particles, and is remobilized as a result of the biological decomposition of particles in deeper water (Baxter et al., 1995; Hirose et al., 2003).

In South Pacific surface water, the effective half-lives of the radionuclides investigated appear to be longer than in the North Pacific. When corrected for radioactive decay, surface ^{137}Cs in the South Pacific (except for Box 11) has gradually increased over the past three decades. This may suggest that ^{137}Cs in the North Pacific is transported to the South Pacific because the major input of ^{137}Cs due to global and local fallout occurred in the North Pacific.

When the ^{137}Cs data for the North, Equatorial, and South Pacific are grouped, the corresponding mean effective half-lives are 13 ± 1 (North), 22 ± 1 (South), and 23 ± 3 y (Equatorial Pacific). All Pacific data together give an effective half-life of ^{137}Cs of 14 ± 1 y. The corresponding ^{90}Sr and ^{239,240}Pu effective half-lives for the whole Pacific Ocean are 13 ± 1 and 7 ± 1 y, respectively (Table 5.3).

3. The ^{137}Cs time series in the Indian Ocean

Surface water ^{137}Cs concentration time series for Boxes 15–17 of the Indian Ocean is presented in Fig. 5.45. The estimated effective half-lives of ^{90}Sr, ^{137}Cs, and ^{239,240}Pu in surface water for different latitudinal boxes are given in Table 5.3. ^{90}Sr data were very sparse so any estimation of effective half-lives was not possible. ^{137}Cs data enabled to calculate the effective half-life which is 20 ± 2 y for the

TABLE 5.3 Mean effective half-lives of ^{90}Sr, ^{137}Cs, and ^{239,240}Pu in surface water.

		Mean effective half-life ± 1σ[a](y)		
Area	**Boxes**	**^{90}Sr**	**^{137}Cs**	**^{239,240}Pu**

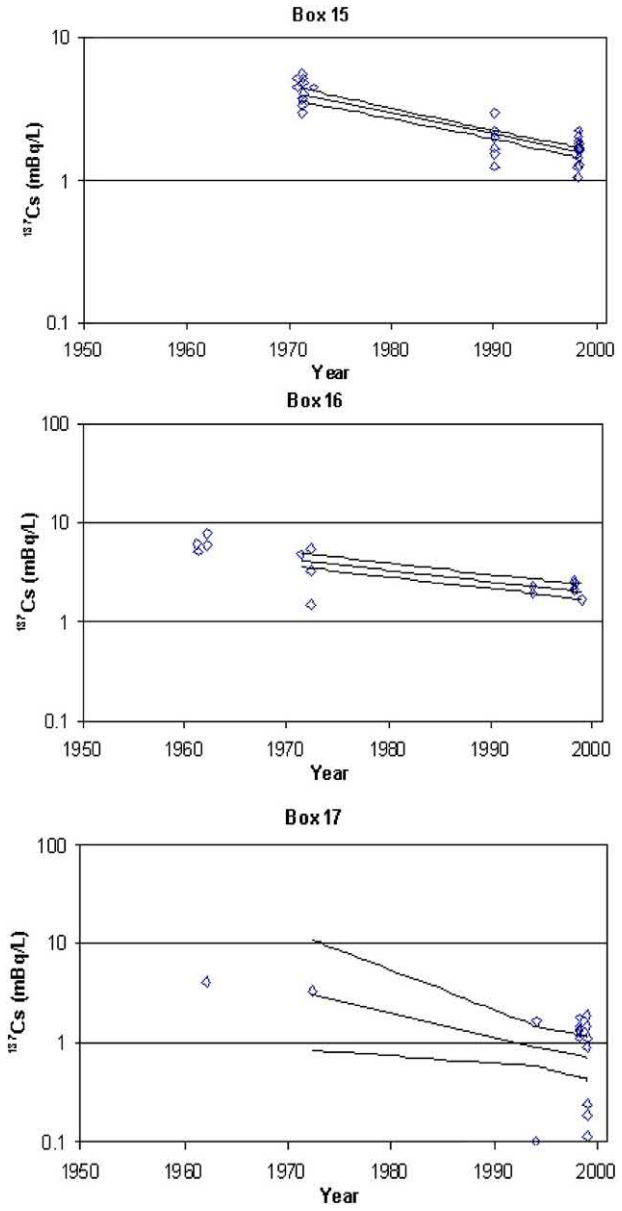

FIGURE 5.45 The ^{137}Cs surface water time series in some of the boxes of the Indian Ocean.

North and 22 ± 4 y for the South Indian Ocean. The average value for the all Indian Ocean is 21 ± 2 y. The uncertainty in ^{239,240}Pu data was too high, except for Box 17 which gave an effective half-life of 9 ± 1 y.

Data for all oceans (Table 5.3) gave the mean effective half-lives for ^{90}Sr and ^{137}Cs as 19 ± 3 and 20 ± 2 y, respectively. As expected, the half-life is similar for both radionuclides; therefore, one can accept a mean value of 19 ± 2 y. The ^{239,240}Pu effective half-life in surface water is 9 ± 1 y. The corresponding residence times of ^{90}Sr (^{137}Cs) and ^{239,240}Pu in surface water are 27 ± 2 and 13 ± 1 y, respectively. The differences between the effective residence times/half-lives of ^{90}Sr and ^{137}Cs are, within uncertainties, the same. Longer residence times can be seen in both the central Pacific and the central Atlantic Oceans.

The results obtained in the framework of the WOMARS project provided the most complete data set available on levels of anthropogenic radionuclides in the marine environment. The results have been used as the international reference source on the average levels of anthropogenic radionuclides in the marine environment, so that any further contributions from nuclear reprocessing plants (Povinec et al., 2003c), radioactive waste dumping sites (Sjöblom et al., 1999; Povinec et al., 2001a, 2001b), nuclear bomb test sites (Povinec et al., 1999), and nuclear accidents (Povinec et al., 2003c) can be identified.

4. Radionuclide tracing of water masses in the South Indian Ocean

The South Indian Ocean plays a key role in the exchange of water masses between the Equator and Antarctica (Ganachaud and Wunsch, 2000), and between the Southern Hemisphere basins (Ridgway and Dunn, 2007), important for a better understanding of global oceanic processes and the climate (Broecker, 1991; Key et al., 2004). South of the 40 degrees S, the wind-driven Antarctic Circumpolar Current (ACC), going around Antarctica, transports cold waters from the Atlantic Sector of the Southern Ocean via the South Indian Ocean to the South Pacific Ocean. The banded structure of the ACC in the South Indian Ocean consists of several narrow jets associated with sharp hydrographic fronts due to the presence of the Crozet and Kerguelen Plateaus (Tomczak and Godfrey, 1994). From the north of the Crozet Islands to the downstream area, there exists a very strong triple frontal zone where the Agulhas Front (AF), Subtropical Front (STF), and Subantarctic Front (SAF) converge into a narrow band of 100–200 km wide, with sharp across-front changes in temperature, salinity, and oxygen content (Park et al., 2002). Strong ocean currents formed in this area characterize the South Indian Ocean as the most dynamic region of the World Ocean (Rahmstorf, 2006). The dominant current system affecting the circulation in the Crozet Basin is the AF, characterized by warm and saline subtropical waters carried by the Agulhas Return Current (ARC). Extending eastward into the basin, up to 60 degrees E, the AF recirculates to the north, as a part of the southern limb of the anticyclonic Indian Ocean Subtropical gyre (Park et al., 2002). The STF forms a boundary between the subtropical surface water and cooler, fresher subantarctic surface water (Pollard et al., 2002). It represents the northernmost frontal jet that passes through Drake Passage and is generally regarded as circumpolar in extent. The SAF is located at the northern boundary of the Polar Frontal Zone (PFZ), a transition region between the SAF and the Polar Front (PF).

The distribution of radionuclide tracers in the South Indian Ocean is therefore expected to be controlled by the banded structure of the fronts. It has therefore been a great challenge to collect water samples in such a complex and dynamic region, and to use isotopic tracers (^{3}H, ^{14}C, ^{129}I, and stable ^{2}H and ^{18}O) to investigate the movement of water masses in the frontal zones (Lee et al., 2009a, 2009b; Povinec et al., 2011a, 2011b).

Ocean observations and water sampling (1999) was carried out as a part of the ANTArctic RESearch (ANTARES) IV cruise (Park et al., 2002; Coppola et al., 2004, 2006; Lee et al., 2009b) in the offshore of the northwest of Kerguelen Islands and east of Crozet Islands between 32 degrees−48 degrees S and 51 degrees−70 degrees E. The observed ^{3}H, ^{14}C, and ^{129}I water profiles (Fig. 5.46) show typical features—the concentrations were highest at the surface (or subsurface at 100−200 m), then were gradually decreasing with depth, and relatively invariable with depth in deep and bottom waters. ^{3}H concentrations were below detection limit (0.02 TU) between 1000 and 2500 m at Sts. 7 and 3; however, levels comparable to surface were observed at bottom waters at both stations. In contrast to this, St. 8 shows threefold higher ^{3}H levels for the surface waters. The ^{14}C profile also shows a downward transport of bomb-produced ^{14}C to the depth of about 2000 m. The ^{3}H, ^{14}C, and ^{129}I data clearly show the presence of different water masses in the Crozet Basin. The ^{3}H concentrations largely decrease below the 1000 m water depth at which CDW (Circumpolar Deep Water) appears, formed by the deepwater circulation and ventilation south of 40 degrees S (You, 2000). The depletion of ^{3}H in the CDW in the STF and SAF fronts may be related to the intrusion of North Atlantic Deep Water (NADW) especially to LCDW (lower CDW), characterized by salinity maximum (Park et al., 1993). NADW injects its water into the CDW in the South Atlantic by mixing and entrainment, and then flows into the southwest Indian Ocean, south of Africa between 35 degrees S and 40 degrees S. Considering very low ^{3}H concentrations (5−24 mTU) observed in the South Atlantic bottom water (Jenkins et al., 1983), which is predominantly affected by the NADW, and taking into account the replenishment of the CDW by lateral transport of the NADW from the South Atlantic to the South Indian Ocean on a time scale of 4−10 y, the contribution of the NADW to the CDW may explain the observed ^{3}H minima. Except for the AF, STF, and SAF, which control radionuclide distribution in surface and subsurface waters, several other water masses can be identified in the basin (Fig. 5.47). The intermediate waters, represented by AAIW (Antarctic Intermediate Water), eliminate the differences observed in the surface layer. The same is true for the deep and bottom waters. Higher ^{129}I levels observed between 1500 and 2500 m water depths are probably due to the presence of NIDW (North Indian Deep Water). The lowest ^{129}I levels found at 1000−2000 m water depth may be due to intrusion of NADW carrying low

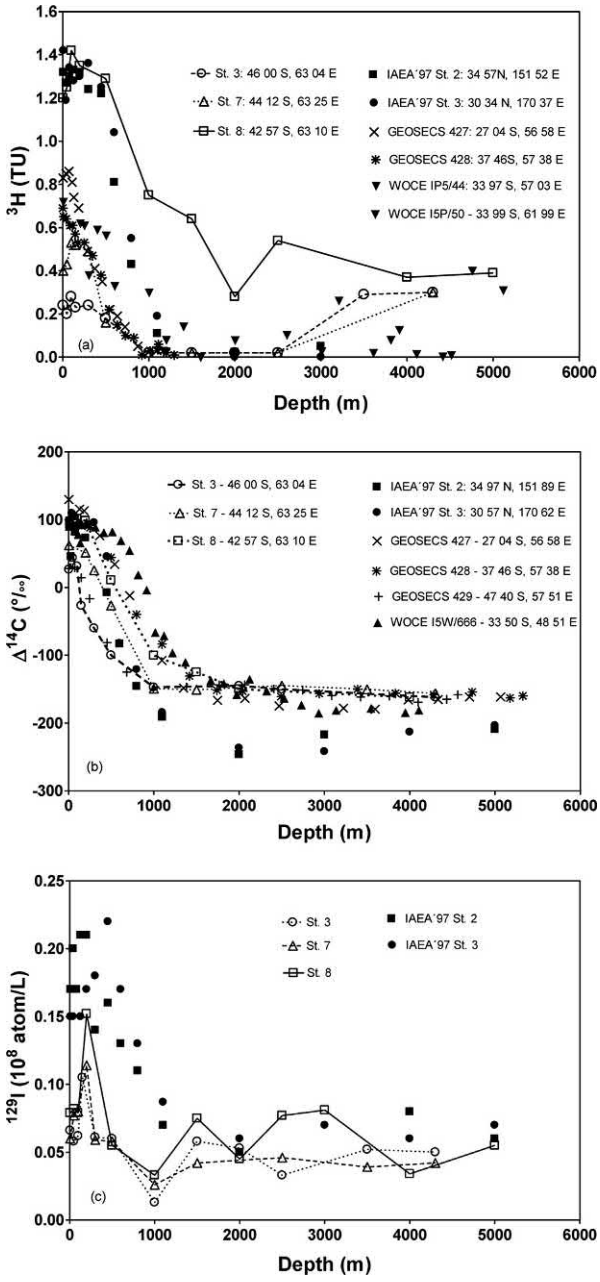

FIGURE 5.46 The ^{3}H, ^{14}C, and ^{129}I water profiles in the South Indian Ocean compared with nearest GEOSECS (Östlund and Brescher, 1982; Stuiver and Östlund, 1983) and WOCE (www.eWOCE.org) stations. ^{3}H, ^{14}C, and ^{129}I obtained for the N. Pacific (IAEA′97 cruise, Povinec et al., 2003a, 2010) are also shown.

radionuclide concentrations. Low, but measurable ^{129}I levels were found at bottom waters which could be attributed to AABW (Antarctic Bottom Water).

The spatial distribution of ^{3}H in the South Indian Ocean (Fig. 5.48) suggests that the highest levels were observed in the main stream of the subtropical gyre. It is evident that the gyre flow is strongest at 40−43 degrees S, west of 65 degrees E, where highest ^{3}H levels were observed. This is a

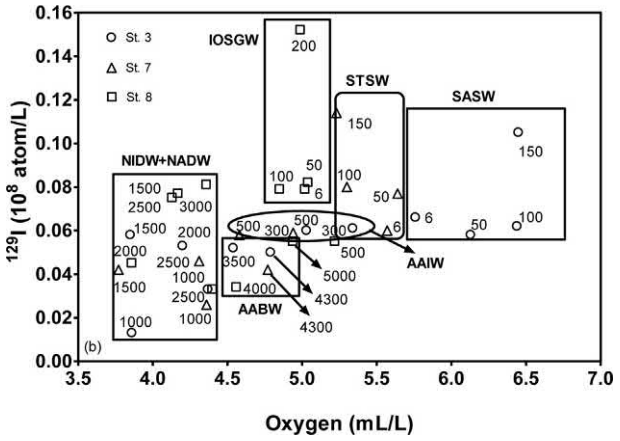

FIGURE 5.47 The dependence of ^{129}I concentration in seawater on the dissolved oxygen. Different water masses could be identified: IOSGW—Indian Ocean Subtropical Gyre Water, STSW—Subtropical Surface Water, SASW—Subantarctic Surface Water, AAIW—Antarctic Intermediate Water, NADW—North Atlantic Deep Water; NIDW—North Indian Deep Water, AABW—Antarctic Bottom Water. Water depths in meters are also shown. *Modified after Povinec et al. (2011a).*

clear influence of the gyre on the downstream radionuclide transport from its western boundary associated with the Agulhas Retroflection (Povinec, 2010b). The atmospheric deposition of global fallout tritium in the Southern Hemisphere was highest during the late sixties in the latitude belt 40−50 degrees S (Weiss and Roether, 1980). However, ^{3}H water profiles across the basin, combined with WOCE data south of 34 degrees S (decay-corrected to 1999), show higher surface and subsurface ^{3}H levels at 20 degrees S and 40 degrees S latitude belts. This indicates an accumulation of tritium within the subtropical gyre on a time scale of several decades. The gyre acts as a reservoir, maintaining higher radionuclide concentrations in the region. Simultaneously, higher tritium levels can be seen in the transect around 40 degrees S and 60 degrees E, at water depths below 3000 m, which should be due the advection of AABW.

The ^{14}C distribution map with the combined WOCE and ANTARES data for the South Indian Ocean is also presented in Fig. 5.48. We can see high ^{14}C concentrations observed along the subtropical gyre (20−40 degrees S) at the top 500 m, and a sharp decrease south of 40 degrees S, as observed in the ^{3}H data as well.^{14}C water profile data clearly show a penetration of bomb ^{14}C around 40 degrees S (transect at 60 degrees E) down to almost 5000 m (we could see this for tritium as well), which documents that the South Indian Ocean is an important sink of anthropogenic carbon. The high phytoplankton biomass in the studied region was found to be fueled by the natural iron inputs from shallow topography close to islands (Pollard et al., 2009).

We may conclude that the radionuclide variations with latitude observed in the South Indian Ocean are not due to the latitudinal atmospheric deposition patterns of global fallout, but due to the redistribution of radionuclides by ocean currents and mixing, and due to spatial constraints given by different water masses present in the region. The South Indian Ocean appears to have been acting on a time scale of several decades as a reservoir of contaminants transported from the Northern Indian and Pacific Oceans. The observed distribution of isotopic tracers reflects the complex dynamics and advection of different water masses, which makes this basin one of the most interesting oceanographic places in the world ocean.

B. Southern Hemisphere Ocean Tracer Studies

As an example of recent studies on the distribution of radionuclides in the world ocean, we shall discuss results obtained in the framework of the Southern Hemisphere Ocean Tracer Studies (SHOTS). The project was carried out during 2002−10 by the international collaboration comprising laboratories from the IAEA (Environment Laboratories, Monaco), Japan (Meteorological Research Institute, Tsukuba; Japan Agency for Marine-Earth Science and Technology, Yokosuka; Sophia University, Tokyo; University of Kanazawa), Slovakia (Comenius University of Bratislava), and South Korea (Korea Institute of Nuclear Safety). Several analytical laboratories participated in the project as well. The results of this study were recently published as a special issue of the journal *Progress in Oceanography* (Aoyama et al., 2011; Gastaud et al., 2011; Hirose et al., 2011; Kumamoto et al., 2011; Povinec et al., 2011a, 2011b; Sanchez-Cabeza et al., 2011; Tsumune et al., 2011; Levy et al., 2011).

It has been recognized that global fallout ^{137}Cs may be used for tracing exchange of seawater between the ocean basins because higher deposition regions of global fallout radionuclides have been found in the western part of midlatitudes in the North Pacific Ocean (Aoyama et al., 2006; Inomata et al., 2009). In the framework of the SHOTS project, water profile samples were collected during the round-the-globe BEAGLE2003 (Blue Ocean Global Expedition). The samples were analyzed for ^{137}Cs, ^{3}H, ^{90}Sr, and Pu isotopes, as well as for other tracers (e.g., nutrients).

As an example of low-level γ-spectrometry applications in marine sciences, we shall present high-density ^{137}Cs profiles in the water column of the world ocean. These are the first high-density ^{137}Cs profiles obtained till now for the main oceanic basins. It has been possible to get such profiles, thanks to analysis of ^{137}Cs in underground laboratories, which were able to achieve the required sensitivity for 10-fold smaller volumes of water samples. With the sampling of small (10 L) water samples, it was possible to use Rosette/CTD systems, which was not possible before, as large-volume samplers (>100 L) were required. The sampling of water column at large volumes resulted in long sampling times, which had strong financial limitations, as the ship time became too expensive.

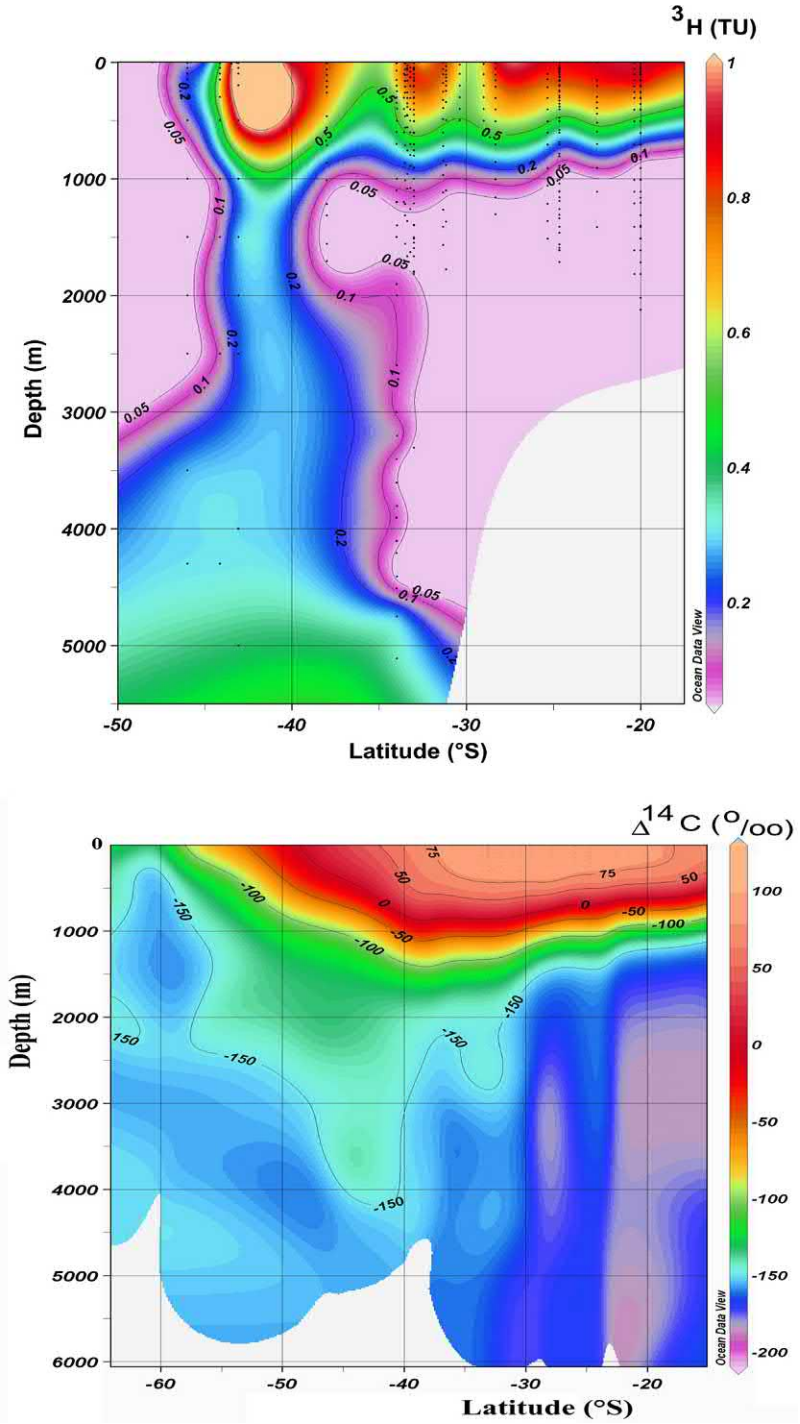

FIGURE 5.48 Spatial distribution of ^{3}H and ^{14}C in waters of the South Indian Ocean (ANTARES data were combined with nearest WOCE stations (www.eWOCE.org)). Higher ^{3}H concentrations were observed at the main stream of the Indian Ocean Subtropical Gyre at ~40 degrees S (as well as at ~20 degrees S, as indicated by the WOCE data). Downward tritium and radiocarbon transport around 40 degrees S (at 60 degrees E) can be seen as well. For the color version of the figure, the reader is referred to the online version of the book. *Modified after Povinec et al. (2011a).*

The ^{137}Cs transect along the 20 degrees S latitude in the Atlantic, Indian, and Pacific Oceans is shown in Fig. 5.49 (Sanchez-Cabeza et al., 2011; Povinec et al., 2011a, 2011b; Aoyama et al., 2011). The main feature presented in this figure is a transport of global fallout ^{137}Cs from the northwestern Pacific Ocean to the South via the Equator, and its accumulation in the Tasman Sea (Hirose et al., 2007, 2009; 2011; Aoyama et al., 2011). The ^{137}Cs labeled

waters are transported via the Indonesian Seas to the Indian Ocean, where they are again accumulating in the subtropical gyre operating at 20 degrees and 40 degrees S. Finally, the ^{137}Cs is transported by the Agulhas current system to the South Atlantic Ocean, where it became a part of the South Atlantic circulation.

We shall discuss in more detail the circulation processes in the Indian Ocean. Fig. 5.49 shows a presence of two cores of higher ^{137}Cs concentrations at 100 degrees E and 60 degrees E in the water column depth between 100 and 200 m. The subsurface maximum of ^{137}Cs concentration measured near 100 degrees E (2.1 mBq/L) is the highest level observed in southern hemisphere seawater, which is of the same level as the maximum ^{137}Cs concentration observed in North Pacific surface water (Povinec et al., 2003a). It is impossible to construct the observed ^{137}Cs cores only from a direct input of global fallout ^{137}Cs onto the Indian Ocean. Therefore, the ^{137}Cs cores must be due to an input of the North Pacific ^{137}Cs throughout the Indonesian seas into the cyclonic eddy of the Indian Ocean Subtropical gyre. By a factor of three increase of ^{137}Cs inventories then would be expected from global fallout in the South Indian Ocean along the 20 degrees S latitude (up to 1240 Bq/m^2), which are comparable with ^{137}Cs inventories in the northwestern Pacific, confirming an input of the North Pacific ^{137}Cs into the South Indian Ocean subtropical gyre. The estimated residence time of ^{137}Cs in surface waters of the subtropical Indian Ocean (~30 y) is twofold higher than for the North Pacific Ocean, documenting an accumulation of cesium in the Indian Ocean subtropics. All these findings suggest that the South Indian Ocean subtropical gyre is a significant reservoir of anthropogenic pollutants that have been transported from the North Pacific Ocean to the south on a time scale of several decades, which has important implications for the protection of the marine environment.

Fig. 5.49 also shows ^{3}H profiles in the world ocean obtained in the framework of the WOCE project (www.eWOCE.org). We can see that the ^{3}H profiles obtained 10 years earlier for the Indian Ocean have similar features, i.e., the existence of two ^{3}H maxima for subsurface waters at 100 degrees and 60 degrees E. The ^{137}Cs and ^{3}H sections

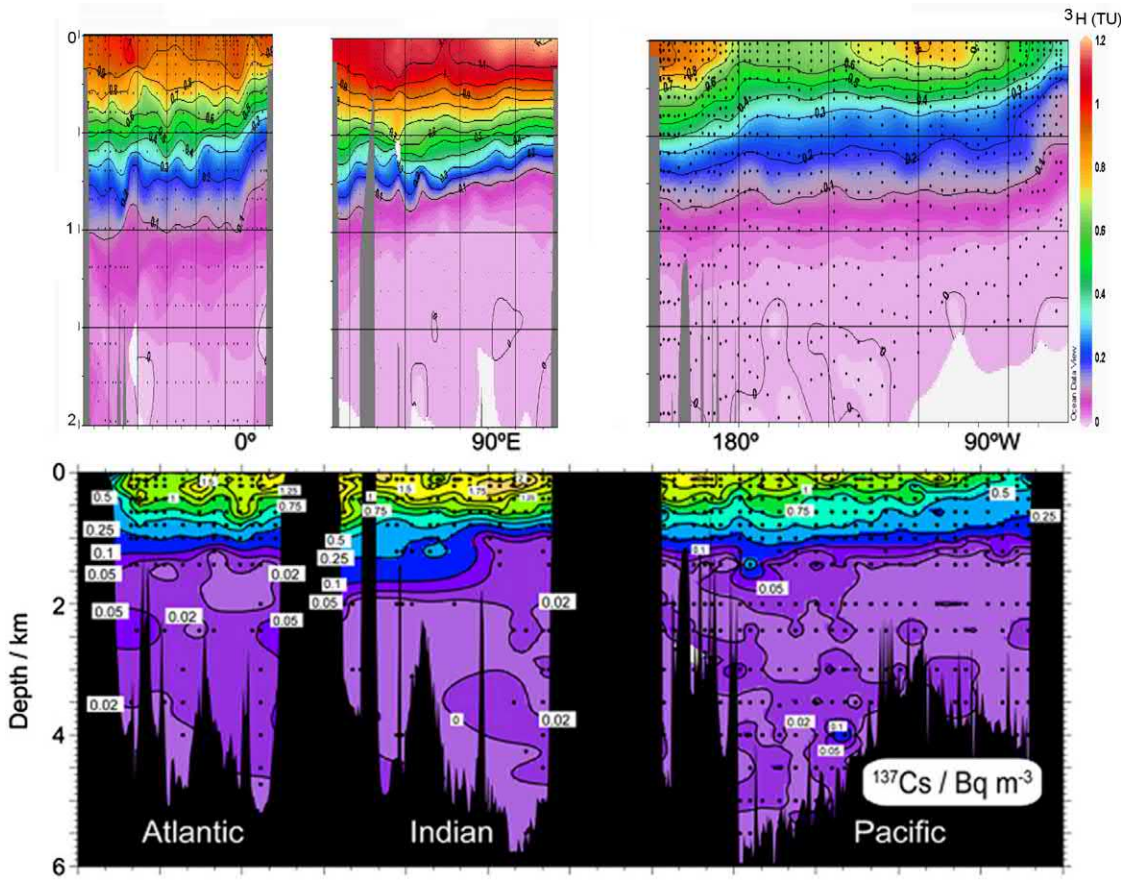

FIGURE 5.49 Tritium (WOCE data, www.eWOCE.org) and ^{137}Cs (SHOTS data after Aoyama et al., 2011; Povinec et al., 2011b; and Sanchez-Cabeza et al., 2011) profiles in the world ocean waters along 20 degrees S. For the color version of the figure, the reader is referred to the online version of the book.

provide valuable information on differences in the spreading of water masses between the main oceanic basins, and from the surface into the interior of the world ocean on a time scale of about 10 y.

C. Marine radioactivity impact of the Fukushima accident

The high tsunami, which followed after the strong earthquake of magnitude 9 on March 11, 2011, damaged the Fukushima Dai-ichi Nuclear Power Plant (NPP) in Japan, resulting in large radionuclide releases. Three nuclear reactors which were in operation during the earthquake could not cool down because of loss of electricity. The total atmospheric releases of ^{131}I and ^{134}Cs + ^{137}Cs were estimated to be around 153 PBq and 15−20 PBq, respectively. The discharged radionuclides also included ^{3}H, ^{14}C, ^{90}Sr, ^{132}Te, ^{132}I, ^{136}Cs, etc., as well as radioactive noble gases (^{133}Xe, ^{135}Xe) (Povinec et al., 2012a, 2012b, 2013a; Aoyama et al., 2013, 2016; IAEA, 2015; Hirose, 2016). As the prevailing wind direction in Japan was from the west to the east, the radioactive plume was mainly transported over the Pacific Ocean to America, and then over the Atlantic Ocean to Europe (Masson et al., 2011; Povinec et al., 2013a, b, c).

The nuclear accident at the Fukushima Dai-ichi NPP increased ^{137}Cs concentrations in coastal seawater in March 2011 up to 68 kBq/L, eight orders of magnitude above the global fallout background (Povinec et al., 2013a; Povinec and Hirose, 2015). This increase was due to direct liquid releases of ^{137}Cs contaminated fresh and later also seawater to coastal waters, which was estimated to be around 4 PBq (Tsumune et al., 2012; Povinec et al., 2013a; Aoyama et al., 2016). The ^{131}I/^{137}Cs activity ratio in surface seawater offshore Fukushima indicated that most of the radiocesium observed in coastal waters was the result of a direct discharge to the ocean (Hou et al., 2013). Due to the transport of water masses from the Japanese coast to the open western North Pacific by the coastal currents (Nakano and Povinec, 2012; Tsumune et al., 2012), the high ^{137}Cs concentrations observed in 2011 in coastal seawater decreased rapidly with apparent half-life of about 1 year (Povinec and Hirose, 2015). The typical ^{137}Cs activity concentrations in coastal waters in 2011−12 were from a few mBq/L to a few Bq/L (Aoyama et al., 2013; Buesseler et al., 2012; Povinec et al., 2013a, 2017; Kumamoto et al., 2013).

From a radiological point of view, ^{137}Cs has been considered to be the most important anthropogenic radionuclide in the marine environment because of its large releases, relatively long half-life, and its relative high bioavailability. It represents the anthropogenic radionuclide without a natural contribution, which was released in large quantities after atmospheric nuclear weapons tests, as well from the Chernobyl nuclear reactor accident, and after authorized releases from nuclear reprocessing facilities to coastal waters (Livingston and Povinec, 2000, 2002). When comparing the Fukushima atmospheric radionuclide releases with the Chernobyl ones, we see that they were lower for ^{131}I and ^{137}Cs by about a factor of 12 and 7, respectively. The Fukushima accident was classified on the INES (International Nuclear and Radiological Event Scale) scale at the maximum level of 7 (IAEA, 2011), similarly as the Chernobyl accident. The largest radioactivity (around 950 PBq) released to the atmosphere till now was, however, from atmospheric tests of nuclear weapons.

The ^{137}Cs due to its large releases to the marine environment with subsequent impact on marine biota, as well as due to its accumulation in human tissues has been recognized as the most important radionuclide for delivering radiation doses to the public from the consumption of food (Aarkrog et al., 1997; Livingston and Povinec, 2000; Povinec and Hirose, 2015). Fukushima-derived radiation doses estimated for the Japanese population from consumption of seafood were estimated to be (0.6 ± 0.4) mSv/y. The individual effective dose commitment from consumption of radioactive-contaminated fish caught in the open Pacific Ocean was estimated to be (0.07 ± 0.05) mSv/y. These doses are comparable or much lower than doses delivered from the consumption of natural ^{210}Po in fish and in shellfish (0.7 mSv/y), and they are below the worldwide accepted limit of 1 mSv/y (Povinec and Hirose, 2015). More detail information on the environmental radioactivity impact of the Fukushima accident can be found in books (Povinec et al., 2013a; Nakanishi and Tanoi, 2013).

As there has not been serious radiological consequences from the Fukushima-derived radionuclides in the marine environment, recent investigations have been focusing on using Fukushima radionuclides as tracers in oceanographic studies, namely on investigations of oceanic currents, transport of water masses and investigation of processes in the water column (Nakano and Povinec, 2012; Povinec and Hirose, 2012; Povinec et al., 2013c, 2017; Kumamoto et al., 2013, 2014; 2015; Aoyama et al., 2013, 2016; Inomata et al., 2017; Hirose and Povinec, 2018; Kaizer et al., 2018b).

XI. Conclusions

There have been several important innovations in sampling, shipboard measurements, and laboratory analysis of radionuclides in the marine environment. Innovations in the RMTs included applications of high-efficiency HPGe detectors used both in the laboratory and on shipboard. Stationary underwater γ-ray monitors based on NaI(Tl) detectors with satellite data transmission, and towing systems based on NaI(Tl) and HPGe detectors have been used for the monitoring of radionuclides in seawater and on the seabed.

SAS remains a powerful technique for the analysis of α-emitters because of the simplicity of measurement, reasonable resolution, and sensitivity for radionuclides with shorter half-lives. Low-activity samples, however, require

long counting times, and the separation of ^{239}Pu and ^{240}Pu is difficult, and at very low levels impossible because of very low counting rates.

The most important achievements for laboratory analysis of γ-emitters in the marine samples have been the development of high-efficiency HPGe detectors operating in underground laboratories, sometimes with anticosmic shielding. For example, thanks to decreasing the water volume required for analysis by about a factor of 10 (to about 10 L), it has been possible to carry out investigations on the spatial distribution of ^{137}Cs in the water column of the world oceans.

In the mass spectrometry sector, a new state-of-the-art TIMS, operating in multidynamic mode with a multicollector detection system, achieved better precision and accuracy in isotopic ratio and isotope concentration measurements. The TIMS is now the most sensitive low-energy mass spectrometry technique, relatively free of interferences, widely used for mass spectrometry of long-lived actinides. The ICP-MS has proved to be powerful tool for the analysis of long-lived radionuclides because of its high sensitivity, rapid analysis, multi-isotopic composition capability, and the low cost per analysis. Nevertheless, there could be problems with molecular, isobaric, and isotopic interferences even if careful purification procedures are used. The RIMS with its sensitivity similar to ICP-MS is still not a "desktop" technique that would permit widespread use; however, it is important as a complementary technique, almost free of interferences, e.g., for the certification of reference materials.

The most exciting breakthrough in the analysis of long-lived radionuclides in the marine environment has been made in the AMS sector. The AMS systems operate at the highest sensitivities with minimum sample size, and small matrix and interference effects. However, AMS operations are complex, and experienced operators are needed, which means this method is costly. However, small AMS systems have been developed recently which are of comparable size to sophisticated ICPMS and TIMS.

Natural radionuclides such as ^{210}Pb, ^{210}Po, radium, uranium and thorium isotopes, and others, have been used widely as natural tracers of water and sediment dynamics, particle association, transport, and fate. For example, indirect measurements of particulate organic carbon fluxes using ^{234}Th/^{238}U disequilibria in the water column contributed to a better understanding of environmental change. Another example is ^{210}Pb dating of sediments which has provided temporal information necessary for the interpretation of the depositional history of nonradioactive contamination in coastal sediments. The radiotracers have improved our knowledge of the transfer of radionuclides and critical elements, such as toxic metals, to marine organisms. This has been especially important for a better understanding and assessment of the impact of both radioactive and nonradioactive contamination in coastal areas. The main target areas are those which have been impacted by land-based sources of contamination, and they have been used extensively for marine food resources.

Analysis and applications of anthropogenic radionuclides in the marine environment have also been mastered. These contributed to better understanding of water circulation between the oceanic basins, and processes in the water column and in sediment. Anthropogenic radionuclides from global fallout (such as ^{3}H, ^{14}C, ^{90}Sr, ^{137}Cs, ^{241}Am, Pu isotopes, and others), Chernobyl and Fukushima accidents (Povinec et al., 2013a; Hirose and Povinec, 2015) have been due to their unique time-marker labeling of seawater, marine organisms, and sediments widely used as oceanic tracers. They will further contribute to the wide growth of knowledge of the physical, chemical, biological, and sedimentary processes, which occur in the oceans. Given the relevance of the marine processes to studies of the linkages between oceans and climate, the anthropogenic radionuclides in oceans will be exploited as useful tracer tools for many decades to come.

Great innovations have been made in the analysis of radionuclides on particles, where several new techniques have been successfully applied including SIMS, AMS, scanning electron microscopy coupled with X-ray detectors, microbeam XRF analysis, synchrotron radiation-based XRF, and other techniques. The new technologies enabled us to proceed from bulk sample analyses to single microparticles analyses, and they will be widely applied in speciation studies of radionuclides associated with colloid and particles for a better understanding of processes in the water column, water−sediment interactions, and biological uptake of radionuclides.

However, there is still room for new exciting developments. As examples we could mention PIMS and laser-based analytical technique for ^{14}C analysis, which represent alternative techniques to AMS. Ultra-trace isotope detection of noble gases (^{39}Ar and ^{81}Kr) is still a challenging task, which has recently been addressed by a magneto-optical trap and collinear laser photon burst spectroscopy. Laser microprobe mass analysis (LAMMA), Fourier transform-ion cyclotron resonance (FT-ICR) method, and atom trap trace analysis (ATTA) are the new technologies, which could improve detection limits by several orders of magnitude. New trends in ultralow-level technologies may be expected with further developments of new mass spectrometry methods, probably based on ion traps technologies. The single atom-counting technologies thus will become available for a wide range of applications in various branches of the sciences. A further transfer in philosophy of analyses from bulk sample analyses to compound-specific isotope analyses with online coupling of analytical instruments will continue. Results obtained with coupling of GC/MS with AMS are very encouraging, and they will surely bring new applications in science (Povinec et al., 2009).

These new developments will further enhance applications of radionuclides as tracers in marine studies. Thanks to new isotopic tracers, better detection limits, and smaller samples, new exciting investigations are expected to be carried out, which will further improve our knowledge of oceanic processes. They will also contribute to a better understanding toward protecting the marine environment, elucidating the impact of the climate change on the world ocean.

Acknowledgments

The authors express their appreciation to colleagues from the IAEA-EL (J.-F. Comanducci, I. Levy, L. Liong Wee Kwong, H. Nies, B. Oregioni, I. Osvath, M.K. Pham, and others) and the Comenius University (R. Breier, M. Ješkovský, J. Kaizer, I. Kontuľ, J. Staníček, I. Sýkora, A. Šivo, and others) for cooperation in the development and applications of radiometric and mass spectrometry methods for the analysis of radionuclides in the marine environment.
