CLAUDE BOUCHARD

# HANDBOOK OF OBESITY

Etiology and Pathophysiology  
Second Edition

## Preface to the Second Edition

The publication of the first edition of the *Handbook of Obesity* occurred just as the Food and Drug Administration requested the recall of fenfluramine and dexfenfluramine. Each drug alone and in combination with phentermine had been associated with a rash of valvular heart disease. These cases were similar to some seen with the carcinoid syndrome that secretes serotonin. There was an accumulation of material on the aortic valves in the heart that made them leaky. The good news is that many of these valvular lesions have been reversible when the drugs were discontinued, and there are no cases known to us of progression after the drugs were stopped.

Thus, at the time the first edition of the *Handbook of Obesity* was published, the chapters dealing with fenfluramine and combination therapy were already out of place. In addition, there were few drug treatments on the horizon.

In spite of this negative impact, the scientific advances preceding the publication of the first edition had been substantial. As we began to plan the second edition, we reviewed each of the 49 chapters in the first edition. The major changes were in the therapeutic area where many new drugs were under evaluation and where new strategies for prevention of obesity were being evaluated.

Based on these advances in the therapeutic area, we added 12 new chapters, which made a substantially

longer volume with 61 chapters. We thus decided to divide the handbook into two separate volumes. The first deals with the prevalence, etiology, and consequences of obesity. In the second volume we have included the chapters dealing with evaluation, prevention, and treatment.

In this volume we cover the history, definition, prevalence, etiology, and pathophysiology of obesity. The prevalence of obesity continues to increase rapidly (Chaps. 4, 6, and 7). At present more than 60% of adult Americans are overweight and more than 30% are obese. Important ethnic differences led to the addition of a chapter dealing with this important subject (Chaps. 2 and 3). We also have a new chapter on the fetal origins of obesity and the impact that the intra-uterine environment has on future risks for developing obesity. The costs of obesity have become more important for individual nations, and the chapter on this subject has been expanded (Chap. 8).

Genetic and molecular biology are important areas for research and are promising the pharmaceutical industry new approaches to the problem (Chaps. 9 and 10). The importance of animal models has resulted in the addition of a second chapter on this area (Chap. 12). The regulation of food intake in animals and humans provides important new insights into the ways they choose and regulate their energy intake (Chaps. 13–16). The epidemic of AIDS has added a new variety of

fat accumulation associated with treatment with proteases and we have added a chapter to cover this area (Chap. 19). The importance of visceral and total body fat continues to expand. One of the key new developments of the 1990s was the recognition that the fat cell is one of the most important endocrine cells in the body. We have recognized this with several chapters on adipose tissue (Chaps. 17, 18, 20, 21, and 22). We have also recognized the importance of obesity in the function of the classical endocrine glands such as the adrenal, thyroid, pituitary and gonads (Chaps. 25, 26, and 27). The other side of the energy balance from food intake is energy expenditure. This subject too receives substantial discussion in several chapters (Chaps. 23, 24, and 28). Muscle metabolism and nutrient partitioning are the final two chapters in this section.

Obesity has a myriad of effects on the health of human beings. Obesity increases the risk of death, as discussed in Chapter 31. The metabolic syndrome, as a collection of findings that predict health risks, has become considerably more important in the past decade

and has been discussed by one of the scientists who originated this concept (Chap. 32). We have also invited chapters dealing with the cardiovascular system, blood pressure, lipoproteins, diabetes, gall bladder disease, pulmonary function, arthritis, and pregnancy. To end this volume we have included a discussion of the role of physical activity in health and the effect of obesity on the quality of life (Chaps. 42 and 43).

We are indebted to a number of people for this volume. Ms. Nina Laidlaw and Ms. Heather Miller at the Pennington Biomedical Research Center have provided able assistance to the editors. At Marcel Dekker, Inc., Ms. Moraima Suarez has taken the principal role. We are both indebted to each of these three people. Without the excellent writing from each of the authors and their collaborators, we would not have the superb chapters that make up this volume. We thank all of them.

*George A. Bray*  
*Claude Bouchard*

## Preface to the First Edition

This volume has been designed to provide up-to-date coverage of the range of subjects that make up the field of obesity research. The chapters have been written by many of the leading scientists and clinicians in the field.

We have divided the book into four sections. Part one deals with the history, definitions, and prevalence of obesity. The first of these nine chapters outlines the history of obesity using a series of timelines to put the important events in the development of obesity research into the historical context. This is followed by a chapter written by the three editors on definitions that can be used to frame the subject matter of obesity. A chapter on the measurement of body composition follows. The global prevalence of obesity in children and in the elderly is then presented in three separate chapters. This section ends with a discussion of the behavioral and psychological correlates of obesity, and the cultural context in which obesity is viewed by different ethnic groups.

The second section focuses on the etiological factors involved in the development of this problem. The first chapter is a detailed presentation of the genetics of human obesity. A genetic approach has proved particularly important since the discovery of leptin and the rapid mapping of genetic loci that are associated with the development of obesity. A great deal has been learned about obesity from the study of animals models, a variety of which are presented by two of the experts in the field. The third chapter deals with the rise of genetic

approaches to obesity, which has been aided by advances in molecular biology. There follow three chapters on the intake of food. One of these deals with this problem in humans, the second with the problem in animals, and the third with the neural basis for the intake of food in both humans and animals. Together these chapters provide a vivid view of the current standing of the field of nutrient intake.

Our understanding of the importance of adipose tissue has steadily increased, from regarding it as a simple storage organ to recognizing it as a secretory organ as well. The important differences between white and brown adipose tissue have also been elucidated, and their role in the development and maintenance of human obesity defined. These concepts are developed in the next four chapters. The final group of chapters in the second section deals with energy expenditure. There is a chapter on energy expenditure and thermogenesis during rest and one on physical activity and its relation to obesity and food intake. Finally, the roles of the endocrine system, the autonomic nervous system, and substrate handling are discussed. From this second section the reader should obtain a detailed understanding of the genetic basis of obesity; the role and control of food intake in the development of obesity; the way fat cells function as a storage, thermogenic, secretory organ; and, finally, the way in which energy expenditure is controlled and involved in the development of obesity.

The third section deals with the pathophysiology of obesity, that is, the mechanisms by which obesity produces damaging effects on health. The first two chapters in this section deal with the role of central fat and the metabolic syndrome. This is followed by a detailed discussion of the effects of obesity on a variety of individual organ systems. Three chapters are devoted to problems of the cardiovascular system and lipoprotein abnormalities, which are important consequences of obesity. Diabetes is one of the most frequent problems associated with obesity, as explained in one chapter. The ways in which obesity enhances the risk of gall bladder disease are developed in another chapter. This is followed by a clear discussion of the pulmonary problems arising from obesity, one of which (the Pickwickian syndrome, or sleep apnea) is named after the famous fat boy, Joe, in Dicken's *Pickwick Papers*. Obesity has important effects on the risk for gout and arthritis and this is discussed in a separate chapter. Two chapters in this section deal with the effects of obesity on endocrine function and pregnancy. Finally, the problem of weight cycling and the risk of intentional and unintentional weight loss are discussed in two chapters that have picked up important themes of obesity research and put them into a valuable perspective.

The final section deals with prevention and treatment. Since an ounce of prevention is worth a pound of cure, the section begins with a chapter on prevention. This is followed by a clinically useful set of guidances for

the evaluation of the overweight patient. The cornerstones for treatment of obesity—behavior therapy, diet, and exercise—are presented in three separate chapters. These are followed by three important chapters on the management of diabetes, hypertension, and hyperlipidemia in the obese individual. Finally, there is a chapter on the current status of pharmacological treatment of obesity and a chapter on the surgical approaches that can be used for an individual for whom other approaches to treatment have failed.

The preparation of this volume has required the work of many people. First, we want to thank the authors and their secretarial assistants for submitting the chapters so promptly. This will make the entire volume timely. Several individuals in the editors' office have also played key roles in moving this forward. We want to thank especially Ms. Millie Cutrer and Terry Hodges in Baton Rouge, Ms. Karen Horth and Ms. Diane Drolet in Quebec City, and Ms. Jean James in Aberdeen. The guiding hand at Marcel Dekker, Inc., who has been so valuable in nudging and cajoling us along when we needed, is Ms. Lia Pelosi. We thank you all and hope that the readers appreciate the important role each of you, and others we have not mentioned, including especially our long-suffering families, has made to the success of this volume.

*George A. Bray

## **PART I HISTORY, DEFINITIONS, AND PREVALENCE**

|  |     |
|--|-----|
| 1. Historical Framework for the Development of Ideas About Obesity<br><i>George A. Bray</i>  | 1   |
| 2. Evaluation of Total and Regional Adiposity<br><i>Steven B. Heymsfield, Richard N. Baumgartner, David B. Allison, Wei Shen, ZiMian Wang, and Robert Ross</i> | 33  |
| 3. Ethnic and Geographic Influences on Body Composition<br><i>Paul Deurenberg and Mabel Deurenberg-Yap</i>   | 81  |
| 4. Prevalence of Obesity in Adults: The Global Epidemic<br><i>Jacob C. Seidell and Aila M. Rissanen</i>  | 93  |
| 5. Fetal Origins of Obesity<br><i>David J. P. Barker</i>   | 109 |
| 6. Pediatric Overweight: An Overview<br><i>Bettylou Sherry and William H. Dietz</i>  | 117 |
| 7. Obesity in the Elderly: Prevalence, Consequences, and Treatment<br><i>Robert S. Schwartz</i>  | 135 |
| 8. Economic Costs of Obesity<br><i>Ian D. Caterson, Janet Franklin, and Graham A. Colditz</i>  | 149 |

## **PART II ETIOLOGY**

|  |     |
|--|-----|
| 9. Genetics of Human Obesity<br><i>Claude Bouchard, Louis Pérusse, Treva Rice, and D. C. Rao</i> | 157 |
|--|-----|

|     |  |     |
|-----|--|-----|
| 10. | Molecular Genetics of Rodent and Human Single Gene Mutations Affecting Body Composition<br><i>Streamson Chua, Jr., Kathleen Graham Lomax, and Rudolph L. Leibel</i>                                    | 201 |
| 11. | Rodent Models of Obesity<br><i>David A. York</i>   | 255 |
| 12. | Primates in the Study of Aging-Associated Obesity<br><i>Barbara C. Hansen</i>  | 283 |
| 13. | Behavioral Neuroscience and Obesity<br><i>Sarah F. Leibowitz and Bartley G. Hoebel</i>   | 301 |
| 14. | Experimental Studies on the Control of Food Intake<br><i>Henry S. Koopmans</i>   | 373 |
| 15. | Diet Composition and the Control of Food Intake in Humans<br><i>John E. Blundell and James Stubbs</i>  | 427 |
| 16. | Central Integration of Peripheral Signals in the Regulation of Food Intake and Energy Balance:<br>Role of Leptin and Insulin<br><i>L. Arthur Campfield, Françoise J. Smith, and Bernard Jeanrenaud</i> | 461 |
| 17. | Development of White Adipose Tissue<br><i>Gérard Ailhaud and Hans Hauner</i>   | 481 |
| 18. | Lipolysis and Lipid Mobilization in Human Adipose Tissue<br><i>Dominique Langin and Max Lafontan</i>   | 515 |
| 19. | Lipodystrophy and Lipoatrophy<br><i>Steven R. Smith</i>  | 533 |
| 20. | Uncoupling Proteins<br><i>Daniel Ricquier and Leslie P. Kozak</i>  | 539 |
| 21. | Peroxisome Proliferator-Activated Receptor $\gamma$ and the Transcriptional Control of Adipogenesis<br>and Metabolism<br><i>Lluís Fajas and Johan Auwerx</i>   | 559 |
| 22. | Biology of Visceral Adipose Tissue<br><i>Susan K. Fried and Robert R. Ross</i>   | 589 |
| 23. | Resting Energy Expenditure, Thermic Effect of Food, and Total Energy Expenditure<br><i>Yves Schutz and Eric Jéquier</i>  | 615 |
| 24. | Energy Expenditure in Physical Activity<br><i>James O. Hill, W. H. M. Saris, and James A. Levine</i>   | 631 |
| 25. | Endocrine Determinants of Obesity<br><i>Jonathan H. Pinkney and Peter G. Kopelman</i>  | 655 |
| 26. | Endocrine Determinants of Fat Distribution<br><i>Renato Pasquali, Valentina Vicennati, and Uberto Pagotto</i>  | 671 |
| 27. | Sympathoadrenal System and Metabolism<br><i>Eric Ravussin and Ian Andrew Macdonald</i>   | 693 |
| 28. | Energy Expenditure and Substrate Oxidation<br><i>Jean-Pierre Flatt and Angelo Tremblay</i>   | 705 |

|  |     |
|--|-----|
| 29. Skeletal Muscle and Obesity            | 733 |
| <i>David E. Kelley and Len Storlien</i>    |     |
| 30. Nutrient Partitioning                  | 753 |
| <i>Samyah Shadid and Michael D. Jensen</i> |     |

### PART III PATHOPHYSIOLOGY

|  |      |
|--|------|
| 31. Obesity and Mortality Rates                                    | 767  |
| <i>Kevin R. Fontaine and David B. Allison</i>                      |      |
| 32. Etiology of the Metabolic Syndrome                             | 787  |
| <i>Per Björntorp</i>   |      |
| 33. Obesity as a Risk Factor for Major Health Outcomes             | 813  |
| <i>JoAnn E. Manson, Patrick J. Skerrett, and Walter C. Willett</i> |      |
| 34. Effects of Obesity on the Cardiovascular System                | 825  |
| <i>Edward Saltzman and Peter N. Benotti</i>                        |      |
| 35. Obesity and Lipoprotein Metabolism                             | 845  |
| <i>Jean-Pierre Després and Ronald M. Krauss</i>                    |      |
| 36. Obesity and Blood Pressure Regulation                          | 873  |
| <i>Albert P. Rocchini</i>  |      |
| 37. Obesity and Diabetes   | 899  |
| <i>Jeanine Albu and F. Xavier Pi-Sunyer</i>                        |      |
| 38. Obesity and Gallbladder Disease                                | 919  |
| <i>Cynthia W. Ko and Sum P. Lee</i>                                |      |
| 39. Obesity and Pulmonary Function                                 | 935  |
| <i>Shyam Subramanian and Kingman P. Strohl</i>                     |      |
| 40. Obesity, Arthritis, and Gout                                   | 953  |
| <i>Anita Wluka, Tim D. Spector, and Flavia M. Cicuttini</i>        |      |
| 41. Obesity, Pregnancy, and Infertility                            | 967  |
| <i>Stephan Rössner</i>   |      |
| 42. Physical Activity, Obesity, and Health Outcomes                | 983  |
| <i>William J. Wilkinson and Steven N. Blair</i>                    |      |
| 43. Obesity and Quality of Life                                    | 1005 |
| <i>Donald A. Williamson and Patrick M. O'Neil</i>                  |      |

# Historical Framework for the Development of Ideas About Obesity

**George A. Bray**

Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

## I INTRODUCTION

*Religions dissipate like fog, kingdoms vanish, but the works of scientists remain for eternity.*

Ulug Beg, 15th century  
(cited in Uzbekistan:  
Macleod and Maghew, p 17.)

*We do not live in our own time alone; we carry our history within us.*

Gaarder (1:152)

*The goal of historical scholarship is said to be to reconstruct the past, but the only past available for reconstruction is that which we can see from the present. The nature of science as an analytical discipline, involved at one and the same time in the uncertainties of discovery and in the accumulation of a body of objective knowledge, raises some special problems of historical reconstruction.*

Crombie (2:4)

This last quote applies admirably to this chapter on the history of obesity “as an analytical discipline. . . and the accumulation of a body of objective knowledge.” In this chapter I will explore the historical framework in which this accumulation of a body of objective knowledge about obesity has occurred. I am not a historian and thus lack the perspective of someone trained in that

field. I am rather a practicing scientist who has tried to understand the processes of experimental science to apply them to improving my own science. In an earlier review (3) I covered a number of concepts in the history of obesity. Other historical milestones for obesity have been examined in the selections I wrote for the Classics in Obesity section of the journal *Obesity Research* (4–33). This book will build on these earlier papers and attempt to place these contributions to the field of obesity into a broader historical context (34,35).

This part of the chapter is divided into sections. The first will review the limited data on obesity in prehistoric times. The second section will consider obesity from the beginning of recorded history (ca 3600 BC) to the onset of the scientific era (ca AD 1500). The third section will cover the development of concepts about obesity in the scientific era from AD 1500 to 1900, and the fourth section will deal briefly with the 20th century. Although these divisions are arbitrary, they provide the framework that will be used in this chapter.

To facilitate placing the scientific events discussed in this chapter into a broader historical context, I have prepared a series of timelines beginning in AD 1500. Each one covers one century, and places historical developments in the fields of science and other social and political events in relation to milestones in obesity. Although the discussion will range into fields prior to the beginning of the period called the “scientific era” (AD 1500 to the present), the timeline begins

with the period which I have called the scientific era (ca AD 1500) and continues to the present. The prescientific era is defined for the purpose of this paper as prior to the development of the printing press by Gutenberg in 1456, but for convenience, it will be dated at AD 1500.

Clearly, there were many important scientific and mathematical advances before 1500 (36,37). However, the advent of printing with movable type and the appearance of the scientific method led to an accelerating rate of scientific advance after AD 1500. The timeline consists of 11 separate lines, showing developments in science and technology, anatomy and histology, physiology, chemistry/biochemistry, genetics, pharmacology, neuroscience, and clinical medicine. Observations in clinical medicine related to obesity antedate 1500, but the impact of many discoveries on scientific medicine was delayed until the beginning of the 19th century. If one wanted a demarcation line for the beginning of modern medicine, it might well be the French Revolution (1789–1800) (38,39).

## II PREHISTORIC MEDICINE (~3000 BC)

### A Paleomedicine

The study of medicine prior to written history can be done from artistic representations, from skeletal finds and related artifacts. Among the earliest evidence of man's therapeutic efforts were those aimed at the relief of fevers and burns, attempts to relieve pain and to stop bleeding. Trepanning, or drilling holes in the skulls to let out "evil spirits," to treat "epilepsy," or to relieve skull fractures, was practiced in many parts of the world up to the 19th century. The medicine man and the relation of magic and religion to healing and disease are prominent features of prehistoric medicine are present and in some rural cultures, even today. That obesity was known in this early period is evident from Stone Age artifacts.

### B Stone Age Obesity

#### 1 Paleolithic Artifact

Table 1 is a list of several artifacts from the paleolithic stone age that depict obesity. These artifacts were found across Europe from southwestern France to Russia north of the Black Sea. The location in which they were found and their appearance is shown in Figure 1. They were produced during a fairly narrow time frame in the early Upper Paleolithic period (Upper Perigordian or Gravettian) some 23,000–25,000 years ago (40). They

**Table 1** Paleolithic Venus Figurines with Prominent Obesity

| Place found                     | Number found | Height  | Composition |
|---------------------------------|--------------|---------|-------------|
| Willendorf, Austria             | One          | 11 cm   | Limestone   |
| Dolni Vestonice, Czechoslovakia | Many         | 11.4 cm | Terracotta  |
| Savignano, Italy                | One          | 24 cm   | Serpentine  |
| Lespugue, France                | One          | 14.7 cm | Ivory       |
| Grimaldi, France                | Many         |         | Terracotta  |
| Laussel, France                 | Many         | 40 cm   | Terracotta  |
| Kostenki, Russia                | Many         | 47 cm   | Ivory       |
| Gagarino, Russia                | Many         |         | Ivory       |

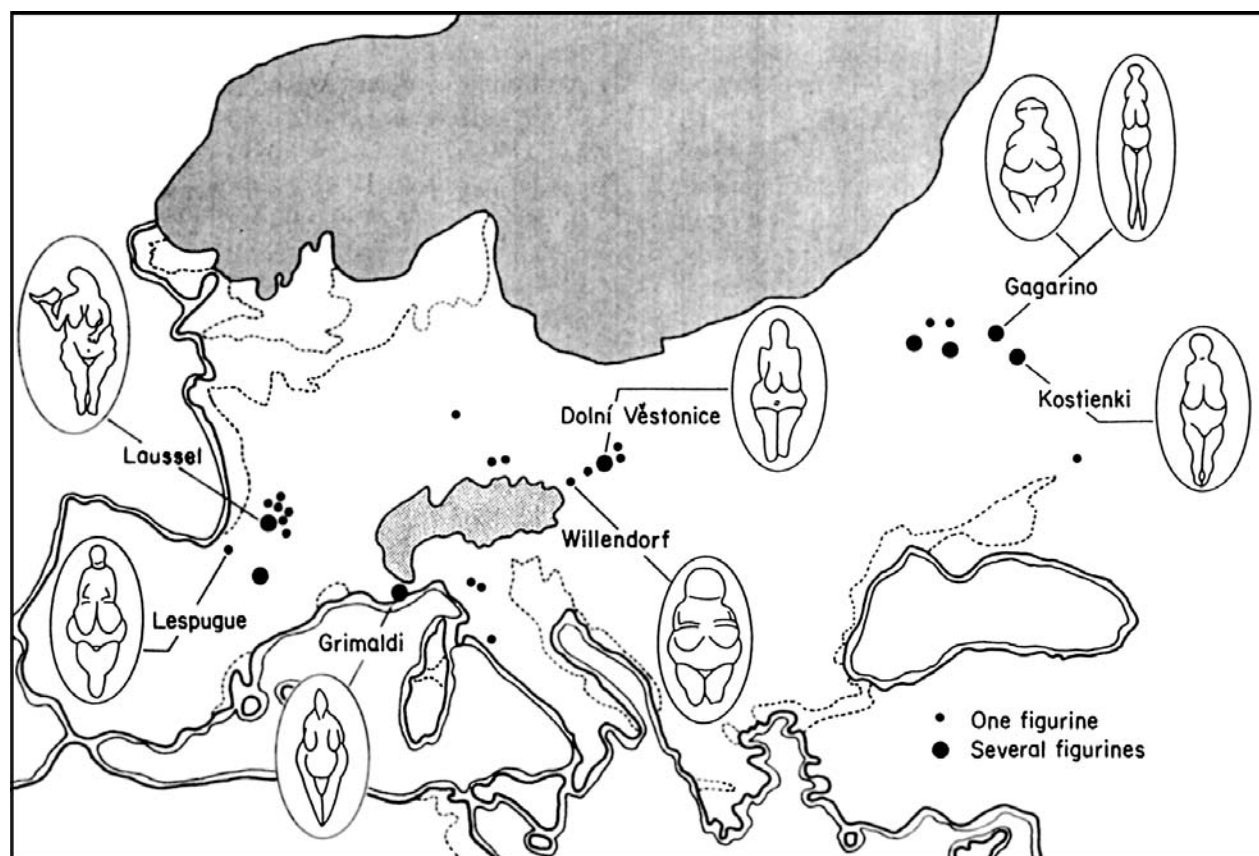

are distributed over > 2000 km from west to east. Their composition is ivory, limestone, or terracotta (baked clay). The most famous of these is the Venus of Willendorf, a small statuette measuring 12 cm in height with evidence of abdominal obesity and pendulous breasts (41). The similarity in design of these artifacts as shown in Figure 2 suggests that there may have been communication across Europe during this period of glaciation.

This and the other paleolithic female figurines are frequently viewed as primordial female deities, reflecting the bounty of the earth (42). In a review of historical ideas published as a thesis in 1939, Hautin (43) concludes that these figures prove the existence of obesity in the paleolithic era and that they also symbolize the expression and possible esthetic ideals of the period. "The women immortalized in stone age sculpture were fat; there is no other word for it. . . [O]besity was already a fact of life for paleolithic man—or at least for paleolithic woman" (42).

#### 2 Neolithic Artifacts

The Neolithic period spans the time from 8000 BC to ca 5500 BC. This period saw the introduction of agriculture and establishment of human settlements. The Neolithic age and the Chalcolithic or Copper age, which continued to 3000 BC, were notable for numerous Mother Goddess artifacts found primarily in Anatolia (currently Turkey). The richest finds are from the excavations at Catalhoyuk and Hacilar and are from the period between 5000 and 6000 BC. Most of these figurines are made of terracotta, but a few are of limestone or alabaster. Their corpulence is abundantly evident in the pendulous breasts and large abdomino-gluteal areas. They range in height from 2.5 to 24 cm, but most are between 5 and 12 cm. They are seated,

**Figure 1** Map showing location of the paleolithic “Venus” figurines. Note that obese figurines have been found throughout Europe and in the Middle East.

standing, or lying. One of the most famous from Catalhoyuk is 20 cm tall. She sits on a throne with two lions serving as her arm rests. The figurines from this period show exaggeration of the hips, belly, and breasts, with genital areas indicated by triangular decoration, symbolizing motherhood and womankind, attributes which are shared by later Mother Goddess figurines from Kybele to Artemis. It is important to note that no deity or mythological figure has ever borne as many different names as the Mother Goddess. On the Kultepe tablets (1800 BC) she is known as Kubaba; the Lydians called her Kybebe; the Phrygians, Kybele; and the Hittites, Hapat. In ancient Pontic Comana (near Tokat) and Cappadocian Comana (Kayseri), she was known by the ancient Anatolian name of Ma. She was Marienna and Lat to the Sumerians, Arinna to the people of the Late Hittite period, Isis to the Egyptians, Rhea to the Greeks, Artemis to the Ephesians, and Venus to the Romans. The name Kybele has even survived into modern times as the Anglo-Saxon Sybil and its variants, and Turkish

Sibel. At Catalhoyuk she is depicted as giving birth to a child; at Hacilar she is holding a child. This child is represented in later mythology by gods such as Attis, Adonis, and Tammuz (44).

### III MEDICINE AND OBESITY FROM RECORDED HISTORY TO AD 1500 (PRESCIENTIFIC MEDICINE)

Medical traditions have developed in all cultures. Several of these are described below, along with evidence that obesity was present. Evidence for obesity has been identified in all of these medical traditions and geographic regions, suggesting that independent of diet, the potential to store nutrients as fat was selected for by evolution at an early period in human development.

Medical traditions are an integral part of all societies. Many factors influence the cultural sophistica-

**Figure 2** Similarity in design of the “Venus” figurines. All of the figures identified have similar structural features, although they were composed of several different materials. This similarity suggests that there may have been communication or migration among these sites during the Upper Paleolithic period.

tion achieved by these societies, including agricultural practices, development of writing and metallurgy, and the political climate. Several of the most sophisticated cultures have developed between two great river systems, and this has given rise to the two-rivers hypothesis of cultural development. These rivers are the Yellow River and the Yangtse River in China; the Ganges and Indus Rivers in India; the Amu Darya and Syr Darya Rivers in Central Asia; and the Tigris and Euphrates Rivers in the fertile crescent of the Middle East. In all of these societies, whether in two rivers or otherwise, there have been many examples of “obesity.”

### A Mesopotamian Medicine

The Tigris and Euphrates River basin was the land of healers and astrologers. Cuneiform writing, libraries, sanitation, and medical knowledge are evident by 3600

BC. Of the 30,000 clay tablets with cuneiform writing that were recovered in the library at Ninevah from ca 2000 BC, 800 are related to medical matters. The medical armamentarium of Sumerian physicians consisted of more than 120 minerals and 250 herbs including cannabis, mustard, mandragora, belladonna, and henbane (45). A terracotta statuette showing enormously fat thighs and arms was found at Susa in the middle Elamite period in the 12th century BC (46,47), indicates the continuing representation of obesity in artifacts of the female body.

### B Egyptian Medicine

Paralleling the Mesopotamian medical tradition was the tradition of medicine in Egypt where the relationship between priests and physicians was very close. Imhotep, who became the god of healing, began as a Visier to King Zoser (2900 BC). Imhotep was a man of great accomplishment who in addition to being a physician was an architect, a poet, and a statesman. Two major archeological finds, the Edwin Smith papyrus (48), written between 2500 and 2000 BC, and the Ebers papyrus, written ca 1550 BC, provide major knowledge about medicine in Egypt. Obesity was known to the Egyptians. A study of royal mummies showed that both stout women (Queens Henut-Tawy and Inhapy) and stout men were not uncommon in Egypt, at least not among the higher classes, although “obesity was regarded as objectionable” (49). Several examples of obesity are also seen in the stone reliefs which were the principal artistic medium. A doorkeeper in the temple of Amon-Ra Khor-en-Khonsu; a cook in Ankh-ma-Hor’s tomb (6th dynasty) (50); a fat man enjoying food presented to him by his lean servants in Mereruka’s tomb; the local yeoman, the famed Sheikh et Balad (49); and the grossly obese harpist playing before the prince Aki (Middle Kingdom) (51). Studies of the skinfolds of mummies such as Amenophis III and Ramses III show that they were fat (51). One of the most interesting figures is that of the Queen of Punt from the temple of Queen Hatshepsut, Deir el-Bahri (18th dynasty). She has marked steatopygia and appears to have shortening of the lower extremities, suggesting dyschondroplasia or dislocated hips (49–52).

### C Chinese and Tibetan Medicine

The early Chinese believed that disease was sent by the gods or by demons. Bone inscriptions indicate the presence of leprosy, typhoid fever, cholera, and plague. Anatomic dissection was not permitted because of

ancestor worship. The Yellow Emperor (Huang Di) and the Divine Farmer (Shen Nong Bencaojing) are the legendary founders of Chinese Medicine (53). The Chinese pharmacopeia contains 365 herbal medicines. The Hung Tu Hei Ching (Yellow Emperor's Inner Canon) dates from 200 BC and is a dialogue on bodily functions and disease. In China, Zhang Zhongjing was considered the Father of Medicine, the equivalent of Hippocrates in Greece. Zhang described symptoms and treatment for many diseases. Hua Toh (3rd century AD) is the only known surgeon from ancient China. Acupuncture, the art of treatment by inserting sharp needles into the body, was developed and reached its zenith in China. This technique of placing sharp objects in the pinna of the ear to reduce "appetite" has been used to treat obesity.

The Tibetan offspring of the Chinese Tradition is beautifully illustrated in the 17th-century treatise *The Blue Beryl*, composed by Sangye Gyamtso, the scholar and regent of Tibet. It is an erudite yet practical commentary on the ancient text entitled *The Four Tantras* (54). In this text obesity is described as a condition requiring catabolic treatment. It also notes that "overeating. . . causes illness and shortens life span. It is a contraindication to the use of compresses or mild enemas." For treatment of obesity two suggestions are made: "The vigorous massage of the body with pea flour counteracts phlegm diseases and obesity. . . . The gullet, hair compress and flesh of a wolf remedy goiters, dropsy and obesity" (54).

#### D Indian Medicine

The fourth great medical tradition is that of Indian medicine (53). In the sacred medical texts of Ayurvedic medicine, sin was viewed as the cause of disease, and medical knowledge was closely interwoven with religion and magic. The Caraka Samhita was the first document on Indian medicine, and the Susruta Samhita was the second great medical Sanskrit text. The Caraka Samhita described 20 sharp and 101 blunt instruments as well as an operating table. At least 500 drugs are listed along with 700 medicinal herbs including, among others, cinnamon, borax, castor oil, ginger, and sodium carbonate. The Ayurveda recommended the administration of testicular tissue (organotherapy) as a cure for impotence as well as for obesity (55).

#### E Meso-American medicine

Prior to the "discovery" of the New World by Columbus in 1492, there were three high cultures in the Meso-

American world. The Incas occupied the highlands along the west coast of what is now Peru. The Mayan culture occupied the Yucatan Peninsula and surrounding areas of Central America, and the Aztecs controlled the central plateaus of Central America. When Columbus, Cortez, and their compatriots arrived in the new world, the Meso-American cultures were exposed to several devastating diseases, including measles, smallpox, and chickenpox, which were more lethal than the military armaments the invaders brought. The Pre-Columbian Americans still lived in a Stone Age culture, but were highly sophisticated in their knowledge of mathematics, astronomy, and language. Among the most useful drugs discovered in the New World was the Cinchona bark (quinine), which was used to treat fevers, including malaria. Diseases were believed to be caused by supernatural, magical, and natural causes. Treatment was related to the cause (56). One of the sources of information about disease in Pre-Columbian societies is their sculptured artifacts. These figurines represent malnutrition, deformity, and physical illness (57). Some of the individuals represent people suffering from various diseases including spinal defects, endemic goiter, obesity, eye diseases, and skin ailments (57).

#### F Greco-Roman Medicine

From the vantage point of Western civilization, Greco-Roman medicine has been the major source of our medical tradition. The health hazards associated with obesity were clearly noted in the medical writings of Hippocrates, where he states, "Sudden death is more common in those who are naturally fat than in the lean" (58). These traditions also note that obesity was a cause of infertility in women and that the frequency of menses was reduced in the obese.

Galen was the leading physician of Roman times. His influence on medicine and medical teaching lasted more than 1000 years. He identified two types of obesity, one he called "moderate" and the other "immoderate." The former is regarded as natural and the other as morbid.

Descriptions of sleep apnea associated with obesity also date from Roman times. Dionysius, the tyrant of Heracleia of Pontius, who reigned ca 360 BC, is one of the first historical figures afflicted with obesity and somnolence. This enormously fat man frequently fell asleep. His servants used long needles inserted through his skin and fat to awaken him when he fell asleep. Kryger cites a second case of Magas, King of Cyrene, who died in 258 BC. He was a man "weighted down

with monstrous masses of flesh in his last days; in fact he choked himself to death” (59,60).

## G Arabic Medicine

With a decline of Roman influence after AD 400, scholarly activity shifted from Rome to Byzantium and then to the broader Arabic world following the rise of Islam in the 7th century. One of the leading figures of this medical tradition was Abu Ali Ibn Sina, or Avicenna in its Westernized form. Like Galen, he was an influential author who published more than 40 medical works and 145 works on philosophy, logic, theology, and other subjects. Obesity was well known to this Arabic physician. His approach to treating obesity is described later.

With increasing trade and travel, the European culture gradually reestablished contact with Arabian medicine and the Roman traditions it absorbed. Both the Crusades and the invasions by the Arabs of the Peloponessus and southern Spain brought an infusion of classical knowledge from which came the Renaissance and the beginning of the “scientific era” (2,61).

## IV SCIENTIFIC MEDICINE (1500 TO PRESENT)

The remainder of this chapter will focus on science and medicine since 1500. Medieval science (1150–1450) was constrained by the earlier Greek paradigm of Aristotelian science and the Arabic renderings of these teachings by Avicenna. With the introduction of instruments such as the mechanical watch, the magnetic compass, and the magnifying glass, it became possible to quantify and critically examine some features of human experience and the underlying philosophical tradition. Out of this interaction grew the experimental method of verification and falsification which provides the basis of the Scientific Era (62).

In the following sections, I will review each of the major areas that affect the development of the “science of obesity.” To put this in the broader context, the reader is referred to the timeline in Figures 3–7.

### A Anatomy

The date 1543 is pivotal in the story of anatomy and for scientific thought in general. That was the year that Vesalius published his treatise on human anatomy (63), the first truly modern anatomy based on his own

dissections. Andreas Vesalius was only 28 years old when he published his masterpiece. In 1543, Copernicus (64) also published his book on the solar system, arguing that planets revolved around the sun. In his accurate and careful dissections, Vesalius showed that the human body could be directly explored by appropriate experimental methods. In so doing, he applied the concept of direct verification and experimental manipulation and identified a number of inaccuracies in the anatomy of Galen, which appears to have been based on animal dissections and treatment of wounded gladiators.

A key element in communicating these discoveries, including those of Vesalius and Copernicus, was the process of movable type and printing invented by Gutenberg. This technical development was followed by the steady distribution of printing presses throughout Europe over the next 50 years. The printing press made classical literature widely available and made it possible to communicate original observations to an ever-growing audience in a relatively short time, as contrasted to handwritten books. The revolution in communication had begun, and the age of anatomy, ushered in at the beginning of the 16th century, expanded rapidly. This was also the peak of the Renaissance. Up to the 16th century, Galen and his writings from Roman times and the Canons of Avicenna from Arabic medicine had been the main source of information about anatomy, physiology, and clinical medicine. Although there is no clear evidence that either Galen or Avicenna ever dissected a human cadaver, their influence was only broken by the application of direct observation and verification after hundreds of years.

The first anatomical dissections of obese individuals are attributed to Bonetus (65). Other descriptions appear in the publications by Morgagni (66), by Haller (67,68), and most particularly by Wadd (69). Of the 12 cases presented in Wadd’s book, *Comments on Corpulency, Lineaments of Leanness*, two had been examined at postmortem and had been found to have enormous accumulations of fat. This was the first instance of a monograph devoted to obesity that contained anatomical dissections.

### B Microscopic Anatomy (Histology)

The invention of the microscope in the 17th century moved anatomy to the next level. By the middle decades of the 17th century, early microscopists had begun to publish the results of their histologic investigation using simple microscopes. The important initial observations by Malpighi (70), Hooke (71), and Leeuwenhoek (72)

| TIMELINE 1500 - 1600   |                                   |  |  |  |   |  |  |   |  |

Figure 4 Timeline for developments in science, obesity, and contemporary events in the 17th century.

| TIMELINE 1700 - 1800  |   |  |  |  |  |   |   |  |  |
|---|---|--|--|--|--|---|---|--|--|
| Science and Technology  |   | 1714-Fahrenheit invents 212° temperature scale |  | 1735 - Linnaeus publishes <i>Systema Natura</i> (plant classification) |  | 1742 - Celsius invents 100° scale       |   | 1770 - Watts invents steam engine                            | 1793- Whitney invents cotton gin             |
| Anatomy and Histology   |   |  | 1733-Cheselden <i>Osteographa</i>                  |  | 1761 - Morgagni publishes <i>The Seats and Causes of Disease</i> |   | 1774-William Hunter publishes <i>Gravid Uterus</i>        |  |  |
| Physiology  |   |  | 1726 - Hales - first measurement of blood pressure |  | 1752-Reamur, digestion of food                                   |   | 1759-66 - Haller publishes <i>Prima Linæ Physiologiae</i> | 1777 - Lavoisier describes respiratory gas exchange          |  |
| Chemistry / Biochemistry  | 1708 - Stahl enunciates phlogiston theory |  | 1732 - Boerhaave publishes <i>Elementa Chemiae</i> |  | 1766-Cavendish discovers hydrogen                                |   | 1771 - Priestly and Scheele discover oxygen               | 1781-Cavendish synthesizes water                             | 1784 - Lavoisier develops oxygen theory      |
| Genetics  |   |  |  |  |  |   |   |  |  |
| Pharmacology  |   |  | 1730 - Frobenius makes "ether"                     |  |  |   |   | 1785 - Withering describes foxglove (digitalis) for "Dropsy" |  |
| Neuroscience  |   |  |  |  | 1753 - Haller describes sensibility of nerves                    |   |   | 1791- Galvani animal electricity                             |  |
| Clinical Medicine   |   | 1721 - Philadelphia Hospital founded           | 1727-Short: <i>First Monograph on Corpulence</i>   | 1751-Pennsylvania Hosp. founded  | 1753-Lind's <i>Treatise on Scurvy</i>                            | 1768-Heberden describes angina pectoris | 1778-Mesmerism demonstrated in Paris                      | 1796 - Jenner, small Pox vaccination                         |  |
|   |   |  |  |  | 1760-Fleming's book <i>Corpulency</i>                            | 1761-Auenbrugger on percussion          | 1786-Hunter on venereal disease                           | 1787-Harvard Med. Sch founded                                |  |

Figure 7 Timeline for developments in science, obesity, and contemporary events in the 20th century.

identified the pulmonary circulation, the fine structure of small animals and red blood cells, among others.

Gradually, the sophistication of the microscope improved, first with the introduction of the compound microscope and then with achromatic lenses. These developments made microscopes sufficiently powerful to define intracellular structures. This led to the concept of the "cell" as the basic unit of life by the middle of the 19th century. It was the combination of the compound achromatic microscope, which allowed sufficient resolution to distinguish the multiple intracellular components of cells, coupled with the intellectual genius of Schwann (73) and of Schleiden (74) that recognized the unifying principles of the cell wall, nucleus, and an area of structures surrounding this nucleus as the basic elements of cell biology. Shortly afterward, the first substantial textbooks of microscopic anatomy were published (75,76), and shortly after that, the recognition of the fat cell as a member of this group. A description of the growth and development of fat cells was published in 1879 by Hoggan and Hogan (77). In his early observations on the development of the fat vesicle, Hassall (78) suggested that certain types of obesity might result from an increased number of fat cells. It was more than a century later that the work of Bjurlf (79), of Hirsch (80), and of Bjorntorp (81) elaborated this important concept as the "hyperplastic" form of obesity. Within 20 years following the promulgation of the cellular theory of biology (73,74), Virchow (82) provided a cellular interpretation of pathology. The next advance in microscopic anatomy was the introduction of the electron microscope by Knoll and Ruska in 1932 (83), which has provided a detailed look at all elements of the fat cell (84).

### C Physiology

The application of experimental methods is nowhere better illustrated than in the discovery of the circulation of the blood by William Harvey in 1616, which he published in 1628 (85). His theory is monumental in the way that experimental observations and human reasoning were brought together. His theory of the circulation of the blood was published before the capillaries that connect the arterial and venous circulations had been described (70). While in medical school in Padua, Harvey had seen his professor, Fabrizio of Aquapendente, demonstrate the presence of valves in the veins that only allowed blood to flow one way. At some point between his graduation from Padua in 1596 and his anatomic dissections at the Royal College of Physicians in London in 1616, he realized the impor-

tance of the valves in the veins (86). He presented his "discovery" to the Royal College of Physicians in 1616 to a ho-hum reception. Gradually, the importance of the discovery and of the method by which he argued its cogency became apparent. He demonstrated experimentally that the valves in the veins allowed blood to travel in only one direction. From the limited quantity of blood in the body, he argued that the blood must circulate and be reused. It was, however, not for another 50 years that the capillary circulation was demonstrated by Malpighi (70).

The early physiological studies by Harvey on the circulation of the blood set the stage for further work in physiology. Two of these themes are particularly relevant to obesity. The first is metabolism and the second digestion. In 1614, Santorio (87,88) described his metabolic balance, a pulse watch for measuring the pulse and a way of measuring temperature. He was following the dictum of his contemporary, Gallileo, who said: "Measure what can be measured, and make measurable what cannot be measured" (1). The balance that Santorio constructed consisted of a platform on which he could sit, counterbalanced by a beam to which weight could be added or subtracted to record changes in his weight related to bodily functions. With this system, he could measure his food intake and his excretory losses. In more recent times, Newburgh and his colleagues (89) used a similar method to record the loss of water with respiration and showed that it accounted for ~24% of the heat produced by the body. The seminal contributions to metabolic work qualify Santorio Santorio for the title of Father of Metabolic Obesity.

The second group of physiological studies that relate to obesity were those on the gastrointestinal tract and digestion. In 1752, Reamur (90) succeeded in isolating the gastric juice from his pet kite and showed that it digested food. Later in the 18th century, Spallanzani (91,92) showed that gastric juice would digest food and prevent putrefaction outside the body. The American William Beaumont (93) published data from his direct observation of digestion made possible by studies of a patient, Alexis St. Martin, who suffered a bullet wound in his abdomen that healed with a fistula allowing direct observation of the stomach and its contents (93). Understanding of the way food was digested and absorbed was advanced by Magendie and his distinguished pupil Claude Bernard, one of the leaders of the French physiological school. It was Bernard who demonstrated the digestive function of the pancreas (94).

These 18th- and 19th-century observations on digestion were followed in the early 20th-century by the seminal and long-lasting theory that hunger resulted

from gastric contractions. This theory was based on direct measurements of the association of gastric contraction with hunger by Washburn and Cannon (95) and independently by Carlson (96).

#### D Chemistry and Biochemistry

Modern chemistry might be traced to the 17th century work of Robert Boyle, who established the concept of chemical elements (97,98). By the late 17th century, Boyle (98) recognized that when a lighted candle went out, a mouse living in the same environment rapidly died. It was clear that some important element was present in the air that was essential for life and for the candle to burn. At the beginning of the 18th century, Georg Stahl (99) postulated that this substance was phlogiston. It was not until the work of Priestley (100), of Scheele (who simultaneously discovered what we now call oxygen) (101), and particularly of Lavoisier (102), that the Phlogiston Theory was replaced by the Oxygen Theory of Combustion.

The Oxygen Theory culminated from the research of Lavoisier in the last three decades of the 18th century. Lavoisier recognized that oxidation meant combining with oxygen. His experimental work showed that metabolism was similar to combustion (102). Lavoisier's death at the hands of Revolutionary French government in 1794 deprived humanity of one of its great intellects.

The legacy of Lavoisier from the 18th century served as the basis for the laws of the conservation of mass and energy (103) and formed the basis for the work of Rubner (104,105), who formulated the Law of Surface Area based on the observation of a linear relationship between metabolic expenditure of animals of many sizes and their surface area [body weight]<sup>0.7</sup>. This Law of Surface Area and the work of Voit and Pettenkofer (106) in Germany were the framework on which Atwater and Rossa constructed the first functional human calorimeter at Wesleyan College in Middletown, CT, in 1896 (107). The instrument served as a tool for extensive studies on metabolic requirements during food intake and on the effects of starvation by Atwater (108) and by Benedict (109,110).

Following the work of Atwater and Benedict in the early 20th century, studies using metabolic chambers languished until after World War II. The earliest of these post-World War II chambers was built in Paris, France, and at the National Institutes of Health in Bethesda, MD. However, it was the chamber built in Lausanne, Switzerland, by Jequier (111) that provided the most extensive and continuing series of studies on

energy expenditure in human subjects in the post-World War II period. This chamber and similar units built in Phoenix, AZ, are patterned after the one in Lausanne and the one in London built by Garrow (112), have shown that for human beings, fat-free mass provides a slightly better relationship for energy expenditure than surface area. Utilizing this information, several predictors of obesity have been developed including a low metabolic rate, a high rate of carbohydrate oxidation as indicated by a high RQ, and insulin sensitivity (113).

The study of energy expenditure in human beings and animals has advanced rapidly in the past two decades following the introduction of doubly labeled water as a technique for measuring total energy expenditure in free-living subjects (114). Doubly labeled water measures energy expenditure by following the path of deuterium and oxygen through the metabolic pathways in the body. Deuterium can only be excreted as water, while <sup>18</sup>O can be excreted as water or as carbon dioxide following respiratory combustion of carbon containing compounds. Thus, the ratio of deuterium to <sup>18</sup>O gradually diverges following the administration of these isotopes as water, and this rate of diversion can be used to calculate energy expenditure if the respiratory quotient is known. Application of this technique to human beings shows that overweight people underestimate their dietary intake more than do normal-weight people (111,115). This tool has provided a new paradigm in which to assess energy needs and questions the validity of data obtained from dietary records.

The chemistry of biological systems was the natural outgrowth of chemistry. The term "biology," as the study of living things with the "cell" as its basal unit, was a 19th-century concept. Biological chemistry or biochemistry is also a 19th-century concept that may be dated from the demonstration by Wohler (116) in 1828 that urea, an organic molecule, could be synthesized from inorganic materials.

The study of body composition was also an important 19th-century contribution to the biochemistry of obesity. Chemical analysis of human cadavers was conducted, and the fat stores in adipose tissue were demonstrated to be primarily triglyceride (116).

Biological chemistry in the mid-19th century was dominated by Claude Bernard (117) and his teacher Magendie (118) France and by Liebig and his studies of food chemistry in Germany (119). Magendie was a leader in the application of the experimental method to the study of living animals. His pupil, Claude Bernard, discovered liver glycogen as the source of blood glucose (117). He also showed that damage

(pique) to the hypothalamus could produce glycosuria. His scientific philosophy was one of “gradualism.” Scientific theory would naturally lead to step-by-step progress, a concept that was a dominant element in the 19th-century philosophy of science. This concept of gradualism is in sharp contrast to the concept of paradigm shifts (120) and scientific revolutions (121) (see Sec. V).

Claude Bernard’s contemporary in Germany was Liebig. His concept that the carbohydrates, proteins, and fat were all that were needed for human nutrition served as the basis for nutritional science during much of the 19th century. Overthrow of this theory by the discovery of vitamins at the turn of the 20th century gave birth to a new and broader field of nutrition (122). The development of nutrition through the first half of the 20th century is epitomized by the discovery of vitamins and their function. This era largely closed in 1948 with the elucidation of the structure of vitamin B<sub>12</sub>. With the closing of this era, the impact of macronutrients again took center stage through the recognition of the role of dietary fats and obesity as “causes” of chronic disease (123,124).

The 20th century saw an explosion in the application of chemical and biochemical techniques to the study of obesity. Sophistication in the measurement of body components has greatly expanded. The work by Benke, Feen, and Wellman applied the techniques of density for quantitating the fat and nonfat compartments of the body (125). This methodology has been supplemented since World War II by the application of radioactive isotopes (126) to the study of body composition by many workers (127). New techniques have continued to provide ever better ways of characterizing the human body. Radioactive isotopes have largely been replaced by stable isotopes. The introduction of ultrasound for measuring fat thickness, of computed axial tomographic (CT) scans, and magnetic resonance imaging (MRI) scans to measure regional fat distribution, the use of dual-energy x-ray absorptiometry to measure body fat, lean body compartments, and bone mineral, and the use of whole body neutron activation have provided sophisticated techniques for accurate and detailed determination of body composition in vivo (128).

## E Genetics and Molecular Biology

The setting for the biological revolution of the last quarter of the 20th century had its roots in the mid-19th century with the publication by Darwin of the *Origin of the Species* (129) and by Mendel of the unitized

inheritable traits subsequently called genes (130). In the early 20th century, Garrod suggested the concept of “metabolic” disorders in a classic monograph (131). Genetic work was greatly aided by the use of the fruitfly, *Drosophila*, with their giant chromosomes, and of mice, whose breeding cycle was relatively short. Gradually, genetic material was traced to the nucleus and to deoxyribonucleic acid (DNA). A new field of molecular biology was born from the seminal work of Watson and Crick published in 1953 (132), who proposed the double-helix model for the structure of this DNA leading to the “cracking” of the genetic code and the development of the tools of molecular biology. With these techniques it became possible to identify and isolate the genes underlying the rare forms of inherited obesity in animals and human beings (133–135). The Human Genome Project has now completed the sequencing of all of the genes in *Drosophila melanogaster* (136) and the human genome.

The first genetic breakthrough in the study of obesity came in 1992 with the identification of the genetic defect in a mouse called the Yellow Obese mouse. The agouti gene that produces this defect provides the information to make a 133-amino acid peptide (133). In the Yellow Obese mouse, the agouti gene is expressed in many tissues where it is not normally expressed. The resulting agouti protein serves as a competitor for melanocortin receptors and through this mechanism can account for the yellow coat color, hyperphagia, and obesity present in these animals.

Shortly after the discovery of the agouti gene, the genetic defect in the ob/ob mouse was identified (134). The ob gene is altered with a stop message (codon) at amino acid 105. This truncates the normal 167-amino acid protein called leptin. Leptin in the normal animal appears to signal the brain about the state of peripheral fat stores and their adequacy for reproduction. Leptin is also involved in modulating a number of other steroid messages. In the obese (ob/ob) mouse, leptin will reverse the obesity and correct the other defects.

The third obesity gene to be cloned was the gene for the recessively inherited FAT mouse (135). The nature of this gene defect was suspected from the high levels of pro-insulin in these animals. Cleavage of insulin to proinsulin requires the enzyme carboxypeptidase-E. It was subsequently determined that this gene was defective, resulting in defective synthesis of hormones and neuromediators, from pro-hormones and pro-neuromediators.

Genetic susceptibility for human obesity has also benefited from the advances in genetics and molecular biology (136). Beginning with the work of Davenport

(137) on the inheritance of body mass index in families and the work of Verscheuer on identical twins (138), a growing body of data argues that important components of total body fat mass and fat distribution are inherited (139,140). From this basis in epidemiological data, a search has begun for the genes involved in human (141) and animal forms of obesity. From the studies of responsiveness to dietary fat in animals, at least 12 different genes have been identified as playing a role (142,143). In human beings, a large and growing number of candidate genes have been explored for their possible relationship with the development of obesity and several have been shown to contribute in small ways to this syndrome (141).

## F Pharmacology

The field of pharmacology, the study of drugs and their biological effects, grew from a base in chemistry (144) and the early findings in biology. Its early successes included the isolation of morphine, strychnine, emetine, and quinine, and the publication of the first *Pharmacopoeia* by Magendie in 1822 (145). One of the major advances in this field in the 19th century was the introduction of anesthesia, which was discovered almost simultaneously by three Americans—Crawford Long, W.T.G. Morton, and Horace Wells—between 1842 and 1846 (146–148). The first effective public demonstration was given in the Ether Dome of the Massachusetts General Hospital in Boston in October 1846. This was followed by the introduction of carbolic acid to reduce infection in the operating room by Sir Joseph Lister in 1865 (149,150).

The 19th century also saw a number of efforts at “pharmacologic” treatment of obesity. Among these were the use of hydrotherapy and various laxatives and purgatives. Thyroid extract was also initially used to treat obesity in the late 19th century, beginning in 1893 (151).

A key element in the entire field of pharmacology was the discovery of aniline in the 19th century (152). Developed by the dye industry, aniline served as the base for synthesizing numerous drugs in the 20th century and for the “magic bullet” concept of Ehrlich (153). Dinitrophenol was one of those aniline products. It was introduced for treatment of obesity, when weight loss was noted in workers in the chemical industry who handled dinitrophenol. This drug was subsequently abandoned after it produced cataracts and neuropathy. This tragedy of treatment shows the need for careful clinical evaluation of drugs before they are made available for general clinical use (154).

Amphetamine was a second product of the synthetic organic chemical industry that was used for treatment of obesity. In the 1930s, dextroamphetamine, which was synthesized in 1887 (155), was shown to produce weight loss in individuals being treated for narcolepsy (156). Because amphetamine is addictive, it fell into disrepute and led to a negative view of all drugs with a similar chemical structure. However, the similarity of chemical structure on paper proved misleading pharmacologically. The  $\beta$ -phenethylamine chemical structure is the backbone of amphetamine ( $\alpha$ -methyl- $\beta$ -phenethylamine). Amphetamine affects two neurotransmitters, dopamine and norepinephrine. Modifying the  $\beta$ -phenethylamine structure can completely change the effect on neurotransmitters. Phentermine is a  $\beta$ -phenethylamine cousin of amphetamine that affects primarily norepinephrine. Fenfluramine, another  $\beta$ -phenethylamine cousin, is pharmacologically unrelated to amphetamine since it only affects serotonin.

## G Neuroscience

A neural basis for some kinds of obesity became evident at the beginning of the 20th century. The case reports by Babinski (157) and by Frohlich (158) were preceded by a case reported by Mohr (159). Each report described single individuals who developed obesity in association with a tumor at the base of the brain. This important clinical finding opened a new field of research and heralded the development of techniques to produce obesity by injection of toxic material such as chromic oxide at the base of the brain (160) or, more specifically, by localized electrolytic or thermal damage to specific hypothalamic nuclei (161). Such a specific anatomic localization of hypothalamic centers where damage would produce either increased food intake (damage to ventromedial hypothalamus) or decreased food intake (damage to lateral hypothalamus) (162) led, in 1954, to the dual center hypotheses of Stellar (163), which served as the basis for thinking about hunger and satiety for the next 20 years.

It soon became clear that hyperphagia was not essential for the development of obesity after a hypothalamic lesion (164) or in genetically obese mice (165). One explanation for the development of obesity without hyperphagia was provided by the autonomic hypothesis (166) based on the observations of increased activity of the parasympathetic nervous system (vagus nerve) (167) and reduced activity of the sympathetic nervous system (168). This insight, coupled with the role of brown adipose tissue and

the thermogenic component of the sympathetic nervous system in heat generation in small animals and in inhibiting food intake, has been central to the development of  $\beta$ -adrenergic drugs as potential agents for treating obesity (169).

The discovery of a number of peptides that are present in both the brain and the gastrointestinal tract has brought together the areas of neuroscience and physiology in the control of body fat and obesity. Secretin was the first GI hormone found (170). Subsequently, cholecystikinin was found to stimulate contraction of the gallbladder and then to reduce food intake (171). Of the many peptides now known, neuropeptide-Y is among the more interesting because it will stimulate food intake and produce obesity when given continuously (172).

## H Clinical Medicine and Obesity

Well before the Scientific Era, which I have dated as beginning in AD 1500, individuals with massive obesity have been noteworthy. Table 2 lists some of the largest individuals on record. Cases of monstrous obesity have been noted since antiquity (59,60,173,174). In the 19th century, Dubourg (175) discussed 25 cases, Schindler (176) identified 17 such cases, and Maccary 11 (177). Individual cases have also been reported by many other authors (178–187). These individuals were frequently noted for their “odd” or “monstrous” appearance. The outlook for this group was particularly bleak from both a clinical and a social perspective.

These case reports beg a very important question that has only recently begun to be answered: Are all cases of obesity the same? Classification of obesity can be viewed as one component of the more general efforts to classify diseases that began when Galen labeled them moderate or immoderate. Although many classifications of disease exist, one of the most interesting was the effort to classify disease based on the classification of plants and animals introduced by Linnaeus (188). His system involved giving each individual a genus and species name and categorizing the genera into classes, orders, and phyla. Although Sydenham began such a systematic classification of disease, the two best-known efforts to classify diseases in this way were published by Sauvages (189) and Cullen (190). In both of them obesity was called “polysarcie.” In the English translation of Cullen’s work, Obesity is in Class III, The Cachexias: It is listed under the second order called Intumescenciae with a genus name of *Polysarcia* (*Corporis pinguedinosa intumescencia molesta*). Obesity, as a word to describe increased fatness, gradually replaced

**Table 2** Cases of Extraordinary Obesity

| Name       | Gender | Age at death | Maximum weight (kg) | Ref.  |
|------------|--------|--------------|---------------------|-------|
| Lambert    | M      | 39           | 335                 | (1)   |
| Bright     | M      |              | 280                 | (182) |
| Darden     | M      | 59           | 462                 | (3)   |

| King       | F      | 35           | 381                 | (3)   |

Sporadic cases of obesity have been noted since antiquity. Gould and Pyle (174) describe a large number of cases of massive obesity in children and adults. They cite the writings of Athenaeus who described Denys, the tyrant of Heraclea, as so enormous that he was in constant danger of suffocation, which was treated by putting needles in the back of his chair. Several other very fat people identified by Gould and Pyle are William the Conqueror; Charles le Gros; Louis le Gros; Humbert II, Count of Maurienne; Henry I, King of Navarre; Henry III, Count of Champagne; Conan III, Duke of Brittany; Sancho I, King of Leon; Alphonse II, King of Portugal; the Italian poet Bruni who died in 1635; Vivonne, a general under Louis XIV; Frederick I, King of Wurtemberg, and Louis XVII.

polysarcie, embonpoint, and corpulence during the 19th century. A more detailed discussion of the classifications of obesity beginning with the division into endogenous and exogenous by Von Noorden can be found in elsewhere (155).

The small monograph written by William Wadd in 1829, entitled *Comments on Corpulency, Lineaments of Leanness* (69), presents a series of clinical cases of morbidly obese individuals presented both descriptively and in several cases graphically. Most of the cases were from his medical correspondence, a characteristic way of evaluating patients by “consulting physicians” since the physical examination was not a part of the usual clinical visit in the early 1800s. Of the 12 cases in his book, all but one was in men. Weights were noted in five cases and ranged from 106 kg (16 st; 10 lb; or 234 pounds) to 146 kg (23 st; 21b; or 324 pounds). Two of the cases examined at postmortem had enormous accumulations of fat. Although autopsy observations

of obese individuals had been made previously, this was the first instance in which they were included in a monograph devoted to obesity and leanness.

Wadd notes that sudden death is not uncommon in the corpulent, thus revalidating Hippocrates. His statement, “A sudden palpitation excited in the heart of a fat man has often proved as fatal as a bullet through the thorax” is consistent with the association of obesity and sudden death noted in the ongoing Framingham Study. In several of the cases, corpulent patients were seeking specific pills to treat their obesity. Wadd makes a distinction between the therapeutic activists and those favoring less aggressive therapy with the homeopaths being at the far extreme with minimal dosage of medication. “Truly it has been said—some Doctors let the patient die, for fear they should kill him; while others kill the patient, for fear he should die.”

One important lesson from the study of massively obese individuals was the association of obesity with sleep apnea, a disease often referred to as the Pickwickian syndrome (191,192). Patients with alveolar hypoventilation, which produces this syndrome, date back to Greco-Roman times (59,60). The earliest published medical report of hypoventilation and its consequences was that by Russell in 1866 (193), although he did not know its cause.

Other clinical subtypes of obesity, in addition to the massively obese, have been gradually defined. Cases of hypothalamic injury with obesity have been identified since 1840 (159), and received particular attention following the reports by Babinski (157) and by Frohlich (158). In the early 20th century, Cushing recognized (194) that obesity was associated with basophilic adenomas of the pituitary gland (195). Cushing’s syndrome can also be caused by medication with adrenal steroids. A number of nonsteroidal drugs, including phenothiazines, some antidepressants (amitriptyline), some anticonvulsants (valproate), antiserotonin drugs (cyproheptadine), and antidiabetic drugs can also cause weight gain. Other endocrine diseases such as hypogonadism and isolated growth hormone deficiency are also associated with increased fat deposits. Several rare genetic disorders have obesity as finding (141). Finally, a sedentary life-style and a high-fat diet, particularly in animals, have been reported to produce obesity.

Besides the lessons from individual patients, which have been provided by these case reports, there are the lessons that come from evaluation of collective data. Quetelet (196) was one of the leaders in developing “mathematical” methods to evaluate populations. He developed the concept of the “average man” and used the ratio of weight divided by the square of stature or

height ( $\text{kg/m}^2$ ) as a measure of an individual’s fatness. This unit, the body mass index, might be termed the Quetelet Index (QI) in honor of the man who developed what has become a widely used way of evaluating weight status.

The life insurance industry has extended the population-based view of obesity (124). As early as 1901, data began to appear showing that both excess amounts of weight and central distribution of this weight were associated with shortened life expectancy. Because of the financial need to relate risk to the cost of life insurance, the insurance industry has continued to provide data showing these relationships. These data were responsible for stimulating evaluation of the association of weight status with mortality risks in several population-based studies (197–201). In all of these studies, a curvilinear increase in risk of mortality is associated with rising weight or body mass or QI index.

Although the relationship of central fat to increased mortality could be discerned in these early insurance studies, it remained for Vague (202) to bring this concept to the attention of health professionals. Although Vague’s data are clear, the adipomuscular ratio that he used to measure fat distribution was a complex one and it remained for the simpler measurement of waist circumference divided by hip circumference (WHR) and the subscapular skinfold measurement to provide the wide recognition for the risk that centrally located fat poses. With better methods of measuring fat distribution with CT and MRI scans, it is now clear that increased visceral fat is an important component in the health risks associated with obesity.

## I Treatment of Obesity

### 1 Treatment with Diet and Exercise

*In America there are fewer cures for obesity undertaken than abroad ... because ... there are fewer obese people here.*

Carter et al. (203)

This statement was made in 1917, but time and the tides have now produced an epidemic of obesity in America (204).

The clinical approach to treatment of obesity long antedates the Scientific Era. From the time of Hippocrates (205) and Galen (206) in the prescientific era, diet and exercise were an integral part of the therapeutic regimen for obese patients. Hippocrates, the “Father of Medicine,” suggested in the 5th century BC:

Obese people and those desiring to lose weight should perform hard work before food. Meals

should be taken after exertion and while still panting from fatigue and with no other refreshment before meals except only wine, diluted and slightly cold. their meals should be prepared with a sesame or seasoning and other similar substances and be of a fatty nature as people get thus, satiated with little food. They should, moreover, eat only once a day and take no baths and sleep on a hard bed and walk naked as long as possible (205).

Galen, nearly 2000 years ago, outlined his approach to treatment of the obese as follows:

I have made any sufficiently stout patient moderately thin in a short time, by compelling him to do rapid running, then wiping off his perspiration with very soft or very rough muslin and then massaging him maximally with diaphoretic unctions, which the younger doctors customarily call restoratives, and after such massage leading him to the bath after which I give him nourishment immediately but bade him rest for a while or do nothing to which he was accustomed, then lead him to a second bath and then gave him abundant food of little nourishment so as to fill him up but distribute little of it to the entire body (206)

From this Greco-Roman beginning dietary treatment can be traced to the Arabic tradition in medicine. In the first book of his *Cannon*, Avicenna describes how to reduce the overweight individual:

The regimen which will reduce obesity. (1) Produce a rapid descent of the food from the stomach and intestines, in order to prevent completion of absorption by the mesentery. (2) Take food which is bulky but feebly nutritious. (3) Take the bath before food often. (4) Hard exercise... (207)

When the Western medical tradition moved to Europe in the 11th to 13th centuries, so did the concepts of hygiene, diet, and exercise. These were embodied in the “institutes of medicine,” a major component of medical education for centuries. One of the most widely used guides was the *Regimen Sanitatis* (208) developed in the school at Salerno, Italy, in the 12th century, which did not specifically provide advice for obesity. Chaucer, the 14th-century poet, did reiterate the advice flowing from Hippocrates when he said; “Agonyes glotonye, the remedie is abstinence.” (Against gluttony the remedy is abstinence.)

Dietary treatment in the 18th century was summarized by Tweedie:

In attempting its cure, when the habit is threatened with any morbid effects, from the plethora existing either in the head or lungs, this must be removed by a bleeding or two; and as corpulent people do not bear blood-letting well, purging is most to be depended upon for the removal of the plethora (209).

He also says, “The diet should be sparing. They should abstain from spirits, wines and malt liquors, drinking in their stead, either spring water, toast and water or else water agreeably acidulated by any pure vegetable acids.” Finally he increases exercise gradually.

The 18th-century Italian layman Cornaro (210) became a champion of dietary moderation after he successfully conquered his own obesity. At the beginning of his book he says: “O wretched, miserable Italy! Does not though plain see, that gluttony deprives [us] of more soul years, than either war, or the plague itself could have done?” Cornaro’s doctor’s advice was to eat or drink nothing that was not wholesome and that only in small quantities.

Comments on obesity have occasionally come from the field of gastronomy, the classic work by Brillat-Savarin in 1826 being the best known. This masterpiece has been published in many attractive and beautifully illustrated editions (211). He attributes obesity to several causes:

1. The first is the natural temperament of the individual.
2. The second principal cause of obesity lies in the starches and flours which man uses as the base for his daily nourishment.
3. A double cause of obesity results from too much sleep combined with too little exercise.
4. The final cause of obesity is excess, whether in eating or drinking.

From this, Brillat-Savarin moves to treatment. He says: “Any cure of obesity must begin with the three following and absolute precepts: discretion in eating, moderation in sleeping, and exercise on foot or on horseback.” Having said this much he goes on to say: “Such are the first commandments which science makes to us: nevertheless I place little faith in them. . .” He then goes on to recommend a diet low in grains and starches.

In spite of the long history of dietary recommendations for treatment of obesity, it wasn’t until 1863 that the first “popular” diet book appeared. This was a

small, 21-page pamphlet published privately by William Banting entitled “A Letter on Corpulence Addressed to the Public” (212). The demand was so great that a second, hardcover edition was published within a year. In this pamphlet, he recounted his successful weight loss experience using a diet prescribed by his ear surgeon, William Harvey (213). The immediate success of this pamphlet led to reprinting worldwide and a popularization of the term “Bantingism” as a reference to dieting.

#### **Banting’s Cure (very severe)**

Breakfast, 8 AM: 150–180 g (5–6 oz) meat or broiled fish (not a fat variety of either); a small biscuit or 30 g (1 oz) dry toast; a large cup of tea or coffee without cream, milk, or sugar.

Dinner, 1 PM: Meat or fish as at breakfast, or any kind of game or poultry, same amount; any vegetable except those that grow underground, such as potatoes, parsnips, carrots, or beets; dry toast, 30 g (1 oz); cooked fruit without sugar; good claret, 300 cc (10 oz). Madeira or sherry.

Tea, 5 PM: Cooked fruit, 60–90 g (2–3 oz); one or two pieces of zwieback; tea, 270 cc (9 oz) without milk, cream, or sugar.

Supper, 8 PM: Meat or fish, as at dinner, 90–120 cc (3–4 oz); claret or sherry, water, 210 cc (7 oz).

Fluids restricted to 1050 cc (35 oz) per day.

From these humble beginnings, diet books by professionals, self-styled professionals, and lay people have continued to appear, particularly as the concerns about obesity as a health and cosmetic problem have increased (35).

I have summarized two diets from the early 20th century to show the approaches that were used at that time (203).

#### **Von Noorden’s Diet**

Von Noorden, one of the leading scholars of obesity at the beginning of the 20th century, based his dietary approach on an estimate of an individual’s caloric requirement. Basal calorie needs were estimated from ideal weight. For this he assumed that a 70-kg individual would require 37 kcal/kg, or 2590 calories. If the individual weighed an extra 30 kg, they would need 1110 extra calories to feed this extra 30 kg. Von Noorden’s first-degree reduction diet reduced energy to 80% of the basal needs, or for the 70-kg individual to 2000 kcal/day. His second-degree reduction diet reduced intake to 60% or 1500 kcal/

day for the individual requiring 2500 kcal/day. His third-degree reduction, which was only infrequently used, lowered calories to 40% or 1000 kcal/day. His dietary approach also reduced fat to 30 g/day. His protein allowance was 120–180g/day with carbohydrate in the neighborhood of 100 g/day. His menu plan, adapted from Carter et al. (203), is summarized below:

|              | Minimal                                 | Maximal                             |
|--------------|---|-------------------------------------|
| Protein      | 120 g (4 oz)<br>492 cal                 | 180 g (6 oz)<br>738 cal             |
| Fat          | 30 g (1 oz)<br>280 cal                  | 30 g (1 oz)<br>280 cal              |
| Carbohydrate | 100 g (3 1/3 oz)<br>410 cal<br>1182 cal | 120 g (4 oz)<br>492 cal<br>1510 cal |

A sample of the Von Noorden Diet is shown below:

Breakfast: Lean meat, 80 g (2 2/3 oz); bread, 25 g (1 oz); tea, 1 cup with milk, no sugar

Midforenoon: One egg

Luncheon: Soup, 1 small portion; lean meat, 160 g (5 1/3 oz); potatoes, 100 g (3 1/3 oz); fruit, 100 g (3 1/3 oz);

Afternoon: 3 PM: Cup of black coffee,

4 PM: Fruit, 200 g (6 2/3 oz)

6 PM: Milk, 250 cc (8 oz)

Dinner: Meat, 125 g (3 1/6 oz); bread (graham), 30 g (1 oz); fruit, small portion as sauce without sugar; salad, vegetable or fruit, radishes, pickles

#### **Ebstein’s Diet**

At the other extreme is the high-fat diet illustrated by Ebstein. Ebstein modified existing diets by allowing a considerable amount of fat and restricting the carbohydrates by forbidding all sugar, sweets, and potatoes, but allowing 180–210 g (6–7 oz) of bread. Vegetables that grow aboveground are allowed, and all sorts of meat, especially fat meat, is permitted. Fats are allowed, 120–180 g (4–6 oz) per day. He used a three-meal plan with the largest meal at midday.

Breakfast: One large cup of black tea, without cream or milk, or sugar; white or brown bread, 60 g (2 oz) with plenty of butter

Dinner: 2 PM. Clear soup, meat 120–180 g (4–6 oz) with gravy, and fat meat is especially recommended; vegetables in abundance (as noted above); small amount of fresh or stewed

fruit (without sugar) or salad; two or three glasses of light white wine. Shortly after dinner a cup of tea is allowed with sugar or milk.

Supper: 7:30 PM. Large cup of tea, without sugar or milk; one egg with or without a small portion of meat, preferably fat. Occasionally a little cheese or fresh fruit.

Total values: Protein, 100 g (3 1/3 oz); fat, 85 g (3 oz); carbohydrate, 50 g (2 2/3 oz)

These two themes, the low-fat/high-protein/high-carbohydrate diet and the high-fat/low-carbohydrate diet were repeating themes through the 20th century, but their origins were in the late 19th century. Had either of these approaches “cured” obesity, as their proponents often suggested, there would have been no need for the continual supply of new diets which we saw throughout the 20th century (35).

As a prelude to its clinical application the metabolic features of starvation were explored by Benedict using metabolic chambers (109,110) and the suggestion that calories could be dissipated by *luxuskonsumption*, or burning off of unneeded calories, was promulgated by Gulick (214) and Neumann (215) but challenged by the critical studies of Wiley and Newburgh (216).

A practical application of the work on starvation was published by Evans et al. (217), who showed the potential benefits of a very low calorie diet. Although Evans continued to publish on this approach to diet until the beginning of World War II (217), this idea was lost sight of until “fasting” was reintroduced as a treatment for obesity by Bloom in 1959 (218). Following his enthusiastic report, the use of liquid formula diets that were initially popularized from the Rockefeller University metabolic ward increased gradually and then rapidly increased until a major crisis followed with the report of 17 deaths in patients using a formula diet compounded from gelatin (219). Although the Gelatin Commission in France in the 19th century (220) had concluded that gelatin was an inadequate protein, this lesson was relearned painfully in the 1970s (122,221). New diets subsequently appeared using high-quality protein, and sales reached another peak in the late 1980s. When the U.S. Government raised concerns about these diets and other “commercial weight control” programs (222), there was a rapid and sudden decrease in public interest and a loss of commercial profitability.

## 2 Behavior Modification

One of the central developments in the treatment of obesity in the 20th century was in the behavioral field.

Following the introduction of psychoanalytic techniques by Freud and his colleagues (223), several theories were proposed suggesting that obesity might result from “personality” disorders. These were carefully tested and found to be wanting (224). That obesity had important social components, however, became clear from its relation to socioeconomic status (225). The prevalence of obesity was found to be much higher in the lower social and economic groups than in the higher social and economic groups in the seminal Manhattan study.

Although psychoanalytic approaches were unproductive as a basis for treatment, other avenues of behavioral research were productive. One of these flows from the work on conditioned reflexes by Pavlov and his followers (226), and another from the work on operant behavior by Skinner (227,228). It was an adaptation of these latter techniques that was used by Stuart (229) in his classic study in 1967. Stuart treated 11 patients, 8 of whom were available for follow-up at the end of the year. In this group, weight losses using techniques of monitoring food intake and manipulating the environment in which it was eaten were indeed striking. Subsequent to this seminal work, the principles of behavior modification have been widely applied, and some would consider them to have been central to the treatment of obesity in the late 20th century.

## 3 Pharmacotherapy

As the understanding of pharmacology has increased, so too has its application to treatment of obesity become more focused. Although one might call Withering the Father of Pharmacology because he published his findings on digitalis (230) in 1785, the first chemical work was in the early 19th century and during the important period of French hegemony in medicine (38). A summary of 19th century treatments is provided by Sajous (231):

Besides the familiar dietetic treatment, thyroid gland is used to enhance catabolism, but not in the large doses usually prescribed, which provide hypercatabolism and greatly weaken the patient. From 2 to 3 grains (132 to 196 mg) t.i.d. are enough to increase gradually the lipolytic power of the blood. Potassium iodide in increasing doses can be used instead, when thyroid extract cannot be obtained. Hyoscine hydrobromate 1/100 grain t.i.d. assists the reducing process by increasing the propulsive activity of the arterioles and causing them to drive an excess of blood into the fat-laden areas. Carlsbad, Homburg, and Marienbad waters owe their virtues mainly to the alkaline

and purgative salts they contain, especially sodium sulphate. As a beverage alkaline Vichy water is advantageous to enhance the osmotic properties of the blood and facilitate the elimination of wastes.

Shortly after their discovery in the 19th century, endocrine organ extracts were used for the treatment of obesity as early as the 1890s (231):

The fact that thyroid preparations in sufficient doses promote the rapid combustion of fats has caused them to be used extensively in this disorder. In large doses (thyroid gland) . . . imposes hyperoxidation upon all cells . . . we behold gradual emaciation beginning with the adipose tissues, which are the first to succumb. Hence the use of thyroid preparations in obesity. Sajous goes on to say that small doses (66 mg or 1 grain) are indicated in all cases to begin with: "Briefly, in all cases of obesity in which thyroid gland is rationally indicated, the feature to determine is whether directly or indirectly hypothyroidia underlies the adiposis" (231).

Sajous also describes the use of testicular extracts: "Testicular preparations, including spermine, have been recommended in a host of disorders, particularly . . . obesity . . . but others again have failed to obtain any favorable results" (231).

The first serendipitous observation on the use of aniline-derived drugs was the publication by Lesses and Myerson (156) of the hypothesis that amphetamines might be useful in the treatment of obesity. This molecule underwent many chemical modifications including the synthesis of fenfluramine, a drug that was shown to act on serotonergic mechanisms. Realizing that both serotonergic and noradrenergic receptors were involved in modulating food intake, Weintraub et al. in 1992 published a 4-year study showing that combination therapy might be better than monotherapy (232). This classic series of papers has opened a whole new pharmacologic approach to obesity. As has often happened in obesity, this strategy came to an abrupt end in 1997 when valvular insufficiency was reported (233), leading to withdrawal of fenfluramine and dexfenfluramine from the market.

#### 4 Surgery

Surgical intervention for excess fat can be dated from Talmudic days. According to Preuss (234), Rabbi Eleazar was given a sleeping potion and taken into a marble chamber where his abdomen was opened and many

basketfuls of fat were removed. "Plinius also describes a very similar 'heroic cure for obesity': the son of the Consul L. Apronius had fat removed and thus his body was relieved of a disgraceful burden." More recently, in AD 1190, a surgeon cut open the abdomen of Count Dedo II of Groig in order to remove the excessive fat from him (p 215). Following the advent of anesthesia in 1846, this procedure has been revived.

The historical view of gastrointestinal function in relation to obesity may be perceived to have reached its zenith (or nadir, depending on one's perspective) with the introduction of gastrointestinal operations for obesity. Three operative approaches have been developed to treat obesity.

The first procedure reported by Kremen (235) was a jejunoileal bypass on a single patient. Believing that if weight were lost, patients would be able to maintain the weight loss, Payne and DeWind performed a series of 11 jejunocolic anastomoses that produced significant diarrhea and weight loss (236). When the patients were reanastomosed, they regained weight. Against this background, these authors and many others carried out jejunoileal bypass operations that were associated with numerous metabolic and infectious complications and were largely discontinued as a surgical approach to obesity in the 1970s.

An alternative approach to altering gastrointestinal function to treat obesity was developed by Mason and Ito (237) who performed the first gastric reduction operation. These procedures have now become the dominant operative procedures for the treatment of obesity and are the subject of a major clinical trial in Sweden (238).

## V TOWARD A SCIENCE OF OBESITY

Toward the end of the Middle Ages, two historical and philosophic traditions, one of Indo-European origin with Greco-Roman philosophy as its base, and the other of Semitic origin with the Hebrew and Christian traditions as its base, reached a form of resolution synthesis in the Hegelian sense (239) from which the Renaissance and Modern Science both took their roots (1,240).

The modern scientific tradition is the tradition of "experimental" science. That is, progress was made by designing "experiments" to test hypotheses and apply mathematical analysis to the results. The fruitfulness of this tradition is everywhere around us. Its application to obesity has come, as it has come to all other areas, but progress has been slow. From the beginning

of the Scientific Era (AD 1500) to the beginning of Modern Medicine (AD 1800), only a few scholarly theses with obesity as the subject matter had been published (241–246). In general, these theses reflected the traditions of Hippocrates, Galen, or Avicenna, as interpreted in the more contemporary traditions provided by the iatrochemical and iatromechanical views of the words originating in the mechanical and chemical explanations of life. As interest in obesity increased, a much larger number of theses with obesity as the subject were published in the 18th century (247–280), which also saw publication of the first monographs on the subject (281,282). Table 3 is a list of most English, French, and German monographs up to 1950 (281–321).

There were two works published in English before 1800. The first of these was by Thomas Short (281). He begins by saying, “I believe no age did ever afford more instances of corpulency than our own.” From Short’s perspective, treatment of obesity required restoring the natural balance and removal of the secondary causes. One should, if possible, pick a place to live where the air is not too moist or too soggy, and one should not reside in flat, wet countries or in the city or the woodlands. He thought that exercise was important and that the diet should be “moderate spare and of the more detergent kind.”

**Table 3** Monographs on Obesity

| English         | French        | German             |
|-----------------|---------------|--------------------|
| 18th century    |               |                    |
| Short (281)     |               |                    |
| Fleming (282)   |               |                    |
| 19th century    |               |                    |
| Wadd (69,296)   | Maccary (177) | Kisch (302)        |
| Chambers (297)  | Dancel (300)  | Ebstein (303)      |
| Harvey J (298)  | Worthington   |                    |
| Harvey W (299)  | (301)         |                    |
| 20th century    |               |                    |
| Williams (304)  | Leven (313)   | Von Noorden (318)  |
| Christie (305)  | Haeckel (314) | Pfaundler (319)    |
| Rony (306)      | Le Noir (315) | Gries et al. (320) |
| Rynerason and   | Boivin (316)  | Bray (321)         |
| Gastineau (307) | Cref and      |                    |
| Craddock (308)  | Herschberg    |                    |
| Bruch (309)     | (317)         |                    |
| Mayer (310)     |               |                    |
| Garrow (311)    |               |                    |
| Stunkard (312)  |               |                    |

A second monograph by Fleming (282) listed four causes of corpulency. The first cause is “the taking in of too large a quantity of food, especially of the rich and oily kind.” He went on to note that not all obese people were big eaters. The second cause of obesity is “too lax a texture of the cellular or fatty membrane. . .whereby its cells or vesicles are liable to be too easily distended.” The third cause was an abnormal state of the blood that facilitated the storage of fat in the vesicles.

Finally, defective evacuation was also an important cause. Since Fleming believed that sweat, urine, and feces all contained “oil,” he believed that the treatment for obesity was to increase the loss of “oil” by each of these three routes. Thus, laxatives and diuretics could be used for treatment.

From the beginning of the 19th century, the base of medical literature relating to obesity increased rapidly. *Corpulency* and *polysarcy* were the terms most in use at the beginning of the 19th century, but by the end of the century, *obesity* had replaced both of them. Additional monographs on obesity appeared in English, French, and German. The cell theory was proposed and fat cells were identified. The laws of thermodynamics were developed and tested in animals and human beings by the first part of the 20th century.

I have picked the year 1850 as a dividing line for the beginning of a modern science of obesity (283). This was the time when the French Clinical School which began at the French Revolution went into its long decline and the German Laboratory School began its rapid ascent. This was after the fat cell had been described, the Quetelet (BMI) Index had been published, and the conservation of energy had been proposed (284). From 1850 to the beginning of World War II, the hegemony of German Laboratory Science in the field of obesity and elsewhere was evident (283).

With the advent of the 20th century, concerns about the relation of obesity to health risks gradually replaced concerns about being underweight (35). As the 20th century progressed, four themes coalesced to form the basis of a modern science of obesity. These include the behavioral or psychological aspects of obesity, the physiological approach to a controlled system of food intake, the cellular basis for obesity centered in the growing diversity of cellular functions for the fat cell, and the genetic and molecular biological approaches to understanding the problem.

From the beginning of World War II and the monograph by Rony (306), a period of American hegemony began. In the post–World War II period, the growth of the National Institutes of Health has served as a major stimulus for research in obesity

(285). Several important events occurred which brought the scientific threads of obesity together. The first was the formation of many associations for the study of obesity. The first of them was formed in the United Kingdom and held its first meeting in 1968 (286). This was followed in 1972 by the first Fogarty Center Conference on Obesity (287), and 1 year later by the First International Congress on Obesity (288). Following that congress, it was clear that a journal devoted to obesity was needed, and the *International Journal of Obesity* began publication in 1976 under the editorship of Dr. Alan Howard and Dr. George Bray. The first meeting of the North American Association for the Study of Obesity was held at Vassar College in Poughkeepsie, NY, in 1982. Subsequent International Congresses were held in 1977 in Washington, DC (289); in 1980 in Rome (290); in 1983 in New York City (291); in 1986 in Jerusalem (292) in 1990 in Kobe, Japan (293); in 1994 in Toronto (294); in 1998 in Paris (295); and in 2002 in Sao Paulo. In 1986 the International Association for the Study of Obesity was formed under the leadership of Dr. Barbara Caleen Hansen. As growth continued, a second journal appeared in 1980 under the title *Obesity and Weight Regulation*. This journal, like so many others, succumbed in part because it was not part of one of the national associations. *Obesity Surgery* was the third journal to be founded and was followed in 1993 by *Obesity Research*, published by the North American Association for the Study of Obesity. This rapid growth of scientific institutions surrounding a scientific discipline is characteristic of developments which have sprung up throughout the scientific sphere to provide a way of focusing the activities of scientists in a *manageable way*.

## I INTRODUCTION

Quantifying the amount and distribution of adipose tissue and its related components is integral to the study and treatment of human obesity. Body composition research is a field devoted specifically to the development and extension of methods for in vivo quantification of adipose tissue and other biochemical and anatomical components of the body. This review focuses on methods of estimating body composition components in the context of evaluating human obesity and its associated risks.

The chapter first describes the organization of human body composition with an emphasis on body adiposity. The human body can be organized into five levels of increasing complexity—atomic, molecular, cellular, tissue system, and whole body. Obesity-related components are recognized at each of the five body composition levels.

A general review is next provided on approaches to measuring body composition components, especially fat mass, adipose tissue, and related components. Two main groups of methods are reviewed: those that are useful mainly in research laboratories as reference methods, including whole-body  $^{40}\text{K}$  counting, neutron activation analysis, hydrometry, underwater weighing/air plethysmography, dual-energy x-ray absorptiometry, multicomponent models, and imaging methods such as computerized axial tomography and magnetic resonance imaging; and those that are applicable in field settings including anthropometry and bioimpedance analysis. An overview of method errors is included in the next section.

Body composition methods for quantifying regional and whole-body obesity-related components are now available for the quantitative in vivo study of human obesity.

## II BODY COMPOSITION AND ENERGY EXCHANGE

An individual's body mass reflects total lifetime nutrient and energy balance. Energy balance, or stores, the difference between energy ingested as food and organic compounds oxidized as fuel, can be physiologically allocated into three main molecular components—the small storage carbohydrate glycogen pool, the larger structural and functional protein pool, and the variable lipid or fat storage pool (Fig. 1) (1). Taken together with associated water and minerals, the collective energy compartment is reflected by and changes parallel with body mass. It is within this dynamic model of energy exchange and storage that the study of human body composition and obesity resides.

While the molecular level is ideally suited for thermodynamic analysis, energy stores can be envisaged as comprising the six classic levels of biology, atomic, molecular, cellular, tissue-organ, whole-body, and population. The first four of these levels are depicted in Figure 2 (2). In this review we examine each of the major compartments at these four levels and explore means by which they can be quantified in laboratory and field settings. Our focus is on measurement of adiposity-related components in the overall context of this book. Other reviews and monographs examine body composition in general with specific areas of focus including elements, molecular components, body cell mass, tissues including bone and skeletal muscle, and visceral organs (see Appendix).

## III ADIPOSITY COMPONENTS

Adiposity generally reflects energy stores, and excess stored energy and body weight are the hallmark of hu-

**Figure 1** Interrelations between energy intake, output, and stores. (From Ref. 1.)

| <i>Atomic</i>       | <i>Molecular</i> | <i>Cellular</i>   | <i>Tissue-Organ</i>                 |

**Figure 2** First four of the five levels of human body composition. Components related to “fatness” are identified by bold enclosure. ECS and ECF are extracellular and intracellular solids, respectively. (From Ref. 2.)

man obesity. Each body composition level of the individual has a representation of adiposity (3). We now review the main features of the five body composition levels with a focus on adiposity-related components.

### A Atomic Level

The human body is composed of 11 elements that account for > 99.5% of body weight (Fig. 3) (1). Three of these elements, carbon, hydrogen, and oxygen, are found in storage triglycerides or “fat” (Table 1). The average proportions of triglyceride as carbon, hydrogen, and oxygen are considered stable at ~76.7%, 12.0%, and 11.3%, respectively. These stable elemental proportions allow the development of methods for deducing total body fat from total body carbon and other elements.

Carbon is the characteristic component of adiposity at the atomic level. Reference Man, for example, contains 16 kg carbon, and 60% or 9.6 kg of carbon exits in adipose tissue (4).

### B Molecular Level

The main atomic level elements, including trace elements that occur in low but essential concentrations, combine to form various chemical compounds that may be grouped into the broad classes that define the molecular level of body composition. The main components of the molecular level are shown in Figure 4 and include water, lipids, proteins, minerals, and glycogen (3). Each of the nonaqueous components represents many differ-

**Figure 3** Atomic level of body composition. (From Ref. 3.)

ent but closely related chemical compounds. For example, the “protein” component consists of several hundred different specific proteins.

Lipid is the main molecular-level component of interest in the study of human obesity. The term lipid refers to all chemical compounds that are insoluble or weakly soluble in water, but are soluble in organic solvents such as chloroform and diethyl ether (5). Lipids isolated from human tissues include triglycerides, sphingomyelin, phospholipids, steroids, fatty acids,

**Table 1** Chemical Formulae and Elemental Stoichiometry of Representative Triglycerides

| Formulae               | Elemental content (%) |          |        |
|------------------------|-----------------------|----------|--------|
|                        | Carbon                | Hydrogen | Oxygen |
| $C_{57}H_{104}O_6$     | 77.4                  | 11.8     | 10.9   |

and terpenes. Triglycerides, commonly referred to as “fats,” are the primary storage lipids in humans, and comprise the largest fraction of the total lipid component. At present there is limited information on the exact proportion of total lipids as triglycerides, or the amount of within and between-person variability. Comizio et al. (6) examined the proportion of total body lipid as triglyceride in the adult rat under usual dietary conditions and with dietary energy restriction without and with swimming exercise. The authors observed that with negative energy balance and weight loss there were parallel losses of total body triglyceride and lipid. The fraction (mean  $\pm$  SD) of total lipids as triglyceride was  $0.83 \pm 0.08$  in the control rats with lowering at 2 and 9 weeks of energy restriction to  $0.82 \pm 0.04$  ( $P = \text{NS}$  vs. control) and  $0.70 \pm 0.15$  ( $P = .05$ ) and at 9 weeks for energy restriction plus exercise to  $0.67 \pm 0.09$  ( $P = .003$ ). The Reference Man reportedly has 13.5 kg of total lipid, of which 12.0 kg, or 89%, is “fat” (4).

A summary of molecular-level component characteristics is presented in Table 2. These characteristics are used in developing body composition methods, and their application will be presented in later sections. An important feature of the molecular level is the “stable” relationships that exist between the various components. These stable relations form the basis of many widely used body composition methods. The three most important of these are the hydration of fat free mass (i.e., TBW/FFM), potassium content of fat free mass

(i.e., TBK/FFM), and densities (D) of fat and FFM. These assumed stable or relatively stable relations allow development of two component molecular level models consisting of fat and FFM.

The hydration of FFM is among the most important stable relations applied in body composition research (7–9). A strong correlation with an intercept not significantly different from zero was observed between total body water (TBW) and FFM across mammals ranging in body mass from mouse to gray seal (10). The mean ratio of TBW/FFM for the mammals was ~0.73 and this ratio is among the best-known stable body composition associations. This constancy provides a means of estimating total body fat in vivo: body fat = body mass – FFM = body mass – TBW/0.73.

The total body potassium (TBK) to FFM ratio was historically important as it formed the basis of many classic body composition studies that explored fat and FFM relations. A mean TBK/FFM ratio of 68.1 ± 3.1 mmol/kg was derived by Forbes et al. (11) based on the whole-body chemical analysis of four human cadavers. This ratio was then introduced and applied as an in vivo method for estimating total body fat mass in vivo: body fat = body mass – FFM; = body mass – TBK/68.1. However, this ratio actually varies considerably across sex and age (12). The total body potassium to FFM ratio is thus not widely used today as improved methods of evaluating total body fat in vivo are available.

The relatively stable densities of fat (0.9007 g/cm<sup>3</sup>) and FFM (1.100 g/cm<sup>3</sup>) are the basis of many body composition models and were first suggested six decades ago by Behnke et al. (13). The simplest model consists of two components and is derived from two simultaneous equations:

$$\text{body mass} = \text{fat} + \text{FFM} \quad (1)$$

$$\text{body mass}/D_b = \text{fat}/0.9007 + \text{FFM}/1.100 \quad (2)$$

Solving the two simultaneous equations,

$$\text{body fat mass} = (4.95/D_b - 4.50) \times \text{body mass} \quad (3)$$

where D<sub>b</sub> is body density measured by the underwater weighing technique. However, the assumption of a constant FFM density of 1.100 g/cm<sup>3</sup> causes some model error as FFM density actually varies, although within a relatively narrow range (14). To avoid this model error, three-, four-, and/or five-component models were developed for measuring total body fat with improved accuracy (15).

## C Cellular Level

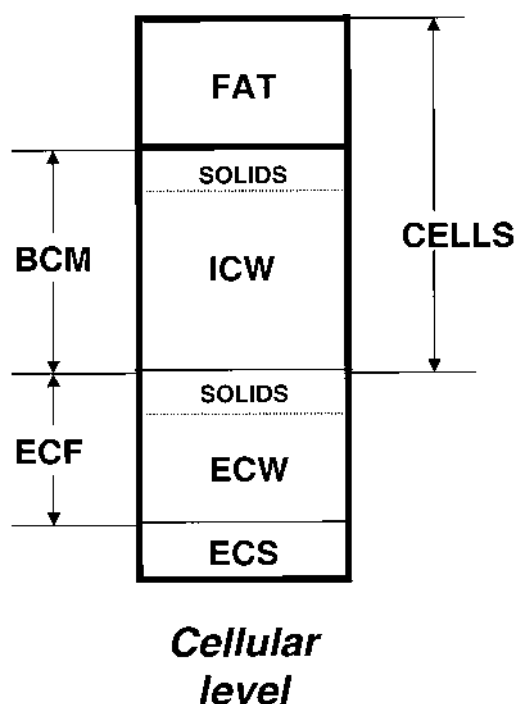

The cellular level includes three main components, cell mass, extracellular fluid, and extracellular solids (Fig. 5). Cells can be divided into specific types such as connective, epithelial, nervous, and muscular. Adipocytes or fat cells serve as the primary storage site for triglycerides. All mass can be separated into two components, one metabolically active “body cell mass,” and the other triglycerides, or “fat.” The concept of body cell mass was originated by Moore and refers to the compartment actively involved in energy consumption and heat production (7). Extracellular solids consist mainly of bone minerals and collagen, reticular, and elastic fibers.

The following are some of the important assumed stable cellular level relationships applied in body composition models: K/intracellular water = 159 mmol/kg H<sub>2</sub>O = 6.22 g/kg H<sub>2</sub>O; K/body cell mass = 4.69 g/kg; Ca/extracellular solids = 0.177 kg/kg; and extracellular water/extracellular fluid = 0.92.

## D Tissue Organ Level

The main components at this level are adipose tissue, skeletal muscle, bone, and visceral organs (e.g., liver, kidneys, heart, etc.) (Fig. 6). The adipose tissue component includes adipocytes with collagenous and elastic fibers, fibroblasts, capillaries, and extracellular fluid.

Human adipose tissue is often assumed to have an average composition consisting of 80% lipid, 14%

**Figure 5** Cellular level of body composition. BCM, body cell mass; ECF, extracellular fluid; ICW, intracellular water; ECS, extracellular solids; and ECW, extracellular water. (From Ref. 3.)

water, 5% protein, and <1% mineral, and a density of  $0.92 \text{ g/cm}^3$  at body temperature (4). However, this average belies the large variation observed in adipose tissue composition. Level of adiposity, age, gender, and heredity all play an important role in determining adipose tissue composition, notably fat content. Martin and colleagues suggest that for every 10% increase in relative adiposity there is a corresponding rise in adipose tissue lipid fraction of 0.124 (16). A notable feature of adipose tissue is the large extracellular fluid compartment relative to cell mass. Of the 14% of average adipose tissue samples as water, 11% is extracellular water.

An important aspect of obesity research is examination of regional adipose tissue biology. Adipose tissue can be classified as two main types, subcutaneous and internal (Table 3) (4,17). Adipose tissue occurs in abundance in subcutaneous sites and is known to gross anatomists as superficial fascia, defined as the adipose tissue between the skin and the muscles. Subcutaneous adipose tissue also occurs in and around female breasts. Subcutaneous adipose tissue has also been partitioned by Kelly et al. into the plane superficial to the fascia within subcutaneous adipose tissue and that below this fascia, so-called deep subcutaneous adipose tissue (18).

Internal adipose tissue is found in the visceral compartment and in nonvisceral sites. The most important internal adipose tissue component in the obesity field is found in the visceral compartment. The word *viscera* is Latin for “organs in the cavities of the body,” usually applied to the heart and lungs as thoracic viscera and the stomach and intestines as abdominal viscera. Since there are three main body cavities—thoracic, abdominal, and pelvic—there are three corresponding visceral adipose tissue (VAT) components (Table 3). However, the medical literature varies widely in defining VAT based on imaging methods. This topic is reviewed in the section on imaging methods. Very few human studies in the obesity field examine intrathoracic VAT, including pericardial, epicardial, and periaortic adipose tissue.

Of the nonvisceral internal adipose tissue, interstitial adipose tissue is interspersed within the cells of a tissue (e.g., skeletal muscle) so tightly that it may be included with the tissue/organ at dissection. Adipose tissue is almost absent in some anatomic sites such as the penis,

scrotum, labia minora, nipple, nose, ear, eyelids, and brain. Some triglyceride exists within skeletal muscle, liver, and other nonadipose tissue cells, although this component is classified as intracellular lipid. Each anatomic adipose tissue component has specific metabolic and functional characteristics.

Illustrations of the subcutaneous, visceral (i.e., peri- and pararenal, mesenteric, omental), interstitial, and marrow adipose tissue compartments of the Visible Man are shown in Figures 7 and 8 for the midabdominal region and leg, respectively (17).

### E Whole-Body Level

Skinfolds, circumferences, and linear dimensions are all measurements at the whole-body level. These measurements are often used with prediction equa-

**Figure 7** Cross-sectional photograph of National Library of Medicine's Visible Man at the midabdominal region with identified adipose tissue components. (From Ref. 17.)

tions to estimate components at the other four body composition levels.

## IV MEASUREMENT METHODS

### A Body Weight and Stature

Standardized methods have been described for measuring weight and stature, as well as other anthropometric variables (19). For most clinical research purposes, it is desirable to measure body weight to the nearest  $\pm 0.1$  kg using a high-quality calibrated beam-balance or electronic scale. Subjects should be measured either nude or wearing standardized light clothing of known weight.

**Figure 8** Cross-sectional photograph of National Library of Medicine's Visible Man at the mid-upper arm region with identified adipose tissue components. (From Ref. 17.)

If heavier clothing is worn, it is necessary to estimate and record the additional weight of this clothing. The presence of edema, a common problem in severely obese subjects, should be noted. A variety of practical problems may be encountered when measuring the weight of obese subjects. Severely obese patients may have difficulty standing on standard scales, which may be too narrow or too high above the floor for an individual with balance problems. Specially designed chairs or sling-scales may be used.

The preferred method of measuring stature is to the nearest  $\pm 1$  cm using a wall-mounted stadiometer. Inexpensive, plastic stadiometers are available for clinical use that have acceptable accuracy. Close attention should be paid to standardized positioning of the subject when making the measurement (19). As for weight, a variety of practical problems may be encountered when measuring the stature of obese subjects. For example, the standard method requires the subject to stand erect with head, shoulders, and buttocks against the stadiometer board. This positioning may be difficult to achieve for obese individuals with large, protruding buttocks.

It is sometimes considered difficult and expensive to measure weight and stature in very large epidemiological surveys, and it is usually not possible to obtain measurements of past weight or stature for retrospective studies. In these settings many investigators have relied on self-reported weight and stature. This requires the assumption that the subjects know and can report their weight and stature both accurately and reliably. It is possible to verify this assumption in a subsample of participants with measured values in a cross-sectional survey, but this is difficult in retrospective studies where recalled weight or stature may be many years in the past.

Among adults, self-reported weight and height are generally highly correlated with measured weight and height. Correlations for reported stature range from 0.53 (20) to 0.99 (21); and those for weight range from 0.89 to 0.99 (21). The magnitudes of the correlations vary somewhat across studies and in relation to age and sex. In any event, high correlations do not necessarily reflect accuracy, since systematic differences (i.e., constant and relative biases) between self-reported and measured values may exist regardless of the strength of the correlations. Biases in the self-reporting of weight and height have been documented. Obese people tend to underreport their weight more than nonobese people. Women consistently underreport their weight and men tend to underreport it when they are overweight and over-report it when they are underweight.

Recall of weight and height at earlier ages, reports by surrogates (e.g., parents, spouses, children, siblings), and records from driver's licenses (22) can also be used in place of measured variables. These can be expected generally to have less reliability and accuracy than self-reported current weight, and correlations with measured weight are considerably less. There is little evidence that self-measurements are any more accurate or reliable than simple self-reported estimates.

Body weight and stature can be used to estimate "relative weight." The more common approach now used worldwide is to calculate body mass index (BMI) (weight/stature<sup>2</sup>). The objective of weight-stature indices such as body mass index is to obtain a measure of body weight (W) that is independent of stature (S). An example of such an index is given in Eqs. (4) and (5), which are based on the assumed relationship

$$W/S^b = a \quad (4)$$

and

$$W = aS^b \quad (5)$$

In Eq. (4) and (5), *a* and *b* are constants. These equations indicate that for any increment in *S*<sup>*b*</sup>, body weight changes in a proportional manner so as to keep the *W/S*<sup>*b*</sup> ratio constant. The great statistician and anthropometrist Lambert-Adolphe-Jacques Quetelet first observed that among adults weight in kilograms seemed to increase in proportion to the square of stature in meters (23). Quetelet's Index, *W/S*<sup>2</sup>, was further established to be a useful index for grading adiposity in population studies by Keys, who appears to have been responsible for renaming it the "body mass index" (24). It is now conventional to refer to *W/S*<sup>2</sup> as the BMI, but the reader should be aware that an infinite number of weight-stature indices can be constructed using different powers of stature, as well as weight (25). Historically, various investigators have presented arguments for the merits of different values of *b* in *W/S*<sup>*b*</sup>, based on the influence of age, gender, race, and even disease risk on the association between weight and stature (26–30). Benn even suggested that the power coefficient, *b*, should be established empirically within a population rather than applying a common coefficient across all populations (31).

It is important to keep in mind that the underlying assumption in the use of body mass indices is that they reflect variation among people in body adiposity (32). Garn et al. (33) cogently reminded us of three limitations to this assumption: (1) the correlation of BMIs with stature may be influenced by age; (2) BMIs may be influenced by body proportions, specifically leg length

relative to trunk size; and (3) BMIs may be correlated with lean as well as fat mass. Quetelet's Index, or BMI, is not perfectly correlated with body fatness:  $r$ 's with percent body fat range widely from about .40 to .90 across various studies. Moreover, the association of BMI with percent body fat may be nonlinear, especially at higher levels of adiposity (34). This suggests that the index can vary in sensitivity for grading body fatness among populations. Abdel-Malek and associates (25) presented a method for empirically determining powers for both weight and stature that would maximize the association between total body fat or percent body fat and weight-stature indices in a group or subsample of a population. As for the approach of Benn (31), this method has not been widely applied.

A potentially more troublesome problem is the fact that body mass indices are also associated with FFM. This is because weight includes FFM and stature is not correlated perfectly with FFM. As a result, body mass indices tend to retain significant correlations with FFM even when powers of  $b$  are found that minimize the correlation between weight and stature. The net result is that there may be a considerable range of body fatness (or leanness) among individuals with the same body mass index (35,36). The magnitudes of the associations of body mass indices with fat and fat free components are also influenced by age, gender, and racial differences in body composition, and by variation in body proportions. Substantial misclassification bias can result when people are classified as "overweight" or "obese" using cutoff values that do not take these factors into consideration (36,37).

Body weight and stature, or indices such as BMI, can also be used in equations to estimate body composition. As an example, percent body fat can be calculated using the following equation:

$$\begin{aligned} \%fat = & 64.5 - 848 \times (1/BMI) + 0.079 \times age \\ & - 16.4 \times sex + 0.05 \times sex \times age + 39.0 \\ & \times sex \times (1/BMI) \end{aligned} \quad (6)$$

with  $sex = 1$  for male and  $0$  for female (38). Body fat in this investigation was evaluated using a four-component model as the reference method. The percent fat prediction formula is applicable in Caucasians and African Americans and a separate equation is available for use in Asian subjects.

## B Component Reference Methods

Body composition methods vary in several characteristics including cost, safety, technical complexity, port-

ability, accuracy, reproducibility, and requirement for subject participation. In the section that follows we organize methods for convenience into two main groups, "reference" methods that are often applied in small-scale studies requiring high accuracy and reproducibility, and "field" methods that require reference method calibration and that are appropriate for use in epidemiological studies.

### 1 $^{40}\text{K}$ Counting

Whole-body  $^{40}\text{K}$  counting is a classic and widely used technique for evaluating adiposity (11). The natural abundance of  $^{40}\text{K}$  in the human body is constant at 0.0118% of total body potassium.  $^{40}\text{K}$  is radioactive and emits a characteristic 1.46 MeV  $\gamma$ -ray that can be counted by detection systems with appropriate shielding from natural background radioactivity.

The procedure is to first measure  $^{40}\text{K}$  in a whole-body counter and then calculate total body potassium from  $^{40}\text{K}$ . Once total body potassium is known, FFM can be estimated by assuming a constant relationship between total body potassium and FFM,

$$\text{FFM} = \text{TBK}/\text{ratio} \quad (7)$$

where "ratio" is the assumed constant proportion of FFM as potassium. The estimated ratio for Reference Man is 63.3 mmol/kg and reflects the summed potassium proportions of all organs and tissues, notably skeletal muscle mass (Table 4) (4,39). Relative organ proportions vary among individuals and, accordingly, several suggested sex- and age-specific TBK/FFM ratios are recognized and applied in estimating FFM (12). Total body fat is calculated as the difference between body weight and FFM.

The total body potassium method of estimating FFM and fat mass is of great historical significance. Many early obesity studies were carried out with total body potassium measured by whole-body counting as the reference method for fat and FFM. Whole-body and regional counters are costly, and there are important technical issues that require attention to achieve accurate results. Today there are methods of equivalent, if not greater, accuracy for quantifying fat and FFM that are more available to research laboratories and are of equal or lower cost.

Total body potassium can also be measured using dilution of the radioactive isotope  $^{42}\text{K}$  (7). This method is useful in specialized whole-body counter calibration studies, but has no practical application in the study of human obesity. The 12.4-hr half-life of  $^{42}\text{K}$  and the radiation exposure involved preclude the routine use of

**Table 4** Reference Man's TBK/FFM Ratio Calculated from 14 Tissues/Organs

| Tissue/organ    | Fat-free mass (kg) | $f\text{FFM}_i$ | $(\text{K}/\text{FFM})_i$ | $(\text{K}/\text{FFM})_i \times f\text{FFM}_i$ |

this isotope. Exchangeable potassium ( $\text{K}_e$ ), which accounts for most of total body potassium, can also be measured using a combination of exchangeable sodium and total-body water measurements and this might be a useful approach at centers in which whole-body counters are unavailable.

Although the application of total body potassium as a measure of adiposity in human obesity research is limited, total body and exchangeable potassium provide useful measures of body cell mass. The body cell mass compartment is often considered a measure of metabolically active tissue. The measurement and interpretation of body cell mass is discussed in detail by Moore and colleagues (7). Recent studies also support the use of total body potassium in skeletal muscle mass measurement.

## 2 In Vivo Neutron Activation Analysis

A group of methods referred to as whole-body counting/in vivo neutron activation analysis can be used to estimate adiposity-related components. The methods share in common the ability to quantify all main elements at the atomic body composition level in vivo including H, C, N, O, P, Ca, Cl, K, and Na (3). Once these elements are known, it is possible to calculate,

using simultaneous equations, the main molecular level components such as fat, protein, water, and minerals. Components at other levels, such as body cell mass, extracellular fluid, intracellular fluid, and skeletal muscle can also be calculated using models based on measured elements.

Only a few centers throughout the world are capable of measuring all of the major elements, while several additional centers are capable of measuring one or two elements. Whole-body counting alone can measure naturally occurring  $^{40}\text{K}$ . When subjects are activated with a neutron source first and then placed back in a whole-body counter, additional elements such as Na, Cl, Ca, and P can be quantified by "delayed-gamma" neutron activation. Two other methods, prompt-gamma neutron activation and inelastic neutron scattering methods are used to measure elements such as N, H, C, and O. Each neutron activation system is unique and many alternative methods have been advanced over the years.

In this section we provide a selective review of one representative adiposity measurement method, the multicomponent total body carbon method of estimating total body fat mass. This method provides the main concepts related to all in vivo neutron activation methods.

The total-body carbon method represents an evolution of neutron activation methods at the Brookhaven National Laboratory in Upton, NY. The total body carbon method provides fat estimates that are independent of the two-component total body potassium, water, and underwater weighing methods. This method can be used as a reference method for evaluating other body composition methods.

The initial model for estimating fat mass developed by Cohn and colleagues at Brookhaven was relatively simple (40). There were two measured elements, N and Ca, which were used to calculate total body protein and bone mineral, respectively. Tritium dilution volume was used to estimate total body water, and fat mass was then calculated as the difference between body weight and the sum of total body protein, water, and minerals. Additional improvements in the model were made by Heymsfield et al. as new information became available (41). The most recent advance occurred when Kehayias and colleagues introduced inelastic neutron scattering for measuring total body carbon (42,43).

The total body carbon method is based on the observation that almost all body carbon is incorporated into four components at the molecular level of body composition, fat, protein, glycogen, and bone mineral. Kyere and colleagues (44) first proposed a model in

which fat could be calculated from total body carbon. This model was later improved by Kehayias et al., who proposed four simultaneous equations (42,43),

$$\text{TBC} = 0.77 \times \text{fat} + 0.532 \times \text{protein} + 0.444 \times \text{glycogen} + \text{carbon in bone mineral} \quad (8)$$

$$\text{TBN} = 0.16 \times \text{protein} \quad (9)$$

$$\text{Glycogen} = 0.044 \times \text{protein} \quad (10)$$

$$\text{Carbon in bone mineral} = 0.05 \times \text{TBCa} \quad (11)$$

where all units are in kg, and TBC, TBN, and TBCa represent total body carbon, nitrogen, and calcium, respectively. Solving the simultaneous equations for fat mass,

$$\text{total body fat} = 1.30 \times \text{TBC} - 4.45 \times \text{TBN} - 0.06 \times \text{TBCa} \quad (12)$$

This last equation indicates that the total body carbon method measures total body fat as a function of three elements, C, N, and Ca.

There are two important issues to consider with respect to Eq. (12) are the coefficients constant, and can total-body carbon, nitrogen, and calcium be measured accurately? Equation (8) includes the proportions of total body carbon as fat, protein, glycogen, and bone mineral. Equations (9), (10), and (11) include the ratios between protein and nitrogen, glycogen and protein, and carbon and calcium in bone mineral. All of the ratios in Eqs. (9)–(11) are assumed constant, and it is useful to consider this assumption in some detail.

Although triglycerides extracted from human tissues vary in fatty acid composition, their carbon/triglyceride ratios (C/TG) are very close to 0.77 (Tables 1 and 2). The various stoichiometries indicate that the C/TG ratio varies within a narrow range (0.759–0.774). It is therefore reasonable to assume a constant C/TG ratio of 0.77 in Eq. (8), (13).

Total-body protein can be calculated from total body nitrogen, and nitrogen can be measured by prompt- $\gamma$  neutron activation analysis. This calculation is based on the assumption that a constant ratio (0.16) exists between nitrogen and protein [Eq. (9)]. Protein includes almost all compounds containing nitrogen, varying from simple amino acids to complex nucleoproteins (45). The current suggested chemical formula for protein is  $\text{C}_{100}\text{H}_{159}\text{N}_{26}\text{O}_{32}\text{N}_{0.7}$ . The C/protein and N/protein ratios in this widely accepted formula are 0.532 and 0.16, respectively. Chemical analysis confirmed the ratios' validity for most proteins analyzed, although a few specific proteins have N contents that

are different from 0.16 (e.g., 0.137 and 0.172 for albumin and collagen, respectively). The chemical analysis of two cadavers, however, yielded whole body N/protein ratios of 0.156 and 0.158, close to the assumed value of 0.16 (46).

Glycogen is not included in most body composition models owing to its small amount. In the total body carbon method for estimating fat, glycogen content was included because of the high C/glycogen ratio of 0.444. In the model of Kehayias et al. the glycogen/protein ratio was assumed constant at 0.044 (42). This consideration must be approximate because the concentrations of glycogen in liver, skeletal muscle, and heart vary significantly with fasting and feeding. Total body glycogen content is  $\sim 0.3$ – $0.5$  kg and thus the total amount of carbon in glycogen is only  $\sim 0.2$  kg. The model error from the assumed constant glycogen/protein ratio therefore has only a small effect on the accuracy of total body fat estimates.

The main compound of bone mineral, calcium hydroxyapatite  $[\text{Ca}_3(\text{PO}_4)_2]_3 \text{Ca}(\text{OH})_2$ , does not contain carbon. Biltz and Pellegrino found that the ratio of carbon to bone calcium is 0.05 g/g (47). It is known that almost all body calcium is incorporated into bone mineral. The total body carbon method estimates carbon in bone mineral, presumably incorporated as carbon in bicarbonate, from total body calcium [Eq. (6)]. Although the carbon/calcium ratio is an approximation, errors in this proportion have only a small effect on fat estimates as with glycogen.

The total body carbon method does not consider the carbon in soft tissue minerals as  $\text{HCO}_3^-$ . This is because the very small amount of carbon in soft tissue minerals has almost no impact on fat estimates.

From the above discussion it is clear that many assumptions are needed in developing the total body carbon method for measuring total body fat. The main assumptions, however, appear to be highly stable, and position the total body carbon-fat estimation method as a means of analyzing human chemical composition in vivo. Returning to the second aspect of the total body carbon method, measurement of C, N, and Ca, all three elements are quantified by neutron activation analysis.

Total body carbon is measured by inelastic scattering which is based on the reaction (42,43)

Fast incoming neutrons that interact with matter by inelastic collisions result in prompt nuclear de-excitation with  $\gamma$ -ray release ( $n, n'\gamma$ ). Total-body nitrogen is

measured using prompt- $\gamma$  neutron activation analysis, and its reaction is (48):

Delayed- $\gamma$  neutron activation is used to measure total body calcium based on the reaction (49):

The notation for this reaction is given as [ $^{48}\text{Ca}(n,\gamma)^{49}\text{Sc}$ ] for [target nucleus (incident particle, emitted particle) residual nucleus]. All three of the neutron activation analysis methods involve radiation exposure, and this is the main disadvantage of the total body carbon method. The average exposure is 80, 575, and 50 mrem for prompt- $\gamma$ , delayed- $\gamma$ , and inelastic scattering neutron activation analysis, respectively.

The between-measurement coefficients of variation for total body carbon, nitrogen, and calcium are 3.0%, 2.7%, and 0.8%, respectively. The propagated error in the total body carbon method of measuring total body fat is 3.4–4.0% (42).

The total body carbon method is not widely used in the study of body composition since only a few laboratories in the world have the necessary three neutron activation systems. However, the total body carbon method is important because it is based on highly stable models that are not affected to an appreciable degree by age, sex, ethnicity, or disease. In some respects, at least conceptually, the total body carbon method approaches the potential accuracy in estimating total body fat afforded by lipid extraction of human cadavers.

### 3 Hydrometry

Dilution methods, including those for total body water, or “hydrometry,” include a group of body composition methods designed to quantify fluid compartments and the components that exist entirely within body fluid compartments such as exchangeable potassium, sodium, and chlorine. All dilution methods are based on the use of a labeled tracer with three properties: (1) it has the same or similar distribution space as the component analyzed; (2) it has a distinct property (e.g., radioactivity or color) that can be quantitatively measured; and (3) it is nontoxic in the amounts used. A dose of tracer (T) is administered to the subject, and after an equilibration interval, a portion of the tracer exchanges

with other molecules or is excreted; any excreted tracer can be measured in urine. The tracer that remains in the body (T') then homogeneously distributes within the unknown component (C) volume. The following model then applies (50),

$$P^* = R \times (C + T') \quad (16)$$

where T' represents the known amount of tracer in the body at equilibrium, P\* is the known measured distinct tracer property, and R is the ratio of P\* to the sum of C and T'. Because T' is much smaller than C, the model can be simplified to

$$P^* = R \times C \quad (17)$$

One can analyze a sample of the unknown component such as blood or a piece of tissue. Because the tracer is homogeneously distributed in the unknown component,

$$\Delta P^* = R \times \Delta C \quad (18)$$

where  $\Delta C$  and  $\Delta P^*$  are the measured unknown component mass and tracer property, respectively. Combining this formula with the above equation, a dilution model is derived,

$$C = [P^* \times \Delta C] / \Delta P^* \quad (19)$$

In the model, P\* is known and  $\Delta C$  and  $\Delta P^*$  can be measured in samples. The unknown component (C) volume can thus be calculated.

Although dilution methods are widely used in the measurement of extracellular fluid, plasma volume, and exchangeable electrolytes ( $K_e$ ,  $Na_e$ , and  $Cl_e$ ) (50), the most important use in the obesity field is measurement of total body water. This is because water is the largest component at the molecular body composition level in normal adults and also because water occupies a relatively constant fraction of FFM, usually assumed as 0.73 based upon classic *in vitro* experiments. The stable hydration fraction of  $\sim 0.73$  is recognized from human cadaver studies (Table 5) and, within a reasonable range, is also observed across all adult mammals (Fig. 9)(8–10).

Water labeled with either of two isotopes of hydrogen (deuterium,  $^2\text{H}_2\text{O}$ ; tritium,  $^3\text{H}_2\text{O}$ ) or oxygen ( $\text{H}_2^{18}\text{O}$ ) has been used to quantitate total body water by the dilution method in healthy and diseased individuals (51). The use of deuterium and  $^{18}\text{O}$ -labeled water-stable isotopes is safe and preferred for children and pregnant women. The assays for these two isotopes in biological fluids rely on labor intensive techniques such as mass spectrometry. Tritium is radioactive and should not be used in children or in pregnant women. On the

**Table 5** Fat-Free Body Mass Hydration (TBW/FFM) Evaluated in Nine Adult Human Cadavers

| Gender | Age (yr) | BM (kg) | TBW (kg) | FFM (kg) | TBW/FFM | Cause of death         |

Source: Ref. 10.

other hand, it is somewhat easier to measure with widely available scintillation counters (51).

Once the dilution volume is known, total body water volume and mass can be calculated from isotope exchange fraction and water density. Each of the three isotopes measures a specific dilution volume that is somewhat larger than the actual volume. For the two hydrogen isotopes, tritium and deuterium, the dilution volume is larger than actual total body water because the H atoms in the tracer exchange with H atoms bound to carboxyl, hydroxyl, and amino groups (52). Similarly, the  $^{18}\text{O}$  tracer exchanges with oxygen atoms in carboxyl and phosphate groups (53). Exchange of labeled atoms

with unlabeled atoms from molecular components may vary owing a number of factors, but most investigators assume a stable exchange of  $\sim 4\%$  for tritium and deuterium and  $\sim 1\%$  for  $^{18}\text{O}$  (53). Thus, total body water is calculated as the product of isotope dilution volume and a correction factor that accounts for isotope exchange (e.g.,  $^3\text{H}_2\text{O}$  and  $^2\text{H}_2\text{O}$  dilution volumes  $\times 0.96$ ;  $\text{H}_2^{18}\text{O}$  dilution volume  $\times 0.99$ ). At present, there does not appear to be a universally accepted, fully valid method of estimating isotope exchange. Total-body water volume is converted to mass using the density of water at body temperature ( $0.9937 \text{ g/cc}$  at  $36^\circ\text{C}$  or  $0.9934 \text{ g/cc}$  at  $37^\circ\text{C}$ ). Total body water, once known, can then be used to estimate total body fat and FFM as:  $\text{FFM} = 1.37 \times \text{TBW}$ , and  $\text{fat} = \text{body weight} - \text{FFM}$ .

The total body water method is widely used, and the specific isotope selected depends on available funds, analytical facilities, and subject characteristics. An important feature of the total body water method is the availability of stable isotopes, thus eliminating radioactivity from the analysis for use in children or pregnant women. The subject evaluation portion of the total body water method can be carried out in field settings, and some investigators use this approach in phenotyping subjects in remote settings. The total body water method can also be used as the reference for total body fat in remote settings when developing ethnic-specific calibration equations for calibrating bioimpedance and anthropometric methods. The total body water method is also a reasonable approach for estimating adiposity in morbidly obese patients for whom other methods may not be suitable. The validity of the assumed stable FFM hydration (0.73) in morbidly obese subjects is unknown.

**Figure 9** Total body water versus fat-free body mass, both expressed in logarithms, for humans and eight mammalian species. (From Ref. 10.)

An important concern is bias error due to systematic variation in the TBW/FFM ratio with age, gender, race, obesity, disease, or other factors. As an example, TBW/FFM is known to be higher in infants and young children than in adults (54). Some have speculated that the TBW/FFM ratio is decreased in obesity and elevated in elderly people (55,56). Certain diseases (e.g., renal disease, congestive heart failure) clearly result in alterations in the TBW/FFM ratio. Lastly, the early phase of weight loss (i.e., the first 1–2 weeks) with obesity treatment may be associated with relatively greater water loss than of other FFM components and thus the assumed TBW/FFM ratio may not be constant during the phase of dynamic weight change (57).

#### 4 Hydrodensitometry/Air Displacement Plethysmography

##### a. *Hydrodensitometry*

Hydrodensitometry, often referred to as underwater weighing, is one of the oldest *in vivo* methods of analyzing human body composition as a two-component (i.e., fat and FFM) model (58).

Hydrodensitometry is based on the Archimedean principle that a solid object submerged in water is subject to a buoyant force that is equal to the weight of the water displaced by the object, or the loss in weight of the object when it is weighed while submerged in the water. Thus, the specific gravity or “density” of the object can be determined from the weight of the object divided by the loss in weight when submerged in water. The human body generally has a density close to that of water (i.e., 1.0 g/cm<sup>3</sup>). Individual deviations from this value are mainly due to the amount of fat in the body. Because fat is less dense than water, the lower the body density, the greater the amount of body fat. Behnke was the first to show that this method could be used to deduce the percentage of weight that is fat from body density using a simple two-component model that assumes specific densities for fat and fat-free fractions of body weight (13,59).

Lipid extracts of human adipose tissue, which are mostly triglycerides, have a mean density of 0.9007 g/cm<sup>3</sup> at body temperature (60) (Table 2). The density of FFM has been estimated to be 1.100 g/cm<sup>3</sup> based on data from cadaver studies (61). Fat-free body mass is assumed to be composed of constant proportions of water (73.2%), minerals (6.8%), and protein (19.5%) with residual amounts (<1%) of other chemical components (e.g., glycogen). The densities of these individual chemical components are also considered to be constants at body temperature (Table 2). Human body

densities generally vary between 1.08 g/cm<sup>3</sup> (very lean) and 1.03 g/cm<sup>3</sup> (moderately obese). Obese subjects will have body densities <1.03 g/cm<sup>3</sup>, and severely obese people may have densities <1.00 g/cm<sup>3</sup>.

The most commonly used two-component model for estimating body composition from body density measured by underwater weighing was derived originally by Siri [Eq. (1)](62). A revised model proposed by Brozek et al. (61) gives slightly lower estimates in obese subjects due to somewhat different underlying assumptions regarding the densities of fat (0.8888 g/cc) and fat-free (1.1033 g/cc) components. Additional revised models have been proposed that adjust the coefficients in two-component equations for systematic differences in the composition of FFM associated with age, sex, ethnicity, and level of fatness (14,54,56). These adjusted equations should not be applied without, verifying in a random subsample of a study population that the assumed deviations in fat-free composition actually occur. None of these equations consider human individual variability in the composition of FFM that may occur independent of age, sex, ethnicity, or obesity. As the composition of FFM may change with short-term weight loss, two-component models based on body density alone may provide inaccurate estimates of the amount of fat lost during the early phase of obesity treatment (63).

A limitation of the underwater weighing method is that accurate measurements require active participation and effort by the subject being measured. In the conventional approach, the subject must submerge their body completely while exhaling maximally, and then hold their breath and body position for several seconds until a weight measurement is obtained. Some individuals cannot perform adequately, and underwater weighing is not feasible in very young children, frail elderly, or those with serious cardiovascular or pulmonary diseases. In those who can perform the procedure, errors may occur owing to body movement and the buoyant effects of air in the gastrointestinal tract and lungs. Errors due to movement during submersion may be reduced by the use of electronic load cells and stable chair systems, rather than spring scales and body slings. It is not feasible to measure the amount of air and gas in the stomach and intestinal tract, and a fixed value is usually assumed (~100 mL).

The larger air volume in the lungs is adjusted for by measuring residual lung volume when the subject is out of the water using a spirometer with He dilution or N washout, or during weighing with systems designed for this purpose. The simultaneous measurement of residual lung volume and underwater weight may be pre-

ferred because it controls for the effects of the increased pressure of water on the thorax during immersion. Some studies suggest, however, that these effects are small and result in only a slight reduction in residual volume in normal subjects (64). Maximum effort and compliance by the subject during spirometry, whether in or out of the water, and repeated measurements of residual lung volume may be more important. Inaccurate measurements of air in the lungs can be a major source of error when estimating body density from underwater weighing.

Although feasible, underwater weighing of obese subjects may present special problems. Obesity is often associated with respiratory problems and reduced lung function, which may make it more difficult to obtain accurate measurements of residual lung volume. As obese subjects have a strong tendency to float owing to their low body density, it may be necessary to use a weight belt, or other tare weight system, to completely submerge the body. The tare weights must be measured and recorded carefully to obtain an accurate underwater weight. Despite these limitations, high levels of precision can be achieved in most obese subjects with underwater weighing. Moreover, underwater weighing may be the only practical method of measuring body fat in very obese subjects who cannot be evaluated by other methods. The minimum possible technical and biological errors from all sources for percent body fat by underwater weighing has been estimated to be about  $\pm 2.5\%$  (65). This represents an ideal, however, that can be achieved only if careful attention is given to optimizing the performance of subjects and the quality of the equipment, and if all model assumptions are valid.

Assuming subjects are comfortable with water submersion, the hydrodensitometry method is very safe. Underwater weighing systems range in price and at the low end can be built quickly at low cost. Once built, the systems are usually not transportable.

#### *b. Air Displacement Plethysmography*

Air displacement plethysmography (ADP) is a technique designed to replace hydrodensitometry in the approximation of body composition (66). The governing principle is essentially that of hydrodensitometry—that the density of a human body can be used to approximate two-compartment body composition, fat and FFM. In ADP, however, body volume is evaluated by measuring air displaced by a body's introduction to a controlled environment.

Attempts in a number of forms have been made throughout the years to replace hydrodensitometric

measurement with ADP. However, these approaches were unsatisfactory for a number of reasons, but owing particularly to complications arising from the introduction into the measurement chamber of the human body itself (e.g., changes in temperature, air composition, etc.). Such problems have largely been addressed with the commercial ADP system now available (BOD POD Body Composition System, Life Measurement Instruments, Concord, CA) (66).

The BOD POD measurement system is comprised of an electronic scale and the BOD POD unit itself, both routed through a computer operated by a technician (66). The measuring process is relatively simple. First, the subject, wearing a form-fitting bathing suit and swim cap, is weighed on the scale. The subject is then seated in the front chamber of the calibrated BOD POD unit. An egg-shaped capsule, the unit has a large window that allows the subject to see outside, making for a more comfortable environment. A moving diaphragm mounted between the front and rear chambers, 450 and 300 L, respectively, oscillates during the measurement process to create in the two chambers volume perturbations of exactly equal magnitude. Air between the two chambers is constantly mixed during measurement, and the subject breathes through a filtered tube as thoracic volume change due to breathing is recorded. Thus are addressed the effects of changes in isothermal conditions and air composition.

Once measurement is complete, the software provided with the system records the subject's volume and density and, using the Siri equation [Eq. (1)], calculates and records the subject's body composition. Studies have indicated that the reproducibility of percent adiposity measurement using the BOD POD is high, with between-trial SD reported at 0.4% and CV 1.7%  $\pm 1.1\%$ , both marginally lower than for hydrostatic weighing (67). Some investigators have found a trend in the BOD POD toward underestimation of body density as compared to hydrodensitometry, creating a small but statistically significant difference in percent fat (68). There are now many studies reporting good agreement between BOD POD percent fat estimates and those provided by other reference methods such as DXA. Systems are reportedly in development that are suited for young children for whom the present BOD POD is not ideally designed.

Benefits of this ADP system include the ease of use relative to hydrodensitometry, minimal requirement for subject participation, and high level of reproducibility. Subjects and technicians also require a minimal amount of instruction, the process takes only a few minutes for each subject, and the chamber is relatively

accessible for the elderly, disabled, and obese. A limitation of the ADP system is that the chamber, while mobile for field use, weighs > 135 kg, and transporting the entire system might prove difficult. Nevertheless, BOD POD systems are in use at settings involved in phenotyping remote populations. Clothing restrictions can be of some concern for individual patients; for example, the manufacturer's instructions advise that subjects should wear a swim cap and tight-fitting swimsuit to ensure accuracy. Furthermore, the size of the chamber may be restrictive for very large people. Finally, the cost of the BOD POD may be prohibitive for some who would wish to use the system.

### 5 Dual-Energy X-Ray Absorptiometry

Anthropologists and health care workers in the field of metabolic bone disease have long required a means for quantifying bone mass. In the past, the preferred approach was to expose one side of the subject's wrist to a photon-emitting radioactive source while a scintillation counter was positioned on the other side of the wrist (69). The number of counts detected served to indicate the amount of attenuating calcium or bone present. The wrist was typically the site of choice for measurement because at that part bone is the main attenuating tissue, unlike conditions at the hip or spine

where soft tissue is also present. Later, investigators explored means of evaluating hip and spine, as those are two bone areas of clinical concern for the study of osteoporosis. The single-photon system evolved to a dual-photon system, and is now based on a filtered x-ray source and is commonly called dual-energy x-ray absorptiometry (DXA) (69). In order to quantify bone mineral within a soft-tissue containing pixel, DXA systems required information about soft tissue composition. The capacity for quantifying the fat and lean soft tissue content of a pixel evolved into DXA's central role in modern body composition analysis.

All DXA systems in general operate on similar principals, although important technical details prevail (70) (Fig. 10). An x-ray source provides a broad photon beam that is usually filtered, thus yielding two main energy peaks. Some systems use a pulsating voltage source to produce the two energy peaks. The emitted photons traverse the subject's tissues; the extent of the attenuation that follows depends on the tissue's elemental makeup. Elements of low atomic weight, such as hydrogen, minimally attenuate photons whereas elements such as calcium are highly attenuating. The difference in attenuation between the two energy peaks is particular to each element, and thus to each tissue. The characteristic attenuation signature for fat, lean, and bone mineral allows one to develop pixel-by-pixel composition estimates using a series of

**Figure 10** Schematic representation of DXA system (left) and three-component model consisting of bone mineral, lean soft tissue, and fat. (From Ref. 17.)

assumptions and reconstruction algorithms (70). Some systems use a simple “pencil beam” configuration as the patient is scanned, while others are based on a “fan beam” configuration of x-ray source and detector. Fan beam systems tend to be faster, requiring just several minutes for each scan; pencil beam models have a longer scan time. Accuracy varies between system designs and software. The manufacturer performs calibrations that allow resolution of the three molecular level components, bone mineral, fat, and lean soft tissue (Fig. 4). Once systems are operational, system calibration and functional evaluations are also carried out on a regular basis. DXA x-ray exposure is minimal ( $<1$  mrem), allowing for safe longitudinal studies in children and adults.

DXA estimates the three molecular level components for the whole body and separately for the arms, legs, and trunk. The body segment estimates are somewhat less precise and accurate than those for the whole body (69). The accuracy of DXA systems is influenced by the thickness of the energy-absorbing tissues in the path of the x-ray beam, and accuracy decreases with increasing thickness due to beam hardening. Manufacturers of DXA systems include correction algorithms in their operating software for the effects of body thickness, although different versions of software may provide somewhat different body composition estimates (71).

Several studies have compared DXA with physicochemical analyses of pig carcasses, and generally show better results for larger animals, and application in infants and small children is now well accepted (72–74). New, specially designed DXA systems are proving useful in phenotyping fatness in small animals such as the mouse. DXA has also been evaluated using experimental models composed of measured amounts of biological tissues or non-biological tissue-equivalent materials (75,76). In vivo studies of DXA accuracy can be separated into experimental versus observational groups. In experimental studies, packets of lard have been placed on lean subjects to simulate increased amounts of adipose tissues (74,77). These studies have produced mixed results that seem to depend on where the additional lard was placed on the body (trunk vs. legs), the type of scanner, and the version of software used. Other experiments have tested the effects of changes in hydration of the FFM using either patients undergoing hemodialysis or volunteers ingesting large amounts of water. Generally, DXA has been shown to measure changes in body fluids accurately and to correctly attribute these changes to the lean soft tissue mass (78). A recent study with phantoms supported by

theoretical calculations suggests that percent fat estimates by DXA are minimally influenced by changes in hydration within the physiological range (79). Observational studies have compared DXA, with favorable outcomes, to estimates from hydrodensitometry, total body water, and multicomponent models in subject groups over wide ranges of body fatness (80,81). It is important to note that few studies were specifically designed to test the accuracy of DXA in moderately or severely obese subjects.

Most studies show that DXA estimates of body composition are highly reproducible. This has been evaluated in a variety of experiments. Reported technical errors for estimates of percent fat ranged from 0.3% to 1.4%; errors for FFM range from 0.3 to 0.9 kg (69,80). Reported coefficients of variation range from 0.5% to 4% for percent body fat, 1% to 1.7% for fat mass, and 0.7%, to 1.0% for FFM (78,82). Although there is substantial evidence that DXA estimates lose accuracy with increasing body thickness, reports are conflicting as to whether thickness results in a systematic bias toward either over- or underestimation of body fatness (76). These conflicting results might be attributable to the use of different scanners and versions of software incorporating different calibration standards and thickness corrections. In any event, it is reasonable to expect that DXA estimates will lose both accuracy and precision in thicker obese subjects.

The DXA approach is rapidly becoming the most available and established of the reference body composition methods as systems are well designed and provide accurate and reproducible results, studies in children are possible, and there exists the possibility of transporting systems in a mobile van. The disadvantages of DXA are that it cannot be used in pregnant women, the cost of purchasing and operating the system is relatively high, and very large or obese subjects cannot be easily accommodated on most available systems. An ongoing and unresolved debate centers on the superiority of fan beam versus pencil beam systems, and on other system characteristics that differ among manufacturers.

The application of DXA to the body composition analysis of obese patients is subject to additional practical limitations. Many obese individuals will simply be too wide for the scan field ( $\sim 190 \times 60$  cm) as the soft tissue falling outside of the scan field will not be included in the body composition analysis, resulting in biased estimates. As a result, DXA manufacturers generally do not recommend scanning individuals  $>100$  kg body weight. This represents a serious limitation to the application of DXA body composition analysis, and it also

may limit the accuracy of regional body composition data. For example, it may not be possible to abduct the arms sufficiently from the trunk, or to separate the legs sufficiently at the thighs, in obese subjects to obtain accurate estimates of separate arm and leg soft-tissue masses. Tataranni and Ravussin (82) described an approach that combines information from two DXA scans taken for each side of the body in obese subjects. This approach appears to provide reasonably accurate estimates, compared to those from hydrodensitometry, but requires careful attention to subject positioning in the scan field and also adds significantly to total scan and data analysis time. As an alternative, the authors suggest multiplying body weight by percent fat estimates from a half-body scan in order to derive total body estimates. This method is likely to be accurate, albeit only in subjects with little anatomical asymmetry between the right and left halves of the body.

## 6 Multicomponent Models

A supplementary approach to the two-compartment hydrodensitometry or ADP methods is to use multicomponent methods that include measures of total body water, bone mineral mass, and soft tissue mineral mass in addition to body density, assuming fixed densities for each component (Table 2) (83–85). Multicomponent models are designed to provide estimates of three or more components. Adding more measured components reduces the number of applied model assumptions and multicomponent methods are often applied as the criterion against which other methods are compared (86).

Selected examples are provided in Table 6 of three-, four-, and five-component methods of estimating fat mass along with the measurable quantities and simultaneous equations upon which they are based (83–90). The equations in Table 6 are based on component densities at body temperature, which ranges between 36°C and 37°C (Table 2). In certain groups, such as children, elderly, African-American, or sick patients, these methods may provide more accurate estimates of body fatness than the simpler, two-component models. Precise measures of total body water, bone mineral mass, and soft tissue mineral mass are required, however, to avoid swamping the gain in accuracy with increased propagated errors of the additional measurements (91). In addition, the benefit in terms of improved accuracy should always be evaluated in relation to the increased cost associated with obtaining the additional measurements of total body water, total body bone mineral, and soft tissue mineral (86). These

costs may be justified when the goal is to estimate changes in body fat over time, as in clinical weight loss studies, and in evaluating the accuracy of other potential reference methods.

## 7 Imaging Methods

Imaging methods, such as CT and MRI, are considered the most accurate means available for *in vivo* quantification of body composition on the tissue system level. Although access and expenses remain obstacles to routine use, these imaging approaches are now used extensively in body composition research. CT and MRI are the methods of choice for calibration of field methods designed to measure adipose tissue and skeletal muscle *in vivo*, and are the only methods available for measurement of internal tissues and organs. More recently both methods have been employed to measure the quality of various tissues, in particular, skeletal muscle tissue.

### a. Computed Tomography

The basic CT system consists of an x-ray tube and receiver that rotate in a perpendicular plane to the subject. CT measures are 0.1–0.2 Å, 60–120 kVp x-rays that are attenuated as they pass through tissues (92). Attenuation is expressed as the linear attenuation coefficient or CT number. The CT number is a measure of attenuation relative to air and water. The CT numbers of air and water are defined as –1000 and 0 Hounsfield number (HU), respectively. The x-ray beam attenuation is related to three factors: coherent scattering, photoelectric absorption, and Compton interactions (92). Physical density is the main determinant of attenuation and, therefore, CT number. There is a linear correlation between CT number and tissue density (93,94). Each of the image pixels or voxels has a CT number which gives contrast to the image. Image reconstruction is usually done with mathematical techniques based on either two-dimensional Fourier analysis, filtered back-projection, or a combination of these methods.

CT body composition methods are designed to quantify components at the tissue system level of body composition. The main components are adipose tissue, skeletal muscle, bone, visceral organs, and brain. Cross-sectional images are composed of picture elements or pixels, usually 1 × 1 mm squares. Slice thicknesses vary, and when considered in three dimensions, the image consists of volume elements or voxels. Each pixel/voxel is assigned a value on a gray scale that reflects the composition of the tissue.

**Table 6** Representative Multicomponent Methods for Measuring Total Body Fat

| Reference               | Required measurements |               | Simultaneous equations  | Fat mass equation  |

Abbreviations: BV, body volume (liter); BW, body weight (kg); FM, fat mass (kg); Mo, osseous mineral; Ms, soft tissue mineral (kg); TBBM (kg) = ashed bone from DXA  $\times 1.0436$ .

Source: Ref. 15.

Quantifying tissue volume by CT requires two steps. First, the tissue area ( $\text{cm}^2$ ) on each cross-sectional CT image is determined using one of two methods (95,96). In one technique, the investigator traces the perimeter of the target tissue with a light pen or track ball controlled cursor. The area of the circumscribed tissue is then calculated, usually with software installed on the CT scanner console. The second approach employs a computerized edge detection procedure that identifies the area of the target tissue by selecting pixels within a given HU range, for example  $-190$  to  $-30$  HU for adipose tissue (96). Automated procedures are now becoming

available. Once the tissue areas ( $\text{cm}^2$ ) are quantified for a series of images, the total volume can be calculated by integrating data from multiple contiguous slices. The tissue mass can be then calculated if a value for the density of the tissue is assumed.

CT tissue area and volume measurements have been shown to be highly reproducible. Kvist et al. (96) reported an average error of  $\pm 0.6\%$  for whole body adipose tissue volume for duplicate measures in four subjects. Chowdhury et al. (95) reported intraobserver errors for a large number of CT-measured body composition components. Some examples are for skin =  $2.4\%$ , total adi-

pose tissue = 0.4%, and heart = 3.4%. An earlier report by Brummer et al. (97) indicated interobserver errors of 0.7%, 0.4%, and 2.1% for total adipose tissue, skeletal muscle, and visceral organs, respectively.

Several studies have established the accuracy of area and volume measurements from CT. Heymsfield et al. (98) reported that organ masses estimated using CT were highly reproducible and agreed with actual mass to within 5–6%. Rossner and colleagues (99) found good agreement between CT and cadaver adipose tissue areas and ratios ( $r$ 's ranged from .77 to .94). Chowdhury and colleagues (95) reported that the average difference between body weight and mass determined from CT measured tissue volumes was  $0.024 \pm 0.65$  kg and the coefficient of variation was 0.85%. Wang and colleagues (100) reported that body volume calculated from 22 CT slices was highly correlated with body volume from underwater weighing in seventeen men ( $r = .99$ ,  $P = .0001$ ,  $SEE = 1.9$  L,  $n = 17$ ), although there was a statistically significant difference between the mean values (CT =  $74.8 \pm 13.9$  L vs. UWW =  $73.6 \pm 13.7$  L,  $P < .02$ ). This difference between mean volumes may be due to difficulty in accurately estimating residual lung volumes and in quantifying lung parenchymal volume by CT.

Heymsfield and colleagues were among the first to explore the use of CT in body composition research. They initially used CT to quantify the cross-sectional area of arm muscle in 1979 (101); subsequent reports described methods of estimating visceral organ volumes (98) and VAT (102). Borkan and colleagues were the first to systematically evaluate VAT in 1982 (103). Sjöström and colleagues introduced whole-body imaging and multicomponent analysis to quantify total body and regional adipose tissue, skeletal muscle, bone, and other organ/tissue volumes (104).

In recent years CT has been employed to measure the quality of various tissues—in particular, skeletal muscle tissue. The focus has been to establish the lipid content as altered fat deposition in skeletal muscle is linked to reduced insulin-stimulated glucose uptake. An increased muscle lipid content has also been noted in older persons and is associated with muscle wasting diseases (105,106). As noted above, CT is capable of distinguishing different tissue types on the basis of their attenuation characteristics, which in turn are a function of tissue density and chemical composition. Skeletal muscle attenuation is determined by measuring the mean attenuation value from all pixels within the range of 0–100 HU. The lower the mean attenuation value, the greater the infiltration of lipid within the muscle. As an additional means of characterizing muscle composition, the distribution of attenuation values is described as

representing two components on the basis of muscle density. One-component, normal-density muscle is defined as muscle pixels with attenuation values within 2 SD of the mean attenuation value observed in lean, normal muscle (31–100 HU). The second component, low density muscle, is defined as muscle with below normal attenuation values (0–30 HU).

The reliability and validity of in vivo measurement of skeletal muscle attenuation was recently studied by Goodpaster et al. (107). Single-slice CT scans performed on phantoms of varying lipid concentrations revealed good agreement between attenuation and lipid concentration ( $r^2 = .995$ ). The test-retest coefficient of variation for mean attenuation values obtained from two CT scans performed on six volunteers was 0.51% for the mid thigh and 0.85% for the mid calf. Although additional validation studies would be useful, preliminary findings suggest that the variability of muscle composition values by CT is low and that the method provides accurate estimates of lipid content, albeit by comparison to phantoms.

Early studies that employed CT to measure muscle composition found associations between reduced skeletal muscle attenuation and aging (108), Duchenne muscular dystrophy, and other myopathies (109). More recently, Goodpaster et al. have observed that the mean muscle attenuation within skeletal muscle is reduced in obesity and type 2 diabetes mellitus (110), and that weight loss increases the mean attenuation value of muscle (111). These unique applications of CT represent a major advance in the study of altered muscle composition in vivo with numerous applications in both applied and clinical medicine. An example of this approach is given in Figure 11.

In a manner similar to that used to determine skeletal muscle density, CT has also been employed to determine the density of liver tissue (112). As with muscle, the lower the Hounsfield units, the lower the liver density and the greater the fat content of the liver. Therefore liver density is inversely related to liver fat and thus is a surrogate for it (113). Several investigators have employed CT to measure liver composition in various cohorts. A focus of this research has been to determine possible links between fatty liver and insulin resistance (114). Determination of liver fat “fatty liver” may provide novel insight into the relationship between abdominal obesity, in particular visceral fat, and increased metabolic risk. Björntorp hypothesized that the metabolic importance of visceral fat may be due to the delivery of free fatty acids into the portal system exerting potent and direct effects on the liver. Indeed, it is now well established that the plasma free fatty acid

**Figure 11** CT images of the proximal thigh for a lean (left) and obese (right) subject. The darker-appearing pixels within the skeletal muscle tissue of both subjects have attenuation values (Hounsfield Units) between 0 and 100. Skeletal muscle attenuation is determined by measuring the mean attenuation value from all pixels within the range of 0 to 100 HU. The lower the mean attenuation value, the greater the infiltration of lipid within the muscle. The mean attenuation value of the skeletal muscle of the obese subject is lower (i.e., darker pixels) by comparison to the lean subject.

concentration is a primary modulator of hepatic insulin resistance (115). This is consistent with the knowledge that in men and women omental and mesenteric adipocytes are metabolically more active by comparison to abdominal subcutaneous adipocytes. Thus sustained differences in portal concentration of free fatty acids may at least partially explain the hepatic and peripheral insulin resistance that characterize visceraally obese older persons. Although it is not possible to readily access the portal circulation *in vivo*, it is reasonable to expect that sustained delivery of free fatty acids to the liver would cause an increase in the infiltration of lipid within the liver—hepatic steatosis or “fatty liver.” Consistent with this position, evidence suggests that visceral fat is a positive correlate of liver fat in men (112), but not women (116).

#### *b. Magnetic Resonance Imaging*

The estimation of body composition components on the tissue system level using MRI is essentially the same as for CT. The two methods differ mainly in the manner in which the images are acquired, which has subsequent bearing on practical considerations of cost and applicability, as well as technical aspects of image analysis, relative accuracy, and reliability.

MRI does not use ionizing radiation. Instead, it is based on the interaction between hydrogen nuclei (i.e., protons), which are abundant in all biological tissues, and the magnetic fields generated and controlled

by the MRI system’s instrumentation. Hydrogen protons have a nonzero magnetic moment which cause them to behave like tiny magnets. When a subject is placed inside the magnet of a magnetic resonance imager, where the field strength is typically 10,000 times stronger than the earth’s, the magnetic moments of the protons align themselves with the magnetic field. Having aligned the H protons in a known direction, a pulsed radiofrequency field (RF) is applied to the body tissues causing a number of hydrogen protons to absorb energy. When the RF is turned off, the protons gradually return to their original positions, releasing in the process the energy that they absorbed in the form of an RF signal. It is this signal that is used to generate the magnetic resonance images by computer.

Foster et al. (117) were among the first to illustrate the applicability of MRI to body composition analysis. Hayes et al. (118) first demonstrated the quantification of subcutaneous adipose tissue distribution in human subjects using MRI. A variety of studies have subsequently used MRI to quantify adipose tissue and/or lean tissue areas or volumes in children (119), normal males and females (120–122), obese males and females (123,124), diabetics (124), and elderly people (125). To date several groups have employed MRI to evaluate whole body adipose tissue and lean tissue distribution in human subjects (120–122c).

Historically, an important problem with the application of MRI to body composition analysis has been the substantial time needed to obtain images of

sufficient quality and resolution for reliable measurements. For example, depending on the pulse sequence used, the acquisition of a set of MRI images for the abdomen could require between 8 (120) and 16 min (126). Recent advances in MRI technology have reduced the time needed to obtain the same quality images of the abdomen to ~25 sec, and a series of images for whole body analysis can be acquired in <30 min (127). These advances should make MRI a much more accessible instrument for body composition studies in the future.

A multislice MRI protocol for whole body analysis is illustrated in Figure 5 (127). The pulse sequence used to obtain images of the abdomen in this protocol requires 26 sec. During this time the subject must hold his/her breath to reduce the effects of respiratory motion on image quality.

A factor that has impeded the use of MRI in body composition analysis has been the availability of appropriate image analysis software. In contrast to CT, this software is not generally included on most MRI control consoles. As a result, MRI image data usually must be translated and downloaded to a separate workstation with image analysis software. Once this is accomplished, the approach to the analysis of MRI images is similar to that used for CT images. The perimeter of the tissue of interest can be traced using a light pen or mouse-controlled pointer, and the area within the perimeter can be calculated by multiplying the number of pixels in the highlighted region by their known area (128,129). Alternatively, image segmentation algorithms can be used that highlight all pixels within a selected range of intensities believed to be representative of a specific tissue. The latter approach, however, is considered more problematic when applied to MRI than to CT images for three reasons: (1) the distributions of pixel intensity (gray scale) values for different tissues overlap more for MRI than for CT images; (2) noise due to respiratory motion blurs the borders between tissues in the abdomen to a greater extent in MRI than in CT; and (3) inhomogeneity in the magnetic field can produce "shading" at the peripheries of MRI images.

Once tissue areas have been quantified from MRI images, volumes ( $\text{cm}^3$ ) and masses may be calculated in a manner similar to that described above for CT. Ross (120), however, has defined a somewhat different mathematical formula for deriving tissue volumes from measurements of a series of axial MRI images. This formula recognizes that each image has a slice thickness and that the pixels identified for a tissue are actually volume elements, or voxels. Thus, the formula is based

on volumes of truncated cones defined by pairs of consecutive images as follows:

$$V = d \times \sum_{i=1}^n \left\{ \frac{h}{3} \times \left[ (A_i + A_{i+1}) + (A_i + A_{i+1})^{0.5} \right] \right\} \quad (20)$$

where  $V$  is total tissue volume,  $A$  and  $A_{i+1}$  are the two consecutive images, and  $h$  is the distance between slices.

Several studies support the accuracy of MRI estimates of human adipose tissue and skeletal muscle and some examples are presented in Table 7. Using a rat model, Ross et al. (130) reported that whole carcass chemically extracted lipid was highly correlated with MRI adipose tissue mass ( $r = .99$ ,  $P < .01$ ) and that the standard error of estimate was 8.7%. Fowler et al. (128) compared MRI adipose tissue measurements to those obtained by dissection in a group of lean and obese pigs. The authors observed that the distribution of MRI adipose tissue correlated strongly with adipose tissue distribution by dissection ( $r = .98$ ), and that the mean square error was 2.1%. Engstrom et al. (131) compared the cross-sectional area measurements of skeletal muscle determined from the proximal thigh in cadavers to the corresponding MRI-measured cross-sectional areas and reported that the correlation coefficient between the two approached unity ( $r = .99$ ). Abate et al. (129) compared MRI measures of abdominal subcutaneous and visceral adipose tissue to that obtained by direct weighing of the same adipose tissue compartments after dissection in three human cadavers. In this study the authors subdivided VAT into intraperitoneal and retroperitoneal depots. For the various compartments the mean difference between the two methods was 0.076 kg or 6%.

Overall, the reported reliability of body composition estimates from MRI is somewhat less than that for CT as shown by the examples in Table 8. Seidell et al. (134) reported CV%'s for repeated measurements of total, visceral, and subcutaneous adipose tissue areas for the abdomen of 5.4, 10.6 and 10.1%, respectively. Baumgartner et al. (135,136) reported CV%'s of <5% for total and subcutaneous adipose tissue and 16% for VAT, which were calculated from two repeated measurements by two independent observers on 25 sets of images. For skeletal muscle, Mitsiopoulos et al. (133) report that the intraobserver correlation for duplicate MRI measurements obtained at the mid thigh level in vivo is 0.99 with a standard error of 8.7  $\text{cm}^2$  or <3%.

It is important with MRI to distinguish error associated with repeated analyses of the same image from that associated with repeated acquisition of the image. There are at least three studies that report reliability

data for repeated image acquisitions (128,129,160,188). The CVs for measurements of subcutaneous abdominal adipose tissue areas measured for two images taken at the same level range from 1% to 10%. The reported CVs for VAT are somewhat higher, ranging from 6% to 11% (Table 8). Overall, these reported CVs for MRI are about two to three times greater than those for studies using CT.

Ross et al. (120) described special, interactive image analysis software that allows the analyst to correct misclassified pixels. Although training and experience are needed to use this software, reliability equivalent to those for CT can be achieved. Decreased scan times and other improvements in imaging techniques should further increase the reliability of future MRI body composition analyses. A more detailed review of the

procedures used to determine body composition using MRI can be found elsewhere (138,140).

To date the principal application of MRI in human body composition research has been to characterize the quantity and distribution of adipose tissue and skeletal muscle. MRI has been employed to measure adipose tissue and lean tissue in fetuses (142), children (119), normal-weight males and females (120–122), obese males and females (123,124), and diabetic (124) and (125) elderly populations. While the aforementioned studies base their observations in large measure on a single MR image, it is also possible to acquire whole body MRI data in ~30 min (Fig. 12). The acquisition of whole-body MRI offers distinct advantages in assessing the influence of weight loss on body composition. For example, weight reduction scenarios may induce re-

gional changes in adipose tissue or muscle. Thus, if an increase in skeletal muscle in one anatomical region is masked by a loss of skeletal muscle in another, only MRI studies could discover it. Indeed, whole-body MRI protocols have been employed to make important observations with respect to the effects of various perturbations on total and regional adipose tissue (143,144) and skeletal muscle distribution (145). Whole-body MRI has also been used to describe age-related muscle loss “sarcopenia” (146). Using fewer images, several investigations have employed MRI to assess the influence of weight loss (145), inactivity (146,147), and resistance training (148) on region-specific changes in skeletal muscle.

Similar to CT, recent evidence suggests that MRI may also be employed to measure the quality of in vivo skeletal muscle (149). Because proton MR imaging integrates, rather than separates, the signals from distinct protons within the image voxel, conventional MRI is not useful for determining, for example, the concentration of lipid or water in skeletal muscle. To obtain

basic information within the tissue volume of interest requires application of “chemical shift” imaging techniques. Several chemical shift methods have been developed which separate the water and fat signals from the region of interest, creating the potential to determine water and fat contents of skeletal muscle. Tsubahara et al. (150) demonstrated a  $^1\text{H}$  chemical shift imaging technique (Dixon method) to measure the fat and water content of skeletal muscle in men and women varying widely in age. Ross et al. reported preliminary findings using a spiral MR imaging scheme for direct quantification of the lipid MRI signal in skeletal muscle (149). In this approach, the signal from the water protons is selectively spoiled prior to excitation and spatial encoding of the signal from the lipid protons. The acquisition scheme is combined with the use of a three-point Dixon technique, short echo times, and mapping of radiofrequency inhomogeneities in order to minimize known biases in the MRI signal.

Figure 13 illustrates a representative comparison between conventional and lipid images obtained from

**Figure 12** Illustration of the MRI protocol used to acquire axial images throughout the whole body. Both sequences employ a T1-weighted spin-echo scheme. The principal difference is that the abdomen sequence uses a one-half Fourier transformation pulse sequence (1/2 NEX). Using these parameters reduces the time required to obtain the data set to 26 sec during which the subject is asked to hold his/her breath. Although the signal-to-noise ratio is decreased using this scheme, the limitation is offset by the reduction in respiratory motion artifact normally associated with the acquisition of MR images in the abdomen region.

a single subject. Absolute lipid concentration is achieved by aligning cylindrical lipid phantoms of known concentration within the field of view during image acquisition. The signal intensity for each phantom is determined and subsequently used to derive a regression equation (i.e., signal intensity vs. concentration). The signal intensity from various regions of interest (ROIs) within skeletal muscle are then obtained and applied within the regression formula to determine absolute lipid concentration for the given ROI. Although preliminary evidence suggests that this method may be employed to characterise and distinguish the lipid concentration in lean and obese muscle (149), it is noted that with this MRI method it is not possible to separate the lipid measurement into intra- and extramyocellular compartments. Partitioning the lipid signal into separate compartments is accomplished using  $^1\text{H}$  MRS (magnetic resonance spectroscopy), details of which are reported elsewhere (151).

In addition to quantification of muscle lipid using  $^1\text{H}$  MRI, Constandinides et al. (152) have recently demonstrated the feasibility of using sodium ( $^{23}\text{Na}$ ) MRI to quantify sodium concentration in human muscle and, using a 3D Twisted Projection Imaging scheme with a 1.5-T scanner, provide evidence that  $^{23}\text{Na}$  MRI can accurately and reliably measure variations in sodium

content that are characteristic of normal and diseased muscle. In this study it was also shown that  $^{23}\text{Na}$  MRI may be used to characterize the selective recruitment of muscle during exercise, knee cartilage degeneration in osteoarthritis, and atrophy in myotonic dystrophy. The potential application of  $^{23}\text{Na}$  MRI for the diagnosis of muscle dystrophy in aging muscle is particularly promising. Although  $^1\text{H}$  MRI facilitates diagnosis of muscle atrophy in advanced states, elevations in sodium concentration within skeletal muscle, characteristic of the imbalance in sodium homeostasis in muscle dystrophy, by  $^{23}\text{Na}$  MRI may foreshadow the onset of muscle dystrophy and/or muscle wasting commonly observed in the elderly.

Although these initial observations for both  $^1\text{H}$  and  $^{23}\text{Na}$  MRI are restricted to skeletal muscle of the lower limb, they represent unique applications of MRI that can be utilized to obtain novel insight into the composition of skeletal muscle and its metabolic capacities, insights which are highly relevant to the adverse health consequences of, for example, obesity, diabetes and aging.

position is the measurement of abdominal adipose tissue distribution. CT and MRI are uniquely capable of distinguishing between the subcutaneous and visceral adipose tissue depots that comprise abdominal obesity. Clearly, the ability to measure abdominal subcutaneous and visceral adipose tissue using these methods represents a major advance in our understanding of the relationships between obesity phenotype and health risk. Numerous studies have now clearly identified that division of abdominal adipose tissue into visceral and subcutaneous depots provides novel insight into the relationship between abdominal obesity and related comorbid conditions; however, the independent contribution of these adipose tissue depots to metabolic risk remains a topic of debate (153,154).

Abdominal subcutaneous and intraabdominal adipose tissue depots can be further subdivided according to differences in anatomical and metabolic characteristics. This topic was introduced in an earlier section and an anatomic classification of adipose tissue is presented in Table 3. Abdominal subcutaneous adipose tissue measured by CT can also be subdivided into superficial and deep compartments using the fascia superficialis (Fig. 14). The rationale for such a division comes from

animal studies indicating that adipocytes within the deep compartment are more metabolically active than superficial adipocytes (155). If the same heterogeneity exists in humans, segmentation of the subcutaneous depots may clarify which subcutaneous abdominal adipose tissue depot is the stronger correlate of insulin resistance. Indeed, Kelley et al. (18) report that among men and women combined, glucose uptake is strongly correlated with both visceral and deep subcutaneous adipose tissue.

As the fascia superficialis is not visible with MRI, it is not possible to determine deep and superficial adipose tissue depots in a manner similar to CT. However, because the majority of deep subcutaneous adipose tissue is located in the posterior half of the abdomen, a line can be drawn dissecting the abdomen into posterior and anterior depots (Fig. 14). In this way it is assumed that posterior subcutaneous AT measured by MRI is analogous to deep subcutaneous AT measured by CT. This is reasonable given that approximately three-fourths of the “deep” subcutaneous AT is located in the posterior abdomen (18,156). Using this method Misra et al. (157) report that the posterior compartment (analogous to deep subcutaneous AT), when compared

**Figure 14** (Left) CT image of the abdomen illustrating the subdivision of abdominal subcutaneous adipose tissue (AT) into “deep” and “superficial” depots using the fascia superficialis (highlighted for clarity). The “deep” layer surrounds the abdomen but the majority of deep subcutaneous AT is located posteriorly. (Right) MRI image of the abdomen at the L4-L5 level. The fascia superficialis on MR images is often difficult to observe using standard acquisition sequences thus, an arbitrary line is drawn horizontally using the vertebral disk as an anatomical landmark to divide abdominal subcutaneous AT into “anterior” and “posterior” depots. In men “posterior” AT is analogous to “deep” subcutaneous AT because a majority the deep AT is located in the posterior region. This assumption is likely untrue for women.

to anterior compartment mass, displayed a stronger relationship with insulin-mediated glucose disposal.

The subdivision of abdominal subcutaneous adipose tissue based on metabolic characteristics is analogous to the partitioning of intra-abdominal adipose tissue into intraperitoneal and retroperitoneal depots on the premise that nonesterified fatty acids from intraperitoneal adipose tissue alone (i.e., omental and mesenteric adipocytes) are delivered directly to the liver, the so-called portal theory (115). Subdivision of visceral AT into intraperitoneal and retro-peritoneal depots on MRI or CT images is not straightforward because the peritoneum is not visible using either method (Fig. 14). Thus intra-abdominal adipose tissue is subdivided into intraperitoneal and extraperitoneal adipose tissue areas ( $\text{cm}^2$ ) at the L4-L5 level using the mouse pointer to draw a straight line across the anterior border of the L4-L5 disk and the psoas muscles continuing on a tangent toward the inferior borders of the ascending and descending colons and extending to the abdominal wall. For images in which the kidneys appear, an oblique line is drawn from the anterior border of the aorta and inferior vena cava to the anterior border of the kidney extending to the abdominal wall. On all images extraperitoneal adipose tissue is defined as the adipose tissue located posterior to the lines drawn (Fig. 14). Whether subdivision of visceral adipose tissue into intraperitoneal and retroperitoneal depots provides additional insight into the relationships between visceral adipose tissue and metabolic risk per se remains unclear. Whereas some report that intraperitoneal adipose tissue is a strong correlate of insulin resistance (158), others report that subdivision of visceral adipose tissue into intraperitoneal and retroperitoneal depots provides no additional insight (159).

Apart from the segmentation of abdominal adipose tissue depots, there is considerable variation among studies using multiple image protocols for both the number and location of the CT or MRI images used to determine either abdominal subcutaneous or intra-abdominal adipose tissue volume (121,160). This may also partly explain large differences among studies for estimated intraabdominal adipose tissue volumes in apparently similar populations. To be consistent with the definition of intra-abdominal adipose tissue as adipose tissues that are portally drained, it is suggested that the L9-L10 and S2-S3 intervertebral spaces be used to define the upper and lower intra-abdominal adipose tissue landmarks. The L9-L10 space corresponds to an anatomical position marginally above the hilar region of the spleen, whereas the S2-S3 space corresponds anatomically to the rectosigmoid junc-

tion. These two landmarks define a region within which the majority of intra-abdominal adipose tissue is portally drained.

It is not yet firmly established whether single or multiple images are needed to accurately estimate intra-abdominal adipose tissue. The area of intra-abdominal adipose tissue from a single L4/L5 image correlates highly with intraabdominal adipose tissue volume (96,120). In addition, intra-abdominal adipose tissue area determined from a single slice appears to correlate as strongly with metabolic variables as do volumes from multiple images (122). On the other hand, it may be preferable to quantify intra-abdominal adipose tissue volumes in studies designed to develop anthropometric prediction equations. Sjöström et al. (104) presented data suggesting that the error associated with total adipose tissue prediction by anthropometry can be reduced if intra-abdominal adipose tissue volume is measured using multiple images.

#### *d. Imaging Summary*

Several factors should be considered when choosing a study imaging method. Both CT and MRI produce high-resolution scans of all major tissue system level body composition components. Both methods are very expensive and require high technical skill for application. In general, CT has been shown to provide more reliable data than MRI, although this is changing rapidly with the introduction of new imaging techniques and image analysis software. A major advantage of MRI is the lack of ionizing radiation. There are no known health risks associated with MRI at the current magnet field strengths of about 1.5 T. Newer scanning protocols are rapid and cost is usually reduced. The small-bore magnets create a problem for claustrophobic patient, and very obese patients cannot usually fit within the magnet core. An important advantage of CT is that instruments are widely available. A second advantage of CT is the high resolution of images and the consistency of tissue attenuation values from scan to scan. Within reasonable limits, water, skeletal muscle, adipose tissue, and other components have similar Hounsfield unit distributions within and between scans. The consistency of attenuation data allows development of standardized protocols for reading scans and separating various tissues from each other.

The cost of CT scanning is variable and access during peak patient hours may be limited. The major disadvantage of CT is the associated radiation exposure. This limits the study of children and of women in childbearing years. Regional studies with appropriate scanner settings substantially lower radiation dose

compared to whole-body studies. Radiation exposure is still a concern in long-term longitudinal studies with repeated measurements over time. Lastly, some very obese patients may be too large to fit within the scanner and our experience is that CT study is limited to patients below about BMI 35 kg/m<sup>2</sup>.

## C Component Field Methods

### 1 Anthropometry

Anthropometry is the least expensive, most widely used method of assessing human body composition. Anthropometric measurements are used in clinical and epidemiological studies to grade the degree of adiposity in individuals and groups and to estimate the prevalence of overweight and obesity in populations. The measurements are also used to describe the anatomical distribution of adipose tissue and to classify individuals and groups with regard to the “type” of obesity—“centralized” or “peripheral.” The various measures, and the ratios or indices derived from them, are important for evaluating the health risks associated with excess body fatness or obesity and any changes that occur during treatment of obese patients (36,161).

The anthropometric measurements considered as most useful in assessing obesity include weight, stature, skinfold thicknesses, circumferences of the trunk and limbs, and sagittal trunk thickness. Ultrasound is considered in this section as a “quasi-anthropometric” method that is being applied increasingly in clinical studies to quantify adipose tissue distribution. It is placed here, instead of in the section on imaging, because of the limited nature of the regional body composition information provided.

Anthropometric variables do not correspond directly to body composition components but are superficial, somatic measures that are influenced by, and consequently correlated with, variation in the underlying components. Anthropometric variables can therefore be used either as “proxy variables” for the underlying components or in body composition prediction equations. The following sections will consider the merits and limitations of these two different approaches to using weight, stature, skinfold thicknesses, circumferences, and sagittal trunk thickness to grade or predict body adiposity, classify individuals or groups as “obese,” and describe adipose tissue distribution.

#### a. Skinfoldds

These are measurements of a double thickness or “fold” of skin, underlying fascia, and subcutaneous

adipose tissue that are taken using calipers at standardized locations on the body. The essential technique is to pinch and elevate a skinfold at specific anatomical sites using the thumb and fingers and to measure the thickness of the fold with specially designed calipers. These measurements are correlated with, but are not directly representative of, the actual thickness of subcutaneous adipose tissue. This has been illustrated by comparisons of skinfold thickness measurements with radiographic and ultrasound measurements of subcutaneous adipose tissue thickness at different anatomical sites (51,162,163). Because ~70–90% of total adipose tissue is subcutaneous, skinfold thicknesses can be used to grade or predict total body fat (164). In addition, since the thickness of subcutaneous adipose tissue varies among anatomical locations, skinfold thicknesses are useful for describing subcutaneous adipose tissue distribution or “fat patterning.” They are not useful, however, for predicting amounts of intra-abdominal adipose tissues.

Carefully standardized methods of measuring skinfold thicknesses have been developed and it is important to adhere strictly to these to ensure reliable measurements that are comparable with published tables of reference data, and that can be used in appropriate equations for predicting body fat (165). A variety of skinfold calipers are available and measurements may differ systematically among brands depending on quality and the control of pressure between the jaws of the calipers. Jaw pressure is important because skinfolds vary within and between individuals in compression when measured (162,165). Variability in compression is a major factor affecting the reliability of skinfold thickness measurements. Calipers with different jaw pressures will produce systematically different readings, and those with manually controlled jaw pressures will be less reliable than those with built-in spring mechanisms. As a result, the use of different brands of skinfold calipers within a study is not recommended unless their systematic differences are known. Research-quality calipers (e.g., Holtain, Lange, Harpenden) exert a constant pressure of 10 g/cm<sup>3</sup> between the jaws and have a finer scale of measurement (i.e., 0.1-mm intervals) than the inexpensive, plastic calipers marketed for clinical use (165).

In theory, skinfold thicknesses can be measured anywhere on the body that a double fold of skin and subcutaneous adipose tissue can be pinched and elevated. In practice, only a few standard sites are commonly measured based on their accessibility, ease of measurement, and high correlation with measures of total body fat. The triceps and subscapular sites meet these criteria best

in most sex, ethnic, and age groupings, and are used widely for grading adiposity (19,165).

Skinfold thicknesses are also used in equations that predict body density, total body fat mass, or percent body fat. The most widely used equations are those of Jackson and Pollock (163) and Dumin and Womersely (164). When applied with close attention to proper measurement technique, these equations can predict percent body fat with errors of 3.5–5% and a 95% confidence interval between  $\pm 7$ –10% (65). An advantage to the use of skinfold thickness prediction equations is that they estimate rather than grade the underlying variables of interest (e.g., body density, total body fat, percent body fat). Subsequent analyses can then deal directly with associations between the estimates and the various outcomes of interest, rather than with indirect associations with imperfect proxy variables or indices. This can greatly facilitate interpretation of some associations as long as the predicted values can be considered accurate. A disadvantage is that body composition prediction equations based on skinfold thicknesses are “population specific.” As a result, they must always be cross-validated in at least a subsample of a study population before general application. This clearly adds to the expense and difficulty of using these equations. Lohman (65) and Roche and Gue (165) have developed explicit criteria for the evaluation of the accuracy of prediction equations in cross-validation studies.

An important problem is the simple feasibility of obtaining reliable data for very obese subjects. Skinfold calipers can accurately measure skinfolds only up to 40 mm (Holtain) or 60 mm (Lange) in thickness. This may limit the ability to measure skinfolds at some sites and in obese subjects. In addition, the reliability of the measurements may decrease with increasing thickness (162). As a result of these limitations, some may prefer the use of circumference measurements for grading or predicting body fatness or quantifying adipose tissue distribution in obese subjects.

#### *b. Ultrasound*

Ultrasonic measurements of subcutaneous adipose tissue thickness have been explored as an alternative to skinfolds (166). The benefits to ultrasound are: (1) the measurements theoretically have greater validity in relation to actual subcutaneous adipose tissue thickness; (2) they are not affected by variation within and between persons for tissue compressibility; (3) greater thicknesses can be measured than with currently available skinfold calipers; and (4) sites can be measured that are inaccessible to calipers, for example, paraspinal adipose tissue in the lumbar region. There are also two

major drawbacks: (1) the measurements are obtained at considerably increased cost; and (2) reliable measurements can only be made using B-mode imaging ultrasound by highly trained technicians (167). B-mode imaging ultrasound provides a real-time two-dimensional image of skin and subcutaneous adipose tissue and underlying interface with muscle. The image can be frozen and printed, providing a permanent record, and the subcutaneous adipose tissue thickness can be measured using a ruler or digitizer. Considerable skill may be needed in obtaining the images, depending on the ultrasound equipment used, and in identifying correctly the adipose tissue–muscle interface on the image. At some sites, this interface may be easily confused with other fibrous tissue interfaces and bone reflections.

Ultrasound has also been explored as a method of quantifying the amount of intra-abdominal adipose tissues (166,167). This approach appears promising and merits further development since the alternatives are either very expensive (e.g., CT or MRI) or inaccurate (e.g., circumference ratios or prediction equations).

#### *c. Circumferences*

Body circumferences are useful in that, unlike skinfold thicknesses, they can always be measured, even in extremely obese subjects. Circumferences reflect internal as well as subcutaneous adipose tissue, but are also influenced by variation in muscle and bone. As a result, the interpretation of circumference measurements, and especially circumference ratios, is often not straightforward. As for all anthropometric variables, body circumferences should be measured with close attention to standardized procedures (19). Flexible, inelastic cloth or steel tapes are recommended.

The most useful circumferences for grading or predicting body fat and for describing adipose tissue distribution are upper arm, chest, waist or abdomen, hip or buttocks, proximal or midthigh, and calf (19,165). Waist or abdomen circumferences are usually very highly correlated with total fat mass and percent body fat in men ( $r > .85$ ); in women, hip or thigh circumferences may have slightly higher correlations. Correlations of upper arm, thigh, and calf circumferences with measures of body fat are somewhat lower, and these circumferences tend to be more strongly influenced by variation in appendicular skeletal muscle.

#### *d. Adipose Tissue Distributions*

Numerous epidemiological and clinical studies have established that centralized obesity, in which fat is stored preferentially in adipocytes on and within the trunk rather than the extremities, represents the obesity

phenotype that conveys the largest risk for morbidity and mortality from the major chronic diseases: heart disease, cancer, and diabetes (36,168). A variety of anthropometric approaches have been developed to grade or classify centralized adipose tissue distribution. Recent efforts have been focused on developing equations for predicting the amount of VAT, which is believed to be the main aspect of centralized obesity associated with risk. The following section reviews the merits and limitations of these anthropometric approaches.

Skinfold thicknesses have been used to describe primarily the distribution of subcutaneous adipose tissues. This aspect of the adipose tissue distribution has been called “fat patterning,” to distinguish it from the more general form that includes the amounts and distribution of internal adipose tissues (169,170). Historically, three main approaches have been used to describe fat patterning: pattern profile, ratio, and principal-components methods. The pattern profile method was first applied by Garn (169) and compares two or more groups graphically for mean values of skinfold thicknesses across several anatomical sites. It provides a useful, visual comparison of differences or similarities between groups for anatomical variation in subcutaneous adipose tissue thickness. Cluster analysis provides a more sophisticated, statistical approach to defining pattern profiles (171).

A variety of skinfold thickness ratios have been used to index fat patterning. The ratio of the subscapular to triceps skinfolds is one of simplest and most widely used. Some consider it to be important to include a skinfold on the leg, such as the lateral calf or medial thigh skinfold (172). The advantages of the ratio approach are that it requires few variables and simple computation, and provides a single continuous variable for grading subjects. Three problems can be identified, however, with ratio indices of fat patterning: (1) they tend to be correlated with total fat mass or percent body fat; (2) they may have poor sensitivity and validity with regard to the latent variable, subcutaneous adipose tissue distribution; and (3) it may be difficult to determine whether a correlation with another variable (e.g., serum HDL cholesterol) is due to variation in the numerator or denominator of the ratio. The use of a greater number of skinfolds and the sum of all skinfolds in the denominator may partly alleviate these problems. Principal components analysis is a more sophisticated statistical approach to constructing fat pattern indices. This approach summarizes the information in several skinfold variables in a smaller number of new, statistically independent indices (173). When this method is

applied to data for several skinfold variables, it provides the best “reference” measures for judging the validity and sensitivity of simpler ratio indices.

The main criticism of skinfold thickness methods in the study of obesity is that they do not capture variation in the amounts of internal adipose tissues, especially those surrounding the viscera. Visceral adipose tissue has been recognized as the main aspect of adipose tissue distribution that is associated with increased risk for chronic disease (168). As a result, many prefer indices based on circumferences that are believed to include variation in VATs. The most popular circumference index is the “waist/hip ratio” (WHR), followed by the “waist/thigh ratio” (WTR). The waist/hip ratio was the first used to assess the associations between adipose tissue distribution and chronic disease morbidity and mortality (173–177). Numerous studies have now shown that WHR is an independent predictor of metabolic disturbances including insulin resistance, dyslipidemia, hypertension, and atherosclerosis (178–180). Similar associations have been also been reported for WTR, as well as for skinfold thickness indices and some other circumference indices such as the “conicity index” (180,181). In general, the association of risk factors, as well as morbidity and mortality, with circumference indices tends to be somewhat stronger than with skinfold thickness indices of adipose tissue distribution. This is generally thought to be due to either the increased measurement error in skinfold thicknesses, or the influence of VAT volume on waist circumference. As for BMI or skinfolds, cutoff values for WHR have been recommended for defining “upper-body obesity” (179). The recommended values generally used are  $>0.95$  in men and  $>0.80$  in women. It is important to recognize that these values were selected based on the increase in risks with increasing WHR and not on the association with adipose tissue distribution.

There are several problems in the use of circumference ratios as indices of adipose tissue distribution. First, standard definitions of the circumferences are not always followed, making it difficult to compare results across studies (182). For example, the “waist” circumference has been defined variously as at the level of: the smallest circumference on the torso below the sternum, the umbilicus, the lower margin of the ribs, and the iliac crests. The “hip” circumference has been defined as at the level of: the iliac crests, the anterior iliac spines, the greater trochanters, or maximum posterior protrusion of the buttocks. There may be considerable differences among circumferences measured at these locations. Some may vary between subjects in relation to bone landmarks (e.g., smallest circumference on torso below

the sternum), or may be difficult to identify in obese subjects. There is scarcely any difference between a “waist” circumference measured at the level of the umbilicus and a “hip” circumference measured at the level of the iliac crests in most subjects. Obviously, “waist” circumference in one study may be the same as “hip” circumference in another when both are defined as at the level of the iliac crests.

In obese subjects, the identification of the “waist” may be extremely subjective, if not impossible, and the measurement is more correctly defined as an abdominal circumference. The location of the abdominal circumference in relation to a soft tissue landmark, such as the umbilicus, is not recommended because many obese subjects will have an extremely pendulous abdominal adipose panniculus. The umbilicus may be directed downward and located well below the horizontal, transverse plane of the midabdomen. This may lead to considerable variation among subjects in the definition of this measurement. In addition, a pendulous panniculus may result in overlapping of abdominal and hip circumferences or interfere with the standard measurement of hip circumference.

A second problem is that circumferences are influenced by variation in muscle and bone as well as adipose tissues, as noted previously. These influences may be particularly difficult to sort out when ratio indices are used. It has been assumed conventionally that increased WHRs mainly reflect increased VAT, based on studies that report significant correlations between WHR and VAT area, as measured using imaging methods. Some studies, however, have reported significant correlations with measures of cross-sectional muscle area also, in particular those for the pelvis or hips (135). Thus, variation in WHR may reflect the effects of increased VAT on waist circumference (i.e., numerator) as well as decreased gluteofemoral muscle on hip circumference (i.e., denominator). This influence of muscle has been recognized increasingly and may be important in understanding the relationship of WHR to chronic disease risk. Larsson et al. (175) reported that the risk of heart disease was greatest in those with lower BMIs and high WHRs. Filipovsky et al. (181) reported that all-cause and cancer mortality over 20 years of follow-up in the Paris Prospective Study was greatest in those with low BMIs but high WTRs. The low BMIs in this study might reflect low muscle mass, rather than low fat; subsequently, the high WHRs or WTRs might reflect a combination of increased VAT and muscle loss (36). It should be remembered that the phenotype originally described by Vague (183), who first drew attention to the association of body composition and metabolic

disease, consisted of an expanded abdominal fat mass in conjunction with thin legs. The latter might reflect muscle atrophy associated with disease as much as lack of subcutaneous adipose tissue on the extremities. This potentially important association between visceral adiposity and skeletal muscle was reemphasized by Björntorp (168).

A third problem is the strong correlation of circumferences and circumference ratios with total adiposity. This makes it difficult statistically to separate the effects of centralized adipose tissue distribution from obesity. This confounding is further exacerbated by the moderate positive correlations of body fatness and centralized adipose tissue distribution with age. Many early studies that reported significant correlations between WHR and VAT did not control for the confounding influences of age and BMI. Seidell et al. (134) reported that WHR did not correlate significantly with the ratio of visceral to subcutaneous adipose tissue, as measured using CT, after adjustment for age and BMI. Similarly, Ross et al. (120) reported that, after controlling for both age and adiposity, WHR explained only 12% of the variation in absolute levels of VAT in men. Furthermore, the observed relationship between WHR and relative VAT was nonexistent. Thus, while WHR is an independent predictor of numerous metabolic aberrations, its association with risk may not be attributed simply to its association with the amounts of either absolute or relative VAT.

Several investigators have argued that simple waist circumference is a better index of variation in VAT than WHR (184,185a–185c); it is important to note, however, that waist circumference is very highly correlated with total adiposity ( $r > .90$ ) in most populations. Also, the error of prediction of VAT from waist circumference, alone or in combination with other variables, is large (120,134). Ross et al. (120) reported that the sensitivity and specificity of waist circumference for predicting absolute values of VAT was poor. These observations are explained in large measure by the intraindividual variation in the visceral to subcutaneous adipose tissue ratio. It is important to establish whether reductions in VAT are related to concurrent reductions in WHR or waist circumference. Some have reported that WHR changes with weight loss, while others do (120,186,187). Ross et al. (188) reported that diet and exercise induced reductions in VAT that were significantly associated with reduced waist circumferences in obese male ( $r = .69$ ) and female ( $r = .47$ ) subjects. For the two groups combined, a 1-cm reduction in waist circumference was associated with a 4% reduction in VAT ( $P < .01$ ). The standard deviation associated with

the 4% reduction in VAT per centimeter reduction in waist circumference, however, was also 4%. This suggests that the ability to quantify small changes in VAT volume from waist circumference is limited by interindividual variations in the reduction of abdominal subcutaneous and lean tissue. Thus, whereas changes in visceral obesity are clearly associated with changes in waist circumference, it is not possible to accurately predict small changes in VAT.

A final proviso is that hip circumference may have predictive value for outcome in a direction opposite to that of waist circumference. In a recent study, Seidell et al. (185c) observed the traditional association between a large waist circumference, dyslipidemia, insulin levels, and glucose concentrations in Quebec City residents. Narrow hips were also independently associated with an adverse metabolic profile. Accordingly, a narrow waist and large hips may be protective against cardiovascular disease and the authors suggest that the specific effects of each circumference measurement are not well captured in the WHR.

Efforts to develop equations for predicting VAT have not generally been successful. The errors associated with these equations tend to be large: 25–40% (120,134,184–187). This level of accuracy is clearly insufficient for estimating changes in individuals and may be inadequate for comparing groups. Few of these equations have been cross-validated in independent samples. Future efforts to develop this approach have value, however, given the inadequacies described above for skinfold and circumference indices. At present, it would appear that new or different anthropometric measurements will be needed to increase the accuracy of prediction equations to acceptable levels. One measure that has been suggested is the sagittal thickness of the trunk or abdomen.

Several studies have suggested that sagittal trunk thickness correlates more highly than other anthropometric variables with the volume of VAT quantified by imaging methods (185,189). As a result, it may be useful both as a simple index, like waist circumference, or as an independent variable in equations for predicting VAT. There is present no standardized technique for measuring sagittal trunk thickness, and, to date, its use has been limited mostly to clinical studies.

Sagittal trunk thickness may be defined as the maximum diameter of the abdomen in the sagittal plane. As for circumferences, this measurement may be obtained technically in all subjects regardless of obesity level. Bony landmarks for the standard location of this measurement have not been identified: alternative possibilities include the xiphoid process of the sternum, the

fourth lumbar vertebrae, or the iliac crests. It is important to note that the choice between these landmarks will result in measurements at very different levels on the trunk or abdomen. Sliding calipers with long, parallel blades are necessary for this measurement.

Although sagittal trunk thickness may be taken with the participant standing, measurement in the supine recumbent position may be preferred to maximize the association with the latent variable, intra-abdominal adipose tissue volume. Theoretically, when a person with an enlarged intra-abdominal adipose tissue mass lies supine, the mass shifts cranially, causing anterior projection of the abdomen, which is measured as increased sagittal thickness (189). When a person is standing, gravity pulls the intra-abdominal adipose tissue mass downward, and the maximum sagittal thickness may be located somewhat lower. It is important to keep in mind that the level of the maximum measurable diameter, either supine or standing, will likely vary among some subjects. The extent to which these measurements are influenced by the amount of subcutaneous abdominal adipose tissue, and shifts in its distribution between supine and standing measurements, is not well established.

Results for the use of sagittal thickness to grade or predict VAT volume in several Swedish studies have been summarized by Sjöström (189). VAT volume was estimated using seven cross-sectional CT scans of the abdomen. Sagittal thickness was measured on the CT image at the level of L4-L5. VAT volume was regressed on sagittal thickness (ST) in 17 men producing an equation,  $VAT (L) = 0.731 \times ST (cm) - 11.5$ , ( $R^2 = 0.81$ ). This equation was later cross-validated in two independent samples of 7 and 13 men, respectively, with virtually indistinguishable results. A similar regression equation was developed using data for 10 women and cross-validated in nine independently selected women:  $VAT (L) = 0.370 \times ST (cm) - 4.85$ , ( $R^2 = .80$ ). Sjöström and associates also showed that changes in VAT volume were accurately tracked by changes in sagittal thickness in six patients with Cushing's disease during treatment.

Pouliot et al. (185) analyzed associations of sagittal thickness with VAT area on CT images at L4-L5 in 81 men and 70 women, 30–42 years of age. Sagittal thickness correlated better with VAT area than waist/hip ratio in both sexes; however, it was also correlated strongly with subcutaneous abdominal adipose tissue area. Taken together, the results of the studies by Sjöström et al. (189) and Pouliot et al. (185) indicate that sagittal thickness is somewhat more sensitive than conventional indices such as waist/hip ratio for grading or predicting the amounts of VAT.

The measurements of sagittal thickness in these studies were taken from the CT scans, rather than anthropometrically. Sjöström and associates, however, reported that the squared difference between sagittal thicknesses measured anthropometrically and on the CT images in their studies was only 1.7%. In an independent study, Van der Kooy et al. (190) reported a high correlation ( $r = .94$ ) between sagittal thickness measured with the subject standing and from MRI images at the same level. It may be important to consider that the errors of estimation for VAT averaged  $\sim 20\%$  in these studies, which could allow for considerable misclassification when subjects are grouped by sagittal thickness. Lastly, the strong correlation with abdominal subcutaneous adipose tissue areas reported by Pouliot et al. (185) is bothersome since it suggests that sagittal thickness may not accurately discriminate visceral from subcutaneous abdominal adipose tissue.

Whereas establishment of the association of sagittal diameter with the latent variable of interest, VAT, is important, it is also important to examine the sensitivity of this measure in relation to risk factors associated with visceral obesity. Richelsen and Pedersen (191) recently analyzed associations of sagittal thickness and other indices of VAT with serum total cholesterol, triglyceride, LDL and HDL, fasting insulin, and glucose concentrations in 58 middle-aged men. They concluded that sagittal thickness was slightly better correlated with an adverse lipid, insulin, and glucose risk profile than waist/hip ratio. Similar findings were also reported in the study by Pouliot et al. (185). Taken together, these studies suggest that sagittal diameter may be preferred to other indices of VAT as a risk factor in epidemiologic studies of obesity-associated chronic diseases. In this regard, Seidell et al. (192) reported that abdominal sagittal thickness was a strong predictor of mortality in younger adult men enrolled in the Baltimore Longitudinal Study. Further studies are needed to establish the usefulness of sagittal thickness for grading or predicting VAT and as a risk factor in different age, sex, and ethnic groups.

## 2 Bioimpedance Analysis

Bioimpedance analysis (BIA) is a technique for predicting body composition based on the electrical conductive properties of the human body. The ability of the body to conduct an electric current is due to the presence of free ions, or electrolytes, in the body water. The amount of electricity that can be conducted is determined mainly by the total volume of electrolyte-rich fluid in the body. Measures of bioelectric conductivity are therefore proportional to TBW and to body composition com-

ponents with high water concentrations such as the fat-free and skeletal muscle masses. As a result, these methods predict FFM, and fat must be derived secondarily as the difference between body weight and predicted FFM (193).

Many factors other than the amount and electrolyte concentration of body water, however, influence measurements of electrical conductivity. These include body temperature, distribution of fluids between intra- and extracellular spaces, body proportions or "geometry," the amounts and structures of different conductive, as well as nonconductive, tissues, and technical issues such as correct calibration and application of the equipment. The net result is that exact functional relationships between measurements of bioelectric conductivity and TBW or other fat-free components cannot be derived from either physicochemical models or experimentally. Thus, relationships between conductivity measurements and body composition components must be established indirectly by statistical calibration against criterion measures (e.g., estimates of TBW from deuterium dilution analysis or DXA) in a sample of subjects.

Because it is portable, BIA is suitable for field use and is being applied increasingly as a phenotyping method in field settings. The most commonly used BIA method injects a high-frequency, low-amplitude alternating electric current (50 kHz at 500–800 mA) into the body using distally placed electrodes and measures the voltage drop due to resistance with proximal electrodes. Conventionally, surface gel electrodes are used with standardized placements on the right ankle and hand, although other electrode arrangements have been described that allow estimation of segmental (e.g., arm or leg) electrical properties (194). Stainless-steel contact electrodes are also now used in some systems in place of the conventional gel electrodes. The amount of resistance measured ( $R$ ) is inversely proportional to the volume of electrolytic fluid in the body. It is also dependent on the proportions or "geometry" of this volume (i.e., ratio of length [ $L$ ] to cross-sectional area [ $A$ ], or  $R \propto L/A$ ). These relationships have led to the use of the simple formula  $V = \rho L^2/R$  as the theoretical basis of most BIA applications, where  $V$  is conductive volume (e.g., TBW),  $L$  is a measure of body length (usually stature),  $R$  is measured resistance, and  $\rho$  is an estimate of the "specific resistivity" of the conductive material (195).

There are a number of limitations to the validity of this simple formula. The formula is accurate only for a cylindrical conductor with uniform cross-sectional area and homogeneous composition (e.g., a wire). The human body could be described as a series of roughly

cylindrical conductors with variable cross-sectional area and heterogeneous, highly structured composition. The value of  $\rho$  is influenced by all of these factors and consequently cannot be deduced directly. As a result, equations for predicting body composition must be developed based on independent measurements of resistance, stature, and other anthropometric variables, and TBW or FFM in a sample of subjects. Least-squares regression techniques are applied to the data to derive an equation of the basic form:

$$V(\text{i.e., TBW or FFM}) = a + bS^2/R + e \quad (21)$$

where  $a$  is intercept,  $b$  is slope, and  $e$  is residual error or unexplained variation in  $V$  due to random measurement errors and/or misspecification of the parameters ( $a$  and  $b$ ) in the equation. It is not possible to interpret the parameter  $b$  in this equation as an estimate of  $\rho$  in the formula  $V = \rho L^2/R$ , unless the intercept ( $a$ ) and residual error ( $e$ ) approach zero. These conditions are rarely, if ever, met for the reasons given above. The equation may also contain body circumferences and skinfold thickness, although the inclusion of these additional variables reduces the main benefit of BIA relative to anthropometric prediction equations. The reason BIA is becoming increasingly popular is that only a few simple, highly reproducible measurements are needed. Multiple frequency systems are available, but only a small advantage over the conventional 50-kHz systems are noted for estimation of TBW and FFM.

As for most prediction methods, BIA equations tend to lose accuracy when applied to subjects who do not resemble those included in the sample from which the equations were developed. Thus, their generalizability may be limited and all BIA equations should be cross-validated in independent samples to verify their applicability. Few, if any, equations have been developed that can be demonstrated to be applicable to all individuals without regard to age, gender, ethnicity, or obesity. Our experience is that the performance of a particular equation can be unpredictable, even when applied with close attention to measurement techniques and equipment to a sample with characteristics closely similar to those of the source-sample. As a result, it is recommended that any externally-developed BIA equation be cross-validated in a random subsample against estimates from an accepted reference method before general extension to an entire study population.

The relatively low cost, portability, ability to track long-term body composition changes, operation simplicity, and lack of radiation exposure make appropriately developed BIA methods a good choice for field applications.

## V ERRORS OF ESTIMATION

All in vivo body composition methods attempt to estimate or predict the size, volume, or mass of an unknown component from measurements of associated properties or other components using various equations or models. An important area of body composition methodology is quantitative analysis of the magnitudes and directions of the different types of errors that may occur. A variety of previous efforts have been made to address this complicated area (65,196–198), and it would not be appropriate to provide a detailed review in this chapter. The following provides a general overview of basic concepts.

Measurement error can be caused by instrument error and observer error. Instrument error can be minimized by appropriately and rigorously calibrating all measuring devices on a regular basis. Training, periodic evaluations, and a quality control program will help to reduce observer error.

Accuracy is the level of agreement between the measured value and the “true” dimension. Accuracy of a component measurement is usually established by comparison to an accepted reference method or “gold standard.” For example, subcutaneous adipose tissue thickness estimated using a skinfold caliper can be compared to corresponding reference estimates by CT or MRI. Of course any such analysis also includes instrument, observer, and model errors. In clinical situations measurements by an anthropometrist are usually compared to those of a designated “expert” as the reference.

Some body composition measurements are used directly, as for example triceps skinfold thickness as a measure of fatness. Mathematically transforming a skinfold measurement to a component estimate, such as body fat, involves error sources. Methods based upon statistically derived prediction formulas are population specific, and error may arise when applying the prediction formula to a new subject group or outside of the original subject range for age, weight, and stature. Methods based on biological models, such as fat-free mass density (i.e., 1/100 g/cc), include “model” errors. For example, calculation of fat-free mass from the assumed hydration of 0.73 is based on average population values. Actual subject hydration may deviate from the assumed model, and this introduces error into the component (i.e., fat-free mass) estimate.

Precision, as distinct from accuracy, defines the quality of a measurement in terms of being sharply defined or exact. In this sense precision refers to the scale of measurement, as for example a skinfold measured to the nearest 1 mm is more precise than one measured to

the nearest 0.5 cm. A highly precise measurement (e.g., body weight measured to the nearest gram) is not necessarily accurate if the weight scale used is improperly calibrated. The definition of precision overlaps to some extent with that of “reliability.” Reliability is the degree to which a measurement is replicable using the same instrument by the same or a different observer. The linkage to precision comes in that it is difficult for a measurement to be precise or exact if it is unreliable.

The precision of a body composition estimate can be quantified as the variability among repeated measurements over a short time period in the same subject. One approach for expressing precision is the technical error of measurement, which is the standard deviation (SD) of repeated measurements on the same subject by the same or different observers. The technical error of measurement, which is expressed in the same units as the measured quantity, can also be expressed in percent as a coefficient of variation (i.e.,  $SD/mean \times 100$ ).

Reliability is also referred to as “reproducibility” or “repeatability.” Reliability, as distinct from precision, is more commonly expressed in terms of the intraclass correlation among repeated measurements (197), sometimes called the “reliability coefficient.” Measures of reliability often include both measurement error and physiological variation.

The total variation of a component’s mass monitored over time includes measurement variation and biological variation (199). Biological variation occurs even in the healthy individual as weight and fluid balance fluctuate over time. This aspect of measurement variability is the difference between total component mass variation over time and that due to measurement error. Some measures, such as height, are extremely stable in adults while others, such as fluid status, are moderately variable over time. In practice, this biological component of variability is often included in component reliability estimates.

It is important to minimize biological variation for some measurements, as for example impedance with BIA. Impedance varies normally with posture, fluid status, time of day, and menstrual status. Controlling these factors, to the extent possible, will keep the biological component of measurement variability to a minimum.

## VI REFERENCE VALUES

Once collected, body composition data are usually compared to corresponding data from a reference population. Some reference data for the United States noninstitutionalized population are available from the

National Health and Nutrition Examinations Surveys (NHANES) (200). Body weight, height, and BMI values by age, sex, and race from NHANES III are presented in Tables 9–11 (unpublished data).

Extensive reference data are available for skinfold thicknesses at the triceps and subscapular sites that are stratified by sex, ethnicity, and age (200). Additional skinfolds that may be useful for grading adiposity or describing adipose tissue distribution include suprailiac and paraumbilical for abdominal adipose tissue, and medial thigh and medial or lateral calf or leg adipose tissue. Fewer reference data, however, are available for these sites, which limits their usefulness in some contexts.

The commonest way to use skinfold thickness data is to compare individual values or group means to tabulated reference values for appropriate sex, ethnic, and age groupings (200). An implicit assumption is that the reference data are “representative,” in the sense of being collected from a randomly selected sample of a well-defined population as in the NHANES studies.

Skinfold thicknesses can also be used as continuous variables grading adiposity or adipose tissue distribution within a study population. This approach works well if the study population is relatively homogeneous. It works less well if the study population is heterogeneous and the association of the selected skinfold thickness with total fat mass or percent body fat varies by sex, ethnicity, age, or other characteristics. As a result, stratification on sex, ethnicity, and age is generally recommended when skinfold thicknesses are used as continuous measures grading levels of body adiposity in analyses of relative risks or correlations with risk factors. Nationally representative reference data are available for abdominal, hip, and midthigh circumferences from the NHANES III on CD-ROM (National Center for Health Statistics, Hyattsville, MD).

Absolute compartment estimates are often adjusted for body mass and expressed as a percentage or as a height-normalized index (e.g.,  $FFM/Ht^2$ ) (201). There are as yet no appropriately derived and reported “healthy” body composition ranges, and investigators have suggested two interim measures. The first involves population means and ranges based on the NHANES III bioimpedance analysis database (e.g., mean % fat values vs. age by ethnic group; Tables 9–11) (unpublished data). This information allows comparison of the study subject or group to the sex-, age-, and race-specific value observed in the U.S. population. Other large subject databases with group averages for specific populations are reported. The second approach provides predicted percent fat estimates for sex, age, race, and

**Table 9** Selected Anthropometric and Impedance Measures According to Age and Sex for Non-Hispanic Whites: NHANES III (unpublished data)

| Age (years) | Anthropometric measure   | Non-Hispanic white males |       |                    |                | Non-Hispanic white females |       |                    |                |
|-------------|--------------------------|--------------------------|-------|--------------------|----------------|----------------------------|-------|--------------------|----------------|
|             |                          | N                        | Mean  | Standard deviation | Standard error | N                          | Mean  | Standard deviation | Standard error |
| 12–13.9     | Weight (kg)              | 88                       | 51.7  | 12.3               | 1.5            | 101                        | 52.1  | 13.3               | 1.6            |
|             | Stature (cm)             |                          | 159.6 | 8.4                | 0.9            |                            | 157.8 | 8.2                | 1.0            |
|             | BMI (kg/m <sup>2</sup> ) |                          | 20.1  | 3.5                | 0.4            |                            | 20.9  | 4.7                | 0.6            |
|             | TBW (L)                  |                          | 31.3  | 6.3                | 0.8            |                            | 28.5  | 4.2                | 0.6            |
|             | %fat                     |                          | 18.4  | 7.3                | 1.0            |                            | 24.8  | 9.7                | 1.2            |
| 14–15.9     | Weight (kg)              | 82                       | 68.3  | 20.5               | 2.5            | 120                        | 57.8  | 10.5               | 1.2            |
|             | Stature (cm)             |                          | 172.2 | 7.6                | 0.8            |                            | 162.6 | 6.0                | 0.7            |
|             | BMI (kg/m <sup>2</sup> ) |                          | 23.0  | 6.3                | 0.8            |                            | 21.9  | 3.8                | 0.4            |

BMI (38). A BMI-based prediction equation [Eq. (21)] was presented in an earlier section for white and black subjects. The prediction lines for this model are provided in Figure 15 for males and females in three age groups (30, 50, and 70 years). This information allows linkage of percent fat ranges with corresponding BMI ranges for normal weight  $>17.5 < 25 \text{ kg/m}^2$ , overweight ( $\geq 25 < 30 \text{ kg/m}^2$ ), and obesity  $\geq 30 \text{ kg/m}^2$ .

At present there are inadequate data for appropriately derived population or other range categories of subcutaneous, visceral, or other adipose tissue depots.

## VII SUMMARY AND CONCLUSIONS

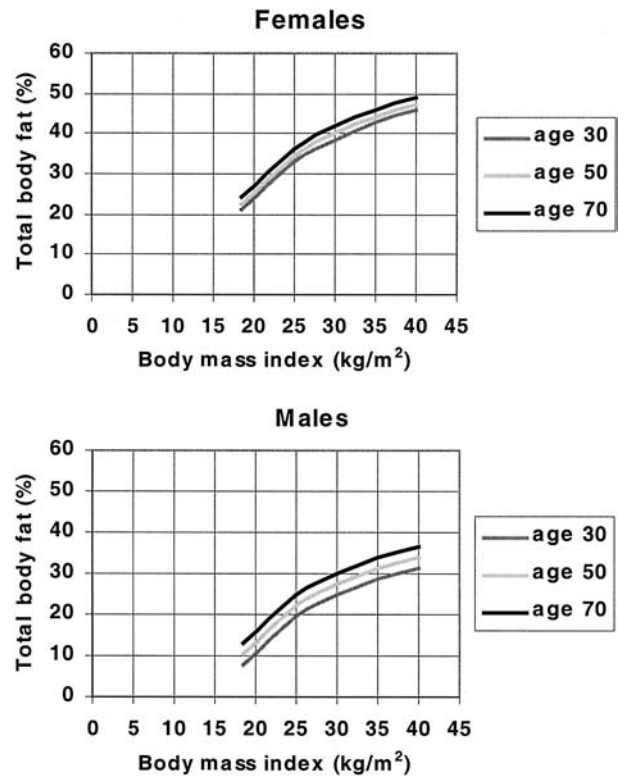

The remarkable technological advances over the past decade provide investigators with the tools needed to evaluate components at all five body composition levels. The applications for body composition analysis abound and dictate the selected method requirements. While our method organization was separated into two categories, laboratory and field, each method has an array of definable characteristics that ultimately determine research and clinical utility. Most methods are capable of providing estimates of more than one adiposity-related component so that the investigator can choose among them depending on instrument availability and specific method features. Some of the qualitative characteristics of the methods reviewed in this chapter are summarized in Table 12. These "gradings" are subjective but should give the reader some idea of how to select a method among those available with consideration for the evaluated subject population. The present overview should be supplemented by the interested reader with in-depth body composition reviews and the available texts published since 1985 are presented in the Appendix.

Body composition analysis is an indispensable research and clinical component that provides important insights into the pathogenesis and treatment of obese animals and humans.

Abbreviations: ANTH, anthropometry; ADP, air displacement plethysmography; BIA, bioimpedance analysis; CT, computerized axial tomography; DXA, dual-energy x-ray absorptiometry; IVNA, in vivo neutron activation analysis; K, potassium; MCM, multicomponent models; MRI, magnetic resonance imaging; N, no; TBW, total body water; UWW, underwater weighing; Y, yes.

Scale: • (least or none)–•••• (most).

<sup>a</sup> Assumes stable isotope.

<sup>b</sup> Assumes four or more components and stable isotope for TBW.

## Ethnic and Geographic Influences on Body Composition

**Paul Deurenberg and Mabel Deurenberg-Yap**

Health Promotion Board, Singapore, Republic of Singapore

### I INTRODUCTION

Body composition information on humans can be collected at various levels, such as atomic, molecular, cellular, tissue, or whole-body level (1). In the case of obesity, the main component of interest is body fat, at the tissue [adipose tissue obtained by computer tomography (CT) or magnetic resonance imaging (MRI) scanning] or molecular level [body fat mass or body fat percent as assessed by densitometry or dual-energy x-ray absorptiometry (DXA) scans]. In addition, the distribution of fat over the body is important. The latter can be evaluated by CT or MRI scans or by anthropometry.

There are many methods to measure or assess body composition, especially for body fat and body fat distribution. Apart from direct methods (chemical carcass analyses or *in vivo* neutron activation analyses, *IVNAA*), these methods can be described as indirect and doubly indirect (2). Indirect methods are validated against experimentally found or calculated quantitative relationships between body parameters and components of body composition as obtained from carcass analyses or *IVNAA*. Doubly indirect methods assess body composition based on statistical relationships between easy measurable body parameters and an indirect method. The resulting formulas are usually population specific and have an estimation error

of 4–5% compared to the method of reference. Table 1 lists methods for the determination of body composition with special reference to body fat. Generally the error of indirect methods is <3%. For doubly indirect methods, the estimation error is larger and is usually ~5%.

Chemical carcass analyses revealed that the chemical composition of the body varies widely among subjects. This is especially true for the amount of body fat. It was found that the variation in body composition among subjects is greatly reduced if the various components are expressed in relation to the fat free body (3,4), and with this the concept of the two-compartment model of body composition was born (5). This concept divides the body into a fat mass, which contains all ether-soluble fat, and a fat-free mass, which is the difference between body weight and the fat mass (FM). Chemically the fat-free mass (FFM) consists of water, minerals, protein, and a small amount of carbohydrate (mainly glycogen and glucose). The carbohydrate component is small and is normally neglected. Carcass analyses revealed that the mean composition of the fat free mass is ~73% water, 20% protein, and 7% minerals (5). This chemical composition of the fat-free mass is confirmed in many modern studies in young adults using *in vivo* techniques (6), although there are slight variations among population groups (7–10). These figures are the basis for a number of indirect

**Table 1** Methods to Determine Body Fat

| Direct                                      | Indirect  | Doubly indirect                  |
|---|---|----------------------------------|
| Chemical carcass analyses                   | Densitometry  | Weight/height indices, e.g., BMI |
| In vivo neutron activation analyses (IVNAA) | Dilution techniques, e.g., deuterium oxide dilution | Skinfold thickness measurements  |
|   | Dual-energy x-ray absorptiometry (DXA)              | Bioelectrical impedance          |
|   | More compartment models                             | Body circumferences              |
|   | CT/MRI scanning                                     |                                  |

CT, computed tomography; MRI, magnetic resonance imaging; BMI, body mass index.

measures of body fat, i.e., for densitometry and for dilution methods.

Assuming a constant composition of the fat-free mass (as above) and given the densities for water (0.993 kg/L), protein (1.340 kg/L) and minerals (3.038 kg/L) at body temperature, the density of the fat-free mass can be calculated as 1.100 kg/L. As the density of the fat mass is 0.900 kg/L, it is obvious that the density of the body will vary between 0.9 kg/L and 1.1 kg/L depending on the amount of body fat. This forms the basis for the densitometric method for the determination of body fat. The volume of the body is measured by either water displacement, air displacement, or underwater weighing (11), and body density is then calculated as weight/volume. Using Siri's (5) formula ( $BF\% = 495/\text{density}_{\text{body}} - 450$ ) or other similar equations, body fat percent can be calculated. Principles and description of different densitometric techniques are given elsewhere (11,12).

The amount of water in the human body can be determined by dilution techniques (13). With these techniques, the subject is given a tracer (usually deuterium oxide, tritium oxide or  $^{18}\text{O}$ -labeled water), and after a suitable dilution time the concentration of the tracer is determined in the body fluids (saliva, blood, or urine). The amount of body water can be calculated from the given dose and the tracer concentration in the body fluid, and, assuming a constant water fraction of the fat-free mass (i.e. 73%), fat-free mass and consequently fat mass can be calculated (14).

## II ACCURACY AND VALIDITY OF REFERENCE BODY COMPOSITION METHODS

How accurate are these techniques? The technical error of these methodologies is small and is in experienced hands with adequate instrumentation not beyond one percentage point of body fat percent (15). Siri (5) calculated that owing to variations in the assumed

constant composition of the fat-free mass, the densitometric method has a methodological error of maximally 2–3%. This was confirmed, for example, in a study by Heymsfield et al. (6) Deuterium dilution results in about the same level of error. For example, if an obese, edematous subject is weighed underwater, the normal calculation formula to convert body density into body fat could overestimate body fat percent by two or three percentage points (due to a larger amount of body water in the fat free mass its density is  $< 1.100$  kg/L). In the same subject deuterium oxide dilution would, however, underestimate body fat percent by some two or three percentage points.

With the development of new body composition techniques such as *IVNAA* and dual-energy x-ray absorptiometry (DXA), and their combined use with densitometry and deuterium oxide dilution, it has become possible to measure body composition using chemically defined multicompartments models (11). The most popular models are a three-compartment model (fat mass, water, and dry fat-free mass) in which variation of the water fraction in the fat-free mass is accounted for, and a four-compartment model (fat mass, water, minerals, and protein). In the latter model, the variation of both the water and the mineral fraction in fat-free mass is accounted for. Although the technical error of these multicompartments models is not lower compared to two-compartment models (15), they do have a smaller methodological error, as the variation in the composition of the fat-free mass is accounted for. This makes the three- and especially the four-compartment model suitable as a reference when it comes to comparing groups in which the composition of the fat-free mass might differ. Such differences are known to exist between age groups (children vs. adults vs. elderly), males and females, and also ethnic groups.

Table 2 provides examples for females from various ethnic groups for body fat percent measured by densitometry alone, (assuming a density of the fat-free mass of 1.1 kg/L) and a four-compartment model. As can be seen, body fat calculated from the Siri formula is gen-

**Table 2** Body Fat Percent in Females of Different Ethnic Groups Measured by Two Body Composition Methods<sup>a</sup>

| Race    | Ref. | BF2c | BF4c | Difference |
|---------|------|------|------|------------|
| Blacks  | 17   | 21.2 | 21.8 | +0.6       |
| Blacks  | 18   | 26.5 | 28.1 | +1.6       |

| Whites  | 10   | 27.7 | 28.9 | +1.2       |

<sup>a</sup> BF2c: body fat from two-compartment model; BF4c: body fat from four-compartment model.

erally lower in blacks and in Asians than body fat from the four-compartment model. In Caucasian groups, the differences between two- and four-compartment models are not so obvious.

There are numerous studies (in vitro as well as in vivo) showing that blacks (most studies refer to African-Americans) compared to Caucasians have higher bone density and bone mineral content as well as higher muscle mass (16). The amount of water in the fat-free mass, however, is not different. As minerals and proteins are the densest components in the fat-free mass, it can be calculated that the density of the fat-free mass blacks is higher than in Caucasians (17,18), although this was not found in all studies (8).

The same holds for the comparison between Asians (Chinese) and Caucasians (10), although less information is available on Asians. Recently it was shown that there are also small differences in the composition of the fat-free mass (in terms of water, mineral, and protein fraction) among (Singaporean) Chinese, Malays, and Indians (9).

Generally, studies among ethnic groups suggest that the use of the classical densitometric method and the use of the Siri (5) formula is likely to lead to biased measurements of body fat percent. Thus for comparative studies among ethnic groups this method is not suitable, unless formulas based on measured rather than assumed densities of the fat-free mass are used (11). For comparative studies, the use of multicompartiment models is recommended to avoid any systematic bias. Multicompartiment methods are, however, expensive, and the instrumentation is not available to many researchers. As the water content in the fat-free

mass is (in most studies) not found to be different from the assumed value of 73%, dilution methods may be a good alternative for comparative studies among ethnic groups (9,14). The method has the advantage that it is "portable," and even researchers who do not have the necessary instrumentation could use the methodology as samples can be sent to specialized laboratories for analyses.

### III ACCURACY AND VALIDITY OF PREDICTIVE BODY COMPOSITION METHODS

Doubly indirect methods rely on a statistical relationship between easily measurable body parameters and body composition as measured by a direct or an indirect method. There are many examples of such methods, and the most often used for the prediction or assessment of body fat are skinfold thickness measurements, bioelectrical impedance measurements, and weight/height indices. All these methods have in common that the standard error of estimate (SEE) of the equation is ~4–5 percentage body fat points and that the prediction equations are not "general" but are population specific. It has to be kept in mind that a SEE of 5% means, that, even if the mean bias is zero in 34% of the population, the differences between measured and predicted body fat percent will exceed -5 or +5 percentage body fat points. In 5% of the population, the error will be higher than -10 or +10 percentage points. Thus, for individual assessments, these methods are not very reliable. Unfortunately, many prediction formulas also have a systematic bias if applied to other populations than the one in which they were developed.

Table 3 gives for three methods an example of systematic bias. In this table, the predictive values from a BMI-based prediction formula (19), an impedance-based formula (20) and a skinfold based formula (21) are compared in Indonesian and Caucasian males and females of comparable age. It is obvious that in Caucasians the differences between measured and predicted values are much lower than in Indonesians. This is not surprising, as the formulas used to predict were all developed in Caucasians. These data show that the interpretation of predicted values from formulas developed in other populations has to be approached with caution.

The reasons for those systematic biases are easy to understand from the principles of the predictive

**Table 3** Measured and Predicted Body Fat Percent in Dutch and Indonesian Adult Males and Females

|                          | Females         |     |            |     | Males           |     |            |     |

BMI: body mass index; BF deuterium, body fat from deuterium oxide dilution; BF BMI: body fat predicted from body mass index using a sex- and age-specific Caucasian prediction formula (19); BF imp: body fat predicted from bioelectrical impedance (20); BF skfd: body fat predicted from skinfolds (21).

methods. The skinfold methodology assumes that the thickness of the subcutaneous fat layer, as it can be measured using skinfold calipers, is representative of the total-body fatness. Skinfold thicknesses at exactly defined sites are then used in a formula that regresses the skinfold thicknesses against a measure of body fat, generally body density. Differences between sexes and age groups are accounted for in most formulas, but less is known about the relationship between subcutaneous fat layer and total fat among ethnic groups. Little is also known about the representativeness of different body sites for the total subcutaneous fat layer in various ethnic groups. What is known, however, suggests that ethnic groups differ in subcutaneous fat pattern. For example, blacks tend to have less subcutaneous fat in the extremities and more subcutaneous fat on the back of the trunk, resulting in a higher trunk-to-extremity skinfold ratio compared to Caucasians. The amount of intra-abdominal or visceral fat is, however, for the same amount of total body fat, lower in blacks. There are indications that the skinfold patterns of other ethnic groups differ also from that of Caucasians (23,24). It is therefore not surprising that the application of skinfold formula often results in biased mean estimates of body fat percent (24). Differences in subcutaneous fat pattern also may explain why formulas using different combinations of skinfolds [as for example the Dumin and Womersley equations (21)] can give different results in the same population. Apart from the problem of different fat patterning, there is the additional problem that the method of reference used to develop the prediction equation may give biased values of body fat in various ethnic populations. Also, different types of skinfold calipers measure different skinfold thicknesses (25). Generally, the skinfold methodology

is less valid in very thin subjects and in the very obese, and the methodology needs trained observers to obtain valid and reproducible results. More research in various ethnic groups has to be done in the area of subcutaneous fat pattern and its relationship with body fat percent based on valid reference methods.

Total body bioelectrical impedance is related to the water content of the body, but it is affected by many other parameters, some of which can be controlled for. The formulas for the prediction of body fat percent using bioelectrical impedance analyses generally have an estimation error of about five percentage body fat points (11). As for skinfolds, also impedance formulas are population specific, and thus predictive values are often strongly biased (see Table 3). The reason for those biases are, in most situations, differences in body build. Also technical error due to lack of standardisation or the use of different instruments can contribute to systematic biases.

In total-body bioelectrical impedance analysis a small alternating current is applied to the body and the resistance or impedance of the body to that current is measured. It is assumed that the human body is a homogeneous conductor. However, the conductivity of the total body is for a large part (> 80%) determined by the extremities, whereas most of the body water is in the trunk. This leads to the observation that subjects with relatively long legs and/or long arms will have relatively (too) high impedance values for their total body water. As a consequence, total body water and fat-free mass will be underestimated by the usual formulas and hence body fat will be overestimated. Relative leg length was discussed as one of the reasons that in Indonesians and Chinese bioelectrical impedance underestimates BF%, as Asians have rela-

tively short legs compared to Caucasians (23,26,27). As relative leg length and relative arm length differ remarkably among ethnic groups (see also Fig. 1), this is something to keep in mind if impedance is used for body composition analyses.

In addition to the “classical” total-body impedance analyzers, which measure the conductivity of the subject from foot to hand while lying supine, there are now various commercially available impedance analyzers that measure impedance from hand to hand (standing) or from foot to foot while standing on a weighing scale. Weight, height, age, and gender are included in the formulas that are incorporated in these instruments. Although these instruments are more convenient to use than the classical impedance analyzers where the subjects had to lie supine, they do not provide better information, and the population specificity of formulas may be even a greater problem. This is understandable, as the “assessed” water content of the extremities (arms or legs) is assumed to be representative for the whole body. It is obvious that this is not true across populations where there are obvious differences in relative leg and/or arm length, but also not in ethnically homogeneous populations. For example, in a subject with relatively highly developed leg muscles, the foot-to-foot impedance analyzer is likely to underestimate body fat percent.

Apart from biases caused by body build differences, the impedance methodology has many other pitfalls,

despite its easy and convenient application. Standardization is very important, not only regarding body position but also regarding environmental temperature. In addition different machines give different readings, and the correct type of electrodes is important as well. However, when compared to skinfold measurements, less experience is needed to perform an accurate measurement. A report of a consensus meeting on the use of bioelectrical impedance in body composition studies has been published (28).

Both the impedance methodology and skinfold thickness measurements are “portable” methods, which can be used in large population studies. Skinfold measurements have the disadvantage that the subject has to be partly undressed and that there is physical contact between the researcher and the subject, which may limit its practical application in certain populations. As increasing fatness results in increasing weight, weight corrected for height methods can also be used as indicators for body fatness.

An appropriate weight/height index has to have a high correlation with body fat, but also a low correlation with body height, as otherwise body fat percent would be systematically over- or underestimated in short people. The most popular of all indices is the body mass index (BMI) or Quetelet Index. The WHO (29,30) recommends the BMI as an indicator of overweight and obesity. The correlation between BMI and body fat percent (BF%) is high (depending on the age group ranging from 0.6 to 0.8), and the correlation found with body height is generally low and not significant.

The BMI can also be used as a predictor for BF%. Several studies have demonstrated a good relationship between the BMI and the amount of body fat if age and sex are accounted for (19,31–33). When using such age- and sex-specific equations percent body fat can be predicted with an error of 3–5%, an error comparable with the prediction error of skinfold thickness or impedance measurements.

In some subjects or groups of subjects, BMI cannot be used to predict body fat, as for example in pregnancy and in body builders. It has to be kept in mind, however, that the BMI also correlates with the fat-free mass. The BMI is in fact not more than a weight index, and as a measure of body fatness it assumes that a fixed part of the index consists of fat-free mass, whereas all exceeding mass is body fat. The situation is not so simple, however, as with increasing body fatness the amount of fat-free mass also tends to increase (more muscle needed to “carry” excess body fat and more bone mass to support the heavier weight).

**Figure 1** Body build and composition data from a Caucasian (Dutch) subject and a Chinese (Singaporean) subject. BMI, body mass index; BF4c, body fat from four-compartment model. (From Ref. 1.)

Moreover, the index assumes that the weight distribution over the body length is homogeneous. However, weight per unit length is higher in the trunk than in the legs. This means that subjects with relatively longer legs will generally have a lower BMI, and thus in those subjects body fat tends to be underestimated with a BMI-based formula. It has been discussed in the literature (34) that the long-leggedness in the Australian Aboriginal accounts for about  $2 \text{ kg/m}^2$  of their low BMI. There are considerable differences in relative leg lengths among ethnic groups (27), with blacks generally having longer legs than Caucasians and some Asians groups having shorter legs than Caucasians. It is clear that this has an impact on the validity of the BMI as predictor of BF%. However, it has to be kept in mind that differences in relative leg length also exist among various African groups (e.g., Ethiopians vs. West African groups) and Asian groups (e.g., Chinese vs. Indians). Also, there is generally a wide variation in relative leg length within a given (homogeneous) ethnic group.

In addition, body build has been shown to have an impact on the BMI/BF% relationship. Although the effect of body build is often not found to be strong in homogeneous populations (35,36), comparisons between different (ethnic) population groups have shown that body build is a contributing factor (37–39).

Figure 2 demonstrates how body build and leg length affect relationship between BMI and body fatness, and Figure 3 shows the impact of relative leg

**Figure 2** Subject A has the same BF% as subject B, but because he has shorter legs his BMI will be higher (more mass per cm length in the trunk). Subject C has the same BMI as subject D, but as his frame is bigger (stockier), he will have more skeletal mass, more muscle mass, and more connective tissue. Therefore for the same BMI he will have less BF%.

**Figure 3** BF%: body fat percent. Bias: measured BF% minus predicted BF% (19). A: without correction; B: corrected for relative leg lengths; C: corrected for frame size; D: corrected for relative leg lengths and frame size. (From Ref. 38.)

length and body build on the BMI/BF% relationship in a group of sex- and age-matched Beijing Chinese, Singapore Chinese, and Dutch Caucasians. As can be seen the relationship between BMI and BF% is different among the three groups, but after correction for relative leg length and/or body build, the differences completely disappear (38). The effect of body build on the BMI/BF% relationship was confirmed in two other studies among ethnic groups (37,39). To visualize how different Caucasians are in relation to Singapore Chinese, two typical subjects from recent studies are shown in Figure 1.

Several studies in different ethnic groups confirm a fairly good relationship between BMI and BF% as long as age and sex are taken into account. In addition ethnicity can have a clear impact on the relationship. From this it may be concluded that if BMI is used to classify people in categories of body fatness, the cutoff points for those categories should ideally be ethnic specific (40).

#### IV DEFINITION OF OBESITY AND BMI CUT-OFF POINTS

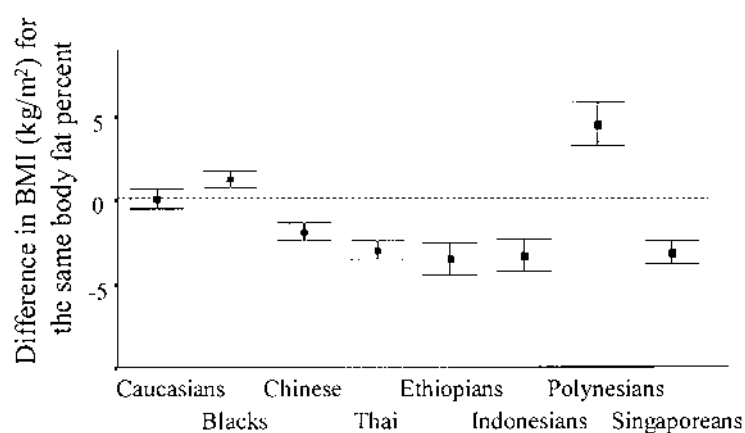

The WHO (30) defines obesity as a condition with excess body fat to the extent that health and well-being are adversely affected. The body mass index is used for the purpose of classification. The suggested cutoff points for overweight ( $\text{BMI} \geq 25 \text{ kg/m}^2$ ) and obesity ( $\text{BMI} \geq 30 \text{ kg/m}^2$ ) are based on observational studies on the relationship between morbidity and mortality and BMI primar-

ily in Caucasians from Europe and the United States. In Caucasians, a BMI of 30 kg/m<sup>2</sup> corresponds to a BF% of ~25% in young adult males and ~35% in young adult females (29), although there are variations around those estimates.

In cross-country or cross-ethnic group comparisons on obesity, two factors should be kept in mind: the body composition part, i.e., the level of body fatness; and the health risks related to overweight/obesity. Because of the differences in the BMI/BF% relationship among ethnic groups, it is clear that a general BMI cutoff point can be questioned. More specifically, a comparison between groups should be based on comparable levels of body fatness, which could be at different levels of BMI. Figure 4 shows calculated BMI cutoff points for obesity in different ethnic groups having the same body fat percent (40). According to this, the cutoff points for obesity might be considerably lower in many ethnic groups than the advocated level of 30 kg/m<sup>2</sup> in Caucasians. The main limitation of the data in Figure 4 is that BF% in the different populations was determined using different techniques, of which the validity in the population under study is not sure. For a comparative study on the relationship between BF% and BMI among (ethnic) groups, a prerequisite is that the reference method to determine body fat percent is valid. As discussed earlier in this chapter, such a method should ideally be a multicompartment model or, alternatively, deuterium oxide dilution.

A recent study in Singapore using a four-compartment model clearly showed differences in BMI/BF% relationship among Chinese, Malays, Indians, also in

comparison to Caucasians (39). The cutoff point that was calculated based on this study was 27 kg/m<sup>2</sup>, which is similar to that suggested by Guricci et al. (22) and currently used in Indonesia. This BMI cutoff point is slightly higher than the one suggested by Ko et al. (41) for Hong Kong Chinese, which is 26 kg/m<sup>2</sup>. Unfortunately, in the study of Ko et al. (41) BF% was assessed by impedance. Although the methodology was validated against DXA, no correction was made for the slight overestimation of impedance against DXA. Moreover, DXA cannot be regarded as a reference technique, and there are numerous studies showing either an under- or overestimation (9,42,43) of BF% from DXA, in some studies also ethnic dependent (9,44). Studies on the relationship between BMI and BF% from impedance were published earlier (45,46). The validity of those studies remains obscure, BIA is too much affected by body build factors (that may differ among groups) to be a reliable reference method. A study showing that the relationship between weight and impedance among some different ethnic groups has similar slopes has been published (47), but this study does not allow any conclusion as the different groups may have differed in body composition. More information on the relationship between BMI and BF% in different (ethnic) groups is needed and ideally multi-centre studies have to be carried out with strict standardisation of methodologies. Those studies should include parameters of body build to enable explanations of possible differences and perhaps to enable corrections of BMI for differences in body build. Implementation of these lower BMI cut-off points for obesity in the population will result in a much

**Figure 4** Adjustments to be made in BMI to reflect equal levels of body fat percent compared to Caucasians of the same age and sex. (From Refs. 39, 40.)

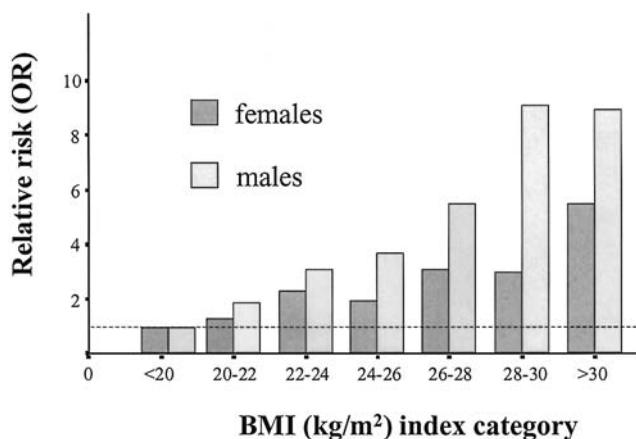

higher prevalence of obesity in many countries/ethnic groups, whereas in other groups the prevalence might become lower.

However, a lowering of cutoff point is not appropriate if there would be no elevated health risk at those lower levels of body mass index. This second aspect should also be carefully studied among different ethnic groups. It is known that in several Asian populations, cardiovascular morbidity and mortality are high and that the risk factors for CVD are high already at very low levels of BMI. For example, Ko et al. (48) showed that Hong Kong Chinese have at a very low BMI a high odds ratio for diabetes, hypertension, dyslipidemia, and albuminuria. Similarly, Figure 5 shows that in Singapore, the odds ratio of having at least one CVD risk factor is high at very low levels of BMI (49,50). Currently the International Obesity Task Force (IOTF) (51) is discussing a revision of BMI-based cutoff points for obesity in the Asian region, suggesting a BMI cutoff as low as 23 kg/m<sup>2</sup> for overweight and a BMI of 25 kg/m<sup>2</sup> for obesity. It seems necessary that redefining cutoff points should be extended to other ethnic groups as well. In the earlier-mentioned meta-analyses (40), it was shown not only that there are differences among clearly different ethnic groups (as Caucasians and Asians), but also that within the “same” ethnic group there might be differences in the BMI/BF% relationship. For example, American Cau-

casians apparently have a lower body fat percent at the same BMI than do Caucasians in Europe (33,40). As both the American and the European data came from various laboratories, most of them using densitometry, it is unlikely that this difference is due to differences in methodology. The black populations groups studied by Luke et al. (46) differed as well, which is confirmed by a study of Long et al. (52). Also, Northern and Southern Chinese differ (38,40), a difference that could be ascribed to body build differences. Wagner et al. (16), in a recent review also stress the need for in-depth studies in blacks to avoid biased estimations of obesity prevalence.

With regard to the relationship between BMI and body composition in different ethnic groups, there are two other interesting points to consider. There is first the definition of underweight. Many Asian populations have a large number of people with a BMI lower than 20 kg/m<sup>2</sup> or even lower than 18.5 kg/m<sup>2</sup>, the BMI value that is suggested by the WHO as cutoff for underweight (30). Those low BMI values are hardly prevalent in adult Western (Caucasian) populations. In the recent (1998) National Health Survey in Singapore, as many 11% of the females and 7% of the males had a BMI below 18.5 kg/m<sup>2</sup>. The proportion of Singaporeans with a BMI < 20 kg/m<sup>2</sup> were 25% and 15% for females and males, respectively (50). There is no reason at all to assume that undernutrition is epidemic among Singaporeans. This suggests that “healthy” BMI values in those populations could be shifted to the left, causing on the one hand higher obesity prevalences, and on the other hand lower undernutrition prevalences.

A second point is that if some ethnic groups have higher body fat percent at a given BMI, their fat-free mass will be lower, resulting in lower metabolic rates for a given weight and height (age and sex). This may shed new light on some reported low values of resting metabolic rate and total daily energy expenditure in certain population groups (53).

**Figure 5** Risk factors: elevated serum cholesterol ( $\geq 6.2$  mmol/L), elevated total cholesterol/HDL cholesterol ratio ( $> 4.4$ ), elevated triglyceride ( $\geq 1.8$  mmol/L), elevated blood pressure ( $\geq 140/90$  mmHg), diabetes mellitus (OGGT  $\geq 11.1$  mmol/L). Data are corrected for age, ethnicity, educational level, occupation, physical activity, smoking, and waist/hip ratio. (From Ref. 20.)

## V BODY FAT DISTRIBUTION

Since the early work of Vague (54), confirmed by many other studies [e.g., by Larson et al. (55)], it is clear that body fat distribution, specifically the amount of intra-abdominal (visceral) fat, is a more important risk factor for metabolic disorders than total body fat. The amount of visceral and subcutaneous abdominal adipose tissue can be assessed by computer tomography (CT) or magnetic resonance imaging (see Sec. 3).

Various anthropometric techniques have been used to predict body fat distribution, for example trunk to total skinfold thickness ratio, sagittal diameter, waist-thigh circumference ratio, waist-hip circumference ratio (WHR), or waist circumference (WC) alone (56). Many epidemiological studies have shown that there is a clearly increased risk for metabolic disorders such as hypertension, glucose intolerance, and hyperlipidemia with increased WHR or WC, and the WHO (30) defines cutoff points for abdominal obesity at a waist circumference level of 80 cm and 95 cm for females and males, respectively, and a WHR of 0.85 and 1.00 for females and males, respectively. Like BMI, these cutoff values are based on observational studies mainly among Caucasians (30). Although all studies in various ethnic groups show a positive relationship between parameters of body fat distribution and morbidity, recent studies suggest that the relationship between anthropometric parameters and the actual amount of visceral fat might differ among ethnic groups. Data from the MONICA study (57) suggest that optimal screening cut-off points (action levels) for WC may be population (ethnic) specific.

However, there is not yet sufficient evidence on the relationship between these indices and visceral fat to justify ethnic specific cutoff points for body fat distribution (58–61), and there is not yet enough information about the relation with these indices with morbidity. Generally African-Americans (children as well as adults) have less visceral adipose tissue as found by CT or MRI than their white counterparts (59,60,62,63). On the other hand, a comparative study among Pima Indians showed that there were no differences in visceral and subcutaneous abdominal fat areas (MRI) with age-, sex-, and BMI-matched Caucasians (64). The main limitation of most studies is the relatively small number of subjects, due to the nature (cost and radiation exposure) of the measurements. Data from NHANES III (65) show that for the same level of apparent body fatness (BMI) the corresponding WC values are higher in Caucasians than in Hispanics and African-Americans. This seems contradictory to the fact that African-Americans have a relatively higher truncal (subcutaneous) fat distribution (16). This shows that anthropometric indicators for body fat distribution have to be interpreted with caution, as the correlation with visceral fat is relatively low (0.4–0.7), which can easily result in misclassification.

Several comparative studies concluded that American blacks and whites differ in their metabolic relationships with body fat and body fat distribution (66,67). On the contrary, Despres et al. (68) showed

that ethnicity per se contributed only little to the variation in lipid profile between blacks and whites after controlling for differences in other variables (among them body mass index and body fat distribution).

In a recent study in Singapore we found that the relative risk for having at least one cardiovascular risk factor (e.g., elevated cholesterol, hypertension, diabetes mellitus) is elevated at levels of WC or WHR far below the WHO cutoff points (50). Using WHO cutoff points for classification of abdominal obesity (30) would miss a large part of the population at risk. This elevated risk could be due to a higher amount of visceral fat at low WC or to other factors, e.g., genetic factors. Further studies in Singapore are needed to determine the relationship between anthropometric measurements (WC and WHR) and the amount of visceral fat by CT or MRI.

Generally, more studies among ethnic groups have to be done to establish the relation between anthropometric indices of body fat distribution and visceral fat. These studies should be complementary to epidemiological studies on the relationship between indices of body fat distribution and disease risks. Results of both laboratory studies and epidemiological studies will provide necessary information to accept existing universal WC and WHR cutoff points or to redefine ethnic-specific cutoff points. As in the case of the relation between BMI and BF%, the use of standardized methodology is of utmost importance to avoid biased outcomes of studies. This standardization would include landmarks for waist and hip circumference and measurements of CT/MRI.

## VI SUMMARY

There is a need for multicenter multiethnic studies on body composition in which methodologies are highly standardized and in which reference methods like a chemically defined four-compartment model or (as a second choice) deuterium oxide dilution for total body fat and scanning techniques for body fat distribution are used. Ideally, those studies should also investigate the validity of predictive methods and search for possible explaining factors in order to possibly generalize prediction equations. Such studies could help in redefining BMI cutoff values for obesity and underweight when combined with data on risk factors such as cardiovascular disease. Similarly, cutoff points for body fat distribution (i.e. waist or waist-hip ratio, skinfold thickness ratios) should be validated and if needed redefined in different ethnic groups.

## Prevalence of Obesity in Adults: The Global Epidemic

Helsinki University Hospital, Helsinki, Finland

### I CLASSIFICATION OF OBESITY AND FAT DISTRIBUTION

The epidemiology of obesity has for many years been difficult to study because many countries had their own specific criteria for the classification of different degrees overweight. Gradually during the 1990s, however, the body mass index (BMI) (weight/height<sup>2</sup>) became a universally accepted measure of the degree of overweight and now identical cutoff points are recommended. This most recent classification of overweight in adults by the World Health Organization is the following (1):

| <i>Classification</i> | <i>BMI (kg/m<sup>2</sup>)</i> | <i>Associated health risks</i>                      |
|-----------------------|-------------------------------|---|
| Underweight           | < 18.5                        | Low (but risk of other clinical problems increased) |
| Normal range          | 18.5–24.9                     | Average   |
| Overweight            | 25.0 or higher                |   |
| Preobese              | 25.0–29.9                     | Increased   |
| Obese class I         | 30.0–34.9                     | Moderately increased                                |
| Obese class II        | 35.0–39.9                     | Severely increased                                  |
| Obese class III       | 40 or higher                  | Very severely increased                             |

In many community studies in affluent societies, this scheme has been simplified and cutoff points of 25 and 30 kg/m<sup>2</sup> are used for descriptive purposes. Both the prevalence of very low BMI (< 18.5 kg/m<sup>2</sup>) and very high BMI (40 kg/m<sup>2</sup> or higher) are usually low, in the order of 1–2% or less. Already researchers in Asian countries have criticized these cut points. The absolute health risk (particularly of type 2 diabetes mellitus) seems to be higher at any level of the body mass index in Chinese and South Asian people, which is probably also true for Asians living elsewhere. There are some suggestions to lower the cut points to designate obesity or overweight by several units of body mass index (e.g., 23 kg/m<sup>2</sup> for overweight and 25 kg/m<sup>2</sup> for obesity) in Asian populations. In countries such as China and India, each with over a billion inhabitants, small changes in the criteria for overweight or obesity potentially increase the world estimate of the number of obese people by several hundred million (current estimates are ~ 250 million worldwide).

Much research over the last decade has suggested that, for an accurate classification of overweight and obesity with respect to the health risks, one needs to factor in abdominal fat distribution. Traditionally this has been indicated by a relatively high waist-to-hip circumference ratio. Recently it has been proposed

that the waist circumference alone may be a better and simpler measure of the health risks associated with abdominal fatness (2). In 1998 the National Institutes of Health (National Heart, Lung, and Blood Institute) adopted the BMI classification and combined this with waist cutoff points (3). In this classification the combination of overweight (BMI between 25 and 30 kg/m<sup>2</sup>) and moderate obesity (BMI between 30 and 35 kg/m<sup>2</sup>) with a large waist circumference ( $\geq 102$  cm in men or  $\geq 88$  cm in women) is proposed to carry additional risk (3).

In this chapter, we focus on the prevalence of overweight and obesity as indicated by the body mass index. The emphasis is on recent surveys and time-trends, and data have been selected that are based on representative population surveys with measured weight and height.

## II PREVALENCE OF OBESITY BY WHO REGION

### A Africa

Table 1 shows the levels of overweight and obesity in women living in Sub-Saharan African countries (4). Obesity is relatively uncommon in all countries. This region is increasingly devastated by the AIDS epidemic

and by chronic malnutrition due to wars and natural disasters. A closer inspection of the data revealed that obesity is relatively more common in urban than in rural areas and more prevalent in women with high socioeconomic status. Data on men are very scarce from this region. There are fragmented data from South Africa which suggest that obesity is relatively common there in both rural and urban areas (5). Table 2 shows the prevalence of obesity in various regions and ethnic groups in South Africa. Mauritius is one of the best-studied parts of Africa with respect to cardiovascular risk factors, but it is also one of the least representative. Over 5000 people were studied in 1987 and 1992. The prevalence of obesity increased from 3.4% to 5.3% in men and from 10.4% to 15.1% in women (6).

### B The Americas

Figure 1 shows the time trends of the prevalence of obesity in men and women throughout the 1990s. The prevalence increased by about 1 percent point per year (7). These data are based on self-reported weight and height, and this probably leads to a considerable underestimation of the prevalence of obesity. The most recent (1988–1994) estimates of obesity in adults in the United States, based on measured weight and height, are  $\sim 20\%$  in men and  $\sim 25\%$  in women (8).

**Table 1** Overweight (BMI 25–29.9 kg/m<sup>2</sup>) and Obesity (BMI  $\geq 30$  kg/m<sup>2</sup>) Levels in Women Aged 15–49 Years in Sub-Saharan Africa

| Country                  | Year of survey | Sample size | % Overweight | % Obese |
|--------------------------|----------------|-------------|--------------|---------|

Source: Ref. 5.

There are important ethnic differences in the prevalence of obesity, particularly in women (Table 3). The women/men prevalence ratio is highest among non-Hispanic blacks (ratio  $\sim 1.8$ ), lower in Mexican-Americans (ratio  $\sim 1.5$ ) and lowest in non-Hispanic whites (ratios  $\sim 1.1$ ).

The prevalence of obesity in Canada is less than in the United States although the most recent estimates are already a decade old. Canada has experienced also an increase in the prevalence of overweight and obesity, particularly in men (Fig. 2, top). The most recent estimates of the prevalence of obesity are 13.4 percent in men and 15.4 in women (9).

Table 4 summarizes some of the prevalence data found in Latin American countries (10–12). Surveys show that obesity is quite common throughout South America and Mexico, particularly among women. Table 5 shows lower estimates of obesity among young adult women, but with the exception of Haiti, all prevalences are of the order of 10% (4). It is likely that these lower estimates are due to the fact that the studies by Filozof et al. (10) also covered middle-aged men and women among whom obesity is much more common than at younger ages.

Socioeconomic conditions in many developing countries are very different from those in countries

**Figure 1** Time trends of the prevalence of obesity (BMI  $\geq 30$  kg/m<sup>2</sup>) in the United States based on the behavioral risk factor surveillance system (self-reported height and weight). The NHANES III (National Health and Nutrition Examination Survey III) was conducted between 1998 and 1994 (depicted here as the midpoint of the survey in 1991) in a nationally representative sample based on measured weight and height. (From Refs. 7 and 8.)

**Table 3** Sex-Specific Prevalence Data of Obesity (BMI  $\geq 30$  kg/m<sup>2</sup>) and Sex Ratio by Ethnicity in Men and Women Aged 20–74 in the United States, 1988–1994

| Race/ethnic group  | Men  | Women | Sex ratio |
|--------------------|------|-------|-----------|
| Non-Hispanic white | 20.0 | 22.4  | 1.12      |
| Non-Hispanic black | 21.3 | 37.4  | 1.76      |
| Mexican-American   | 23.1 | 34.2  | 1.48      |

with established market economies. In such affluent countries, obesity is increasingly limited to those with low socioeconomic status whereas in developing countries obesity is more common in those with relatively high socioeconomic status. In countries undergoing economic transition these socioeconomic relations to obesity may change over time. Opposing trends may be seen within a single country. One interesting illustration of the changing socioeco-

**Figure 2** Time trends in the prevalence of overweight (BMI 25–29.9 kg/m<sup>2</sup>) and obesity (BMI  $\geq 30$  kg/m<sup>2</sup>) in Canadian men (top) and women (bottom). (From Ref. 9.)

nostic dimensions can be found in a paper by Monteiro et al. (13), who have looked at time trends in Brazil by income and degree of urbanization (11). Their results show rapid increases in obesity in Brazilian men in all groups (Fig. 3, top), although the levels of obesity in those with low income from rural areas are still only slightly above 1%. This is low compared to the prevalence of ~10% in urban men with high incomes.

In women, the situation is quite different. Obesity rates are generally higher compared to men in all groups. There were rapid continuing increases in women with low income but in those with high income there seems to be a stabilization or even a decline (Fig. 3, bottom). Such data highlight the profound effect of socioeconomic conditions on the prevalence of obesity.

Cuba is one of the few examples of Latin American countries where the prevalence of obesity has decreased

(14). The collapse of the Soviet Union in 1990 had dramatic effects on the food supply and transportation, leading to decreased energy intake and increased energy expenditure. The resulting drop in the prevalence of obesity is unique in the world (see Fig. 4).

### C Southeast Asia

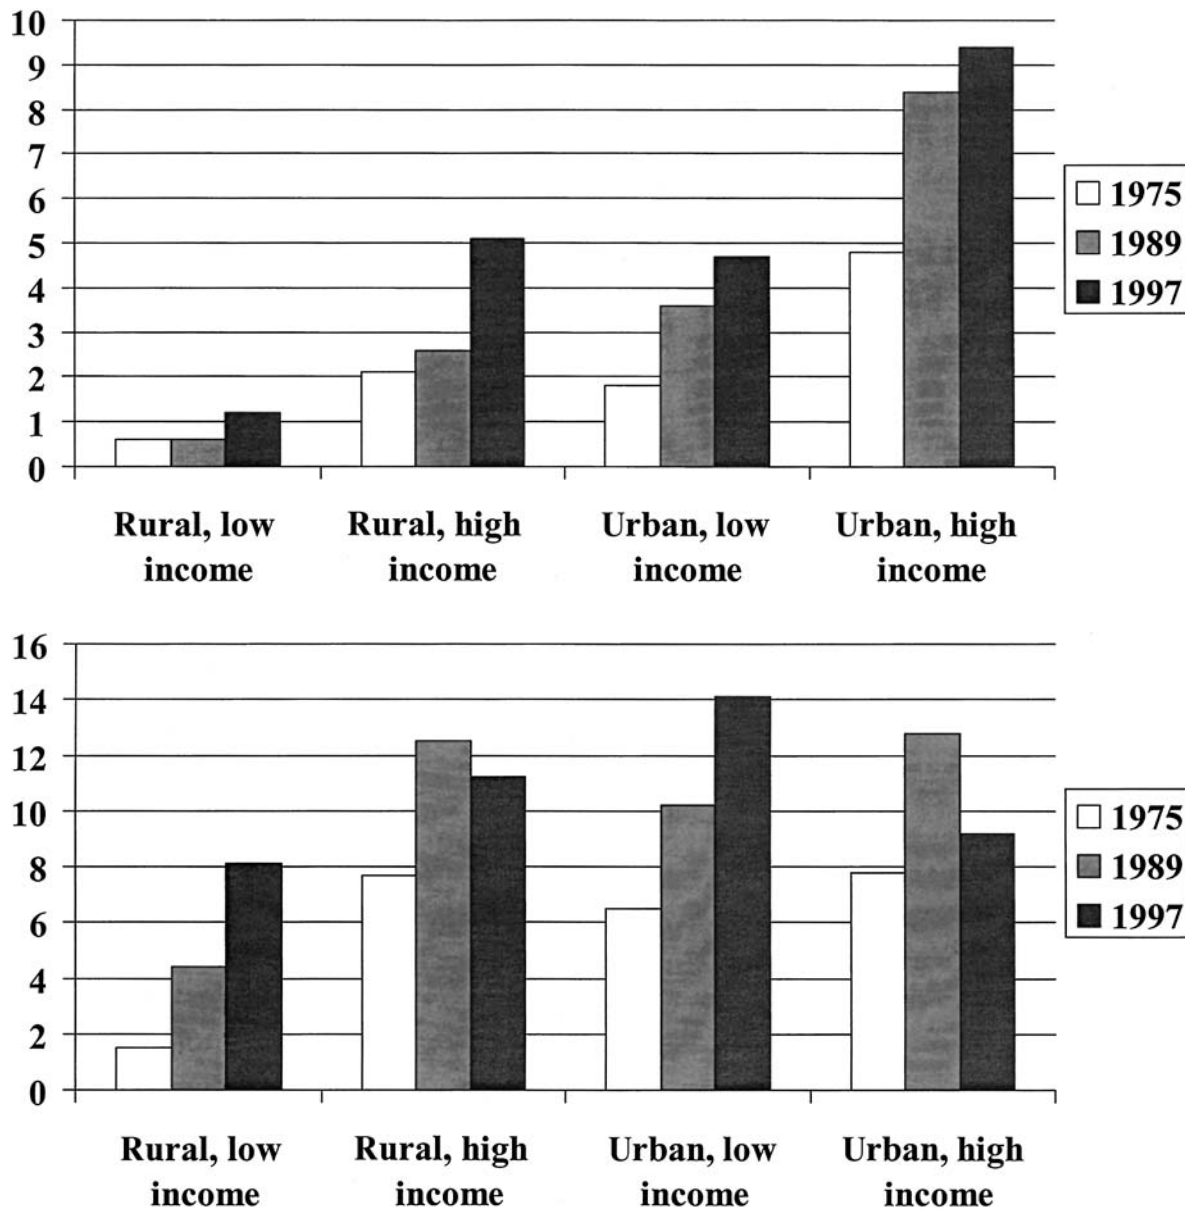

Overweight and obesity are still relatively uncommon in Asia, but this is rapidly changing (15). Table 6 shows that the prevalence of obesity in most large countries is still in the order of 1–5%.

Despite the relatively low prevalence of obesity in Asian populations, the situation there is of particular concern for two reasons. The first is that the prevalence seems to be increasing rapidly, particularly in urban areas (16). Secondly, Asian populations already seem to be particularly prone to develop type 2

**Table 5** Overweight (BMI 25–29.9 kg/m<sup>2</sup>) and Obesity (BMI ≥ 30 kg/m<sup>2</sup>) Levels in Women Aged 15–49 Years in Latin America

**Figure 3** Time trends in the prevalence of obesity ( $\text{BMI} \geq 30 \text{ kg/m}^2$ ) in Brazil by income (highest and lowest quartile of income) and degree of urbanization, in (top) men and (bottom) women. (From Ref. 11.)

diabetes mellitus at low levels of fatness. Uncontrolled diabetes mellitus is a major cause for nephropathy, neuropathy, retinopathy, and arteriosclerosis. The WHO has projected that the number of diabetics worldwide will increase from  $\sim 130$  million patients today to  $\sim 300$  million in 25 years (see Fig. 5). The largest contribution to this increase is expected to come from Asian populations, particularly China and India (17).

#### D Europe

In many reviews it has been shown that obesity (defined as a body mass index of  $30 \text{ kg/m}^2$  or higher) is a prevalent condition in most countries with established market economies (8,16). There is a wide variation in the prevalence of obesity between and within these countries. It is quite easy to find places with at least a twofold difference in the prevalence of obesity within one single

**Figure 4** Time trends in the prevalence of obesity ( $\text{BMI} \geq 30 \text{ kg/m}^2$ ) in Havana, Cuba (before and after the collapse of the Soviet Union). (From Ref. 14.)

country. In countries with established market economies, obesity is usually more frequent among those with relative low socioeconomic status, and the prevalence increases with age until ~60–70 years of age after which the prevalence declines (18). In most of these established market economies it has been shown that the prevalence is increasing over time (8,16). Tables 7 and 8 show the increases in the prevalence of obesity in men and women aged 35–64 years in several centers participating in the WHO MONICA project (19). It is clear that there is a rapid increase in the prevalence of obesity in most centers from countries in the European Union, particularly in men. The prevalence of obesity in men and women in European countries in the EU region (Table 7)

is similar with a women/men prevalence ratio of 1.07 (range 0.56–1.29). In central and eastern European countries (Table 8), the prevalence is generally much higher in women than in men (average women/men prevalence ratio 2.03; range: 1.27–2.87).

In central and eastern Europe countries, the prevalence of obesity in women may have stabilized or even slightly decreased but still it still remains among the highest in Europe. A study by Molarius et al. (19) showed that the social class differences in the prevalence of obesity are increasing with time. Obesity is fast becoming a lower-class problem in Europe.

Figure 6 shows the secular time trends of the prevalence of obesity in the United Kingdom and the Netherlands. In the mid-1980s the prevalence of obesity in men was similar in these two countries but in the United Kingdom the increase in the prevalence has been much more dramatic than in the Netherlands.

Figure 7 shows the women/men prevalence ratio in 1997 in the United Kingdom. The prevalence is similar in 25 to 65-year-old men and women but is progressively higher in women aged > 65 years. It is also higher in women than men in the youngest age group (16–24 years). There are several possible explanations for the higher prevalence in women at older ages. It may be the result of a secular trend in which the prevalence of obesity has increased more in men from more recent birth cohorts than in women of the same age. An

alternative plausible explanation is a biological one. After menopause women may experience a greater increase in body fat mass compared to men as a result of the drop in estrogen levels. A third explanation may be that obese men die more often prematurely than obese women do. The age-standardized absolute risk of some obesity-related diseases such as coronary heart disease is higher among men than among women.

Table 9 shows the prevalence of obesity in some less-studied countries including some countries that were

previously part of the former Soviet Union. In most of these surveys, the prevalence in women was in the order 15–20%, considerably higher than the prevalences observed in men.

### E Eastern Mediterranean

Generally, there is a lack of good representative data (e.g., national surveys) from this region. Table 10 shows the prevalence of overweight and obesity in Northern

**Figure 6** Time trends in the prevalence of obesity (BMI  $\geq 30$  kg/m<sup>2</sup>) in the United Kingdom (Health Survey for England) and the Netherlands (data from the National Institute of Public Health in Bilthoven). (From Ref. 17.)

**Figure 7** The gender ratio (women/men) of the prevalence of obesity ( $\text{BMI} \geq 30 \text{ kg/m}^2$ ) by age in the Health Survey for England (ages 16+), 1997. (From Refs. 17 and 18.)

Africa and the Middle East. The results show that the prevalence of obesity is higher in women than in men (particularly in the Middle East and the Gulf states).

#### F Western Pacific Region

Table 11 shows the prevalence of obesity in selected countries from the western Pacific region (15). Trend data on the prevalence of overweight and obesity are available for Australia, China, Japan, and Samoa. The prevalence of obesity in Australia and New Zealand appears to be in the order of 10–15%, but recent data

from the 1990s are not available (1). Aboriginals have, depending on their degree of “Westernization,” a much higher or lower prevalence of obesity compared to the general Australian population. In Japan, the prevalence of obesity is of the order of 2–3%. In the 1992 Nationwide Nutritional Survey, the prevalence of obesity in China was ~1.2% in men and ~1.6% in women. Some of the Pacific Island populations have extremely high rates of obesity. The prevalence of obesity in Nauru, for example, was reported in 1987 to be ~65% in men and ~70% in women (1). Similar high rates have been observed in urban areas of Papua

New Guinea (36% in men and 54% in women), whereas the prevalence in the highlands was not higher than ~5% in men and women. Urban Samoans in 1991 had a prevalence of 58% in men and 77% in women, and the figures were high in rural areas as well (42% in men and 59% in women).

The International Diabetes Institute has proposed that the international classification of obesity should be modified for Asian countries (15). It recommended that overweight be classified as a BMI >23 and obesity as a BMI of 25 or higher. If such a classification is adapted, then the prevalence of obesity in large countries such as China will be high and rapidly increasing (Fig. 8) (21). There is, however, as of yet, no consensus on this issue, and a large and coherent body of data would be needed before such a proposal could be implemented.

### III EXPLANATIONS FOR THE GROWING EPIDEMIC OF OBESITY

#### A Life-Style Changes

On an ecological or population level these time trends are not too difficult to explain, although the exact quantification of the various factors involved is almost impossible. On the one hand there is an increase in the average energy supply per capita. The World Health Report (23) has estimated that the average energy supply per capita in the world was 2300 kcal in 1963, 2440 kcal in 1971, 2720 kcal in 1992, and will be 2900 kcal by 2010. These increases are obviously not evenly distributed across the world's population and, sadly, many remain undernourished although in Asia (particularly China and India) and most of Latin

**Table 11** Sex-Specific Prevalence Data of Obesity (BMI ≥ 30 kg/m<sup>2</sup>) and Sex Ratio in Selected Studies in the Western Pacific Region

| Country     | Study  | Age (years) | Men         | Women       | Ratio women/men |
|-------------|--|-------------|-------------|-------------|-----------------|
| China       | Chinese National Nutrition Survey, 1992              | 20–45       | 1.0 (urban) | 1.7 (urban) | 1.70            |
|             |  |             | 0.5 (rural) | 0.7 (rural) | 1.40            |
| Japan       | National Nutrition Survey, 1990–1994 n = 12,926      | 35–64       | 1.9         | 2.9         | 1.53            |
| Philippines | Food and Nutrition Research Institute, 1993 n = 9585 | 20 +        | 1.7         | 3.4         | 2.00            |

Figure 8 Time trends in the prevalence of overweight (BMI  $\geq$  25 kg/m<sup>2</sup>) in China. (From Ref. 21.)

Figure 9 Hypothetical calculations of the magnitude of a positive energy balance to gain 10 kg over 10 years. It is estimated that an excess of 20 kcal/day over a 1-year period leads to a weight gain of about one 1 kg. One kilogram of weight gain is estimated to lead to about a 15 kcal/day increase in 24-hr energy expenditure. (From Ref. 24.)

America, these numbers are declining. The number of people with access to at least 2700 kcal has increased from 0.145 billion in 1969–1971 to 1.8 billion in 1990–1992 and is estimated to grow to 2.7 billion in 2010. Even when corrected for the increase in the world's population, this implies a more than 10-fold increase in the number of people having access to high-calorie diets. The globalization of agricultural production and food processing has affected not only the quantity of energy available per capita, but also the energy density.

At the same time there are continuing changes in the physical demands of work and leisure time. Mechanization of many types of work and changes in transportation are causing ever-increasing numbers of people to be sedentary for most of the time.

Increasing sedentary behavior has been proposed to be one of the principal reasons for a further increase in the prevalence of obesity in countries with established market economies. Sedentary behavior is poorly measured by the number of hours engaged in sports only. Large and important differences can be seen in the number of hours spent at sedentary jobs and in front of television or computer screens during leisure time. Transportation is almost certainly a factor as well. For example, in the Netherlands, 30% of short trips are done by bicycle and 18% by walking. In the United Kingdom these percentages are 8% by cycling and 12% walking, and in the United States 1% by bicycle and 9% by walking. Accumulated over a year, these daily activities can easily explain the small but persistent changes in energy balance needed to greatly increase the prevalence of obesity.

Figure 9 shows the disturbances in energy balance necessary to shift one individual's BMI from 23 to 26 kg/m<sup>2</sup>. Energy intake in excess of energy expenditure needs only to be 20 kcal/day to produce weight gain over a year. This is in the order of 5 min less of brisk walking per day or an additional can of beer per week. There are compensating increases in energy expenditure, however, which may range from 15 to 25 kcal/day per kilogram of weight gain in women and men respectively (24), so that the actual increase in energy intake or reduction in energy expenditure to achieve major weight change is much larger.

Given the changes in life-styles over recent decades in many parts of the world, it is not surprising that people gain weight on average. With small changes in average body weight, the prevalence of obesity increases rapidly. For every unit increase in BMI, there is an increase in the prevalence of obesity of about five percentage points (1).

## B Social, Economic, and Cultural Determinants of the Prevalence of Obesity

Many factors affect energy balance and determine obesity. The major determinants can be grouped into three groups (25):

1. Biological influences and unalterable factors (e.g., age, sex, hormonal factors, and genetics).
2. Behavioural influences (which are the result of complex psychological factors, including habits, emotions, attitudes, beliefs, and cognitions developed through a background of learning history).
3. Environmental influences (physical, economic, and sociocultural environment).

With respect to the behavioural and sociocultural factors that affect energy balance and obesity, there are many that relate to eating habits and physical activity. Of the many gender-related social determinants of obesity, we briefly discuss the perception of overweight as a desirable or undesirable trait. The attitudes toward obesity vary greatly across social and ethnic groups, and are related to the economic position of individuals and groups. In many affluent countries women experience social pressures to be thin. Katzmarzyk and Davis (26) studied the body weight and shape of Playboy centerfolds in the period 1978 to 1998 as an example of culturally "ideal" women, and noted that 70% of them were underweight by WHO standards (BMI < 18.5 kg/m<sup>2</sup>). They speculate that this phenomenon helps to explain the high levels of body dissatisfaction and disordered eating among young women. It has been observed that these social pressures toward thinness are greater among women than among men, and greater in women with high educational level compared to those with a low educational level.

The prevalence of obesity is also sharply inversely associated with educational level. Black women in the United States are more likely to be obese than white women, even when adjusted for socioeconomic status, but they are less likely to perceive themselves as being overweight (27). Such epidemiological data would suggest that the perception overweight as an undesirable characteristic may play a role in the prevention of overweight, particularly in young white women of high socioeconomic background in affluent countries. This is undoubtedly an oversimplification, but if true it does so against the potential cost of an increased risk of body dissatisfaction and perhaps disordered eating.

Perceptions of overweight in black women in South Africa from disadvantaged communities in Cape Town, where food insecurity is a continuous concern, are in sharp contrast (28). From a qualitative in-depth survey of overweight women, it was shown that in these communities the concept of an individual voluntarily regulating food intake when food was available was completely unacceptable. Increased body mass index was regarded as a token of well-being in that marital harmony was perceived to be reflected in increased body weight. Overweight children were regarded as reflecting health as it was associated with sufficient food supply and intake. According to a survey in an urban black population in the Cape Peninsula of South Africa, more than half of the women above the age of 35 years were obese ( $\text{BMI} > 30 \text{ kg/m}^2$ ) whereas a considerable proportion of the children were undernourished (5). The Cape Peninsula is an example of a population that has undergone rapid economic transition and which has moved from undernutrition to extreme overnutrition.

Doak et al. (29) similarly described the coexistence of overweight and underweight within households in Brazil, China, and Russia. An underweight child coexisting with an overweight nonelderly adult was the predominant pair combination in all three countries. On an international level, Martorell et al. (4) studied the prevalence of obesity in women aged 15–49 years in different regions of developing countries. The prevalence of obesity was estimated to be ~17% in the Middle East and North Africa, >15% in Central Eastern Europe/Commonwealth of Independent States, ~6% in Latin America and the Caribbean, and <3% in Sub-Saharan Africa. There was a clear positive association between the gross national product (GNP) and the percentage of obesity up to a level of \$1500 GNP. With higher GNPs, the relationship was no longer present. In these countries, obesity was more prevalent in urban than rural areas and in those with high educational level compared to those with low educational level. The relationships between obesity and these indicators of social class sharply diminished with an increase in the countries' GNP.

Such observations illustrate the complexities of the social determinants of obesity. In affluent countries, the social pressures to thinness seem to be more intense in women than in men, and in developing countries the pressures toward high body mass index seem also to be directed mainly to women. In affluent countries, the preoccupation with diet is more common in those with high socioeconomic status, whereas in developing countries a high body mass index is particularly appreciated in those with low socioeconomic status. These

social pressures may reflect many underlying issues among which the food insecurity may be an important and often neglected element (30). In societies where food security is never a problem, obesity is common but not appreciated (particularly in women) whereas in food-insecure societies obesity is uncommon in women but regarded as a desirable trait. In countries undergoing an economic transition and in immigrants from developing to developed countries, their traditional perceptions of ideal body weight in women may be sustained. At the same time, increases in food availability and decreases in energy expenditure promote weight gain. Such a mixture of attitudes and changes of socioeconomic conditions may, in part, explain the exceptionally rapid increase in the prevalence of obesity, particularly in the women in such populations. Why the sociocultural ideals vary more by socioeconomic conditions among women than among men may be explained by the relative importance of energy reserves in women under conditions where the food supply is insecure. The energy reserves required for pregnancy and lactation may provide a biological basis for the cultural perception of an association between obesity and fertility. In situations where food is abundant throughout the year and no strenuous physical activity is required, the cultural ideals about body shape seem to disappear.

#### IV CONCLUSIONS

The prevalence of obesity is increasing at an alarming rate in many parts of the world. In white populations living in the west and north of Europe, in Australia, and in the United States, the prevalence of obesity is equally high in men and women. In countries with relatively low gross national product, such as those in central and eastern Europe, Asia, Latin America, and Africa, the prevalence is 1.5–2 times higher among women than among men. Within affluent societies, the rates of obesity seem to be higher among women at older ages (65 years) and in groups with relatively low socioeconomic status. Obesity is particularly common among women living in relatively poor conditions.

## Fetal Origins of Obesity

**David J. P. Barker**

University of Southampton, Southampton, England

### I INTRODUCTION

Obese children tend to become obese adults, especially if their parents are obese (1,2). One study showed that 80% of children who were overweight at ~12 years of age were obese at ~30 years (3). Among a group of elderly men and women in Helsinki, those who were obese, defined by a body mass index ( $\text{weight}/\text{height}^2$ ) of  $>30 \text{ kg}/\text{m}^2$ , had had above average body mass indices at the age of 7 years (4). Such findings indicate that adult obesity may be initiated or “entrained” during early life (5). There may be critical periods of development when this occurs. Critical periods, during which changes tend to be irreversible, may be distinguished from high-risk periods which occur throughout life and are associated with reversible increases in body weight. Pregnancy and times of emotional stress are examples of high-risk periods. There is evidence for three critical periods for body weight—prenatal, childhood, and adolescence. This chapter focuses on the prenatal period, describing how this may influence later obesity and how it interacts with obesity in childhood and adult life to determine later disease.

### II BODY SIZE AT BIRTH AND LATER BODY COMPOSITION

People who had high birth weight or were heavy during the first year after birth are at increased risk of obesity in later life (6,7). The effect, however, is small. In a study of

military conscripts in Denmark, for example, mean body mass index rose from  $22.7 \text{ kg}/\text{m}^2$  in men whose birth weights were  $<2500 \text{ g}$  to  $24.9 \text{ kg}/\text{m}^2$  in men whose birth weights were  $>4500 \text{ g}$  (8).

People who had low birth weight tend to accumulate fat on the trunk and abdomen, a pattern of adiposity found in the insulin resistance syndrome in which central obesity, impaired glucose tolerance, hypertension, and altered blood lipid concentrations occur in the same patient (9). This disorder is associated with an increased risk of coronary heart disease (10). In two studies in the United Kingdom men who had low birth weight had high ratios of waist-to-hip circumference after allowing for adult body mass index (Table 1) (11). This association with low birth weight has been replicated in a study of men in Sweden (12). In the Swedish study birth weight was also associated with truncal fat, as measured by a high ratio of subscapular to triceps skinfold thickness. After allowing for current body mass index truncal fat increased by 0.30 standard deviations with each kilogram decrease in birth weight.

In one of the U.K. studies placental weight was also available (Table 1). Its association with the waist-hip ratio was in the opposite direction to birth weight so that the highest ratios of waist-to-hip circumference were in men who had had a high placental weight in relation to birth weight. High placental weight to birth weight ratios are a known marker of fetal hypoxia or undernutrition (13–15). The association with placental weight has not been examined in other studies, and may be inconstant because placental hypertrophy is only one

**Table 1** Simultaneous Effects, Regression Coefficients (95% CI) of Birth Weight, Placental Weight, and Adult Body Mass Index on Waist-Hip Ratio (%) in Two Samples of Men in the United Kingdom

|  | Preston<br>(men aged 51) | Hertfordshire<br>(men aged 64) |
|--|--------------------------|--------------------------------|
| Adult body mass index (kg/m <sup>2</sup> ) | 0.70 (0.54–0.86)         | 0.83 (0.75–0.91)               |
| Birth weight (lbs)                         | –0.83 (–1.50 to –0.15)   | –0.29 (–0.52 to –0.05)         |
| Placental weight (lbs)                     | 1.76 (–0.73 to 4.24)     |                                |

of the fetus's responses to undernutrition. It depends on the timing of undernutrition and the mother's nutritional state (14).

Low birth-weight has been shown to be associated with truncal fat in young people. This association occurs across the normal range of birth weight. Among 30-year-old Mexican and non-Hispanic Americans low birth weight was associated with truncal fat but not with a high waist-to-hip ratio (16). Among English girls aged 14–16 years, those who were smallest at birth but fattest as teenagers also had the highest ratio of subscapular to triceps skinfold (17). Among children aged 7–12 years in Philadelphia, there was a similar association between low birth weight and truncal fat deposition with partial correlations between birth weight and the ratio of subscapular to triceps skinfolds of ~0.20, after allowing for body mass index (18). In 8-year-old Indian children the subscapular-to-triceps skinfold ratio fell from 84.8 to 77.7 across what is the normal range of birth weight in India, from 2.0 kgs or less to 3.25 kgs. Above 3.25 pounds the ratio rose to 82.2, which may reflect macrosomia at birth and persisting overweight in the offspring of mothers with gestational diabetes or impaired glucose tolerance (19). No association between birth weight and truncal fat was found in a comparison between 15-year-olds who had low birthweight, <5.5 lbs, and controls within the normal birth weight range (20). This could reflect aspects of body composition specific to babies weighing <5.5 lbs, since as adolescents these low-birth weight babies were markedly thinner than the controls.

High waist-hip ratio and high truncal fat may reflect different aspects of body composition, hormonal status, and metabolism (12). In the Swedish study low birth weight predicted a smaller hip but not a larger waist and therefore did not reflect abdominal obesity. A study of young American men applying for military service led to the same conclusion (21). Birth weight was linearly

associated with body mass index and with the area of thigh muscle but not with subcutaneous fat on the thigh. The association between birth weight and body mass index may therefore have reflected an association with lean tissue rather than fat. Waist-hip ratio and truncal fat also have different metabolic associations. Waist-hip ratio is more strongly associated with serum triglyceride and HDL cholesterol concentrations than is the subscapular-triceps skinfold ratio (22). The associations between low birth weight and these two measures of body composition are likely to reflect influences in the intrauterine environment that are either different or act at different times.

### III FETAL NUTRITION AND LATER BODY COMPOSITION

Nutrition has a central role in the regulation of fetal growth (15). Cross-breeding and embryo transplant experiments in animals show that size at birth is largely determined by the intrauterine environment, with only a small effect from parental genotype (23). The major hormonal mediators of fetal growth are insulin and the insulinlike growth factors (24). These in turn are regulated by fetal nutrient supply (15,25). It is important that “fetal nutrition,” which defines the supply of metabolic substrata to the fetus, is distinguished from maternal dietary intake because the mammalian fetus grows at the end of a long and sometimes precarious supply line, which includes the mother's body composition, metabolic and endocrine status, uterine blood flow, and placental function (15). Notwithstanding this complexity, it is clear from the effects of wartime famine that a mother's diet in pregnancy can influence the body composition of her offspring through their lives.

#### A Undernutrition

Famine began abruptly in western Holland in November 1944 and ended with the liberation by the Allied armies in May 1945. In the early months of 1945 official rations varied between 400 and 800 calories per day. A study of ~300,000 young military conscripts who were born around that time showed that those who were conceived during the famine had higher rates of obesity than those who were either in utero or born when the famine began, or those who were never exposed to famine (26). By the time the men and women exposed to famine in utero reached 50 years

of age, the picture had changed (27). The men conceived in famine were no longer more obese than other men, but the women conceived in famine were on average 7.9 kg heavier than women not exposed to famine; their body mass indices were 7.4% higher, and their waist circumference was 7.4 cm greater. These associations did not depend on their body size at birth: indeed, their birth weights were similar to those of unexposed children—presumably because their mothers became well nourished in the second half of pregnancy.

These fascinating observations suggest that high body mass index and high abdominal fat, for which waist circumference is a validated indicator (28), can originate through fetal undernutrition. The sex differences in response to undernutrition suggest that the processes underlying its association with later obesity are more likely to involve alterations in central hormonal regulatory mechanisms rather than changes at the level of the fat cell.

## B Overnutrition

Studies of the children of women with diabetes during pregnancy provide some of the clearest evidence that obesity may be linked to metabolic experience in utero. Figure 1 shows the change in body mass index from

**Figure 1** Change in body mass index from birth to 17 years in 139 children born to diabetic mothers. (From Ref. 29.)

birth to 17 years in a group of 139 children born to diabetic mothers (29). They are compared with standard growth curves in the United States. Having been heavy and macrosomic at birth, the children's body mass indices became similar to those of other children at the age of 1 year. They remained similar until ~4 years of age, after which they began to increase. They remained overweight up to the age of 17 years. At 14–17 years of age their mean body mass index was 24.6 kg/m², compared with 20.9 kg/m² in a group of control children. The degree of overweight was not related to birth weight or to the level of macrosomia at birth. Because the children were similar to other children at 1 year, their overweight cannot reflect persistence of excessive fat accumulated in utero. Some form of “metabolic programming” is implied. Overweight was related to the concentration of insulin in the amniotic fluid, which suggests that premature activation of the pancreatic beta cells in the offspring of diabetic mothers could be linked to their later development of obesity.

The effects of intrauterine exposure to the metabolic consequences of maternal diabetes could be confounded, however, by genetic influences. To address this, 52 families of Pima Indians were studied in which at least one sibling was born after the mother was found to have diabetes (30). The mean body mass index in these siblings was 2.6 kg/m² higher than in their siblings from nondiabetic pregnancies. Since siblings born before and after diabetes are at the same risk of inheriting genes determining obesity, the difference in body mass index is likely to reflect the effect of intrauterine exposure to diabetes.

## IV INFANT FEEDING AND OBESITY

A recent study of 15,000 children aged 9–14 years found that in those who had been only or mostly fed breast milk, the odds ratio for being overweight was 0.78 (95% CI 0.66–0.91) compared with children who had been only or mostly fed infant formula (31). This apparent protective effect of breastfeeding against obesity persisted after adjustment for energy intake, physical activity, mother's body mass index, and other variables. The same association has not been found consistently in younger children, and there may be a latent period during childhood before it is manifest. A mechanistic explanation of the association is that breastfed babies have greater control of their intake than bottle-fed babies, and therefore develop better self-regulatory mechanisms. Another possibility is that hormones and

growth factors in breast milk permanently change the baby's metabolism. There is no specific evidence for this, but breastfeeding has been shown to be associated with lower levels of cardiovascular risk factors including lower low-density lipoprotein concentrations (32). It seems likely that associations between breastfeeding and later adiposity will prove to be complex.

## V FETAL GROWTH AND OBESITY-RELATED DISEASE INTERACTIONS BETWEEN FETAL GROWTH AND CHILDHOOD BODY MASS

Studies of the fetal and infant origins of obesity are part of a wider field of research on the early origins of adult diseases (33). It is now known that people who had low birth weight, or who were thin or stunted at birth, are at increased risk of type 2 diabetes, coronary heart disease, and hypertension (34–40). These diseases, especially type 2 diabetes, are associated with obesity (41). Their association with small body size at birth has led to the conclusion that they originate in persisting changes in the body's structure, physiology, and metabolism that result from fetal undernutrition and are associated with slow growth in utero (15,33).

Figure 2 shows the path of growth of boys who as adults were either admitted to hospital with coronary heart disease or died from the disease. They belong to

a cohort of 4630 boys born in Helsinki (40). Their body size is expressed as mean standard deviation or Z scores. The Z score for the cohort is set at zero, and a boy maintaining a steady position as large or small in relation to other boys would follow a horizontal path on the figure. Boys who later developed coronary heart disease, however, having been small at birth and during infancy, had accelerated gain in weight and body mass index thereafter. A 1-unit increase in standard deviation score for body mass index between 1 and 12 years was associated with a hazard ratio of 1.20 (95% CI 1.08–1.33). The effect of increase in body mass index, however, was conditioned by birthweight and, more strongly, by ponderal index at birth (birth weight/length<sup>3</sup>), a measure of fatness.

Table 2 shows that at any body mass index at 12 years, the latest age for which there are data, the risk of coronary heart disease was greater in boys who were thin at birth. Findings at younger ages in childhood were similar. In animals accelerated or "compensatory" growth after a period of undernutrition during development can have long-term costs, including reduced life span (42). Whether this general biological phenomenon is related to the association between rapid childhood weight gain and human disease is not known.

The same general pattern of growth, small size at birth and during infancy followed by compensatory growth in childhood, is associated with type 2 diabetes and hypertension (38,39). There are differences in detail

Figure 2 Growth of 357 boys who later developed coronary heart disease in a cohort of 4630 boys born in Helsinki.

**Table 2** Hazard Ratios for Deaths from Coronary Heart Disease According to Ponderal Index at Birth (birth weight/length<sup>3</sup>) and Body Mass Index at 12 Years

| Ponderal index<br>at birth (kg/m <sup>3</sup> ) | Body mass index at 12 years (kg/m <sup>2</sup> ) |               |               |               |

| −29   | 1.3 (0.6–3.0)                                    | 1.5 (0.7–3.2) | 1.6 (0.7–3.6) | 2.1 (0.9–4.6) |
| > 29  | 1.0  | 1.1 (0.4–2.6) | 1.9 (0.8–4.4) | 1.5 (0.6–3.5) |

<sup>a</sup> No. of men.<sup>b</sup> 95% confidence intervals in parentheses.

between the diseases and between the two sexes (43), but the overall picture is the same. Disease is related to the rate of increase in body mass index as well as to body mass index attained at any particular age (38,39). The diseases are therefore related to the tempo of weight gain in childhood as well as to the state of being obese or overweight in adult life. The data from Helsinki can be used to estimate the number of cases of disease that are statistically attributable to fetal, infant, and childhood growth. If, for example, each man and woman in the cohort had had (1) a birth weight above the median for the cohort, 3.4 kg, (2) weight at 1 year above the median, 10.0 kg, and (3) an increase in body mass index between 3 and 12 years below the median increase, 0.5 kg/m<sup>2</sup>, there would have been a 44% (95% CI 27–59) reduction in hospital admissions and deaths from coronary heart disease, a 62% (95% CI 43–79) reduction in the incidence of type 2 diabetes, and a 31% (95% CI 19–43) reduction in the incidence of hypertension.

There are a number of possible processes by which, in humans, undernutrition and small size at birth followed by rapid childhood weight gain could lead to cardio-

vascular disease and type 2 diabetes in later life (38–40). Babies who are thin at birth, having a low ponderal index, lack muscle, a deficiency which will persist as the critical period for muscle growth is ~ 30 weeks in utero and there is little cell replication after birth (44). If they develop a high body mass index in childhood, they may have a disproportionately high fat mass. This may be associated with the development of insulin resistance, as children and adults who had low birth weight but are currently heavy are insulin resistant (19,45), and the adults have high rates of the insulin resistance syndrome (46,47).

## VI INTERACTIONS BETWEEN FETAL GROWTH AND ADULT BODY MASS

The effects of birth weight interact with the effects of body mass index in adult life as well as in childhood. Table 3 shows that the effect of increasing birth weight on reducing systolic pressure is greater among men who have a high body mass index (48). This interaction

**Table 3** Slope of Relation of Systolic Pressure (mmHg) at Age 50 per Kilogram Increase in Birth Weight by Thirds of Distribution of Body Mass Index Among 1333 Men in Uppsala, Sweden

| Men                                      | Body mass index (kg/m <sup>2</sup> ) |                                  |                         |

between birth weight and body mass index was stronger in men who were born at term, and whose low birth weight is therefore due to slow fetal growth rather than premature birth. It was strongest in men who were tall, so that in men who were born at term, who were in the top third of body mass index, and of above median height, a 1-kg increase in birth weight was associated with a 15.9 mm Hg (95% CI 5.2–26.5) fall in systolic pressure. The authors suggested that tall men who had low birth weight had sustained a greater failure to realize growth potential in utero, and this failure that led to a greater increase in blood pressure. Another possibility is that these men had staged more rapid compensatory growth and had therefore sustained higher long-term metabolic costs.

A mechanism other than insulin resistance by which the effects of birth weight and body mass index may interact is through their effects on plasma cortisol concentrations. A recent study showed that fasting plasma cortisol concentrations in adult men and women fell by 23.9 nmol (95% CI 9.6–8.2) with each kilogram increase in birth weight (49). This is thought to reflect persistently increased cortisol secretion in people who grew slowly in utero, and who may have enhanced their glucocorticoid secretion in order to accelerate maturation of key organs including, importantly, the lung (50).

Although obesity is associated with a reduction in plasma cortisol concentrations (51), Table 4, which combines studies in the United Kingdom and Australia (49), shows that the association between high plasma cortisol and raised blood pressure is stronger in people who are overweight or obese. This suggests the existence of a group of men and women who, while becoming overweight, paradoxically maintain elevated plasma cortisol concentrations. It is this group that has the highest blood pressures. This requires further study, but it is part of a framework of ideas that may explain the consistent finding that

obesity amplifies the influence of low birth weight on cardiovascular and metabolic disease.

## VII CONCLUSIONS

Around the world the transition from chronic malnutrition to adequate nutrition, the so-called nutritional transition (52), is characterized by accelerated childhood weight gain and the emergence of adult obesity in people who were undernourished in utero and during infancy. This is the path of growth that leads to cardiovascular disease and type 2 diabetes. The WHO study of the global burden of disease found that, contrary to the preconception that these diseases are “diseases of affluence,” the probability of death from them and other noncommunicable diseases is higher in low-income regions than in high-income regions such as established marked economies (53). One resolution of this apparent paradox is that the high rates of maternal and perinatal disorders, nutritional deficiencies and infective disease which characterize low-income regions lead to poor fetal and infant growth and therefore enhanced susceptibility to the effects of rapid weight gain and obesity.

Although the epidemic of obesity in Western countries is linked to the epidemics of type 2 diabetes and coronary heart disease, the paths of childhood growth that lead to obesity and to these diseases differ. In the Helsinki studies, children who became obese in later life tended to be born with above average birthweight and to continue to have above-average weight in childhood (4). Children who developed obesity-related disorders had below-average body size at birth and at 1 year, and thereafter had accelerated weight gain so that their body mass index reached the average at some point in childhood and thereafter exceeded it (38,39,54). This dissociation in the paths of growth that lead to them may help to explain why despite an increasing prevalence of obesity in Western countries (55) coronary heart disease is declining (56).

To understand the origins of obesity and the disorders to which it is related, we may need to direct our attention away from the lifestyles of adults, however important these may be, to growth and development in utero, and during infancy and childhood. We need to understand how nutrition in early life establishes metabolic and endocrine pathways that lead to obesity and premature death (14). Strategies to prevent obesity-related disorders should include improvements of fetal growth and the prevention of obesity in childhood.

## Pediatric Overweight: An Overview

Bettylou Sherry and William H. Dietz

Centers for Disease Control and Prevention, Atlanta, Georgia, U.S.A.

### I INTRODUCTION

Overweight is one of the most prevalent nutritional problems affecting children in developed countries. In this chapter, we briefly describe the public health importance of pediatric overweight as well its identification, definition, and prevalence. We then address the physiologic changes of adiposity with age, the critical periods for the development of overweight, the associations and potential risk factors in the physical and behavioral environment, and implications for clinical practice. The data reviewed support the assertion that effective prevention and treatment of childhood overweight will have a major impact on the prevalence of adult overweight and obesity and their complications.

Although the intent of this chapter is to provide a perspective of childhood obesity, we will avoid the term "obesity," instead using the term "overweight." Calling children obese may have undesirable sequelae, including various types of psychosocial dysfunction. Thus, we will follow the more preferred terminology.

Today, the diagnosis of overweight connotes a state of ill health and the potential for serious consequences in childhood, adulthood, or both. In the past, it was believed rare for overweight boys and girls to suffer serious health consequences while they were still children or adolescents, and much less was known about the "tracking" of childhood overweight into adulthood or about the consequences for adult health of having been

overweight in childhood. Psychosocial dysfunction, such as poor self-esteem (1,2), was considered the primary reason that parents and pediatricians should be concerned about the overweight child. Now that we know that overweight children commonly have adverse lipid, insulin, and blood pressure levels (3), elevated C-reactive protein (4), type 2 diabetes (5), increased linear growth and advanced bone age (6), hepatic steatosis (7), cholelithiasis (8), as well as a variety of less common disorders such as sleep apnea (9), and that overweight tracks increasingly with advancing age in childhood into adulthood (10,11), we must accord overweight much greater importance among the problems with which pediatricians and families must deal. When we improve our understanding of the consequences of childhood overweight, the dramatic increase in prevalence compels us to give this issue a high priority among our public health concerns.

The adverse consequences of pediatric overweight during childhood warrant more discussion. Of particular concern are the dramatic increase in the incidence of type 2 diabetes in children and adolescents and the fact that this disease is strongly associated with overweight children. In one study of 10- to 19-year-old children in Cincinnati, the incidence of type 2 diabetes increased from 0.7 per 100,000 in 1982 to 7.2 per 100,000 in 1994, and studies from several developed and developing countries document the emergence of type 2 diabetes among children (5). Freedman et al. found

that compared to non-overweight children [body mass index (BMI) < 85th centile], overweight children (BMI > 95th centile) had a significantly increased risk of having elevated fasting insulin levels [odds ratio (OR) = 12.1, 95%, confidence interval (CI) = 10–16], elevated triglycerides (OR = 7.1, 95% CI = 5.8–8.6), elevated systolic blood pressure (OR = 4.5, 95% CI = 3.6–5.8), low levels of high-density lipoprotein (HDL) cholesterol (OR = 3.4, 95% CI = 2.8–4.2), high levels of low-density lipoprotein (LDL) cholesterol (OR = 3.0, 95% CI = 2.4–3.6), and elevated diastolic blood pressure (OR = 2.4, 95% CI = 1.8–3.0) (3). Fifty-eight percent of the overweight children were found to have at least one risk factor, and using overweight as their screening tool allowed them to identify 50% of the children who had two or more risk factors (3).

There is evidence of adverse consequences of child-onset overweight in adulthood as well. In a 55-year follow-up study of adults who were overweight as adolescents, the relative risks of coronary heart disease and atherosclerosis were increased relative to adults who had not been overweight during adolescence (12). These analyses were adjusted for BMI and smoking status at age 53 years. Among the men in this study, there was a significantly greater risk of all-cause mortality and death from coronary heart disease, atherosclerotic cerebrovascular disease, and colorectal cancer (12).

In a second study examining the consequences of child-onset overweight in adulthood, we demonstrated that overweight present in older adolescents and young adults had a substantial adverse impact on a variety of psychosocial outcomes (13). As shown in Table 1, obesity present in young women was associated with an adverse impact on educational attainment, rates of marriage, household income, and poverty status. The persistence of these effects after controlling for a variety

of baseline measures, including self-esteem, parental education, and the income of the family of origin, suggests that obesity is an important determinant rather than a consequence of socioeconomic status in women. Short stature, however, appeared to play a role in men comparable to the role of obesity in women on the social and economic indicators examined. These results suggest that discrimination against obese women is widespread, with grave social and economic consequences. However, although we anticipated that the effects of discrimination would have an adverse impact on the self-esteem of the women included in the study, no such effect could be demonstrated.

Few long-term studies have examined the degree to which excess adiposity in childhood predicts obesity in adulthood. Fatness and fat distribution determined by anthropometric measures in early childhood do not correlate well with fatness and fat distribution present at puberty (14). Retrospective data suggest that ~30% of obese women were overweight in adolescence, but only 10% of obese men were overweight during the same period (14). A review of the literature suggests that almost 40% of overweight children become obese adults, but only 15–20% of obese adults were overweight as children (14–16). However, there is a dose-response effect. Children who are severely overweight are more likely to remain obese as adults than are children who are moderately overweight (17). Because studies differ widely in design, populations considered, definition of overweight, the age at which subjects were measured, and the duration of follow-up, reports of the percent of overweight children who became obese adults vary from 26% to 63% (17).

More recent work on the tracking of overweight from childhood to age 21–29 years shows that for overweight young children, the risk of adult obesity is strongly influenced by obesity in one or both parents. Indeed, parental overweight has consistently been identified as a risk factor for adult obesity (10,11,18–22). Whitaker et al. (10) found among children < 3 years of age that the major predictor of obesity in young adulthood was their parents' obesity status. Compared to children < 3 years old whose parents were not obese, those with both parents obese were nearly 14 times as likely to be obese as an adult (OR = 13.6, 95% CI = 3.7–50.4). The < 3-year-old child's weight status irrespective of BMI was not predictive of adult obesity. As children aged, however, their BMI became more predictive: by age 6, the child's overweight status had become a significant predictor, and by age 15–17 an obese adolescent was 17.5 times as likely to become an obese young adult than was a nonoverweight adolescent (95% CI = 7.7–39.5) (10).

**Table 1** Effects of Obesity<sup>a</sup> in Young Women on Psychosocial Outcomes

| Outcome          | Adjusted difference (95% CI)     |
|------------------|----------------------------------|
| School           | –0.3 year (–0.1 year, –0.6 year) |
| Marriage         | –20% (–13%, –27%)                |
| Household income | –\$6710 (–\$3942, –\$9478)       |
| Poverty          | + 10% (+ 4%, + 16%)              |

<sup>a</sup> Obesity was defined as a BMI greater than the 95th centile for women of the same age studied in NHANES I. The data represent the differences in the outcomes and the confidence intervals of the differences between obese and nonobese women. Results controlled for baseline income, parental education, chronic health condition, height, self-esteem, age, and ethnicity.

Source: Ref. 13.

Lake and colleagues found that children with two obese parents were more likely to be overweight as children and showed the strongest tracking of any group with an elevated BMI from 7 years to age 33 years (19). In another study, changes in childhood BMI appeared to be more related to adult obesity in females than in males (11). Overweight Japanese school children became heavier adults than the general population (20).

Evidence is still inconclusive as to whether it is childhood overweight per se, the persistence of overweight, the length of time one is overweight, or being obese as an adult that increases the risk of adult morbidity and mortality (17). We have ample information from the Bogalusa Heart Study (3,23) that childhood overweight has direct implications for adverse lipid, insulin, and blood pressure levels. In this study, excess truncal fat during childhood was associated with these risk factors as well (23). Tracking studies demonstrate that ~40% of overweight children will be obese as adults (9,15,16), and the tracking of overweight is stronger at about age 18 than during early childhood and early adolescence (10,11). Overweight in childhood is associated in adulthood with early mortality, primarily due to coronary heart disease (17), type 2 diabetes mellitus, colon cancer, gestational hypertension, gout, arthritis, hip fractures, and menstrual problems (15,16).

## II IDENTIFICATION AND DEFINITION

Adiposity, or the amount of body fat measured directly or indirectly, is used to determine overweight status. There are three key issues regarding the identification of overweight children: (1) whether the same measures of adiposity should be used for clinical and research purposes; (2) whether indirect measures of adiposity are adequate for screening purposes; and (3) the recommended cutoff points for defining overweight. From the point of view of those in epidemiology and public health, measures of overweight should be internationally standardized and accepted to ensure comparability of prevalence estimates within and between studies. The measures should have reasonable predictive value for morbidity and mortality, and should be easily and inexpensively obtained, especially in the clinical practice setting. In addition, if the assessment tool is not a direct measure of body fat, it should correlate well with a child's total fat.

Clinicians would no doubt share some of these preferences and would likely add that the measure should be highly specific. Having a specific measure is probably more important than having one that is highly

sensitive (24) because of the great concern of psychosocial dysfunction associated with the diagnosis of overweight and the high prevalence of eating disorders among certain subsets of the pediatric population, such as adolescent girls. Thus, clinicians are likely to favor a measure that minimizes false positives, even if it does not detect all children who are overweight.

Pediatricians commonly used an indirect measure of adiposity, a weight-for-height index, to screen for overweight in children. Previously, weight-for-height was used. However, the new Centers for Disease Control and Prevention (CDC) growth charts provide weight-for-height<sup>2</sup>, or BMI, percentiles for children ages 2–20 years, allowing a single screening tool to be used (and compared) throughout the life span after 2 years of age (25). For children < 2 years of age, weight-for-height is still the screening tool of choice to assess weight status (25). With the exception of 3- to 5-year-olds, BMI is more correlated with body fat than is weight-for-height. Among children and adolescents ages 3–19 years, the correlation coefficients between BMI and percentage of body fatness defined by pooled dual-energy x-ray absorptiometry (DXA), a direct measure of adiposity, range from 0.78 to 0.88, which are higher than those found between DXA and weight-for-height (26). This indicates that BMI-for-age is better than weight-for-height for predicting both underweight and overweight, except among 2- to 5-year-olds, for whom the two approaches are equivalent (26). Thus, for indirectly assessing overweight, BMI can be used for all children ages 2 years and above, although weight-for-height might be substituted for those aged 2–5 years.

More direct assessment of adiposity is possible by several methods including DXA (27,28), underwater weighing, bioelectrical impedance analyses, total body water, and measurement of triceps skinfold thickness. With the exception of triceps skinfold thickness, these methods are still primarily used for research, because they are more complex to obtain and require expensive equipment. Each of these measurement techniques has different assumptions and limitations, yet the percent fat values derived from the methods are highly correlated (28–30). Unfortunately, measurement of triceps skinfold thickness requires calipers, which are not commonly available in pediatrician's offices. More importantly, reproducible skinfold measurements may be a problem. Obtaining reliable triceps skinfold measurements requires practice, and between-observer measurements are not as reproducible as measurements of height and weight. Furthermore, skinfold measurement may become less reliable as body fatness increases. Because skinfold measurements are currently the only practical

direct measure of adiposity available to most clinical practice settings, we recommend using triceps skinfold measurements as the primary diagnostic method for confirming that those overweight are overfat. However, adequate staff training and monitoring of the accuracy of their measurements is crucial to obtain accurate results.

Although both triceps skinfold measures and BMI are correlated with morbidity (3,23), BMI is easier to use as an initial screening tool. BMI and weight-for-height also predict the persistence of obesity into adulthood (10,11). Thus, given all their attributes, the use of BMI (10,11,25,31) for children ages 2–20 years or weight-for-height (25,26,32) for those ages from birth to 5 years appears well suited to estimating the risks for chronic diseases, persistent obesity, or other long-term sequelae of childhood overweight.

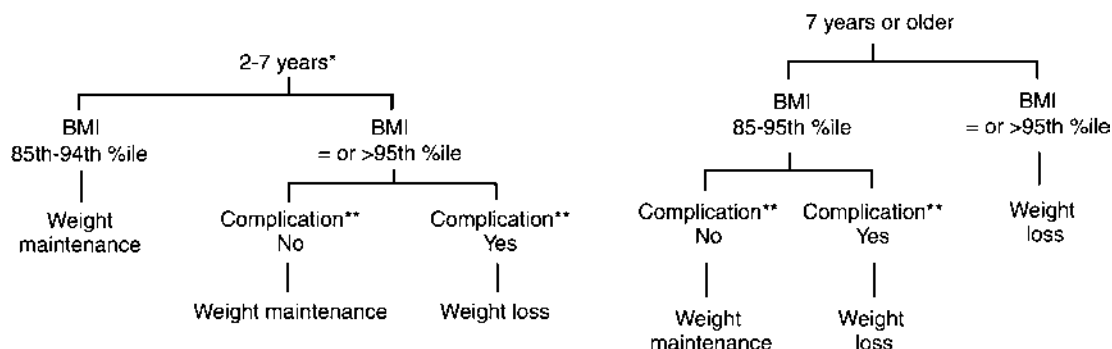

These observations led the International Obesity Task Force (33–35) to suggest that the internationally accepted scheme of BMI cutpoints for adult morbidity be used for children and adolescents. Cole et al. (36) used these criteria to create centile curves based on the centile values identified by the adult cutpoints of 25 and 30 kg/m<sup>2</sup> at age 18 years. These standards have been further refined and clarified by an Expert Committee on Pediatric Obesity established by the Maternal and Child Health Bureau (37), which recommended that children and adolescents with a BMI  $\geq$ 85th centile be screened for complications such as the presence of additional risk factors, including family history, blood pressure, cholesterol, and be evaluated and possibly treated (Fig. 1).

This committee recommended the following defining criteria: children with a BMI  $\geq$ 85th centile and  $<$ 95th centile for the same age and gender be categorized as at risk for overweight and those with a BMI

$\geq$ 95th centile for the same age and gender be defined as overweight. Among children ages 2–20 years, if BMI is at or exceeds the 95th centile for the same age and gender, the diagnosis of excess adipose tissue should be confirmed by triceps skinfold thickness. In addition, it is also useful for selecting intervention strategies to know if the child or adolescent is concerned about his or her weight. Although these cutpoints were originally based on BMI cutpoints for adult morbidity, Freedman et al. (3) found these cutpoints were able to identify adverse lipid, insulin, and blood pressure in childhood as well.

### III PREVALENCE

Prevalence estimates based on BMI and on triceps skinfolds have shown substantial increases in the prevalence of obesity in the United States since the 1960s (21,21a). The prevalence estimates of overweight summarized in Table 2 were based on the new CDC growth chart reference, using the gender- and age-specific 95th weight-for-length and BMI percentile cutoffs to define overweight. In 1999–2000 approximately 12% of 6–23 month olds, 10% of 2–5 yr olds, and 15% of 6–19 yr olds were overweight. For the 2–19 yr olds, there were no significant differences by gender in 1999–2000. Available data indicate that the greatest increases occurred between 1976–1980 and 1988–1994 except for 6–23 month old girls, 2–5 yr old boys, and 12–19 yr old girls, all of whom had greater increases between 1988–1994 and 1999–2000 (21a). Significant increases in the prevalence of overweight between 1988–1994 and 1999–2000 were found for non-Hispanic blacks and Mexican

**Figure 1** Recommendations for weight goals. Patients with acute complications, such as pseudotumor cerebri, sleep apnea, obesity hypoventilation syndrome, or orthopedic problems, should be referred to a pediatric obesity center. \*Children younger than 2 years should be referred to a pediatric obesity center for treatment. \*\*Complications such as mild hypertension, dyslipidemias, and insulin resistance. (From Ref. 37.)

Source: Ref. 21a.

American 12–19 yr olds: their prevalence of overweight increased from 13.4% to 23.6% and from 13.8% to 23.4% respectively (21a). The changes in the thickness of the triceps skinfold were of the same order of magnitude as those seen for BMI (21). Further analyses of BMI and triceps skinfold data indicated that the distributions of these data at least through 1988–1994 have become more right skewed (21,22). There were minor increases in stature between NHANES II and III, but these were not likely to have accounted for the trends seen in BMI (22). Similar analyses of low-income preschool children using the 95th percentile of weight-for-height as the cutoff documented an increase in overweight from 8.5% in 1983 to 10.2% in 1995; using the 85th percentile, the increase was from 18.6% to 21.6% (38). In addition to evidence from these large national survey data, secular increases in relative weight and adiposity have occurred among children in the Bogalusa Heart Study (39).

Racial/ethnic and socioeconomic characteristics affect the prevalence of overweight in children and adolescents. For children and adolescents from 6 months to 19 yrs old, the prevalence of overweight was greater among non-Hispanic blacks and Mexican Americans than for non-Hispanic whites, with the exception of 2–5 yr olds (21a). The presumed lower acculturation of Mexican American children may be associated with their higher prevalence of overweight, as this association defined as adopting the language of a

culture in the first two generations has been observed in Mexican American women (40). Native American children appear at particularly high risk for overweight (41,42): among Navajo 6 to 12 year-olds the prevalence of overweight was 15.2% for boys and 21.1% for girls (43). In contrast to adults, the prevalence of overweight in NHANES III in childhood varied less consistently with socioeconomic status than in previous national surveys. In NHANES III, the only significant association with socioeconomic status was an inverse relationship between family income for non-Hispanic white adolescents and the prevalence of overweight (21).

International comparisons of the prevalence of overweight (weight-for-height  $> 2.0$  SD above the NCHS/WHO reference median) showed that preschool children in Australia and Canada had a higher prevalence of overweight than their counterparts in the United States, while preschoolers in Japan and the United Kingdom had a lower prevalence than did those in the United States (44). A study of the prevalence and trends of overweight among preschool children in 94 countries found a global prevalence of 3.3% with wide variation (44). Developing countries with the highest prevalence were in the Middle East (Qatar), North Africa (Algeria, Egypt, Morocco), and Latin America (Argentina, Chile, Bolivia, Peru, Uruguay, Costa Rica, and Jamaica). Other countries with a high prevalence that were not included in these regions were Armenia, Kiribati, Malawi, South Africa, and Uzbekistan (44).

In Africa and Asia, the prevalence of wasting (weight-for-height  $< 2$  SD below the NCHS/WHO reference median) was 2.5–3.5 times higher than that of overweight (44). Other country reports found that mean BMI appeared to be increasing rapidly among children and adolescents in Denmark (45), Italy (46), Bahrain (47), and Brazil (48).

In the 94-country study cited above, the prevalence of overweight increased in 16 of 38 countries for which trend data were available (44). In Latin American and Caribbean countries, however, no increased trend in the prevalence of overweight among preschool children was

apparent (49). Canadian researchers documented even greater secular trends in the increase in prevalence of overweight among children than has been reported in the United States (50) (Table 3). Between 1981 and 1996, the prevalence of overweight (BMI  $> 95$ th centile) among 13- to 17-year-old Canadians increased from 5% in both boys and girls to 13.5% in boys and 11.8% in girls (50). In contrast, between 1976 and 1994, the prevalence of overweight (BMI  $> 95$ th centile) among 12- to 17-year-old Americans increased from 4.6% to 12.2% in white boys and from 4.2% to 9.4% in white girls (21). Changes in prevalence over time are reported

#### IV CHANGES IN ADIPOSITY WITH AGE

Adiposity changes dramatically in childhood and adolescence. In an early and important series of studies of the body composition of children and adolescents, Cheek described their changes in body fat, determined by measuring body composition with deuterium oxide (57). Based on Cheek's data, body fat as a percentage of body weight in boys increases in the prepubertal phase of growth, then declines coincident with the growth spurt. In contrast, fat as a percentage of body weight remains relatively constant in girls prior to adolescence but increases during the adolescent growth spurt. Between the ages of 10 and 15 years, Cheek estimated that body fat as a percentage of body weight declined from 17.8% to 11.2% in boys but rose from 16.6% to 23.5% in girls. Similar changes were subsequently described by other investigators (58).

Studies of adipocyte size and number in infancy and childhood demonstrate substantial age-dependent variations in their contribution to body fat mass (59,60). Cross-sectional and longitudinal studies of adipocyte numbers indicate that adipocyte numbers increase modestly throughout infancy and childhood in nonoverweight children, but that a pronounced and significant increase occurs after age 10 years. In contrast, the size of fat cells increases to adult levels in late infancy, after which it decreases to the level observed in early infancy in nonoverweight children (59), then remains constant until adolescence. Fat cell size in overweight children continues to increase to adult levels coincident with the development of overweight, after which the cells do not increase in size again until adolescence. In addition, overweight children have more adipocytes than do nonoverweight children, regardless of the age at which they are studied. These data indicate that in late infancy, increases in body fat in nonoverweight children may be primarily attributable to increases in adipocyte size, whereas after age 10 years, increases in body fat in these children reflect an increase in both adipocyte size and number. Among overweight children, both adipocyte size and number are increased from the time they become overweight, irrespective of their age. Weight loss reduces adipocyte size, but does not affect adipocyte number (61).

Changes in the thickness of triceps skinfold parallel the changes in body fat described by Cheek (62). Beginning at age 4–5 years, the triceps skinfold begins

to increase slightly in girls, subsequently increasing more rapidly coincident with the increases in body fat that accompany their growth spurt. In boys, skinfold thickness decreases around age 4 years, increases 1 or 2 years before adolescence, and subsequently decreases coincident with the increase in fat-free mass and decrease in fat mass that accompanies the male adolescent growth spurt.

BMI increases over the first year of life in both boys and girls, then declines to its nadir at age 4–7 years. Thereafter, the BMI begins to increase again in both males and females (63). Clinicians can use the triceps skinfold to clarify whether an increased BMI reflects an increase in frame size and muscle mass or an increase in body fat.

Changes in the distribution of body fat begin immediately prior to adolescence and continue to change throughout this period of rapid growth (14,64). In both genders, body fat shifts from a peripheral to a central distribution. In girls, cross-sectional studies have found that ratios of trunk-to-extremity skinfold thicknesses begin to increase at ~8 years of age and plateau by about age 12 years. In comparable studies of boys, the increase in the trunk:extremity skinfold ratio begins between 10 and 11 years of age, perhaps coincident with their preadolescent increase in fatness. In contrast to girls, no plateau in these ratios appears to occur in boys. By late adolescence, body fat distribution becomes more centralized in males than in females.

The limited studies available suggest that visceral fat deposition also changes substantially through childhood and adolescence. Visceral fat occupies ~50% of the cross-sectional abdominal fat area in 11- to 13-year-old children (65–67), but between adolescence and adulthood, this area increases four- to fivefold (68). However, these measurements are probably not as relevant metabolically as the ratio of intra-abdominal adipose tissue to total body fat. As Goran et al. have pointed out, the ratio of intra-abdominal adipose tissue to total body fat almost triples from early childhood to adulthood (65). Longitudinal or cross-sectional studies to examine the interrelationships between visceral and total body fat in adolescents, and the relationship of changes in the ratio of intra-abdominal to visceral fat to the timing of puberty, have not yet been done.

Although the foregoing studies do not encompass the entire range of childhood and adolescence, they suggest that the most rapid increases in visceral fat occur in late adolescence. In adults, body fatness relates directly to the quantity of visceral fat deposition, and the relationship between total and visceral fat differs by gender (68).

No such data are yet available for adolescents, but a similar relationship would be expected. The mechanisms that control the location and quantity of fat deposited, as well as those that control the changes in body fat that occur at adolescence, remain unclear. As for observed differences in relative weight and overweight between black and white, adolescents (21), analyses of the Bogalusa Heart Study data have shown that after controlling for height, mean relative weight of black girls was consistently greater than that of white girls after the age of 13, and that sexual maturation was a stronger correlate of relative weight among black girls than white girls (69), but we don't know if the higher weight is due to increased adiposity, lean body mass, or heavier bones.

## V CRITICAL PERIODS FOR THE DEVELOPMENT OF OVERWEIGHT

The likelihood that childhood overweight will persist, and therefore the likelihood of adverse consequences of childhood obesity in adulthood, may be related to its age of onset (70). There is a growing body of evidence that two periods and possibly a third appear to constitute specific periods of increased risk for persistence and subsequent disease: the prenatal period, "adiposity rebound," and the period of adolescence. At present, the mechanisms entrained at these periods to promote the increased risk of persistence of obesity or its complications remain poorly understood. In addition, stunting during childhood appears to put children at risk for the development of overweight; this will briefly be discussed in this section.

The most compelling data to suggest that the prenatal period constitutes a period of increased risk for persistent adiposity derive from studies of infants of mothers who had diabetes during pregnancy. Regardless of whether their diabetes was gestational, insulin-dependent, or non-insulin-dependent, these infants tend to be fatter at birth than those whose mothers were nondiabetic or prediabetic during pregnancy (71). Long-term follow-up of infants whose mothers had diabetes suggests they have an increased prevalence of obesity at later ages that extends through adolescence (72). Shorter-term studies further suggest that body weight in such infants normalizes by about 1 year of age but subsequently begins to be higher than the norm between ages 5 and 7 years (73). Pregravid overweight status of the mother has been associated with macrosomia independent of maternal age, smoking status, race/ethnicity, height, parity, gestational age, and sex of

infant (74). In turn, children who were large for gestational age at birth have greater and progressively increasing adiposity through 3–6 years of age than do their normal-size counterparts (75).

The argument that fetal life represents a critical period for adiposity has not been totally resolved, the evidence from the infants of mothers with diabetes notwithstanding. Several large studies have shown an association between high birth weight and child adiposity (75–78) or adult adiposity after controlling for gestational age (77,78), but most did not adjust for confounding variables such as parental fatness, maternal smoking, gestational diabetes, or socioeconomic status (79). Conversely, low birth weight may be associated with an increase in intra-abdominal fat deposition that may in turn account for an increased likelihood of risk factors for cardiovascular disease, including hypertension, diabetes, and hyperlipidemia (80). However, the association between lower birth weight and the development of overweight has not been clearly demonstrated. Although babies with lower birth weight have been shown to have an increased risk of syndrome X and of heart and pulmonary disease in adulthood (81), it is not clear that these consequences are mediated by excess adiposity.

The second period of apparent increased risk for later obesity, "adiposity rebound," involves early acceleration of the BMI after its nadir at 4–7 years of age. This phenomenon appears to be associated with an increased risk of later obesity (82,83). That infants of mothers with gestational or insulin-dependent diabetes during pregnancy also appear to have onset of overweight during this period (74) raises questions as to whether early acceleration of the BMI after its nadir is a risk for later obesity. Other research shows that parental obesity is also associated with early adiposity rebound (84) and that early rebound may reflect overweight associated with maternal diabetes. Thus, whether there exists a true period of risk for the development of overweight at this time, independent of maternal diabetes and/or parental overweight, remains unclear.

Although adiposity rebound has been associated with adult adiposity, this may only be an epiphenomenon (85). Increased BMI at rebound has not yet been associated with higher body fat, nor do we know whether the increased BMI observed in adults who have had early rebound is attributable to greater body fat. In addition, whether age at rebound or the size of the BMI at rebound has the greater influence on adult BMI remains unclear. New evidence shows that the BMI at age 7 years and age at rebound both predict adult BMI (86), and a positive association has been

found between childhood height at age 5 years and adult BMI (87).

The final developmental stage of increased risk, adolescence, may be much more of a concern for females than for males. Females, who mature earlier, are at increased risk for greater BMIs as adults (88,89); the relationship for males is less clear. In addition, while ~30% of obesity present in 36-year-old-women may begin in adolescence, only about 10% may begin then in males (32).

Some evidence from developing countries indicates an increase in overweight among stunted children, but this may be a spurious finding due to limitations in the indices used to define overweight and metabolic differences. As indicated in the first section of this chapter, indices used for evaluating relative weight, such as BMI and weight-for-height, do not directly measure body fat. In the case of stunted children, those with increased BMIs may have an excess of body fat, heavier bones, or larger muscles. On the other hand, metabolic defects may contribute. In Brazil, mild stunting was associated with the percentage of energy from fat and weight gain, suggesting that stunted children may be more susceptible to the effects of a high-fat diet than other children (90). Still another possibility is that stunted children may be more likely to have impaired fat oxidation (91). Evidence from a longitudinal study in Guatemala has shown that severely stunted children have increased abdominal fatness as adults, after controlling for fatness and other confounders (92).

## VI ENVIRONMENTAL ASSOCIATIONS

Most of the variables associated with childhood and adolescent obesity can be categorized under the physical, behavioral, or social environment.

### A The Physical Environment

A U.S. study published in 1984 found that childhood overweight (defined as triceps >95th centile among those included in the study) was associated with region, season, and population density (93), with each of these variables doubling or tripling risk. Compared to the West, the odds ratios for overweight adjusted for region and season of were 3.0 in the Northeast, 2.6 in the Midwest, and 1.2 in the South. Within each region, rates of obesity increased in the winter and spring and decreased in the summer and fall. Also in each region, obesity was more prevalent in highly urbanized areas

than in those less densely populated. The mechanisms that accounted for the environmental associations were not clear.

### B The Behavioral Environment

Dietary intake and the energy spent on activity represent the only discretionary components of energy intake and expenditure. Over the past 30 years, important changes have occurred in family eating patterns, including greater consumption of fast food, carbonated beverages, and preprepared meals. At the same time, some children are less physically active because of increased use of cars, concern for neighborhood safety, and decreased opportunity for physical activity at school or on the way to school. Children's time spent watching television and playing video games has increased. Both the food intake and physical activity of young children are strongly influenced by their parents. Although the literature that examines the effect of the potential risk factors for overweight in children is growing, as yet there are few longitudinal studies of adequate duration and rigor that have identified causal factors.

#### 1 Breastfeeding

Breastfeeding may protect against subsequent overweight in childhood. Two review papers on this topic published in 1999 and in 2001 both failed to find conclusive evidence of a significant positive effect of breastfeeding (79,94). Nonetheless, well-designed studies with large samples that controlled for potential confounders have demonstrated a protective effect of breastfeeding against overweight in childhood. Von Kries et al. (95) found that infants who were ever breastfed were 0.75 (95% Confidence Interval [CI] = 0.57–0.98) times as likely to be overweight (BMI >90th centile German schoolchildren) at 5–6 years of age. Gillman et al. (96) found that infants who were exclusively or mostly breastfed were 0.78 (95% CI = 0.66–0.81) times as likely to be overweight (BMI >95th centile NCHS/CDC reference) at 9–14 years of age. Both studies found a dose-response effect: breastfeeding of at least 6 or 7 months was more protective than <3 months. Although the Hediger et al. study (NHANES III) found an insignificant protective effect (odds ratio for mostly breastfeeding was 0.84, 95% CI = 0.62–1.13) (97), the small sample size of overweight children in this study may have influenced their ability to document a protective effect. Only ~300 of ~2700 children were overweight by 3–5 years of age (97).

## 2 Dietary Practice

The behavior and practices of parents strongly influences the dietary intake of their children. During childhood, parental intake of carbohydrate, fat, and energy appears to account for 23–97% of the variance in children's intakes of these nutrients (98). However, family resemblances in nutrient intake may reflect familial resemblances only in body size, since we do not know from this study whether actual BMIs were comparable. This possibility is strengthened by the observation that the relationship between the preferences of parents and children for specific sets of foods does not differ substantially from the relationship between the preferences of children and unrelated adults (99). Resemblances in nutrient intake, when they occur, appear to reflect a common environment rather than a genetically mediated preference for macronutrients (100).

The family environment has the potential to promote healthy eating. For example, children who eat meals with their family consume more fruits and vegetables, have a more nutritionally dense diet with less of their energy intake derived from fat, and drink fewer carbonated and sugared beverages than do children who do not eat with their families (101). A recent summary of the intakes of youth ages 2–19 years, based on the U.S. Department of Agriculture's 1989–1991 Continuing Surveys of Food Intakes by Individuals, documented that American children have a widespread need for improvement in their diets (102). Indeed, the authors found that only 1% of youth met their recommended intake of nutrients, and membership in this small group was associated with excess intake, especially of fat (102). Daily consumption of three meals of approximately equal energy content may be another potential strategy to reduce adiposity in children (103). Further evidence that food patterns may contribute to overweight is the association between incident overweight and the consumption of sugar-sweetened drinks in school children (104). Interestingly, the available trend data on energy intake among children suggest that it has not changed over ~20 years: total energy intake did not change between 1973 and 1994 among 10-year-old children in the Bogalusa Heart Study (105).

## 3 Child Feeding Practices

Children appear quite capable of self-regulating their dietary intake in unsupervised settings. Their meal-to-meal variation in energy intake is substantial, but variation in day-to-day energy intake is considerably lower (106). Certain parent-child interactions at feeding

may disrupt the ability of the child to regulate intake; the more parents encourage the consumption of certain foods, the less likely children are to eat them (107). Conversely, restricting access to certain foods appears to encourage their consumption when children have access to them (107). In a setting in which the ability of children to adjust their food intake in response to the caloric density of the diet was measured, children whose mothers were more controlling of their food intake were less capable of self-regulation of food intake, and these children had greater body fat stores (108). However, whether the lack of self-regulation is a cause or a consequence of the mother's control remains uncertain. At least two longitudinal studies of children suggest that parental control of child intake is not associated with energy intake and the development of overweight (109,110).

Interestingly, lack of knowledge about a child's intake is also associated with impairment of self-regulation. As a recent Danish study showed (111), the risk of subsequent overweight among 9- to 10-year-old children was not increased by their frequency of consuming sweets or when the mother accepted the child's consumption of sweets, but it was increased significantly if the mother lacked knowledge about her offspring's sweet-eating habits independent of their degree of fatness in childhood, their gender, and their social background.

Parental neglect has predicted overweight in young adulthood independent of gender, age, socioeconomic status, and childhood BMI (112). Additional observations have suggested that psychosocial stress is associated with rapid rates of weight gain (113,114). The greater effects of stress on weight gain in girls may emphasize both their biologic susceptibility to obesity in early puberty, as well as the adverse social effects that obesity imposes on them. In the studies cited, the retrospective collection of data represents a potential source of bias. In addition, these observations do not eliminate the possibility that rapid weight gain caused an increase in psychosocial problems rather than the reverse.

## 4 Physical Activity and Sedentary Behavior

Both activity and inactivity appear to affect the risk of obesity and its complications in childhood and adolescence. In preschoolers, for example, the energy spent on activity appears inversely related to fatness (115). Whether decreased nonbasal energy expenditure on physical activity increases the risk for developing childhood or adolescent overweight has not been clearly

established. As shown in Table 4, the proportion of energy spent on activity, expressed as a ratio of total energy expenditure, appears to increase from infancy and early childhood to adolescence. One explanation for this intuitively unlikely result is that lower nonbasal energy expenditure of early childhood may reflect increased time spent sleeping rather than a decrease in the energy spent on activity.

Not surprisingly, the prevalence of physical activity and sedentary behavior, as well as factors associated with activity levels and overweight in children and adolescents, has varied by study. Unfortunately, the lack of consistency in measures or categories of physical activity and sedentary activity and differences in the samples or populations studied make comparing them difficult. In general, physical activity among children appears to have decreased significantly. For example, research in the United Kingdom among 0- to 14-year-old children found that between 1985 and 1992 the average distance walked annually decreased by 20% and the distance cycled by 26%, while the distance traveled by car increased 40% (121). In their review of studies, Parsons et al. found no association between activity before children are old enough to walk and later fatness; no consistent association was found between activity after children could walk and subsequent fatness (79). Analyses of the NHANES III data found that 80% of 8- to 16-year-old children participated in three or more episodes of vigorous activity each week; rates were lower in non-Hispanic black and Mexican-American girls (122). The Youth Risk Behavior Survey for 1999 and the National Longitudinal Study of Adolescent Health data for 1996 found that approx-

imately two-thirds of youths in grades 7–12 participated in three or more episodes of vigorous activity each week, and minority females other than Asians had lower levels (123,124). One objective for Healthy People 2010 is to increase vigorous physical activity episodes of 20 minutes or more to at least 3 days per week for 85% of adolescents (125). The survey data above demonstrate that non-Hispanic black and Hispanic (or Mexican-American) females are not meeting this objective.

A recent review of studies (126) conducted between 1970 and 1998 found consistent positive correlations of physical activity in children (4–12 years old) with gender (male), having overweight parents, healthy diet, previous physical activity, intention to be physically active, preference for physical activity, access to facilities, and time spent outdoors. The only consistent negative correlate in this review was perceived barriers to physical activity (126). No associations were found between physical activity and socioeconomic status, race/ethnicity, body image, self-esteem, perceived benefits, attitudes toward sweating, other after-school activity, alcohol use, smoking, caloric intake, neighborhood safety, or parents providing transportation (126). In the same review, among adolescents 13–18 years old, physical activity correlated with gender (male), race/ethnicity (white), perceived competence in the activity, intentions to be physically active, previous physical activity, community sports, sensation seeking, parental support, support from others, sibling physical activity, direct help from parents, and opportunities to exercise. The only consistently negative correlates were depression and sedentary activities after school and on weekends (126). In 1996, the Surgeon General's Report (Physical Activity and Health), which reviewed the literature through 1995, found slightly different associations (127). To verify that the potential determinants listed are causally related to physical activities, they need to be examined prospectively and in concert with other potentially associated variables.

Evidence is now available from cross-sectional studies that strongly suggest that television watching is a risk factor for overweight (128,129). In their recent examination of the association among television watching, energy intake, and overweight in U.S. children based on the nationally representative NHANES III, Crespo et al. found that the prevalence of overweight (BMI > 95th centile in NHANES II and III data) was lowest among children who watched ≤1 hr of television per day and highest among those who watched ≥4 hr daily (128). Further analyses of the NHANES III data showed that among the 26% of children who watched ≥4 hr of

**Table 4** Ratio (SD) of Mean Energy Expenditure of Activity to Mean Resting Energy Expenditure for Children and Adolescents. Data Expressed as the Ratio of Total Energy Expenditure (kcal/day)/Resting or Sleeping Energy Expenditure (kcal/day) Metabolic Rate<sup>a</sup>

| Age group (Ref.)  | Males      | Combined <sup>b</sup> | Females    |
|-------------------|------------|-----------------------|------------|
| Infants (116)     |            | 1.35 (.29)            |            |
| 5 years (117)     | 1.36 (.13) |                       | 1.40 (.17) |
| 9–12 years (118)  | 1.61 (.23) |                       | 1.53 (.28) |
| 12–18 years (119) | 1.79 (.20) |                       | 1.69 (.28) |

<sup>a</sup> All studies measured total energy expenditure using the doubly labeled water method. The infant study (116) predicted basal energy expenditure from body weight based on the equation from Schofield (120). The other three studies used ventilated-hood indirect calorimetry to determine basal or resting energy expenditure.

<sup>b</sup> Data not differentiated by gender.

television per day, body fat and BMI were higher than among those who watched < 2 hr (122). Data from the Framingham Children's Study showed that when age, television viewing, energy intake, baseline triceps, and parents' BMI were controlled, inactive children were 3.8 times as likely to have increasing triceps skinfold measurements between age 4 years and entry into the first grade than were active children (130).

Activity levels seem to have a strong familial component. The higher familial correlations for activity within than across generations suggest that the environment is more important than genetics (131). Intensive analyses of a large cohort representing almost 400 families confirmed the observation that stronger correlations of physical activity occurred within the same generation (132), but they also demonstrated a heritability of 29% for level of habitual physical activity. No genetic effect was found for exercise participation (132). In recent studies in which we compared parent and child patterns of activity (personal communication, William H. Dietz, May 25, 2001), measures of vigorous activity were better correlated between spouses than between mother-daughter or father-daughter pairs. In contrast, time watching television was better correlated within families. These results suggest that patterns of inactivity, but not patterns of activity, are correlated within families.

### C Social Environment

Socioeconomic status has not been consistently associated with overweight in childhood, but two studies that controlled for parental fatness found negative associations between parental education and childhood BMI (133,134). In contrast, there is a strong consistent, positive relationship between low socioeconomic status in childhood and fatness in adulthood (79). If women change social class as adults, they are likely to reflect the prevalence of obesity in the social class they join (32,135).

## VII SCREENING OVERWEIGHT

Now that we have an accepted standardized screening tool for identifying overweight and risk of overweight in children, it is important that all infants and children be evaluated for their weight status by their primary care physician. As mentioned previously, Figure 1 gives recommendations for weight goals and referrals to pediatric obesity centers recommended by the Expert Committee on Pediatric Obesity (37).

The evidence that childhood overweight increases the risk of comorbidity in both childhood and in adulthood emphasizes the need to identify overweight children with other risk factors as early as possible. The Expert Committee (37) also recommends that all children and adolescents with a BMI  $\geq$ 85th centile be screened for complications, evaluated, and possibly treated, depending on the findings. The complications that should be sought include hypertension, dyslipidemias, orthopedic disorders, sleep disorders, gallbladder disease, and insulin resistance. In addition, a recent large change in a child's BMI should also be evaluated. The Expert Committee emphasized that clinicians should also seek signs of exogenous obesity such as genetic syndromes, endocrinologic disease, and psychologic disorders. In addition to screening, the committee advocated that an in-depth medical assessment be done for all children and adolescents with a BMI  $\geq$ 95th centile.

This committee also recommended early treatment that involved the family as much as possible. The family's readiness to make changes in diet and lifestyle should determine the pace and intensity of treatment. The family's ability to take responsibility for the lifestyle changes is key to progress and success.

## VIII SUMMARY AND IMPLICATIONS FOR CLINICAL PRACTICE AND PUBLIC HEALTH

In the past two decades, obesity has become one of the most prevalent nutritional diseases among children and adolescents in North America. Comparable international data demonstrate that the prevalence of overweight is also increasing rapidly in developed and developing countries outside of North America. The substantial effects of childhood overweight on morbidity and mortality indicate that effective prevention and therapy for this problem may well have a large impact on the incidence of adult disease. Programs aimed at treatment of overweight children appear to have a substantially better long-term success rate than similar programs in adults (136). Effective interventions to prevent childhood overweight, greater allocation of health care resources, and reimbursement for the treatment of obesity are needed for primary care practitioners to be effective in preventing overweight during childhood. Intervention strategies need to include interventions that address the range of potential risk factors and critical periods. For example, improved understanding of the incentives that promote the initiation

and extended duration of breastfeeding, and the elimination of the barriers that lead to early termination of breastfeeding, must become high priorities. Work site facilities and policies that allow mothers who must return to work to continue to provide breast milk for their infants may represent one of the policy shifts necessary to help address the overweight epidemic (137).

In the public health sector, states are developing state obesity plans that include targeting their high-risk populations and testing intervention programs in these groups. Fresh new ideas for increasing physical activity need to be included at the community level. For example, community planners need to consider opportunities for family physical activity, such as sidewalks, neighborhoods with stores and schools within walking distance, and community parks. Efforts must be directed toward the identification of children who are overweight or at risk for overweight in childhood and toward the propagation of successful treatment and prevention strategies.

## Obesity in the Elderly: Prevalence, Consequences, and Treatment

**Robert S. Schwartz**

University of Colorado Health Sciences Center, Denver, Colorado, U.S.A.

### I INTRODUCTION

In young and middle-aged individuals, obesity is an important metabolic and cardiovascular risk factor that is associated with highly prevalent disorders such as hypertension, diabetes, hyperinsulinemia, dyslipidemia, and atherosclerosis (1). While older individuals may not appear to be obese, they frequently suffer from these obesity-related disorders. This has led some investigators in the field of aging to consider many older individuals as having a “covert” form of obesity. Because the elderly are the fastest-growing segment of our population and contribute disproportionately to overall health care utilization and cost (2), the problem of obesity and obesity-related diseases in this older population could have staggering repercussions to our health care system as a whole, as well as to the lives of many older individuals and their families (3).

This chapter will discuss the scope of the problem of obesity in the elderly, define the body composition and fat distribution changes that normally occur with aging, outline possible etiologic factors in aging-associated obesity and, finally, consider potential treatments.

### II PREVALENCE OF OBESITY IN THE ELDERLY

#### A Age-Related Changes in Weight and Body Composition

Data from the NHANES III study demonstrate that the prevalence of overweight reaches a maximum for both

men (42%, with a mean body mass index [BMI] of 27.6) and women (52%, with a mean BMI of 28.5) between the ages of 50 and 59 (4). In this cross-sectional study (which had no upper age limit for subject entry and specifically oversampled older individuals), both the prevalence of overweight and the mean BMI tended to drop in older age groups, falling to 18% in men (mean BMI 24.7) and 26% in women (mean BMI 24.6) over age 80. There were notable differences in the effects of age on obesity in different racial/ethnic groups. African-American men had the highest prevalence of overweight in the 20–29 age range, but their weight tended to increase relatively less in the older age cohorts when compared to either Caucasians or Hispanics. Hispanic subjects had the highest prevalence of obesity in the 40- to 69-year-old males ( $\approx 50$ –55%). In women a different picture emerged. Caucasian women had the lowest prevalence of obesity in each age group, with a peak ( $\approx 50\%$ ) at 50–59 years. Hispanic women had their highest prevalence of obesity ( $\approx 55\%$ ) at a slightly younger age (40–49 years). African-American women had their peak prevalence of obesity ( $\approx 60\%$ ) at a later age (60–69 years) and had the highest prevalence of obesity overall when compared to the other racial/ethnic groups.

However, these findings may reflect a common problem in interpreting cross-sectional data, a bias due to disproportionately higher death rates in middle-aged obese subjects (5,6), leaving a thinner group of subsequent survivors. A truer understanding of the complex age-related changes in weight or BMI requires longitudinal data. A 15-year follow-up study of seven different

age cohorts of men (21–80 yr at entry) demonstrated a significant difference in the effect of aging on weight or BMI in the different age cohorts (7). The men who were the oldest at entry weighed the least and tended to remain stable or lose a small amount of weight over the period of follow-up, while the younger cohorts were heavier at baseline and continued to gain weight with time. Thus, there was a substantial cohort effect on the relation between aging and body weight. More consistent (and possibly more important) were the changes observed in fat distribution, with all cohorts showing increments in central distribution of fat during the period of follow-up (see below).

The observed changes in weight and BMI with aging are accompanied by profound changes in body composition that can substantially influence the interpretation of data. Studies have consistently demonstrated clinically important losses of fat-free mass (FFM) with age in both men and women. More recent studies have used dual-energy x-ray absorptiometry (DXA) techniques to show that these changes appear to be predominantly accounted for by the loss of muscle mass as represented by reductions in appendicular lean mass (8). This phenomenon has received the appellation “sarcopenia” (9). When defined as an appendicular lean mass (kg/ht in m<sup>2</sup>) of  $> 2$  SD below that for a young reference group, sarcopenia occurs in 24% of older individuals under age 70 and  $> 50\%$  of individuals over age 80 (10).

While the loss of FFM influences many important geriatric care issues, such as strength, endurance and overall functional ability (9–14), here we will consider only how it might affect the determination of “obesity” in older individuals. Because FFM declines by as much as 40% between the ages of 30 and 70 (15–20), at any given body weight or BMI, older persons will be considerably fatter (8,21). Since the content of fat within lean tissues such as muscle is also greater with aging, even the standard measurements of body composition by methods such as computed tomography (CT), magnetic resonance imaging (MRI), and DXA might underestimate actual total body adiposity.

Stature frequently declines (0.5–1.5 cm/decade) with age (15), owing to decrements in the height of the vertebral bodies and shrinkage of intervertebral disk spaces. Therefore, the use of measured present height commonly causes an overestimate of BMI in the elderly (especially in women). This can be corrected by using maximal historical height, but one must be concerned with the usual caveats regarding recall data. A preferred method is the use of knee height as suggested by

Chumlea (22), but, in fact, such corrections for loss of height are seldom used.

Skinfold thickness correlates less well with total adiposity in older individuals (23), making assessment of adiposity by skinfold measurements also difficult to interpret. Furthermore, the change in fat distribution with age makes determination of most peripheral subcutaneous skin fold measures less clinically relevant.

Well-known age-related changes in the composition of FFM can significantly affect the determination of body density and, therefore, body composition using the “gold standard” hydrodensitometry method (24). While the density of fat changes little with aging (0.9 g/mL), variation in hydration state and in bone mineral can distort the actual density of FFM from the value usually assumed in prediction equations (1.10 g/mL). Tissue dehydration would increase the true density of FFM while loss of bone mineral would produce the opposite effect. The loss of total body water with aging would have the more profound effect, and, for any given total body density measure, the established prediction equations would underestimate the amount of adiposity (25). However, studies are not consistent in finding a decline in the hydration state of lean tissue in older subjects (26,27). Whereas one study found no significant change in hydration of lean tissue between young and older women (26), a subsequent study by the same investigators (10) found that total body water declined over a 5-year follow-up period with a trend toward a greater loss in men (−0.04 vs. −0.01 kg/yr). In another study, not correcting for the measured total body water produced a 4% underestimation of percent body fat (%BF) in older women but no significant difference in older men when compared to multicompartmental methods (27). In the latter study, the variation in the measurement of %BF between the two- and four-compartment models was inversely related to the hydration state of the FFM. A recent cross-sectional study found that while total body water declined in both men and women between ages 60 and 80 the decline was significant only in the women (15). The loss of water appeared to be mainly from intracellular fluid. This cross-sectional study found that men lost FFM twice as quickly as women (0.22 vs. 0.10 kg/yr), a rate much greater than that observed in their prospective study (10). Any observed changes in body water with aging may also affect estimates of body composition using total body water or bioelectrical impedance, the latter being a measure that is exquisitely sensitive to hydration state (28).

While there is some disagreement, it appears that significant declines in total body hydration state occur in healthy older persons and may affect estimates of adiposity. The direction of these changes would tend to produce an underestimate of adiposity.

### **B Age-Related Changes in Fat Distribution**

It has been well demonstrated that many of the metabolic abnormalities associated with obesity are strongly and independently related to a central distribution of adiposity (29–34). However, what is less well recognized is that aging is associated with an increasingly more central distribution of adiposity in both men and women (7,35–38). At any given level of adiposity, more fat will be centrally distributed in older individuals. Of interest, a cross-sectional study found no age-related change in fat distribution in men or women between the ages of 60 and 80, suggesting this accumulation may reach its maximum in middle age and early old age (15). Again, the preferential drop out of more obese subjects may bias the interpretation of data from such a cross-sectional study.

Intra-abdominal fat accumulation, known to be independently related to the metabolic concomitants of obesity (39–44), has also been demonstrated to be greater at any given BMI or %BF in older individuals (45–47). While the accumulation of intra-abdominal fat with aging may be progressive in men, it appears to greatly accelerate in women following menopause (62,48).

Although there are racial/ethnic differences in fat distribution (see Chap. 3), relatively little is known about how these are affected by aging. It appears that African-American women have greater central fat distribution than Caucasian women before menopause (50) but that the slope of the increase with age is not different between the two groups. Of interest, NHANES I also noted that central adiposity conferred relatively less risk for cardiovascular disease in black women (51). This finding agrees with earlier reports that central adiposity was not a strong risk factor for the development of non-insulin-dependent diabetes (NIDDM) or atherosclerotic cardiovascular disease in black women (52). Similarly, the Charleston Heart Study determined that central fat distribution did not predict all-cause or coronary heart disease deaths in black women (53). Other studies have found that while Hispanics have a greater central distribution of fat, this was not associated with excess all-cause mortality in subject over age 45 (54). Studies in Japanese-Americans have

demonstrated relatively greater amounts of central and intra-abdominal fat when compared to Caucasians, and a strong relationship exists between intra-abdominal fat and the development of insulin resistance and NIDDM frequently observed in this population (43,44,55).

### **C Menopause and Obesity in Women**

There are relatively few data on changes in adiposity and fat distribution associated with menopause in women. This is an important issue because of the relationships that have been noted between obesity and cardiovascular disease (5), and obesity and certain cancers (56,57) in postmenopausal women. As noted above, body weight reaches its maximum in women very near the time of menopause, and there is an increase in relative adiposity for any given weight or BMI. While some studies find that the increase in weight accompanying menopause is more related to age than menopause itself (58,59), others have noted specific menopause-related increases in BMI, overall adiposity, central adiposity and intra-abdominal adiposity (60–64). A recently published longitudinal study that followed 35 women aged 44–48 for 6 years (65) found that those women who experienced menopause during the period of follow-up lost significantly more FFM (–3 vs. –0.5 kg), and had greater increases in fat mass (FM; 2.5 vs. 1.0 kg), waist-to-hip ratio (WHR; 0.04 vs. 0.01) and insulin (11 vs. –2 pmol/L). The changes were associated with greater reductions in physical activity and resting energy expenditure in the postmenopausal women. In two randomized, placebo-controlled studies in which postmenopausal women were prospectively studied for 2–3 years, hormone replacement therapy prevented the accumulation of abdominal adiposity while having no effect on FFM (63,66).

## **III CAUSES OF OBESITY IN OLDER PERSONS**

### **A Intake Versus Expenditure**

The accumulation of excess calories stored as adipose tissue requires an imbalance in the usually tight relationship between caloric intake and expenditure. While adiposity has a tendency to increase with age, total caloric intake either is unchanged (67) or declines (68) when assessed in longitudinal studies. Furthermore, the increment in adiposity with aging cannot be blamed on increased relative fat intake in the diet (69), since this too

appears to decline with aging (67,68). However, one must always be careful interpreting data on reporting of calorie intake. As compared to doubly labeled water determination of calories intake, underreporting of calorie intake has been found in both male and female older subjects, with greater underreporting in heavier individuals (70). The ability to appropriately detect and respond to a change in body weight also appears to be impaired in older subjects. Two well-controlled feeding trials strongly suggest that in older subjects the regulation of energy intake is impaired in response to either an imposed increase or decrease in weight. After weight loss, older subjects did not appropriately increase their intake, and following weight gain they did not properly reduce their intake when compared to younger controls (71).

It is also likely that the age-related increase in obesity is in some way related to deficits in energy expenditure. This topic has been carefully reviewed (72), and the relationship between resting metabolic rate (RMR) and age appears to be curvilinear if sufficient numbers of older individuals are included. While three-fourths of this decline in RMR can be accounted for by decrements in FFM, one-fourth remains unexplained. Poehlman has suggested that this decline in RMR may be related to inactivity and has demonstrated normalization in older men after endurance training (73). Others have not been able to demonstrate an endurance training-related improvement in RMR in older subjects (74). While the thermic effect of feeding (TEF) may decline with age (75), this may be more related to inactivity than to age itself (72). Furthermore, variability in TEF does not predict subsequent weight gain (76).

## B Inactivity

The component of daily energy expenditure that is most variable among individuals is the thermic effect of exercise (TEE), the energy expended with physical activity. Older individuals are usually less active than their younger counterparts (77,78), and several investigators have proposed that this difference in activity level may account for much of the age-associated gain in adiposity (79). This is supported by 10-year follow-up data from the NHANES-I study, which looked at the relationship between recreational physical activity and subsequent weight gain (80). Both at baseline and at follow-up, physical activity was inversely related to body weight. Low physical activity at follow-up was strongly associated with major weight gain ( $> 13$  kg), and the relative risk of major weight gain, comparing

the low- and high-activity groups, was 3.1 in men and 3.8 in women. This activity component can best be measured by evaluating free-living energy expenditure using the doubly labeled water technique (81). Using this method, reduced physical activity levels are associated with increased %BF (82).

## C Fat Oxidation

Another possible mechanism that could be associated with obesity with aging is abnormal fat oxidation. Indeed, recent studies have demonstrated that fat oxidation is reduced in older individuals at baseline, with exercise, and following a meal (83). It is not clear whether the decrement in fat oxidation is due to the absolute loss of lean mass, a reduced capacity for fat oxidation by aging lean mass, or abnormal hormonal regulation of fat oxidation by estrogen, testosterone, growth hormone, and/or dihydroepiandrosterone (DHEA).

# IV CONSEQUENCES OF OBESITY IN OLDER PERSONS

## A Metabolic

Many of the common obesity-related metabolic abnormalities found in young and middle-aged individuals appear to be related to insulin resistance and hyperinsulinemia, what has come to be called the "insulin resistance" or "metabolic" syndrome (84). While the exact components of this syndrome vary among different populations (85,86), in general it is made up of central obesity (39,87); insulin resistance and hyperinsulinemia (88); abnormal glucose metabolism (89); dyslipidemias (41,90) such as high triglycerides, low high-density lipoprotein (HDL) cholesterol and small, dense, low-density lipoprotein (LDL) particles (91), hypertension (84), and atherosclerosis (92).

These same metabolic disorders are extremely prevalent in older populations. For example, it is well known that glucose tolerance worsens with age, with a 1–2 mg/dL increase in fasting glucose and a 10–20 mg/dL increase in postprandial glucose for each decade after age 30 (93). NIDDM is the fifth most common chronic disease in the elderly, affecting  $> 20\%$  of individuals over age 65, with approximately half of these being undiagnosed (94). Diabetes has profound effects on health care utilization and costs, with up to one-seventh of all health care dollars being spent caring for diabetics (95). While in the past this

high frequency of diabetes and glucose intolerance has been considered to be attributable to aging, more recent studies strongly suggest that most, if not all, of the “age-related” changes in insulin sensitivity and glucose tolerance can be accounted for by changes in body composition, fat distribution, and inactivity (45,96–100).

Similarly, there is an exceedingly high prevalence of hypertension in older individuals (101). It is estimated that between 30% and 50% of all persons over age 65 have hypertension (either systolic-diastolic or isolated systolic), with somewhat lower prevalence rates in studies that require multiple readings to make the diagnosis and higher rates in African-Americans.

Dyslipidemia is commonly noted in obese individuals, especially those with a central or intra-abdominal distribution of fat (41,102). The most commonly described abnormalities include elevations in triglyceride and reductions in HDL cholesterol levels. While similar abnormalities have been detected in older subjects (103,104), these abnormalities occur in both obese and “nonobese” older individuals (105). In two prospective studies, plasma insulin level was found to predict the development of dyslipidemia after either 3.5 or 8 years of follow-up. Apolipoprotein abnormalities have also been described in older subjects, such as increases in Apo B, reductions in Apo AI and the development of dense LDL particles (106). These abnormalities are all similar to those noted with central adiposity (102) and are associated with an elevated risk for atherosclerosis (92).

The relationship between obesity and overall mortality in older individuals has been a point of major controversy for a number of years. Many studies demonstrate that obesity is related to increased mortality in young and middle-aged individuals. The relationship between body weight and mortality was initially noted to be U-shaped, with excess mortality at both extremes of the body weight range. It now seems likely that this curvilinear relationship was due to confounders such as excess cigarette smoking and illness-related weight loss in the lowest weight group. More recent analyses that controlled for these variables have found no increase in mortality in the lowest weight group (5,6).

Andres has suggested that the weight associated with the lowest mortality increases with age (107), while others suggest this is not the case when the data are corrected for smoking and early deaths (108,109). This latter interpretation of the data is expressed in a new review of guidelines for healthy weight (110). Nonetheless, it appears that the relationship between obesity and

mortality changes considerably in the oldest age groups. In a recent evaluation of the very large Cancer Prevention Study I (111), crude death rates (12-year follow-up) did not rise with increasing BMI in subjects over age 75 years who had never smoked and had no evidence of heart disease, stroke, or cancer at baseline. In these subjects, the BMI associated with the lowest risk of all-cause mortality or cardiovascular death was  $\sim 28$ , compared to 20 in the younger age groups. The relative risk (RR) of death from cardiovascular disease was 1.08–1.10 in 30- to 44-year-olds compared to 1.02–1.03 in 65- to 74-year-olds. The interaction between BMI and age was significant for both overall and cardiovascular mortality. When these authors calculated the BMI associated with 20% and 50% excess all-cause and cardiovascular mortality, a sharp rise in the computed BMI was noted after age 65 in both men and women. A decline in the effect of obesity on mortality was also detected by these authors when they calculated other measures of effect such as rate ratio, attributable deaths, excess years of life lost, and the time period by which the rate of death was advanced owing to obesity (112).

There are few data on ethnic differences in the relationship between obesity and mortality in older individuals, but one large prospective study found the lowest mortality in the 60–84th centiles for weight in white men compared to the 40–59th centiles in black men (113). The opposite was true for women, with the lowest mortality in the 40–59th centiles for weight in white women and in the 60–84th centiles for the black women. This study demonstrated a U-shaped curve, with excess mortality at both the lowest and highest centiles for body weight, even when corrected for smoking or when only nonsmokers were included. It was suggested that the added mortality at very low weights in these older subjects might be accounted for by osteoporosis and excess hip fractures.

## B Functional

Functional status is of critical importance in assessing and treating older individuals, and frailty has been closely related to major health outcome measures including mortality in several large prospective studies (114). Therefore, it is reasonable to consider how obesity might affect functional status in older patients. While some studies show that low weight is a risk for frailty (114), obesity has also been related to arthritis (115) and functional decline in older subjects (116).

There are also new data relating both baseline waist circumference and gain in waist circumference over 30

years of follow-up predicted severity of sleep-disordered breathing in older men (117).

## V TREATMENT OF OBESITY IN OLDER PERSONS

### A Effects of Voluntary Weight Fluctuation on Mortality

There is compelling evidence supporting the association of obesity and weight gain with heart disease (118), diabetes (119), and excess all-cause mortality (5). Less clear, however, is the impact associated with losing excess weight.

Several large studies in both middle-aged and older adults find that weight fluctuations, either up or down, are associated with excess cardiovascular and all-cause mortality (120–122), with similar findings in two separate Asian populations (123,124). However, these studies have mostly relied on self-reported weights. In a recent study of 648 Caucasian women aged 65–69, weight change was measured over three assessment periods (baseline, 1 year, and 2 years), and then the subjects were followed for an additional 4 years (125). As with other studies, subjects who experienced weight variability or “cycling” were found to have excess mortality (20% vs. 11 % in weight-stable subjects). Deaths were higher in the low-baseline BMI group (22%) than in the average-weight BMI group (13%). Subjects who lost 4.5% over the measurement period had 25% deaths, and this mortality rate was not greatly affected by the baseline BMI. Weight variability has also been related to the incidence of specific diseases, with higher relative risks found for myocardial infarction, stroke, diabetes, lung cancer, and hip fractures, with greater weight variability in the 33,834 women age 55–69 participating in the Iowa Women’s Health Study (126).

These studies have been rightfully criticized because they often did not distinguish between intentional and unintentional weight loss (127) or failed to take into account important preexisting disease (128). An important study by Williamson et al. (129) has specifically attempted to obviate these problems by evaluating the effects of “intentional” weight loss in >43,000 nonsmoking, *middle-age* (40–64 yr) Caucasian women followed prospectively for 12 years. Early deaths, within the first 3 years, were excluded. The data were stratified by preexisting obesity-related illness, and adjusted for age, baseline BMI, alcohol use, physical activity, and overall health. This study demonstrated that any amount of weight loss in subjects with

obesity-related illness was associated with a 20% decrement in all-cause mortality, due to both a 40–50% fall in cancer deaths and a 30–40% reduction in diabetes-related deaths. The data were much less clear in women without preexisting obesity-related disease who intentionally lost weight.

While it appears that there are potential long-range benefits to weight loss, especially in those in young and middle-age patients with obesity-related disorders, a caveat must be emphasized for the elderly, as weight loss is a common part of the failure-to-thrive syndrome frequently observed in older patients (130). A study by Wallace in a group of outpatient veterans over age 65 demonstrated that involuntary weight loss of  $\geq 4\%$  in 1 year was associated with a 2.5-fold greater risk of dying within the next 2 years of follow-up when compared to non-weight-losers. This was despite a decrement in central distribution of fat in the weight losers. These results were not affected by adjusting for age, BMI, tobacco, and health status. Surprisingly, the relative risk of dying was almost identical in subjects whose weight loss was apparently “voluntary.”

A more recent study evaluated weight loss in 4714 community-dwelling men and women over age 65 as part of the Cardiovascular Health Study (131). Over the first 3 years of examination, 16–19% of subjects met the 5% criteria for losing weight, while 11–16% gained 5% of weight. The hazard ratio for all-cause mortality during a 4-year follow-up period was  $\sim 2.0$  for those who lost  $\geq 5\%$  of body weight during the initial 3 years of observation. Baseline weight or health status did not affect this hazard ratio. The risks for weight loss included older age, multiple drugs, disability, slow gait, weakness, and death of a spouse. Furthermore, the hazard ratio was not affected by the reasons for the weight loss (intentional versus unintentional). The survival curves during the follow-up period were not different for those who were weight stable and those who gained weight.

Another study evaluated 5-year weight change and the 10- and 15-year mortality in 2628 Swedish men and women who were 70 years old at the baseline examination (132). The BMI associated with the lowest 15-year mortality in this older population was 27–29 for men and 25–27 for women. After excluding deaths during the initial 5-year period, the relationship between BMI and mortality was flat in men and U-shaped in women. Weight loss of  $\geq 10\%$  during the first 5-year period was associated with higher mortality at 10 and 15 years even when adjusted for smoking status.

Together, these data strongly suggest that while dietary weight loss in middle-aged patients with obesity-

related illness may positively impact outcomes, weight cycling may produce deleterious effects. In addition, physicians should be very cautious prescribing weight loss in otherwise healthy obese older patients. Some of the discrepancies among studies in the relationship between obesity and mortality may be due to the lack of measurement of body composition. It is likely that loss of fat is associated with improvements in health while the loss of weight alone may be deleterious (133). This concept is especially important in older people where, under some circumstances, substantial loss of lean mass may accompany weight loss.

## **B Dietary Weight Loss Studies in Older Individuals**

There have been few published reports of dietary weight loss interventions specifically in older subjects. While the study by Williamson (129) supports a benefit to intentional weight loss in middle-aged subjects, it is possible that exacerbation of the usual age-related loss of lean mass could be worsened by a weight loss diet. However, in a recently published study of otherwise healthy obese older men (mean of 60 yr) who underwent a 10-month calorie restriction, only 23% of the 9.3 kg of weight that was lost, was lost as FFM (134). This is similar to studies in our laboratory (135) in which 16 healthy obese older men (mean 66 yr) lost 10 kg on a 1200-kcal dietary restriction (Phase I American Heart Association Diet.). In this study only 20% of weight loss was as FFM. The percentages of weight lost as FFM in these relatively healthy older individuals is similar to that found in younger subjects. In both of the above studies, weight loss produced a small but significant improvement in the waist-to-hip ratio. However, in our study, despite a decrement WHR and in intra-abdominal adiposity measured by CT, there was no preferential loss of intra-abdominal fat compared to fat from more peripheral depots. It must be emphasized that subjects in both of these studies were highly screened to be healthy despite their moderate obesity and that these findings may not be generalizable to the population of older individuals who suffer from various clinical disease states.

A recent randomized controlled study compared the effect of a 9-month hypocaloric (AHA Phase I) diet on insulin action and glucose tolerance in middle-aged and older subjects (mean age  $60 \pm 8$  yr) with either normal or impaired glucose tolerance (136). After an average weight loss of 9 kg, there was a significant fall in the glucose area ( $-22\%$ ) following an oral glucose challenge. This reduction in glucose area was related to the

decrease in waist circumference. In fact, almost half of the subjects who initially had impaired glucose tolerance normalized following weight loss. In a subgroup of eight subjects, the weight loss was found to induce a fall in both the first and second phase insulin response to a hyperglycemic clamp and an improvement in insulin action. Early (unpublished) analysis of data from the Diabetic Prevention Program study appears to also suggest that lifestyle-related (diet and exercise) loss of weight of  $\sim 5\%$  is associated with less progression to diabetes in a high-risk (mostly middle-aged) population with glucose intolerance at baseline.

In a study by Dengel et al., weight loss was associated with improvement in the lipoprotein profile, reductions in the LDL/HDL cholesterol ratio and triglyceride concentration and increments in the HDL<sub>2</sub> cholesterol (137). We have noted similar improvements in HDL and triglyceride concentrations but no change in the concentration of total or LDL cholesterol (135). However, there was a 22% decline in hepatic lipase consistent with less dense and less atherogenic LDL particles. Six of the seven subjects who initially had the more atherogenic, small, dense LDL phenotype pattern B reverted to a more favorable LDL pattern A following weight loss. No change was noted in the subjects with pattern A at baseline. Thus, while the concentration of LDL failed to change with weight loss, the size and composition of the LDL particles became more favorable.

There is considerable interest in the potential benefits of chronic calorie restriction to extend life and reduce morbidity (138). This hypothesis that has been proven in rodents is now being tested in nonhuman primates and humans.

## **C Exercise Training in Older Individuals**

Many important benefits of exercise training for older persons have now been documented (139). Exercise alone is not associated with large reductions in adipose tissue mass in intervention studies (140), and it has been estimated that a 6-month period of exercise training alone would reduce fat mass by only 2.6 kg and %BF by only 3%. However, in large population studies, greater physical activity is associated with lower body weight, and higher fitness levels are inversely related to all-cause mortality in subjects at any BMI level (141). Interestingly, the most impressive effect on mortality occurs in subjects with BMIs  $\geq 30$ . There is also good evidence that physical activity is associated with lower blood pressure (142) as well as diabetes (143), dyslipidemia and atherosclerosis (144), all disorders that are common

in obesity. In addition, exercise has been demonstrated to be essential in the successful maintenance of weight loss after dietary restriction (145,146).

There are considerably fewer data on the metabolic effects of an exercise intervention in older subjects, but this has become an area of great interest in recent years. As in other groups, endurance exercise training in older subjects is associated with only modest losses in weight and fat (147,148), consistent with the estimates by Wilmore (140). However, recent studies suggest that the fat lost comes preferentially from intra-abdominal depots (145,146). This may appear to be different from the more general loss of adipose mass with caloric restriction (135). Associated with this preferential loss of central adipose tissue following exercise are improvements in lipid, glucose, and insulin metabolism (97,149,150). For example, after 6 months of intensive endurance exercise subjects lost only 2.5 kg of weight and a similar amount of fat. This was associated with a 20% loss of intra-abdominal adipose tissue area on CT. With these changes, insulin sensitivity improved by >33% despite no improvement in oral glucose metabolism (97). There was a 23% reduction in triglyceride and an almost 70% increment in HDL<sub>2</sub> cholesterol (149).

Recent evidence suggests that most if not all of the metabolic effects of exercise require weight loss and that metabolic improvements are greatly lessened if body weight is purposely maintained (151). Since energy intake has been noted to be increased in free-living subjects who are training (73,147), weight loss is felt to be due to enhanced energy expenditure. While both the thermic effect of exercise and RMR are increased with exercise training (73), it is of interest that 24-hr energy expenditure does not appear to increase in older men with endurance training (152). This suggests that they were more sedentary at other times of the day when they were not exercising. Therefore, the true etiology of the fat loss is unclear but may be related to enhancement of sympathetic nervous system activity (153) or lipid oxidation (154) associated with exercise training.

There are considerably fewer data on the effects of resistance training on adiposity and metabolism in older subjects. While it is now well known that the elderly can improve both their FFM and strength with resistance training (9,155), only recently has it been demonstrated that there are also reductions in both fat mass and intra-abdominal fat mass (156). Newer studies suggest that resistance training may also have positive effects, similar to endurance training on insulin action (157,158), but little or no improvement in lipoprotein profile seems to occur (159).

Numerous studies strongly indicate that both endurance and resistance exercise are beneficial in the elderly. While the amount of weight loss associated with training is small, it may preferentially come from the most critical intra-abdominal depots and thus be associated with substantial metabolic improvement. In addition, exercise is associated with the maintenance or an increment in lean body mass and may be required to maintain dietary weight loss long term.

#### **D Drug Treatment for Obesity in the Elderly**

The use of appetite suppressants to treat obesity in older patients will not be discussed here, and the reader is referred to Chapters 55–59. However, because of the continued interest in the use of trophic factor supplementation in the elderly, it is reasonable to discuss briefly how these factors may affect adiposity and fat distribution.

Ample evidence confirms an age-related decrement in the growth hormone (GH)/insulinlike growth factor-I (IGF-I) axis. These changes have been implicated in the decline in FFM with aging, and may also account for the increase in central adiposity found in the elderly (160). Indeed, studies in both growth hormone-deficient adults replaced with GH and healthy older subjects supplemented with GH demonstrate reductions in both total and central adiposity. It should be noted, however, that supplementation of older subjects with GH is not without significant side effects, and long-term positive effects on lean mass, bone mass, fat mass, and, most importantly, strength and function, remain unproved (161).

A newly published study found that GH and GH plus testosterone supplementation in healthy older men caused within-group reductions in total, visceral, and subcutaneous abdominal fat. Only the changes in subcutaneous fat and total abdominal fat were significantly different from placebo. There were no similar declines in women treated with GH with or without estrogen (162).

Testosterone concentrations also decline with aging in men. There is no consensus about the role that this may play in aging-related obesity or the effects of testosterone supplementation alone on adiposity in older men (163). While one study found no change in weight, body fat, or WHR, another found no change in total fat but a 10% decline in intra-abdominal adiposity after 9 months of testosterone supplementation. As noted above, there are also some data that suggest that estrogen replacement in women can prevent the postmenopausal accumulation of central fat.

Dehydroepiandrosterone sulfate (DHEAS) is the most abundant steroid hormone in humans. Peak

levels are typically reached in the third decade of life and decline steadily thereafter (164). Because it can be converted to testosterone and aromatized to estradiol, DHEAS level may be a determinant of sex hormone-mediated changes in fat accumulation and distribution that occur with aging. There have been few studies of DHEA replacement in people with low DHEAS levels, but there is some evidence for a fat-reducing effect in a controlled trial of DHEA replacement (50 mg/d) for 6 months in 18 women and men, aged 64–82 yr (165). In this study, fat mass was reduced by –1.4 kg in response to DHEA supplementation, and assessment by DXA indicated that the reduction occurred entirely within central body regions in both women and men. Larger clinical trials of trophic factor supplementation in older subjects should be completed in the next 2–3 years.

## I INTRODUCTION

Everyone working in the obesity area wants to know the cost of obesity. They want a magic number, and feel it must be a high dollar cost, which can be used in advocacy with governments and health authorities. The reason for this need is to “raise the profile” of obesity on the health agenda. This, it is hoped, will enable obesity to be treated more appropriately (in proportion to the true public health impact), and for increased resource allocation to obesity prevention. The expected outcome of these invigorated treatment and prevention approaches will reduce future health expenditures on obesity and its related diseases. However, in most countries or health areas, the amount of money available for health care is finite and limited. Given constraints of health care funding, allocation of additional resources to obesity prevention and treatment requires that effective programs must be available. A trade-off therefore exists between prevention of weight gain and obesity and the future health consequences of weight gain. We emphasize both the use and the limitations of calculating or knowing the costs of obesity. While a

costing can be used for advocacy, a change in the costs of obesity may not be the most appropriate or desirable end point of such advocacy. Rather it may be better to aim for changes in such things as disability-adjusted life years (DALYs), quality-of-life measures, or changes in incidence or prevalence of obesity-associated diseases.

This chapter will therefore concentrate on a number of aspects of the economic costs of obesity. Firstly a broad outline of the types of costs will be considered and then a brief review of the reported costs undertaken. Subsequent sections will highlight difficulties in the present reported methods and then the major section will suggest a practical, yet thorough, way to establish the economic costs. It needs to be emphasised at this stage that because of the nature of this Handbook of Obesity, this chapter cannot be a definitive text of all health economics theory and applications, nor can it give exhaustive discussion of all theories. It is our aim to give a summary of reported costs and a practical approach to the methods and requirements to develop one's own systematic approach to determining the costs of obesity.

## II TYPES OF COSTS

When one is considering the economic cost of obesity in direct monetary terms, there are three types of Costs to be considered. These are direct, indirect, and intangible costs.

### A Direct Costs

Direct costs are the health care resources applied to obesity and its attributable conditions. In general these are prevalence studies, with knowledge of the cost within a defined time period. Such studies are often possible to perform given the usual data collection of health departments and authorities. Others will argue that incidence-based studies, which depend on calculating the cost of obesity and diseases occurring within a defined time are preferable. Such studies are more difficult to perform, the data may not be available without a special collection study, and the information they give in terms of monetary cost is no more robust than that from prevalence studies. Most cost-of-obesity studies in the literature are prevalence studies.

### B Indirect Costs

Indirect costs are the reduction in the level of economic activity due to the illness and premature death attributable to obesity. The economic activity is generally considered to be that captured by the gross domestic product (GDP) statistic. Examples are the wages and productivity lost due to sickness and absenteeism produced by obesity or the loss of productivity due to the mechanical difficulties caused by obesity which reduce the efficiency of performing a task. Other factors contributing to the indirect costs of obesity are the disability pensions which are paid because of obesity or its associated conditions and the loss of productivity produced by the premature deaths due to obesity. There are several ways to calculate this cost and it is more difficult to do and more varied in outcome than the health care (or direct) costs.

### C Intangible (Personal) Costs

These are the social and personal costs or losses associated with obesity. While some of these may be relatively easy to estimate, for example, the amount spent on commercial weight loss programs, other aspects are more difficult, variable, and subject to the whim of the individual health economist. An example of the latter would be an estimation of the monetary value of the

reduced quality of life experienced because of obesity. This will require both quality-of-life measures in individuals and populations and an estimate of what is the usual cost of a life-year. In addition, the degree of obesity will have an effect. While there are suppositions and estimations with the other type of economic costs, such factors are probably greater and more variable for intangible costs.

There are also other ways of looking at the economic costs of obesity. These include years lost to disability (YLDs) or disability-adjusted life years (DALYs), or quality-adjusted life years. An example of the use of this type of "cost" may be found in Mathers et al. (1), and this can be contrasted with the "monetary cost" approach by the same authors (2). These different approaches will be discussed later in this chapter. Initially the concentration will be on the economic or monetary costs of obesity. These too must be contrasted with the costs of disease treatment itself. For example Brown et al. (3) have described the treatment costs of type 2 diabetes in this way contrasting diet treatment alone with drug treatment and the treatment of complications. This is a further approach and will be discussed later.

## III REPORTED COSTS OF OBESITY

There are a large number of obesity cost or burden of illness studies. Table 1 gives a summary of those recently published from a variety of different countries and continents. The range of direct costs reported is between US\$77 million for New Zealand (14), a country in which the prevalence of obesity is now 19%, and US\$70 billion in the United States (15), where the prevalence of obesity is some 25% of the adult population. Recently it has been suggested that the direct cost of obesity in Australia is now US\$630 million (S. Crowley, personal communication). The differences in costs reported may reflect different obesity prevalence in the various countries or different absolute health costs in the treatment of obesity and its related diseases. More likely, however, are differences in the methodology of performing the study. Some of these differences (e.g., the body mass index [BMI] cut point used, the diseases included in the costs) will be discussed in the following section.

As a general comment, it appears that the direct cost of obesity in many countries is between 1% and 5% of their health care budget (16). It appears that this cost may be greater in the United States [most recently reported to be 7% of the health care expenditure (15)]. We note that these costs are likely conservative as the

**Table 1** Recently Reported Costs of Obesity from Several Countries<sup>a</sup>

| Country         | Year (Ref.)  | Type of cost      | Amount                           | % Health care expenditure |
|-----------------|--------------|-------------------|----------------------------------|---------------------------|
| United States   | 1995 (4)     | Direct            | US\$ 70 billion                  | 7                         |
|                 | 1995 (5)     | Direct            | US\$51.6 billion                 | 5.7                       |
|                 |              | Indirect          | US\$47.6 billion                 |                           |
|                 | 1990 (6)     | Direct            | US\$45.8 billion                 | 6.8                       |
|                 |              | Indirect          | US\$23 billion                   |                           |
|                 | 1993 (7)     | Direct            |                                  | 6                         |
| Canada          | 1997 (8)     | Direct            | C\$829.4 million– C\$3.4 billion |                           |
| The Netherlands | 1981–89 (9)  | Direct            | DG1 billion                      | 2.4                       |
| France          | 1992 (10)    | Direct            | FF5.8 billion                    | 4                         |
|                 |              | Indirect          | FF0.58 billion                   |                           |
|                 | 1992 (11)    | Direct            | FF4.2–8.7 billion                | 2                         |
| United Kingdom  | 1990–91 (12) | Direct & Indirect | GBP130 million                   | 0.7–1.5                   |
| Australia       | 1989–90 (13) | Direct            | AU\$464 million                  |                           |
|                 |              | Indirect          | AU\$272 million                  |                           |
| New Zealand     | 1991 (14)    | Direct            | NZ\$135 million                  | > 2                       |

<sup>a</sup> These studies used a variety of BMI cut points for obesity and methods for obtaining costs. These are all prevalence studies.

range of conditions included in these estimates has been somewhat limited. In Germany it was found that obesity was associated with more visits to medical care, more prescriptions, and therefore greater health care costs, but obesity was “underreported” or underutilized as a diagnosis in medical records and so the costs of obesity were underestimated (17).

Fewer studies report the indirect costs of obesity, and there is greater variation in these reported costs. Again this reflects both the factors included in indirect costs and the GDP of the country. It appears that indirect costs are generally less than the direct health care costs and vary between US\$140 million for Australia in 1989–90 (13) and US\$47.6 billion for the United States in 1995 (5). While acknowledging that good economic analysis had yet to be performed, Seidell reports that there is good data linking obesity with increased sick leave and disability pensions in Finland, Sweden, and the Netherlands (16). In studies in U.S. organizations, obesity has been shown to be directly linked to absenteeism and therefore increased costs (18,19). Obesity was associated with 1.74 times more “high” absenteeism and 1.61 times “moderate” absenteeism. Interestingly, Burton reported that the BMI range that was the nadir of absenteeism was BMI 25–27 (18). Jeffrey (20) has looked at work site intervention programs and their effect on absenteeism. Over 2 years, smoking cessation programs reduced absenteeism, but weight control programs did not.

There are obviously many problems in calculating the indirect costs of obesity and proper standardized

analyses need to be performed and reported so that comparisons can be made. Difficulties in calculating this cost include getting the average wage lost, the time of absenteeism, the productivity lost, and the number of instances.

A number of incidence studies have been performed. Simply put, these studies take a cohort and follow them for a number of years and document the obesity-related costs of that time period. As the cohort is presumed to be representative of the country or area the costs can be extrapolated. As one example, Thompson and co-workers (21) estimated the lifetime costs of being at various BMI levels. In men at a BMI of 22.5 the lifetime cost of obesity was estimated to be US\$ 19,300; at a BMI of 37.5, the costs were US\$35,200. In women the costs varied between US\$18,600 and \$34,700 for the same range of BMIs. Clearly there is an increase in cost as an individual or group of individuals has or develops a greater BMI. In this study the costs over a period were documented and then extrapolated to obtained lifetime costs (future costs were discounted at an annual rate of 3%). In another incidence study, using a slightly different approach, Allison (22) calculated, using the data from Wolf and Colditz (5), the direct health care costs of obesity over the age range 20–85 with and without accounting for obesity-related deaths. They found the cost of obesity would be 0.89–4.32% of the U.S. health care budget. It is interesting to note that in the U.S. Navy, the cost of hospitalizations for obesity-related diseases was over US\$5 million annually (23).

#### IV PROBLEMS WITH STUDY COMPARISON

There are difficulties and inconsistencies in the reported studies, which make comparisons of the direct costs of obesity in different countries difficult. Some of these problems are:

1. The use of different BMI cut points for overweight and obesity
2. Different obesity-associated diseases used in the analysis
3. Lack of reliable data sets which enable relative risks for obesity related diseases, in the specific community, to be calculated
4. Which cost centers are available (or used) for cost analysis
5. Great differences in the cost of the health care system in different countries (in the United States treatment costs far more than in other countries)

There is even more variation in the factors or items used for the calculation of indirect and intangible costs, and a far greater variation in the health economics methodology. While it may be possible to use a standard approach and standard items for the calculation of direct costs which will allow better comparison (and one such approach is given below in this chapter), it is far less likely that a standard approach to indirect or intangible costs will be developed in the near future.

In the studies described in Table 1 there is variation in the BMI cut points used. For example, in the study by Seidell from the Netherlands (16), the costs were calculated for both overweight and obesity, i.e., for a BMI > 25. It is interesting to note that this study estimated that three-quarters of the costs incurred were for the BMI range 25–30. One percent of health care costs was due to obesity (BMI > 30) itself. In other studies where a BMI > 30 was used, it was found that up to 7% of health care expenditure (15) could be attributed to the direct costs of obesity. In the recent Canadian study, obesity was defined as a BMI > 27 (8). In the incidence study of Thompson (21), several different BMI values were utilized as representing the midpoint of the ranges recommended by the WHO (BMIs of 22.5, 27.5, 32.5, and 37.5 were used). It is difficult to compare costs unless a standard definition of obesity is utilized. It is to be hoped that with the recent publication of the WHO Technical Report on obesity (24), the standard cut points for overweight (called “preobese” in the WHO report) and obesity suggested therein will be utilized.

Different studies use different obesity related diseases. Examples of the diseases included in some of the studies are given in Table 2. Of course costs will vary with the number of diseases included as obesity-associated and studies, which have chosen, for example, not to include musculoskeletal diseases will have lower overall health costs. It is interesting to note that none of the recent studies have included costs due to non-alcoholic steatohepatitis (NASH), which it is estimated

**Table 2** Diseases Used for Calculation of Costs of Obesity in Various Studies

| Disease                                     | United States<br>(25) | Canada<br>(8) | France<br>(10) | United Kingdom<br>(12) | New Zealand<br>(14) | Australia<br>(13) |
|---|-----------------------|---------------|----------------|------------------------|---------------------|-------------------|
| Type 2 diabetes mellitus                    | X                     | X             | X              | X                      | X                   | X                 |
| Coronary heart disease                      | X                     |               | X              |                        | X                   |                   |
| Hypertension                                | X                     | X             | X              |                        | X                   | X                 |
| Dyslipidemia                                |                       | X             | X              | X                      |                     |                   |
| Vascular disease                            |                       |               | X              |                        |                     | X                 |
| Stroke                                      |                       | X             | X              | X                      |                     |                   |
| Gallbladder disease                         | X                     | X             | X              |                        | X                   | X                 |
| NASH  |                       |               |                |                        |                     |                   |
| Cancer                                      |                       |               |                |                        |                     |                   |
| Colon                                       | X                     | X             | X              |                        | X                   | X                 |
| Breast (postmenopausal)                     | X                     | X             | X              |                        | X                   | X                 |

may be the cause of 10% of the cirrhosis in some societies. The reasons for excluding diseases may be practical (no data available, or it is difficult to calculate a local relative risk) or because the disease is not considered important or costly in a specific locality. Still, unless a similar list of obesity-associated disorders is utilized, it will continue to be difficult to compare studies directly. As research continues and the impact of obesity on an increasing range of conditions becomes clearly documented, the evolution of this list of diseases will continue to create problems in looking at the costs of obesity either over time or even over publications from different years. Recent data from the follow-up of the Cancer Prevention Survey II at the American Cancer Society indicate that at least 10% of cancer mortality among men and 15% among women can be attributed to obesity (BMI 30 or greater) (E. Calle, personal communication December 2000). This is a far higher proportion of cancer than previously allocated to obesity in cost estimates.

One of the problems with doing any cost-of-illness study is the calculation of the relative risk of any particular disease in a community. To obtain this there needs to have been a large population-based study with both disease presence and BMI recorded. Even better would be the availability in a community of a number of such data collections over a period of time. This would allow the incidence of disease and relationship to obesity to be determined, which would allow the relative risk of any particular disease to obesity to be calculated. This relative risk is important, because it allows the population attributable fraction (PAF) to be calculated. This latter factor is used in any determination of direct

costs. While the United States has many of these data available (admittedly mainly from studies with Caucasian populations), other countries and communities do not have these data readily available. There is therefore a tendency in studies of the costs of obesity to use relative risks obtained in communities other than the one being studied. This does lead to inaccuracy. The costs obtained can be swayed by the use of a conservative relative risk (RR), or of a higher one. For example, the RR of type 2 diabetes mellitus that has been used in studies ranges between 2.9 and 27.6 (see Table 3). The choice of a particular RR will obviously influence the population attributable fraction and hence the final cost calculated.

The risk of any disease caused by obesity may vary according to the composition of the population, such as the ethnic makeup. It appears that the risk of metabolic disease such as diabetes, hypertension, and dyslipidemia is particularly influenced by ethnic origin. This may be due to a greater propensity for abdominal fat distribution in a given group, or to a specific difference in the relationship between obesity and the particular disease in a given population. For example, it appears that the Chinese population has a greater risk of diabetes, non-alcoholic steatohepatitis (NASH), and dyslipidemia at BMI in the preobese range (BMI 25–29.9) than does the Caucasian population (26). Similarly, the Japanese population has a far greater risk for hypertension. At a BMI of 24.9 (in the healthy weight range) the risk for diabetes is 3.0 and the nadir of risk appears to be at a BMI of 22.6 (27). Until relative risks of obesity related diseases are available for more communities, ethnic groups, and countries, the standard Caucasian RRs will

**Table 3** Relative Risk Values for the Obese Population Used in Recent Studies (see Tables 1, 2)

| Disease                        | U.S. | Canada | France | New Zealand | Australia |
|--------------------------------|------|--------|--------|-------------|-----------|

Ca, cancer; PM, postmenopausal.

continue to be used, probably with an underestimation of the true cost of obesity.

Another obvious problem is what cost centers to include in direct costs. There are a number of obvious possibilities such as visits to physicians and dietitians, hospital and laboratory costs, and drug costs. A list of potential inclusions is given in Table 4. Again, reported costs of obesity will vary depending on which cost centers are included and whether appropriate costings are available in the specific community or country.

There is one final thing that needs to be considered in any comparison of the costs of obesity. The cost of health care varies from country to country. That is, the cost of identical drugs, numbers of physician visits, days in hospital, and so on, will vary. The populations of countries also vary. The absolute cost of obesity will therefore be different in different countries. This is well shown by comparing the United States with New Zealand (Table 1). There is a difference in expenditure of \$45 billion! One way of reducing this difference is to consider the direct cost of obesity as a percentage of health care expenditure, but even this will not totally eliminate discrepancies and differences. Unless there is identical methodology, the use of appropriate relative risks and the cost is expressed per head of population, it will continue to be difficult to compare the cost of obesity in one country with the cost in another.

DALYs are another possible way of looking at potential "costs" of obesity. They can be calculated as the number of years lost due to the premature mortality caused by obesity plus the number of years of healthy life lost due to the diseases associated with obesity. The years of healthy life lost requires the estimation of the incidence of the obesity related health conditions in a specified time period. The methodology has been

described by Murray and Lopez (28). In a recent Australian analysis, obesity itself accounted for 4.3 DALYs, and when this is added to the effect of associated risk factors, physical inactivity (~6.8 DALYs), and lack of fruit and vegetables (~2.7 DALYs), the obesity associated cluster becomes a disease risk (and cost) to rival cigarette smoking (12.1 DALYs in men and 6.8 in women) (29).

## V REQUIREMENTS FOR COST OF OBESITY STUDIES

From the above discussion it can be seen that there are a number of prerequisites before a meaningful cost of obesity study can be performed. There needs to be a good study of the prevalence of obesity (defined using the WHO's suggested BMI cut points). In addition, a standard group of obesity-associated disorders should be included and it is optimal if there are known local RRs of these disorders from previous studies. Such estimates of RR will account for details of ethnic variation that may otherwise not be fully detailed in an analysis. If there are no local RRs, then it would be appropriate to use published values from other countries, trying as best as possible to match ethnic groupings and perhaps using a conservative risk factor as well as a high value. This approach assumes that the physiological and pathologic consequences of obesity are consistent across communities, which is not unreasonable. There also needs to be a standard approach to cost centers used for direct costs. In this way, it will become easier to compare costs across countries and perhaps a little easier to perform the studies themselves if the type of data utilized is standardized and collected.

To estimate the proportion of disease that could be prevented by eliminating obesity, we calculate the population-attributable risk percent (PAR%) or the population attributable fraction. This is the maximum proportion of disease attributable to the specific exposure (such as obesity). PAR% is based on the incidence of disease in the exposed (i.e., obese group) as compared with the nonexposed, taking relative risks from analyses that control for confounders (e.g., age, smoking, dietary intake, etc.). PAR% is calculated using

$$P(RR - 1)/1 + P(rr - 1)$$

where P is the prevalence of exposure in the population and RR the relative risk for disease.

A key issue in estimates of the proportion of disease due to obesity is the reference group. Is the disease

**Table 4** Cost Centers Used in Determination of Direct Costs

|   |
|---|
| Personal health care                            |
| Hospital care                                   |
| Inpatient and outpatient                        |
| Public and private                              |
| Medical services                                |
| GP/primary care consultations                   |
| Physicians' consultations                       |
| Dietitians' consultations                       |
| Other allied health professionals' consultation |
| Drugs   |
| Laboratory services                             |
| Other professional services                     |
| Nursing home care                               |

burden estimated compared to those with a BMI < 25, who are considered average weight, or is a BMI such as 22 used as the reference for estimation. The choice of reference group has a substantial impact on the magnitude of the relative risk, and hence the estimate of the proportion of disease due to obesity. As one compares across studies, the distribution of BMI within the normal range will thus have influence on the observed RR. For example, as more of the population approaches overweight, the comparison of obese versus normal weight is not as extreme a comparison as when most of the population is in the lean end of normal weight. Further, for many obesity-related conditions, even within the normal weight range there is evidence of increased risk with increasing BMI in the normal range. [See figures in Willett et al. (30).] For example, in the prospective Nurses' Health Study, 10-year risk of being diagnosed with diabetes for obese women (30–34.9 kg/m<sup>2</sup>) is 10 (8.4–11.8) times that of women in the average BMI range (<25). However, when BMI of 18.5–21.9 is used as the comparison, the relative risk among obese women is 17.8 (13.4–23.7). In sum, using average weight (BMI < 25) as the reference for estimating the burden of obesity will underestimate the true proportion of disease that is attributable to excess adiposity.

Costs of services must also be estimated. As noted earlier in this chapter these include direct, indirect, and intangible costs. For the direct costs of health services it is important to distinguish true resource costs from typical charges. In countries with systems of health care that use cost accounting and document resource allocation, estimates for the resources used to treat obesity and its consequences are more readily available than in health systems that use mixed models of care including fee for service.

Indirect costs represent the values of lost rather than diverted resources as a result of temporary illness, permanent disability, or premature death. Thus they represent the value of productivity that is lost forever. To estimate these costs one requires the earnings of individuals, the level of labor force participation, and the level of premature mortality according to level of BMI or obesity. These labor force data are typically generated by government agencies.

For both direct and indirect costs, comparisons across nations will again be confounded by the value of resources allocated to health care and the relative earnings of individuals and labor force participation. However, despite these limitations, the percentage of the health expenditures consumed by obesity-related conditions still represents a more intuitive measure than the actual costs of obesity in a given country.

The use of the percentage of health expenditures helps control for the population size.

## VI CONCLUSION

The obesity epidemic is continuing to increase in magnitude globally. Estimates of the costs of obesity provide one measure that integrates the public health burden of this preventable condition and its health consequences. Two factors drive the economic burden of obesity—the prevalence of obesity, and the range of conditions that arise as a consequence of obesity. Uniform classification of obesity will lead to more consistent estimation of the costs of obesity. The prevalence of obesity is, however, expected to rise in many countries given the recent global trends. While published estimates may considerably underestimate the true burden of obesity, the substantial proportion of health expenditures consumed by conditions that arise as a consequence of obesity indicates that perhaps greater priority should be placed on prevention of excess weight gain and the development of obesity. Future studies of the costs of obesity should strive to adhere to the methodologic points summarized in this chapter. However, as new conditions become clearly linked to obesity as our understanding of the health consequences of obesity continue to broaden, the costs of disease will likely also increase purely as a consequence of these new insights, regardless of the proportion of the population who are obese.

## I INTRODUCTION

There are about 250 million adults who are obese and at least 500 million who are overweight in the world at the moment (1). Given these numbers, it is not surprising that the genetics of human obesity is receiving increasing attention. The interest in the causes of the present epidemic of obesity in the Western world and the promise of finding new potentially prophylactic and therapeutic means are largely responsible for this new interest. Excess weight has also become the most important public health problem in the United States and Canada, and this has contributed enormously to the present interest for the molecular and genetic causes of the problem. Several lines of research are currently being explored in the effort to identify the genes involved in causing obesity, rendering someone susceptible to obesity, or determining the metabolic response to an obese state.

This chapter will cover the following major topics: (1) the obesity phenotypes; (2) the findings from genetic epidemiology studies; (3) specific genes and association or linkage with obesity; (4) genotype-environment inter-

action effects; and (5) a brief discussion on useful strategies to undertake the genetic dissection of human obesity. The evidence for a role of genetic factors in energy and macronutrient intake as well as in the various energy expenditure components (resting metabolic rate, thermic response to food, nutrient partitioning, and energy expenditure associated with physical activity) will not be reviewed in any detail here. Two other chapters are dealing with topics of relevance for the understanding of the role played by genetic differences in obesity. One is Chapter 11 by York that reviews the rodent models, including the evidence from transgenics and knockouts. The other is Chapter 10 by Chua et al., which covers in detail the current understanding of the biology of single gene defects leading to obesity in rodents and humans.

## II THE PHENOTYPES

Interest in the genetics of human obesity has increased considerably over the past decade partly because of the realization that some forms of obesity were associated with higher risks than others for

various morbid conditions and mortality rate. Obesity can no longer be seen as a homogeneous phenotype.

Obesity is characterized by excess body mass or body fat without any particular reference to the concentration of fat in a given area of the body. Many obese individuals are characterized by an excess amount of subcutaneous fat on the trunk, particularly in the abdominal area, the so-called android obesity, or male type of fat deposition. Another type is characterized by an excessive amount of fat in the abdominal visceral area and has been labeled abdominal visceral obesity. The last is known as gluteofemoral obesity and is observed primarily in women (gynoid obesity). Thus, excess fat can be stored primarily in the truncal-abdominal area or in the gluteal and femoral area. This implies that a given body fat content, say, 30% or 30 kg, may exhibit different anatomical distribution characteristics.

Strictly speaking, one should therefore talk about the obesities rather than obesity. But the situation is even more complex as the phenotypes are not of the simple Mendelian kind. Segregation of the genes is not readily perceived, and whatever the role of the genotype in the etiology, it is generally attenuated or exacerbated by nongenetic factors. In other words, variation in human body fat is caused by a complex network of genetic, nutritional, metabolic, energy expenditure, psychological, and social variables, all playing a role in the modulation of energy balance and nutrient partitioning. Figure 1 depicts the key determinants and suggests how genetic differences can lead to obesity over time.

It is important to recognize that these phenotypes are not fully independent of one another, as shown by the data of Figure 2. The level of covariation among the

various body fat phenotypes ranges from  $\sim 30\%$  to  $\sim 50\%$  and perhaps more in some circumstances. One implication of the above is that studies designed to investigate the causes of the individual differences in the various body fat phenotypes, including genetic causes, should control for these levels of covariation.

In clinical settings, the body mass index (BMI), measured in  $\text{kg}/\text{m}^2$ , is commonly used to assess the normality of body weight in patients. This is perfectly reasonable as most of the evidence from large-scale prospective studies that have associated obesity with morbidities and premature death is based on the BMI. The correlation between the BMI and total body fat or percent body fat is high in large and heterogeneous samples. The predictive value of the BMI is, however, much less impressive in a given individual, especially when the BMI is  $< 30 \text{ kg}/\text{m}^2$  or so. Thus, the BMI is an indicator of heaviness and only indirectly of body fat (2,3). Any estimate of the genetic effect on BMI should not necessarily be considered valid for adiposity, as it is influenced in unknown proportions by the contribution of the genotype to fat mass, muscle mass, skeletal mass, and other components as well. Nevertheless, the BMI is worth considering because of its clinical validity, simplicity to measure, and widespread use.

The data summarized in Table 1 indicate why the BMI is only a partially acceptable surrogate measure of body fat content. The variance explained by BMI in percent body fat derived from underwater weighing in large samples of adult men and women, 35–54 years of age, attains only  $\sim 40\%$ . At the extremes of the body fat content distribution, BMI is more closely associated with percent body fat; that is, the variance explained may reach 60% and more. This is not

**Figure 1** Diagram of the determinants of positive energy balance and fat deposition with indication about the sites of action of a genetic predisposition.

**Figure 2** Common variance between three body fat phenotypes. Percent fat estimated from underwater weighing; truncal-abdominal fat assessed from skinfolds or CT scans; abdominal visceral fat estimated by CT scan at the L4/L5 vertebrae. (From Ref. 219.)

entirely satisfactory as genetic studies deal with individual differences in the phenotype of interest and, for them to be successful, the phenotype of a complex multifactorial trait must be measured with a reasonable degree of precision.

That percent body fat remains quite heterogeneous at any level of BMI is further illustrated in Table 2, based on data from middle-aged adult males. For instance, in 27 men with a BMI of 28–30, the mean percent body fat was 28, but the range varied from 15% to 41%. We have observed the same phenomenon and with as much heterogeneity in women at all levels of BMI.

The same point can be made for regional fat distribution phenotypes. Thus the correlation between the waist-to-hip circumferences ratio (WHR) and abdominal visceral fat is positive and generally significant in various populations, but the association is charac-

terized by a wide scatter of scores. For instance, in a study of 51 adult obese women, the correlation between WHR and CT-assessed abdominal visceral fat reached 0.55 (4). However, for a WHR of  $\sim 0.80$ , the visceral fat area at the L4-L5 level ranged from a low of  $\sim 50 \text{ cm}^2$  to a high of  $\sim 200 \text{ cm}^2$ . Even though the covariation between total body fat and abdominal visceral fat is statistically significant, the relationship is also characterized by a high degree of heterogeneity. As shown in Table 3, when BMI and percent body fat (%BF) are constrained to narrow ranges, one finds generally a threefold range for the amount of CT-assessed abdominal visceral fat in adult males. Thus in 16 men with BMI values of 30 or 31 and a percentage of body fat ranging from 30 to 33, mean abdominal visceral fat was  $153 \text{ cm}^2$  with a range from  $77\text{--}261 \text{ cm}^2$ . Again, the same lack of coupling among BMI, %BF, and abdominal visceral fat was observed in adult women.

**Table 1** Percent Variance ( $r^2 \times 100$ ) Explained by BMI in Body Composition in Adults, 35–54 Years of Age

|                 | BMI in 342 males | BMI in 356 females |
|-----------------|------------------|--------------------|
| Percent fat     | 41               | 40                 |
| Fat-free mass   | 37               | 25                 |
| Sum 6 skinfolds | 58               | 67                 |
| TER             | 10               | 8                  |

Percent fat and fat-free mass were derived from underwater weighing assessment of body density. TER = ratio of trunk to extremity skinfolds. Trunk skinfolds are the sum of subscapular, suprailiac, and abdominal skinfolds. Extremity skinfolds are the sum of triceps, biceps, and medial calf skinfolds.

Abdominal visceral fat measured by CT scan at the L4–L5 level. Percent fat derived from underwater weighing.

Source: Ref. 219.

The above data suggest that even though it may be necessary to use the BMI or waist circumference for the prediction of abdominal visceral fat in clinical settings, such practice is not desirable in the context of scientific research designed to understand the causes and metabolic consequences of variation in body fat content or in fat topography.

In summary, useful data for the understanding of the genetics of obesity are likely to be obtained if the phenotype falls into one of the following categories: affected (obese) vs. unaffected (nonobese); BMI; indicators of adiposity (fat mass, percentage body fat, sum of several skinfolds); indicators of leanness (fat-free mass); indicators of abdominal obesity (abdominal fat, abdominal visceral fat, waist girth, sagittal diameter).

### III GENETIC EPIDEMIOLOGY OF HUMAN OBESITY

There are several considerations in genetic epidemiological studies of obesity (5). First, obesity is not a simple Mendelian trait. For example, expression of genetic propensities may depend on appropriate environmental stimulation (i.e., gene-by-environment interaction), or developmental stage (i.e., age dependency), or sex (i.e., sex limited). Second, obesity is not a homogeneous trait stemming from a unique gene or set of genes. Third, the trait measured may index other traits such as bone and muscle mass, which also may have separate genetic determinants.

Genetic epidemiological methods are useful for addressing specific questions in human obesity, such as determining if there are genetic factors underlying an obesity phenotype, characterizing the sources of the genetic influence through maternal vs. paternal trans-

mission, and whether the trait is sex limited or age dependent, or if there is assortative mating, etc. Other strategies include documenting the presumptive causes of obesity (e.g., energy intake or energy expenditure), and considering their complex biological and behavioral interactions in a network design (i.e., multivariate genetic epidemiological studies). Here, we briefly describe the types of data and analytical methods commonly used by genetic epidemiologists, and then review the findings for several human obesity traits.

## A Review of Methods

### 1 Multifactorial

Genetic epidemiological studies of human obesity use a variety of family designs and a variety of statistical methods to partition the underlying phenotypic variance of a trait into genetic and environmental sources. In multifactorial studies (i.e., with polygenic and common environmental effects), the basic model is:

$$V_P = V_G + V_C + V_E$$

where the phenotypic variance ( $V_P$ ) is due to the additive genetic variance ( $V_G$ ), common (shared) environmental variance ( $V_C$ ), and the residual or nonshared environmental variance ( $V_E$ ). These factors can be partitioned, in turn, into more specific environmental (sibling vs. spouse vs. between generations) and genetic (gene-by-environment and gene-by-gene interactions, dominance deviations) components. The genetic heritability of a trait is expressed as the percent of total phenotypic variance due to the additive genetic effects ( $h^2 = V_G/V_P$ ), and the common environmental component is the percent due to the common environment ( $c^2 = V_C/V_P$ ).

The specific parameters that can be estimated depend on the study design, with typical designs including family (i.e., parents and their biological offspring), twin, and adoption studies. Design issues have been extensively covered elsewhere (e.g., 6–10), so we will only briefly review them here. For each study design, analytical methods range from relatively simple ones such as computing the familial correlations to more complex model-fitting using path or variance components analysis (11). Each design allows for estimation of specific types of familial effects, although each has underlying assumptions that must be recognized. For example, in the traditional family study (12,13) parents and offspring share both genes and familial environments to some degree, so it is difficult to separate G and C components (see 7). However, results from family studies are more easily generalized to the population at large, and other sources of familial

variance (e.g., spouse resemblance and additional sibship resemblance) can be investigated. Twin studies (14–16) allow for separation of the G component since monozygotic (MZ) twins share 100% of their genes while dizygotic (DZ) twins share half on the average. Major concerns with twin data are that MZ twins may share more common environmental effects (and they do share more dominance deviations) than do DZ twins that can inflate the genetic component (see 6). The correlation between MZ twins reared apart is a relatively unbiased estimate of the broad-sense heritability (additive + dominance), although one must assume that the twins were reared in uncorrelated environments. Full adoption studies (see 17) are useful in separating common environmental effects since adoptive parents and their adopted offspring (and adopted sibling pairs) share only environmental sources of variance while the adoptees and their biological parents share only genetic sources of variance. Assumptions underlying adoption designs include no selective (or late) placement into the adoptive home and that adoptive families are representative of the general population.

Longitudinal assessment (i.e., repeated measures across time) can be applied to any of the family, twin, or adoption designs (see 18–20). Longitudinal study designs are particularly important in obesity research since it is generally recognized that fat accumulates with time, and trends in the familial effect may arise through secular environmental effects, or through age-limited developmental effects of genes as for example the growth spurt at puberty (21). Even more importantly, with body fat accretion up to a new body mass level (e.g., a given obesity level), the causes of the positive energy balance leading to obesity may be progressively masked over time. For instance, an apparent deficit in resting energy expenditure is compensated by an increase in the metabolic mass associated with weight gain (22), similarly for an apparent deficit in lipid oxidation rate which is eliminated when the gain in fat mass has been large enough to ensure a greater reliance on lipid oxidation (23). It adds a dimension to the complex task of understanding the causes of obesity and defining the role of genes. To unmask the true susceptibilities to be in positive energy balance, one has to rely on longitudinal data that will make it possible to define the relevant predictors of obesity and to specify their genetic and molecular basis.

Multivariate assessment is another important design issue in the study of obesity since there are likely to be multiple relevant predictors, each having unique determinants. Multivariate genetic epidemiology studies

simultaneously examine several traits and determine the extent to which the separate measures may be influenced by unique and common genes and environment. The fundamental concept underlying multivariate studies is cross-trait resemblance between pairs of relatives; for example, trait 1 in parents with trait 2 in offspring (see 24). These methods are useful in documenting the complex behavioral and biological interactions in a network design.

## 2 Major Gene

Multifactorial effects typically arise from the action of many genes each having a small and additive influence on the phenotype (i.e., polygenic) that lead to a single normal distribution. However, other types of genetic effects are not necessarily additive (i.e., major gene) and are characterized as a mixture of distributions. Segregation analysis is used to determine whether the trait is due to a major gene that is segregating in families according to Mendelian expectations. In the mixed model (25), the phenotype is composed of the independent and additive contributions from a major gene effect, a multifactorial background, and a unique environmental component (residual). The major effect is assumed to result from the segregation at a single locus, and the transmission pattern from parents to offspring is tested to verify if the gene is segregating according to Mendelian expectations. Some models also allow for genotype-dependent covariate effects [e.g., PAP (26,27), and REGRES (28)]. For example, the major gene effect may depend on the age of the individual (i.e., genes turning on or off over time) or may have different effects depending on sex. Pleiotropic (i.e., single gene influencing multiple traits) and oligogenic (i.e., multiple genes) models also can be tested with multilocus-multitrait segregation models (e.g., 29).

## 3 Combined Models

Complex traits such as obesity involve multiple inter-correlated phenotypes, and it is highly unlikely that we will discover anything close to “the gene” which explains most of the variation for the phenotype. Instead, we expect genetic effects in the oligogenic (few genes) to polygenic (many genes) range, with an elaborate interplay between many factors, including gene-gene and gene-environmental interactions. While a lot of analytic progress has been made using the strategies discussed so far, a combined approach (see 30) is potentially much more powerful and holds great promise for these traits. Combined approaches describe models that include multiple sources of var-

iance, as for example combined multifactorial and segregation models (31–33) and combined segregation and linkage models (28,34,35). Indeed, a combined approach may be the only way to disentangle the interplay of the multiple underlying processes for obesity traits.

## B Review of Findings

### 1 Excess Body Mass or Body Fat

While most multifactorial studies of the BMI show significant familial resemblance, the relative importance of genes and common familial environments varies. Some studies place more importance on the familial environment as compared to polygenic effects (36–40), and others suggest that genetic effects outweigh those of the familial environment (41–49). For example, in MZ twins reared apart (44,48,50), the correlations were very similar to those for MZ twins reared together, suggesting that the shared familial environment had little or no effect. Two of the larger studies of the BMI [Norwegian sample of ~75,000 individuals (51) and > 9000 individuals in Tecumseh, Michigan] (40), suggest that the total additive familial effect may be between 30% and 40% in families. A somewhat higher estimate (69%) was reported in the large Virginia study of adult twins and their families (nearly 30,000 individuals) (52).

Table 4 describes the trends in the heritability levels based upon a large number of studies (53). The results are generally quite heterogeneous. The heritability level is highest with twin studies, intermediate with nuclear family data, and lowest when derived from adoption data. When several types of relatives are used jointly in the same design, the heritability estimates typically

cluster around 25–40% of the age- and gender-adjusted phenotype variance. There is no clear evidence for a specific maternal or paternal effect, and the common familial environmental effect is marginal. The table is based on the trends in ~50 different studies. In most of these studies, the BMI was the phenotype considered. In some cases, skinfolds or estimates of %BF or fat mass were used.

Temporal trends (or age effects) in the familial resemblance for BMI have also been explored (54). Recent studies suggest that age trends in the familial effects of BMI may be primarily genetic in nature and that the trends diverge in different directions between childhood and adulthood. Two studies using path analysis techniques (20,55) suggested that the familiarity increased from birth to adulthood, which Cardon (55), using adoptive and biological families measured longitudinally, attributed to genetic rather than environmental factors. In studies assessing familiarity in adults (56–59), there was a general decrease in the genetic heritability during adulthood. Fabsitz et al. (57) suggested that there were two major genetic effects in male twins, one increasing at or prior to age 20, the other decreasing after age 20. Similarly, a longitudinal analysis of Polish twins suggested a peak additive genetic effect at age ~18 in males and ~14 in females (60). In fact, the largest estimates of genetic heritability for BMI (> 80%) are reported in twins during this age range (e.g., 61). These and other studies (e.g., 62) suggest that although some of the same genes are active across time, there are unique genetic factors active as well.

Different genes may also be responsible for adiposity in the normal or moderate range as versus those leading to massive obesity (63 for review). A common observation is that the obese cases in familial studies of obesity is, on the average, 10–15 BMI units heavier than his/her mother, father, brothers, or sisters (64–66). Such a large difference between a proband and his/her first-degree relative is suggestive of the contribution of a recessive gene having a large effect. In further support, the risk for obesity when a first-degree relative is extremely obese (BMI  $\geq$  40) is higher than when a relative is moderately obese (BMI  $\geq$  30). For example, Price and Lee (67) reported risks of five to nine times higher when there was an extremely obese relative, as compared to a risk of ~2 if the relative was moderately obese. This supports not only a major gene hypothesis, but also that the genetic factors leading to extreme obesity may not be the same as those leading to moderate obesity. These hypotheses can be tested by complex segregation analysis.

**Table 4** Overview of the Genetic Epidemiology of Human Body Fat/Obesity

|                        | Heritability/<br>transmission | Maternal/<br>paternal | Familial<br>environment |
|------------------------|-------------------------------|-----------------------|-------------------------|
| Nuclear<br>families    | 30–50                         | No                    | Minor                   |
| Adoption<br>studies    | 10–30                         | Mixed<br>results      | Minor                   |
| Twin<br>studies        | 50–80                         | No                    | No                      |
| Combined<br>strategies | 25–40                         | No                    | Minor                   |

Source: Ref. 53.

While there is a great deal of heterogeneity among the major gene studies for the BMI (or some measure of height-adjusted weight) using segregation analysis (see Table 5), support for a major gene generally resulted when studies incorporated very large sample sizes (68–70), used samples selected for obesity (7,72), or allowed for genotype-dependent effects in the major gene component (73).

The mixed evidence for a major gene for BMI may be related to several factors, including gene-environment or gene-gene (epistasis) interactions. Gene-environment interactions occur when some genotypes are more susceptible than others; i.e., expression may depend on having an “obesity” gene and exposure to the relevant environmental conditions. Evidence of this is suggested in the experiments on MZ twins’ response to overfeeding (see next section). Major gene effects may also depend on ethnicity (68,74–77). For example, Price and Lee (67) reported higher familial risks for extreme obesity in Caucasians (5–9 times higher) than in African-Americans (3–5 times higher). Evidence for major genes also varies depending whether age and/or sex are factored into the model (78). For example, in one family study the major gene evidence for BMI was ambiguous (79) until genotype-dependent effects of age and sex were considered (73). It is also noted that somewhat different modes of inheritance result among the different studies. For example, while some studies reported no evidence for a major gene (77,79–81), most suggested a recessive locus and a few supported a codominant effect (76). In fact, Price et al. (78) reported a recessive mode when pre- vs. post-WW II-born sibships were analyzed together, but found that a codominant mode best characterized each cohort when analyzed separately. This finding further supports temporal trends (as discussed above) due to cohorts.

Multiple genes, or gene-gene interactions, may also account for the mixed evidence for BMI. For example, Hasstedt et al. (82) and Borecki et al. (83,84) both reported evidence consistent with at least two loci underlying BMI, one leading to extreme obesity and the other for adiposity in the normal-to-moderate range. These findings are appealing given the nature of the BMI measurements; that is, the BMI is a general measure of body build and incorporates fat mass, muscle mass, and skeletal mass. Evidence suggests that there may be major gene effects for fat mass (85,86) and skeletal tissue (87). Moreover, other studies (88) suggest that the major effect of the gene for BMI may be mediated by energy intake and energy expenditure of activity that may also have underlying major gene influences (89).

Further, Mitchell et al. (90) and Kaplan et al. (91) suggested that exercise or activity levels had the potential to suppress the (polygenic) heritability of BMI. Whether the same major gene affects several of these traits (i.e., genetic pleiotropy) or the gene primarily affects one trait (e.g., fat mass or energy metabolism) that in turn affects the BMI, remains to be investigated. Another indicator of overall fatness that is correlated with the BMI is the waist circumference (e.g., 92). Heritability for waist circumference ranged from 46% to 51% in two family studies (93,94), but dropped to <30% after adjusting for BMI in the former study. Thus, similar to BMI, waist circumference appears to index both overall fatness as well as some degree of fat distribution.

Relatively less is known about direct measures of general obesity (i.e., fat mass [FM] and %BF). In Utah families, Ramirez (95) reported that the familiarity for %BF (measured with bioelectrical impedance) was ~25%. In the Quebec Family Study (QFS), the familiarity for %BF (measured with underwater weighing) was 40% and dropped slightly to 36% after adjusting for energy intake and energy expenditure (96,97). In Quebec twins and adopted and biological families, the genetic heritability for each of %BF and FM was ~25%, with an additional 30% due to familial environmental effects (98). Together, these studies suggest that between 25% and 40% of the variance in total fat mass may be genetic due to additive genetic effects.

Somewhat more variance in total fat is accounted for when both multifactorial and major gene effects are included in the models. In the QFS (86), the HERITAGE Family Study (99) and the San Antonio Family Heart Study (85), ~60% of the variance in FM was attributable to familial factors. In the QFS and the San Antonio studies, a recessive locus accounted for up to 45% of the variance (depending on sex), with an additional 22–26% of the phenotypic variance due to (additive) multifactorial effects. However, in the HERITAGE study, the entire familial effect of about 60% was due to a recessive locus with little additional variance due to other familial sources. One of the primary differences among these studies was that in HERITAGE all subjects were selected to be sedentary at baseline (i.e., “environmental” effects due to habitual activity levels were controlled for) while the QFS and San Antonio studies presumably included a range of habitual activity levels among the subjects. Thus, a comparison among these three studies with a greater impact of the major gene in the sedentary sample indirectly supports contentions by Mitchell et al. (90)

Note: Major gene effect is recessive unless otherwise noted.

Abbreviations: ATF (abdominal total fat), BMI (body mass index), ee and ei (energy expenditure and energy intake), %BF (percent body fat, underwater weighing), FM (fat mass, underwater weighing or DXA scan), RFPI (regional fat pattern index), SF (skinfolds) TER (trunk-extremity skinfold ratio), WHR (waist-hip circumference ratio), AVF (abdominal visceral fat, computed tomography scan), PC (principal component), RQ (respiratory quotient), TER-sf or TER-fm or TER-ee,ei (TER adjusted for SF or FM or energy expenditure/energy intake), WHR-BMI (WHR adjusted for BMI), AVF-fm (AVF adjusted for FM), LRC (Lipid Research Center), QFS (Quebec Family Study), NHLBI-FHS (National Heart, Lung, and Blood Institute, Family Heart Study), SOS (Swedish Obese Subjects).

<sup>a</sup> Both random and ascertained (for high lipid value of probands) samples.

<sup>b</sup> Ascertained for obese and nonobese schoolchildren.

<sup>c</sup> BMI adjusted for social class and LRC clinic.

<sup>d</sup> Four ascertained groups: random, lean, heavy, and gain groups of schoolchildren. The gain group includes families of students who gained at least two quartiles of relative weight between two surveys.

<sup>e</sup> BMI is height (linear and quadratic)-adjusted weight using regression analysis.

<sup>f</sup> Multifactorial effect inferred by doubling average residual familial (sibling and parent-offspring) correlations; the major gene effect is genotype dependent on age and sex, and percent of variance accounted for was not reported.

<sup>g</sup> Pre- vs. post-WW cohorts, nuclear families vs. sibship analysis, transformed vs. untransformed; % variance due major gene not reported.

<sup>h</sup> Ascertained via NIDDM sibs.

<sup>i</sup> 2nd maxima was obtained but non-Mendelian, depending on field center.

<sup>j</sup> Ascertained via massively obese probands.

<sup>k</sup> BMI adjusted for energy intake and energy expenditure of activities.

<sup>l</sup> Major non-Mendelian effect. That is, results cannot rule out major gene whose effect is masked by other factors (i.e., another gene, genotype-dependent effects, etc.).

<sup>m</sup> Discriminant score (obese vs. nonobese) of weight, subscapular skinfold, chest depth and adjusted for age, sex, height.

<sup>n</sup> Ascertained through pedigrees with various cardiovascular, coronary heart, and hypertensive disease.

and Kaplan et al. (91) that activity may suppress the heritability levels for total fat.

## 2 Upper Body Fat (Android Obesity)

For the WHR, familiarity estimates varied from 28% in adoptive and biological families (100) to 40–50% in traditional nuclear families (101,102) to over 60% in longitudinal family data (Fels Longitudinal Study) (103). In two other studies (95,104) the familial correlations were either nonsignificant or inconsistent across different family pairs. Two segregation studies of the WHR were recently reported (105,106). In both, a major additive locus was detected accounting for 35–48% of the variance with no additional familial sources of variance detected. However, after removing the effects of total body fat the familial variance was due to multifactorial (polygenic and/or familial environmental) rather than major gene sources, suggesting that the major gene component for WHR may be pleiotropic with respect to total body fat.

Comparison of results across studies for fat distribution using measures of skinfolds is complicated by the fact that different skinfolds are measured in different studies. One of the more widely used measures of fat distribution is the trunk-to-extremity subcutaneous skinfold ratio (TER). Most often, the simple ratio of trunk sum to extremity sum is used, although a few studies use principal components analysis to extract the relevant factors underlying a set of skinfolds. The first component derived from such analysis is generalized fat with nearly equal loading across all skinfold measures. The second component is usually a trunk-to-extremity contrast, and the third (not often reported) is an upper-to-lower contrast. The familiarity for the second (33–52%) and third (31–49%) components (107,108) was likely to be due to genetic factors since spouse correlations were not significant. Path analysis of the second component in French-Canadian biological and adoptive families (109) accounted for ~40% of the familial variance, of which 18% was genetic in origin. After adjusting the second component for BMI (107,108) or total body fat content (110), the genetic heritability increased to 30–50%.

In another study, the phenotypic, genetic, and non-genetic correlation matrices extracted from an analysis of eight skinfold measures in Mexican-American families were analyzed using principal components analysis (111). The results suggested that the pattern of central vs. peripheral fat distribution was largely a function of the genetic correlation structure and was interpreted as evidence for global genetic pleiotropy among the skin-

folds. Familial estimates for the TER using the ratio of simple skinfold sums is ~37% (100) in a large survey of the Canadian population (>18,000 individuals from >11,000 households). As with the principal component, after adjusting TER for percent body fat, the total familiarity increased to >63%, of which 28% was genetic in origin. Similar results were obtained in the sample of twins and adoptive and biological families of the QFS (98).

These results for regional fat distribution suggest that there is a significant familial influence on the pattern of subcutaneous fat distribution and that adjusting for total body fat usually results in an increased familiarity. This implies that for a given level of fatness, some individuals generally store fat on the trunk or abdominal area (android) while others store primarily on the lower body (gynoid). This pattern is consistent with a hypothesis of both genetic pleiotropy (i.e., similar genes affecting both fat distribution and total body fat) and oligogenic (an additional major genetic system specific to fat distribution). This question was more specifically addressed in the QFS using a trivariate familial correlation model (112). In that study, cross-trait familial resemblance (e.g., trait 1 in parents with trait 2 in offspring, or interindividual cross-trait correlations) was examined among %BF, BMI, and TER. The results suggested that although all three measures were significantly correlated within individuals, the interindividual (familial) cross-trait resemblance was significant for BMI with each of %BF and TER (bivariate heritabilities of 10% and 18%, respectively), but %BF and TER showed no cross-trait familial resemblance. Similarly, in another multivariate study using twins, a common genetic component for BMI and WHR accounted for >50% of the covariation (113). The latter study also reported that the genetic correlation between WHR and a skinfold ratio (subscapular to triceps) was not significant, suggesting multiple dimensions of fat patterning. Together, these results support the hypotheses that 1) the BMI may index both total body fat and fat distribution to some degree, 2) some of the same genes may influence total fat and fat distribution (pleiotropic), 3) each of total fat and fat distribution also may be influenced by unique genes and/or environmental factors (oligogenic), and 4) there may be multiple fat topography dimensions.

Relatively few segregation studies have been reported for fat distribution measures. For the TER, no support for a major gene was found in the large Tecumseh sample (70) or in the QFS (54). However, after adjusting the fat distribution measure for overall level of fatness (54), a recessive locus accounted for 37% of

the variance with an additional 29% due to a multifactorial component. These findings are consistent with the hypothesis that there is more than one genetic factor underlying fat distribution, and that removal of the “gene” for total fat allows for a second locus specific to fat distribution to be detected. However, in the HERITAGE study (105), an additive major gene accounting for > 50% of the variance was found, but total fat adjustment had no effect on the major gene inference. This was in contrast to results for WHR in the same study (previously discussed), in which total fat adjustment reduced the major gene inference. Together, these studies support the previous multifactorial studies suggesting that both pleiotropic and oligogenic loci underlie body composition. A putative major locus was also reported in Utah pedigrees (35) for a relative fat pattern index [RFPI = subscapular/(subscapular + suprailiac)], and two recent studies also support major gene effects for fat distribution in other ethnic groups from India (114) and Eastern Europe (115).

### 3 Abdominal Visceral Fat

We are aware of only two family studies investigating abdominal visceral fat—the QFS and the HERITAGE Family Study. Familial correlations in the QFS (116) for abdominal total, abdominal visceral, and abdominal subcutaneous fat tissue were  $\sim 0.35$ , with somewhat lower spouse correlations for total (0.30) and subcutaneous (0.21) and higher spouse correlations for abdominal visceral fat (0.36). The heritability was  $\sim 70\%$  for each of the three measures. The effect of adjusting each of these measures for total body fat was to reduce the magnitude of the familial correlations and thus the heritability estimates (> 55% for total and visceral abdominal fat and 42% for subcutaneous abdominal fat). This suggests that some of the same multifactorial factors (polygenic and/or familial environmental) impact similarly on total body fat and visceral fat. Similar results were obtained in the HERITAGE Family Study (117).

A major gene hypothesis for abdominal visceral fat was examined in the QFS (118) and the HERITAGE (99). In each study, a putative recessive locus accounted for about 50% of the variance, with an additional 20% due to a multifactorial component. However, after adjusting for fat mass, support for a major gene was reduced; although the major effect was significant, the Mendelian and no-transmission (i.e., environmental) models were not resolved. It was suggested that the major gene previously noted for fat mass in these data (86) was also responsible for the major gene detected for

abdominal visceral fat. In other words, genetic pleiotropy was inferred, where the same major gene affected both fat mass and the abdominal visceral fat traits. A cross-trait study conducted between fat mass and abdominal visceral fat (119) supported the pleiotropy hypothesis. The bivariate (cross-trait) familiarity was 29–50% (with sex differences), indicating genetic pleiotropy. Moreover, since the univariate familiarity for each trait was even higher (55–77% for fat mass and 55–65% for abdominal visceral fat), each trait was assumed to be influenced by additional familial factors that were specific to each (i.e., oligogenic). Given the significant spouse cross-trait correlations, at least some of the bivariate familial effect may be environmental in origin. Finally, the visceral fat response to exercise training was also a function of a recessive major gene accounting for 20–25% of the variance (120). However, in this case, adjusting for total fat did not change the major gene inference. This suggests that the genes for visceral fat response to exercise training may be independent from those affecting total level of fatness.

### 4 Lower Body Fat (Gynoid Obesity)

All studies reviewed in the section on android obesity as assessed from WHR, TER, or principal components of sets of skinfolds apply equally well to the evaluation of the genetic components of gynoid obesity. In addition, one other study purported to measure gluteofemoral fat. In a study based on the Danish Adoption Register, participants were asked to match their (and other relatives') body types to one of nine silhouette pictures that ranged from very thin to obese (121). While this measure correlated with the BMI (ranging from 0.63 to 0.88) and with the sum of several skinfolds (ranging from 0.39 to 0.66), the authors suggested that it favored the gynoid type of fat distribution. Relatives were placed in four classes as determined by weight of the adoptee. The mean silhouette score of the adoptees' biological mothers and siblings increased significantly across weight classes, while no mean differences were observed for adoptive relatives, suggesting primarily a genetic control for this measure.

### 5 Relationship Between Total Fat and Fat Topography

The genetic epidemiological studies reported in this chapter regarding total fat and fat topography suggest a complex relationship underlying the etiological causes of their covariation. Most of the evidence comes from studies comparing the multifactorial and major

gene evidence for fat distribution phenotypes both prior to and after adjusting for total fat (using multiple regression). In general, total fat adjustment alters the familial inferences for topographical measures. These studies suggest substantial shared major gene and multifactorial determinants between total fat and abdominal visceral fat, but only the major gene component for total fat mass appears to influence subcutaneous fat distribution.

Regarding the major gene component for subcutaneous fat distribution, prior to adjustment for total fat there was evidence for a major (non-Mendelian) effect for TER, but only after adjustment did the transmission appear to be Mendelian. In other words, the TER may be both a pleiotropic and oligogenic trait, in that removal of the effects due to a putative major locus for total fat leads to the detection of a secondary locus specific to fat distribution. In contrast, adjusting abdominal visceral fat for total fat reduces the evidence for a putative major locus. Together, these results suggest at least two putative major loci underlying obesity phenotypes, one determining total and abdominal visceral fat, and the other determining how subcutaneous adipose tissue is distributed.

Regarding the multifactorial (polygenic and/or common environmental) causes of the covariation between the traits, similar patterns are noted. For subcutaneous fat distribution, the generalized heritabilities increase after total fat adjustment, while bivariate studies find no evidence for a genetic correlation. Together, these results suggest that there are entirely different multifactorial causes for the variations in total fat and subcutaneous fat distribution. For abdominal visceral fat, however, total fat adjustment leads to decreased generalized heritability estimates, with bivariate studies suggesting a substantial bivariate heritability. Thus, total fat and abdominal visceral fat may share many of the same polygenic and/or common environmental factors.

#### IV GENES AND MOLECULAR MARKERS OF HUMAN OBESITY

##### A Review of Methods

This section focuses on association studies with candidate genes and on the results of genomic scans designed to identify genomic regions that harbor genes of importance for obesity. The molecular dissection of complex phenotypes such as obesity is based on two strategies: linkage and association studies. Both rely

on the same principle, i.e., the coinheritance of adjacent DNA markers, with the difference that linkage focuses only on recent and usually observable generations, while association relies on the fact that particular DNA markers can remain together on ancestral haplotypes for several generations, leading to a phenomenon known as linkage disequilibrium (122,123). Reviews of methods and strategies to identify genes underlying complex phenotypes can be found elsewhere (123–126). The number of genes and DNA sequence variations that have been shown to be associated and/or linked with obesity has increased considerably since the first edition of this volume. The yearly updates of the obesity gene map published since 1996 (127–134) provide a good indication of the progress accomplished in the past several years in the search for genes determining human obesity. Other topics of relevance for the understanding of the molecular basis of human obesities can be found in Chapter 10 by Chua et al. All the gene symbols, names, and chromosomal locations of the genes listed in this section are given in the Appendix found at the end of this chapter.

##### B Review of Findings

###### 1 Association Studies

The search for genes influencing overweight and obesity in humans has been thus far mostly based on association studies with *candidate genes*, those with known chromosomal locations that are metabolically or physiologically relevant for the phenotype under study (functional candidate genes). They could also be genes targeted because of their position in a region of the genome (positional candidate gene), near a Mendelian obesity syndrome, within a quantitative trait locus homologous to a locus linked to obesity in animal models (see below) or identified through genome-wide scans of human obesity (see below). The genes showing positive evidence of association with obesity-related phenotypes are listed in Table 6, which provides the chromosomal location of the gene, the phenotypes that were shown to be associated with the gene, and the range of *P* values from the various studies. This list shows that a total of 51 candidate genes have been shown to be associated with obesity-related phenotypes. It should be noted that the table does not include the results of early association studies performed with the ABO (9q34) blood group and the human leukocyte antigen (HLA) system on chromosome 6p21.3. A review of these studies (135) revealed that the results were

**Table 6** Evidence for the Presence of an Association Between Markers of Candidate Genes with BMI, Body Fat, and Other Obesity-Related Phenotypes

| Gene     | Location     | Phenotype   | <i>P</i> value          | Ref.              |
|----------|--------------|---|-------------------------|-------------------|
| TNFRSF1B | 1p36.3-p36.2 | BMI, overweight, leptin   | < .05                   | (223,224)         |

See Table 5 legend for definitions.

rather ambiguous, some studies finding associations with obesity, while others did not.

Despite the large number of positive findings reported in Table 6, it is important to keep in mind that for most of these genes, very few replications in independent populations have been reported and that for many of these genes, there are as many negative as positive results that have been reported. A good example of this is the results obtained with the beta-3-adrenergic receptor (ADRB3) gene. The ADRB3 gene is probably the candidate gene that has been the most widely tested for association with obesity-related phenotypes with positive findings reported for weight gain (137–139), obesity, BMI, and/or body fatness (140–155), and various indicators of abdominal fat (139,146,148,151,154,156) and changes in BMI during pregnancy (137). Despite these positive findings, a whole series of negative results, reviewed elsewhere (129,157,158) has also been reported for the ADRB3 gene. Finally, three independent meta-analyses yielded contradictory results, one concluding that the ADRB3 gene has no effect on obesity (159), another one finding an effect (160), while a third one based only on Japanese studies concluded that the mutation in ADRB3 was associated with obesity (161).

Among the genes listed in Table 6, a few have been shown to be associated with obesity-related phenotypes in at least five different studies. These include the LEP gene, the PPARG gene, the ADRB2 gene, the TNFA

gene, the LEP gene, the UCP2 and UCP3 genes, the GNB3 gene, and the LDLR gene. Other genes that were found to be associated with obesity phenotypes include the TNFRSF1B, HSD3B1, LMNA, ATP1A2, AGT, ACP1, APOB, POMC, ADRA2B, IRS1, APOD, CCKAR, FABP2, UCP1, NPY5R, CART, GRL, ESR1, GCK, NPY, PON2, LPL, CBFA2T1, SUR1, IGF2, INS, APOA4, DRD2, IGF1, CD36L1, HTR2A, HSPA2, NMB, MC5R, MC4R, INSR, LIPE, GYS1, ADA, and HTR2C genes.

## 2 QTLs from Cross-Breeding Experiments

The molecular signature of complex traits such as obesity can also be investigated using experimental crosses among various animal strains. Crosses between two inbred strains of animals diverging for a quantitative trait will create linkage disequilibrium between loci that differ between the two strains, which results in associations between marker loci and linked segregating quantitative trait loci (162). A quantitative trait locus (QTL), thus, simply refers to a locus at which segregation contributes to a quantitative trait. Since the homology between human and several animal genomes is increasingly well characterized, QTL mapping offers a powerful strategy to begin characterizing the molecular basis of complex traits in humans as the QTL identified in animals can lead to the identification of a target human chromosomal region. Reviews of the

methodology underlying QTL mapping in animals can be found elsewhere (125,162–164).

The number of obesity QTLs identified using this strategy has expanded considerably in the past 5 years. In the first edition of this chapter, eight obesity QTLs, all identified from mice crosses, were mapped. The results reviewed in the 2000 update of the obesity gene map (133) reveal that the number of obesity QTLs reached 115. These QTLs have been identified from 19 different mice crosses (81 QTLs), eight different rat crosses (21 QTLs), eight different pig crosses (12 QTLs), and one chicken cross (1 QTL). These QTLs were found to affect a wide variety of phenotypes, including body weight, weight gain, total adiposity, specific fat depots, percentage body fat, heat loss, and food intake and their human homologs are distributed over all human chromosomes, except the Y chromosome. Details about the chromosomal locations of these QTLs and their human homologs can be found in the review paper (133).

### 3 Linkage Studies

Several studies have tested linkage with obesity-related phenotypes. These linkage studies were performed with candidate gene markers or with a variety of anonymous polymorphic markers such as microsatellites. Most of the linkage studies are performed with a large number of polymorphic markers selected to cover the whole genome and test for linkage with a variety of obesity phenotypes in order to detect QTLs. The obesity QTLs uncovered in such genomewide scans provides the identification of chromosomal regions, or in some cases of positional candidate genes, that can be further investigated for their role in the phenotype of interest. The methodology underlying the identification of human obesity QTLs can be found elsewhere (124). The results of the genomewide scans for obesity are reviewed in detail here (Table 7).

## C Linkages from Genomewide Scans of Obesity

### 1 Pima Indians

The first genomewide scan for obesity was performed in Pima Indians and used percent body fat as the phenotype (165). A total of 674 genetic markers with an average intermarker distance of 8.3 cM were tested for linkage with percent body fat measured by underwater weighing in 283 sibling pairs from 88 Pima Indian families. Significant evidence of linkage was reported on 11q21-q22 with a peak LOD score of 2.8 between markers D11S2000 and D11S2366. Another genomic

scan for obesity (451 sibpairs from 127 families) and energy metabolism (236 sibpairs from 82 families) was performed in the same population using 576 markers with a mean spacing of 6.4 cM (166). The phenotypes investigated included, in addition to percent body fat, the ratio of waist-to-high circumference (WTR), 24-hr energy expenditure (EE) and 24-hr respiratory quotient (RQ) measured in a respiratory chamber. For percent body fat, the strongest linkages were detected at 11q21-q22 with marker D11S2366 (LOD = 2.1) and 18q21 with marker D18S877 (LOD = 2.3). No strong evidence of linkage was observed for WTR with all multi-point LOD scores < 1.5. For 24-hr EE, the strongest linkage was observed at 11q23 with marker D11S976 (LOD = 2.0), while for 24-hr RQ linkages were found at 1p31-p21 (LOD = 2.8 with D1S550) and 20q11.2 (LOD = 3.0 with D20S601). Another genomic scan for phenotypes related to diabetes revealed evidence of linkage to BMI (LOD = 3.6) between markers D11S4464 and D11S912 at 11q24 (167) near the dopamine D2 receptor gene. Finally, a fourth genomewide linkage scan based on 770 subjects from 239 families revealed evidence of linkage between plasma leptin levels near marker D6S271 (LOD = 2.1) at 6p21-p12 (168).

### 2 San Antonio Family Heart Study

The results of the genome scans for obesity-related phenotypes in the San Antonio Family Heart Study (SAFHS) has been reported in three papers (169–171). The phenotypes investigated in SAFHS include BMI, body fat mass measured by bioelectric impedance, and plasma leptin levels measured in a sample of up to 470 Mexican-Americans from 10 large multigenerational families. The first study based on a 20-cM map (169) revealed strong evidence of linkage at 2p21 between marker D2S1788 and fat mass (LOD = 2.8) as well as plasma leptin levels (LOD = 4.9). Evidence of linkage with leptin was also observed at 8q11.1. In a second study in which six additional markers were typed around the peak linkage for leptin at 2p21, in addition to the 15 that were already available in the first study, the LOD score for leptin was increased to 7.5 (170). The QTL for leptin identified in SAFHS at 2p21 was partly replicated in a study performed in African-Americans (172). Finally, a genome scan of BMI performed using a 10 cM map revealed evidence of linkage at 6q25, 8p12-p11.2 near the ADRB3 gene and 17q11 (171).

### 3 Paris-Lille French Study

A genome scan for obesity was undertaken in 158 French families from the Hôtel-Dieu Hospital in Paris

**Table 7** Summary of Genome Scan Studies for Obesity-Related Phenotype

| Location                                      | Trait                    | Markers              | LOD score | Candidate gene    |
|---|--------------------------|----------------------|-----------|-------------------|

ASF, abdominal subcutaneous fat; AVF, abdominal visceral fat; FFM, fat-free mass; RQ, 24-hr respiratory quotient.

and the Institut Pasteur in Lille with a morbidly obese (BMI  $\geq 40$  kg/m<sup>2</sup>) proband (173). Strong evidence of linkage with obesity (defined as a BMI  $> 27$  kg/m<sup>2</sup>) was found at 10p12 (LOD = 4.9 with marker D10S197) and with leptin at 2p21 (LOD = 2.7 between markers D2S165 and D2S367) and 5p11 (LOD = 2.9). Two independent studies attempted to replicate the linkage found on 10p12 with obesity in the French population. The first study was performed in 386 subjects from 93 German families with at least two obese children using 11 markers spanning a 23-cM region on chromosome 10 (174). Although the linkage with marker D10S197 was not as strong (LOD = 1.7) as in the French families, evidence of linkage with obesity was observed with 4 other markers (LODs ranging from 1.1 to 2.4) located within 5 cM of the peak linkage found in the French population. The second study investigated linkage between obesity and 13 markers spanning ~110 cM on chromosome 10 in two cohorts: one comprising 862 subjects from 170 Caucasian families, the other comprising 212 individuals from 43 black families (175). Evidence of linkage was found with markers located on 10p in both Caucasians ( $P = .03$  with marker D10S208) and blacks ( $P = .01$  with marker

D10S582) as well as in the combined cohort ( $P = .0005$  with D10S197).

#### 4 University of Pennsylvania Family Study

The fourth genomic scan for obesity was undertaken in 513 individuals from 92 families ascertained through a morbidly obese proband as part of an ongoing linkage study at the University of Pennsylvania (176). Several obesity phenotypes were measured in these subjects including BMI, percent body fat measured by bioelectric impedance, the waist-to-hip circumference ratio and plasma leptin levels. The strongest evidence of linkage reported in that study was between obesity, defined as a BMI  $\geq 30$  kg/m<sup>2</sup>, and three markers spanning 12 cM on chromosome 20q13 (176).

#### 5 Quebec Family Study

The QFS is an ongoing longitudinal family study aimed at the identification of genes associated with obesity and its various metabolic complications in French-Canadian families. Two genomic scans for phenotypes related to obesity were published from this population. One investigated linkage with fat-free mass (FFM)

derived from body density measurements obtained from underwater weighing in 748 subjects from 194 families (177), while the other investigated linkage with abdominal fat assessed by computed tomography in 521 subjects from 156 families (178). Results of the study with FFM revealed evidence of linkage on three different regions: 7p15.3 with marker D7S1808 (LOD = 2.7), 15q25-q26 with a polymorphism within the insulinlike growth factor 1 receptor (LOD = 3.6) and 18q12 with marker D18S535 (LOD = 3.6). In the other genome scan, CT-assessed abdominal fat was adjusted for total body fatness and tested for linkage with 293 markers with a mean spacing of 11.9 cM. A total of nine QTLs, all affecting abdominal subcutaneous fat, were uncovered (178). Two of these QTLs were found to be close to genes involved in the regulation of food intake (4q32 and 17q21), while three others (1p11.2, 9q22 and 17q21) were found close to genes influencing sex steroids. No significant linkage with abdominal visceral fat was uncovered.

## 6 Finnish Families

Another genome scan performed in 367 obese individuals from 166 Finnish families revealed evidence of 2 QTLs influencing obesity, defined as a BMI  $\geq 30$  kg/m<sup>2</sup> (179). The strongest evidence of linkage was uncovered on chromosome Xq24 between markers DX6799 and DX6804 (LOD = 3.5) in a region where the serotonin 2C receptor (HTR2C) gene is located. Evidence of linkage with obesity was also observed in a region of chromosome 18q21 (LOD = 2.4 with D18S1155) flanking the MC4R gene.

## 7 TOPS Family Study

In an attempt to identify QTLs influencing phenotypes associated with the metabolic syndrome, Kissebah et al. (180) tested 2209 individuals distributed over 507 Caucasian families recruited from the TOPS (Take Off Pounds Sensibly) membership. A total of 387 markers, including 17 X-linked and four Y-linked markers, with an average genetic spacing of 10 cM were tested for linkage with seven phenotypes including the following obesity phenotypes: BMI, waist circumference, and plasma leptin levels. The peak LOD scores for BMI (LOD = 3.3) and waist circumference (LOD = 2.4) were found on the same region of chromosome 3 (3q27) close to the marker D3S2427. The candidate genes located in this region of chromosome 3 include glucose transporter 2 (GLUT2) and the adipose tissue-secreted protein adiponectin. Plasma leptin levels showed its strongest linkage signal on chromosome 17p12

(LOD = 5.0) near marker D17S947 in a region where the glucose transporter 4 (GLUT4) and the peroxisome proliferative-activated receptor- $\alpha$  (PPARA) genes are located.

## 8 HERITAGE Family Study

In an attempt to identify genes associated with body composition phenotypes and their response to exercise training, Chagnon et al. (181) measured BMI, subcutaneous fat, %BF, fat mass (FM), FFM, and plasma leptin levels in 522 subjects from 99 Caucasian families of the HERITAGE Family Study cohort before and after 20 weeks of endurance training, and performed a genome scan of the baseline and response (difference between pre- and posttraining values) phenotypes using 344 autosomal markers. Only results from the baseline analyses are presented in Table 7. The strongest multipoint linkages were found on chromosomes 8q23.3 (BMI), 9q34.3 (BMI), 10p15.3-p15.1 (BMI and FM), 12p12.1 (BMI and FM), 14q11-q11.2 (BMI, FM, and FFM). For plasma leptin level evidence of singlepoint linkage was found on chromosome 19p13 with the LDL receptor gene ( $P = .0009$ ). From the same study, a genomic scan focusing on abdominal subcutaneous fat and abdominal visceral fat has also been published. For pretraining abdominal fat measures assessed with computed tomography, promising linkages were noted for AVF on 2q22 and 2q36, and for ASF on several different chromosomes as shown in Table 7 (182). However, the results for ASF on 4q and 11p are considered strongest since they replicate those from the only other genome scan of these abdominal phenotypes (the QFS). For the abdominal fat training responses, promising results were limited to ASF on 7q36.2 (including NOS3), with suggestive findings ( $P < .01$ ) on 1q21.2-q24.1 (S100A, ATP1A2, ATP1B1), 10q25.2 (ADRA2A), and 11p15.5 (IGF2).

## 9 Old Order Amish Population

A genomewide scan of obesity-related traits was also performed in the Old Order Amish population, a rural-living population characterized by considerable homogeneity in lifestyle (183). BMI, waist circumference, %BF estimated by bioelectric impedance and serum leptin concentrations were measured in 672 individuals from 28 extended families ranging in size from three to 69 subjects. Linkage between 357 autosomal markers with average intermarker distance of 10.2 cm and the obesity phenotypes and between leptin concentrations adjusted for BMI (leptin-BMI) was tested using a variance component method. Peak linkages were found

on chromosomes 3p25.2, near the PPARG gene, for %BF, 7q31-q36 and 10p12-p11 for leptin-BMI, 14q22-q31 for waist circumference and leptin-BMI, and 16p for BMI and leptin concentrations. The strongest linkage for leptin-BMI on 10p12-p11 (LOD = 2.7) was ~10–20 cM telomeric to the obesity QTL reported in the French population (173) and replicated in other studies (174,175).

In summary, nine genomewide scans relevant to obesity have been reported to date. They were undertaken among many different ethnic groups. The sampling strategy varies from study to study. The density of the markers used for the genomic scans is also quite variable. Phenotypes and analytical strategies are also different across the nine studies. As is evident from the preceding review, a large number of QTLs have been observed with considerable differences across family cohorts. The latter should not be surprising, considering how little the cohorts, experimental designs, panels of markers, and analytical strategies have in common.

**Table 8** Genomic Regions with Obesity QTLs from at Least Two Studies

| Gene     | Studies                                 | Ref.      |

|          | Quebec Family Study                     | (177,178) |
|          | Pima Family Study                       | (165–168) |
|          | University of Pennsylvania Family Study | (176)     |

What is of great interest, however, is that in 10 cases, two or three of the nine studies have detected evidence for a QTL in the same chromosomal regions. Table 8 lists these 10 regions and identifies the studies with convergent findings in each case. Two of these regions (10p12-15 and 18q12-21) are each supported by the results of three family studies. Overall, these observations suggest that there are probably some common genes and sequence variants involved in the genetic predisposition to obesity among a whole variety of populations or ethnic groups. Further, they suggest that the predisposition to obesity could also be influenced by other genes and alleles whose prevalences and effect sizes vary from population to population.

#### D Linkages with Candidate Genes and Other Markers

Besides the genomewide scans, others have reported evidence of linkage for obesity-related traits with polymorphisms within or around candidate genes. A summary of the positive findings is given in Table 9. The genes involved in the positive finding of linkages are: PGD, LEPR, ATP1B1, ATP1A2, ACP1, POMC, IGKC, GYPA, ISL1, GRL, ADRB2, BF, TNFA, GLO1, NPY, LEP, KEL, ADRB3, ORM1, AK1, SUR1, CCKBR, UCP2 and UCP3, IGF1, ESD, MC5R, MC4R, ADA, MC3R, and P1 genes. None of these linkages was replicated in independent studies.

#### V GENE-ENVIRONMENT AND GENE-GENE INTERACTIONS

Genotype-environment interaction ( $G \times E$ ) arises when the response of a phenotype (e.g., fat mass) to environmental changes (e.g., dietary restriction) depends on the genotype of the individual. Although it is well known that there are interindividual differences in the responses to various dietary interventions, whether in terms of serum cholesterol changes to high-fat diet (184) or in terms of body weight gains following chronic overfeeding (185), very few attempts have been made to test whether these differences are genotype dependent. Most of the genetic epidemiology studies of human obesity have assumed the absence of genotype-environment interactions simply because of the difficulty in handling such interaction effects in quantitative genetic models. Methods from both genetic epidemiology (unmeasured genotype approach) and from molecular epidemiology (measured genotype

**Table 9** Evidence for the Presence of Linkage with Obesity-Related Phenotypes

| Gene <sup>a</sup> | Markers                          | Location      | Phenotypes  | <i>P</i> or LOD value  | Ref.          |

<sup>a</sup> The absence of gene symbol indicates that the linkage study involved a targeted chromosomal region. See Table 5 legend for definitions.

approach) can now be used to detect  $G \times E$  effects in humans. These methods will first be briefly reviewed followed by a summary of our current knowledge about the importance of  $G \times E$  effects for phenotypes related to obesity.

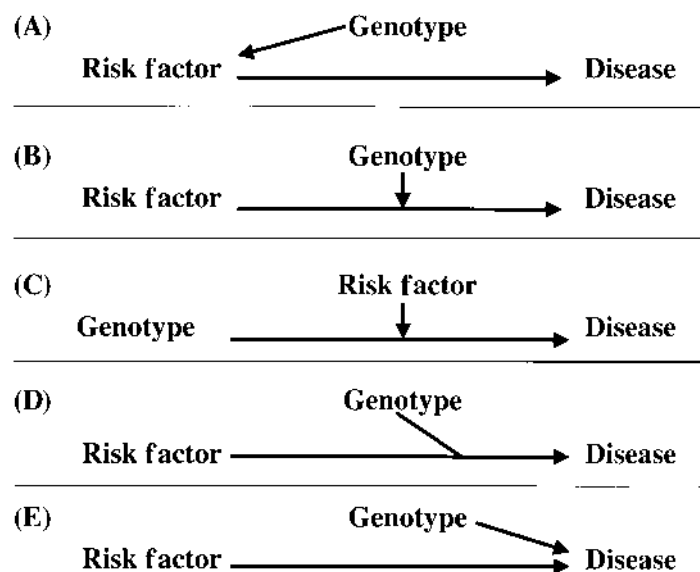

### A Review of Methods

An epidemiologic approach was proposed by Ottman (186) to investigate the relationship between genetic predisposition and associated risk factors and determine if there is support for a  $G \times E$  interaction, and if so, the form it may take. For example, Figure 3 illustrates five plausible models as described by Ottman (186). These models are not path diagrams, but rather are more similar to metabolic paths, and the direction of the arrows denotes direction of causality. The model in Figure 3(A) posits that the genotype increases the expression of the risk factor. In Figure 3(B), the genotype exacerbates the effect of the risk factor. In both cases, only the presence of the risk factor is necessary for disease expression, although the genotype will have some additional effect. Figure 3(C) is the reverse of 3(B), where the risk factor exacerbates the effect of the genotype; only the latter is “required” for disease expression. In Figure 3(D), both the genotype and the risk factor are required to raise risk, and in Figure 3(E),

the genotype and the risk factor each influence risk of disease individually.

The basic approach involves classifying individuals into four groups based on the presence or absence of genetic susceptibility and presence or absence of the risk factor (186). Genetic susceptibility can be measured directly if the susceptibility gene is known or if there are closely linked markers. Even in the absence of any molecular data, however, family history of the disease can be used to develop indicators of genetic susceptibility. In the most simplistic analysis, the pattern of hits and misses in the four groups (assessed with odds ratios) suggests whether or not a particular type of  $G \times E$  interaction (as illustrated in Fig. 3) is consistent. The basic method has been expanded to include assessing relative risks in affected twin pairs with known exposure (187), and in assessing the preventive effects of targeted environmental exposures to genetically susceptible persons in population studies (188). Familial aggregation of disease was also examined within strata based on classifying probands with respect to their relative risks (189). However, none of these methods have been applied to the study of obesity.

Several other genetic approaches can be used to detect  $G \times E$  effects. Two of these strategies are of the unmeasured-genotype approach. The first one would be to incorporate  $G \times E$  effects in the statistical genetic

**Figure 3** Five hypothetical relationships between genetic susceptibility to disease and risk factors for disease. The genetic susceptibility may be either polygenic or due to a dominant, recessive, or X-linked major locus. The risk factor may be only one of many factors associated with disease risk, and may itself have either genetic or nongenetic origins. (From Ref. 186.)

models (190–193). Ignoring such interaction effects when they exist has been shown to reduce the power to detect major gene effects (73,194). Second, using intervention studies we have proposed that one way to test for the presence of a  $G \times E$  effect in humans is to challenge several genotypes in a similar manner by submitting both members of MZ twin pairs to a standardized treatment (environment) and compare the within- and the between-pair variances of the response to the treatment (195). This comparison can be done using a two-way analysis of variance (ANOVA) for repeated measures on one factor (the treatment effect), in which the genotype effect is random, the treatment effect is fixed and twins are nested within pairs. Using this ANOVA, F ratios for the treatment effect and for genotype-treatment effect can be easily obtained. The intraclass correlation can be computed from the within- and between-pair mean squares. The finding of a significantly higher variance in the response between pairs than within pairs suggest that the changes induced by the treatment are more heterogeneous in genetically dissimilar individuals, which will translate into a higher intrapair resemblance in the response.

Some of the conditions that are important to fulfill in this intervention design include (195): (1) determine the twin zygosity as precisely as possible; (2) keep age variation at a minimum; (3) use same-sex twin pairs or control for sex differences if both male and female twin pairs are involved; (4) apply the treatment in exactly the same manner to all twins under rigorously controlled conditions; (5) select phenotypes that are not greatly influenced by prior exposure to the treatment used in the study. In a series of experiments conducted on male MZ twins over the last 10 years in our laboratory, we used either exercise training or overfeeding as treatments to investigate  $G \times E$  effects in obesity-related phenotypes (results described below). Although the design is useful to detect  $G \times E$  effects, there are some important limitations associated with it. First, for obvious ethical reasons, there are limitations regarding the experimental treatments that can be undertaken with human subjects regarding the severity of the nutritional stress imposed and the duration of the treatment. Second, even though it is possible to exert a satisfactory experimental control and reach full standardization over energy intake, it is not possible to fully standardize energy expenditure in positive or negative energy balance studies. Indeed, because of individual differences in resting metabolic rate, thermic effect of food, fidgeting, or variations in the energy cost of weight maintenance associated with changes in body mass, subjects will invariably differ in their levels of energy expendi-

ture. Third, such intervention studies, in addition to being very expensive to undertake, are very difficult to conduct over a long period of time on a large number of subjects.

Four methods can be used to provide evidence for  $G \times E$  effects in humans when molecular markers are available. The first is to compare the influence of a gene on a given phenotype between populations of different ethnic and cultural backgrounds. An example of this approach is provided by the study of Hallman et al. (196), who showed that the effect of apolipoprotein-E polymorphism on total cholesterol levels varied among populations with different amounts of fat in their diet. The cholesterol-raising effect of the  $\epsilon_4$  allele, for example, was found to be highest in populations on high-fat diets like Tyrolea and Finland, and lowest in populations on low fat diets like Japan and Sudan, which provides evidence of gene-diet interaction. The second method consists of comparing the effect of a gene between subgroups of individuals within the same population, but categorized on the basis of variables that can potentially affect the phenotype under study (e.g., sex, age, race, disease status, etc.). An example of this approach could be found in the results of Zee et al. (197), who reported an association between a polymorphism in the LDL receptor gene and hypertension, but only in overweight or obese subjects. In the third method, the response to an environmental stimulus (diet, exercise training, medication, or others) is investigated among individuals with different genotypes at a given gene or marker locus. For example, using an approach similar to the MZ twin experimental design described above, but with singletons instead of twins, it would be possible to study the response to chronic alterations in energy balance as a function of genetic characteristics at specific candidate genes or marker loci. A fourth method is based on the “variability gene” concept introduced by Berg (198). Compared to a “level gene,” which influences the level of a phenotype, a “variability gene” is one that contributes to the framework within which environmental factors cause phenotypic variation or, in other words, to the susceptibility to changes in the environment. To detect this  $G \times E$  effect, it has been proposed that phenotypic differences between members of MZ twins of various genotypes at the genetic locus be compared (199).

An important advantage of the measured genotype approach over the unmeasured genotype approach in the study of  $G \times E$  is that it makes possible the identification of the responsible genes, thereby provid-

ing a means of recognizing individuals at higher risk of disease because of differences in susceptibility to risk factors.

## B Review of Findings

Evidence from both the unmeasured and measured genotype approaches is available regarding the presence of  $G \times E$  effects in obesity-related phenotypes. Using appropriate statistical modeling, three studies reported major gene effects for measures of height-adjusted weight, but only after accounting for age and/or gender effects in the model (73,76,86), suggesting that the effect of this putative gene on body mass is dependent on the sex and the age of the individual, which is a special case of genotype-environment effect.

Using the unmeasured genotype approach, we studied the role of the genotype in determining the response to changes in energy balance by submitting both members of MZ twin pairs to either positive energy balance induced by overfeeding (200,201) or negative energy balance induced by exercise training (202–204). The objective of these studies was to determine whether the sensitivity of individuals to gain fat when exposed to positive energy balance or to lose fat when exposed to negative energy balance was modulated by the genotype. The results of these studies (reviewed below) revealed the presence of significant genotype-energy balance interaction effects for body weight, body fat,

and fat distribution phenotypes, suggesting that genetic factors are important in determining how an individual will respond to alterations in energy balance.

### 1 Positive Energy Balance Experiments

It is generally recognized that there are some individuals prone to excessive accumulation of fat, for which losing weight represents a continuous battle, and others who seem relatively well protected against such a menace. We have tried to test whether such differences could be accounted for by inherited differences. In other words, we asked whether there were differences in the sensitivity of individuals to gain fat when chronically exposed to short- and long-term positive energy balance and whether such differences were dependent or independent of the genotype.

Twelve pairs of male MZ twins ate a 2.4 MJ/day (1000 kcal/day) caloric surplus, 6 days a week, during a period of 100 days (201). Significant increases in body weight and fat mass were observed after the period of overfeeding. Data showed that there were considerable interindividual differences in the adaptation to excess calories and that the variation observed was not randomly distributed, as indicated by the significant within pair resemblance in response. For instance, there was at least three times more variance in response between pairs than within pairs for the gains in body weight, fat mass, and fat-free mass (Fig. 4, left panel). These data, and those of the response to

**Figure 4** Intrapair resemblance in the response of identical twins to long-term changes in energy balance. Left panel: 12 pairs of identical twins were submitted to an 84,000-kcal energy intake surplus over 100 days. Right panel: 7 pairs were subjected to a negative energy balance protocol caused by exercise. The energy deficit was 58,000 kcal over 93 days. (From Refs. 201 and 204.)

short-term overfeeding, demonstrate that some individuals are more at risk than others to gain fat when energy intake surplus is clamped at the same level for everyone and when all subjects are confined to a sedentary lifestyle. The within-identical-twin-pair response to the standardized caloric surplus suggests that the amount of fat stored is likely influenced by the genotype. Similar results were essentially obtained in a shorter (22 days) overfeeding experiment (200).

The long-term overfeeding study also revealed that there was six times more variance between pairs than within pairs for the changes in upper body fat and in CT-determined abdominal visceral fat when both were adjusted for the gain in total fat mass. These observations indicate that some individuals are storing fat predominantly in selected fat depots primarily as a result of undetermined genetic characteristics. It also suggests that variations in regional fat distribution are more closely related to the genotype of the individuals than variations in body mass and in overall body composition.

At the beginning of the overfeeding treatment, almost all the daily caloric surplus was recovered as body energy gain, but the proportion decreased to 60% at the end of the 100-day protocol (205). The weight gain pattern followed an exponential with a half-duration of  $\sim 86$  days. We have estimated that the weight gain attained in the experiment would have reached about 55% of the anticipated maximal weight gain had the overfeeding protocol been continued indefinitely (205). The mean body mass gain for the 24 subjects of the 100-day overfeeding experiment was 8.1 kg, of which 5.4 kg was fat mass and 2.7 kg was fat-free mass. Assuming that the energy content of body fat is  $\sim 22$  MJ/kg (9300 kcal/kg, assuming a 100% triglyceride content) and that of fat-free tissue is 2.42 MJ/kg (1020 kcal/kg), then about 63% of the excess energy intake was recovered on the average as body mass changes. This proportion is of the same order as that reported by other investigators (206,207), i.e., between 60% and 75% of total excess energy intake. There were, however, individual differences among the 24 subjects with respect to the amount of fat and fat free tissue gained.

Resting metabolic rate in absolute terms increased by  $\sim 10\%$  with overfeeding. However, the increase was only marginal when expressed by unit of fat-free mass (208,209). The intrapair resemblance for the changes in resting metabolic rate brought about by overfeeding was significant but became nonsignificant when the changes in body mass or body composition were taken into account. The thermic response to food, as assessed

by indirect calorimetry for a period of 4 hours following the ingestion of a 2.4 MJ (1000 kcal) meal of mixed composition, did not increase with overfeeding when resting metabolic rate was subtracted from postprandial energy expenditure (208). In contrast, postprandial energy expenditure and the total energy cost of weight maintenance increased significantly but the increments were mostly due to the gain in body mass. Interestingly, resting metabolic rate and thermic response to a standardized meal did not correlate with the body mass and adiposity changes just as they did not in a separate overfeeding protocol conducted with singletons (210).

Attempts have been made to identify genetic variants that could account for the differences in response to overfeeding among the 12 pairs of twins. No associations were seen between markers in UCP1, UCP2, and UCP3 genes and body weight or body fatness increases (211). On the other hand, the Gln223Arg polymorphism in the LEPR gene was related to plasma leptin induced changes in response to the long-term overfeeding protocol, with the Gln/Glu genotypes experiencing the largest increases, but it was not associated with body mass and adiposity changes (212). In contrast, Gln27Gln twins at the ADRB2 gene gained more weight and subcutaneous fat than other genotypes with exposure to 100 days of overfeeding (213). Finally, the GG twins at an ApaI (restriction enzyme) polymorphism in the IGF2 gene gained more fat mass and subcutaneous fat with overfeeding than the AA and AG twins (214). These exploratory studies with a small sample size suggest that it may be possible to eventually identify the genes and sequence variants responsible for the genotype-overfeeding interaction effects observed in the 100-day overfeeding experiment with identical twins.

## 2 Negative Energy Balance Experiment

Seven pairs of young adult male identical twins completed a negative energy balance protocol during which they exercised on cycle ergometers twice a day, 9 out of 10 days, over a period of 93 days while being kept on a constant daily energy and nutrient intake (204). The mean total energy deficit caused by exercise above the estimated energy cost of body weight maintenance reached 244 MJ. Baseline energy intake was estimated over a period of 17 days preceding the negative energy balance protocol. Mean body weight loss was 5.0 kg and was entirely accounted for by the loss of fat mass. Fat-free mass was unchanged. Body energy losses reached 191 MJ, which represented  $\sim 78\%$  of the estimated energy deficit. Decreases in metabolic rates and in the

energy expenditure of activity not associated with the cycle ergometer protocol must have occurred to explain the difference between the estimated energy deficit and the body energy losses. Subcutaneous fat loss was slightly more pronounced on the trunk than on the limbs as estimated from skinfolds, circumferences, and computed tomography.

The reduction in abdominal visceral fat area was quite striking, from 81 cm<sup>2</sup> to 52 cm<sup>2</sup>. At the same submaximal power output level, subjects oxidized more lipids than carbohydrates after the program as indicated by the changes in the respiratory exchange ratio. Intrapair resemblance was observed for the changes in body weight (Fig. 4, right), fat mass, percent fat, body energy content, sum of 10 skinfolds, abdominal visceral fat, and respiratory exchange ratio during submaximal work. Even though there were large individual differences in response to the negative energy balance and exercise protocol, subjects with the same genotype were more alike in responses than subjects with different genotypes particularly for body fat, body energy, and abdominal visceral fat changes. High lipid oxidizers and low lipid oxidizers during submaximal exercise were also seen despite the fact that all subjects had experienced the same exercise and nutritional conditions for ~3 months.

Thus, changes in body mass, body fat, and body energy content were characterized by more heterogeneity between twin pairs than within pairs. These results are remarkably similar to those we reported earlier for body mass, body fat, and body energy gains with 12 pairs of twins subjected to a 100-day over-feeding protocol.

## VI RECOMMENDATIONS

The evidence reviewed herein suggests a significant genetic component in human obesity. However, the nature of the evidence and the magnitude of the genetic component varied a great deal depending on the phenotype, and the particular type of genetic epidemiological method used. A picture that is clearly emerging from the diverse findings is that multiple genetic loci are involved in human obesity.

In the present context, it may be helpful to distinguish between *primary* and *secondary* obesity genes, which collectively contribute to and determine the variability in obesity. We define *primary genes* as those whose effect sizes may be large enough to be detected. Likewise, the *secondary genes* for human obesity are those whose effects are likely much smaller and their

detection in the context of obesity may be very difficult. The combined effects of the primary genes may be characterized as oligogenic (few genes each with a large enough effect), and the aggregate effects of the secondary obesity genes may be regarded as polygenic (many genes, each with a small effect). Regardless of the terminology, it is commonly recognized that human obesity involves multiple genes, some with large and some with small effects.

While the model-fitting approaches in genetic epidemiology have been largely successful in demonstrating the underlying complexity in the transmission of human obesity, there are limitations in such studies that necessitate alternatives. One limitation arises because most model-fitting approaches are based on largely untestable assumptions. However realistic some of these assumptions may be, there is always some degree of uncertainty. Second, analysis of multilocus traits like obesity requires more advanced and complex models that are mostly lacking or highly specialized (see 29). For example, when segregation analysis based on single-locus models is applied to a trait determined by two genes, it fails to characterize either gene accurately [even though it can sometimes succeed in inferring a gene with a large effect (215)]. Finally, such model-fitting approaches alone are inadequate for evaluating the specific genetic determinants of human obesity, although they are useful in suggesting possible genetic mechanisms. DNA sequence variants in targeted genes are essential.

We believe that an optimum strategy for complex multifactorial traits such as obesity should combine the strengths of three companion methods so as to maximize our chances of finding the primary genes. Only after finding the primary genes can specialized methods be fruitful in finding the secondary genes.

### A Genetic Epidemiological Model-Fitting Approach

While this approach alone is unlikely to yield major findings, the results can guide our subsequent inquiries, especially when multivariate models and longitudinal studies are employed. This approach could be even more useful after finding specific obesity genes using the molecular approaches discussed below. They will aid in evaluating gene-gene and gene-environment interactions and in characterizing the gene effects. They will also enable investigation as to whether any additional familial (genetic) component exists, after accounting for all known obesity genes, something that can motivate the search for additional genes.

## B Genomewide Explorations

A useful method involves nonparametric sibpair linkage using evenly spaced anonymous markers. To maximize the power, we propose that full sibships be used for this purpose. Each sibship should contain at least two sibs, and at least one of them must be obese or very obese. Sampling from the upper tail is known to be more powerful, and hence requires smaller sample sizes (216). Variance components linkage methodology can then be used to exploit the full variability within sibships [e.g., SOLAR (217) and SEGPATH (218)].

For a trait with a sibling correlation of 0.25, to detect a gene with 80% power that explains 27% of phenotypic variance, one needs a sample of 110 sibpairs (220 subjects) where each pair contains at least one sib whose BMI is in the upper decile. One can attain 90% power with 146 such sibpairs (292 subjects). One can also attain 80% power with 47 sibling triplets (141 subjects) or 90% power with 64 triplets (192 subjects), where each triplet contains at least one sib whose BMI is in the upper decile. These calculations are based on single gene models and zero recombination between the trait and marker loci. Multiple trait loci and nonzero recombination both require considerably larger samples. A sample of  $\sim 300$  sibships of varying sizes, each with at least two sibs and at least one of them above the 90th centile, may be regarded as a minimal design.

Since the gene effects are quite likely mediated by a host of lifestyle and other metabolic factors, it is desirable to obtain as much information on each subject as possible, including detailed phenotypic characterizations. That way, the possible role of these covariates can be incorporated in the data analysis. Also, even though the sampling may be based on BMI, the QTL analysis should be performed for each of the correlated phenotypes (e.g., BMI, %BF, etc.). This will maximize the yield, since different genes may primarily contribute to different components of obesity.

## C Implicating Specific Genes and Mutations

The ultimate goal of the studies designed to understand the genetic and molecular basis of human variation in a trait such as obesity is to resolve the issue in terms of the specific genes and DNA sequence variants. As a result of the advances in the sequencing of the human genome by the public and private institutions,  $\sim 55\%$  of the sequence is now said to be complete and highly reliable. In addition, a draft sequence is also available for  $> 90\%$  of the human genome. For a substantial fraction of the

genome, a reasonably reliable physical map can thus be defined. For some chromosome regions, a complete and fully reliable sequence map exists.

These advances together with the progress in the development of large panels of single nucleotide polymorphisms (SNPs), the availability of efficient high throughput sequencing technologies, and the large repertoire of mapped expressed sequences (ESTs) have increased the ability of investigators to resolve genetic effects in terms of genes and sequence differences. The investigator is typically confronted with two different situations. In the first case, a strong candidate gene has been identified through a variety of strategies, e.g., based on physiopathological reasoning, evidence from a knockout mouse, etc. The goal then becomes one of establishing whether DNA sequence variation in this gene contributes to human heterogeneity in the trait of interest. Informative SNPs and sequencing of targeted regions of the gene such as exons, intronic splicing sequences, short and long promoter regions among affected and nonaffected carefully matched subjects would be the methods of choice. Alternatively, one could apply the same technologies to a large sample of unrelated subjects exhibiting considerable heterogeneity in phenotype and test for genotype differences using a variety of statistical tools.

In the second case, a candidate chromosomal position (for instance, a QTL from a genomic scan) is the starting point. The inventory of genes and ESTs encoded in the region covered by the QTL does not yield strong candidate genes or generate a number of candidate genes, but none with compelling evidence to justify taking it to the next step (see first case). This case is decidedly more complex. The strategy described below will clearly work best when a valid physical map of the region is available.

Increasing the density of polymorphic markers to narrow the size of the DNA fragment underlying the QTL is a critical first step. Adding such markers may typically reduce the size of the chromosomal segment of interest to about one or two megabases. Further decrease in the size of the region can often be achieved by typing a number of SNPs to cover the entire QTL. A combination of single SNP and haplotype studies are then conducted, using association analytical strategies as well as quantitative TDT analysis (QTDT). Constant comparisons between the results of such studies and the features of the physical map and panels of candidate genes and ESTs are absolutely necessary, the goal being to evolve toward one or a few candidate genes or a fragment size amenable to sequencing studies. The

success of this complex process is highly dependent on the quality and informativeness of the populations of normal weight and obese subjects upon which the project is anchored.

Finally, when some obesity genes are found, it would be very useful to type these genes in a large random sample. This will enable estimation of the relevant gene frequencies in the underlying population. More importantly, detailed phenotypic characterization and studies of additional covariates will enable characterization of the gene effects and investigations of gene-gene and gene-environment interactions. This can be achieved through one of several means, for example, by regression of a phenotype (say %BF) on all covariates, measured genotypes, and interactions among them.

This chapter summarizes the data pertaining to the heritability and the contribution of major genes for phenotypes of total body fat and fat topography based on the genetic epidemiology methods. The evidence for a contribution of genetic-environment interaction effects to variation in body mass, body fat, and fat distribution was also considered. The current status of associated and linkage studies conducted on human samples was reviewed. Finally, the chapter suggests a variety of strategies to optimize the search for the genes associated with the susceptibility to obesity and to define the inheritance patterns. This overview of the available evidence highlights the need for the development of longitudinal databases that will increase the chance of untangling causes versus effects of positive energy balance.

#### APPENDIX Symbols, Full Names, and Cytogenetic Location of Genes and Loci Listed in this Chapter\*

| Gene or locus | Name                                   | Location     |
|---------------|--|--------------|
| <b>A</b>      |  |              |
| ACP1          | Acid phosphatase 1, soluble            | 2p25         |
| ADA           | Adenosine deaminase                    | 20q12-q13.11 |
| ADRB2         | Adrenergic, beta-2-, receptor, surface | 5q31-q32     |
| ADRA2A        | Adrenergic, alpha-2A-, receptor        | 10q24-q26    |
| ADRA2B        | Adrenergic, alpha-2B-, receptor        | 2p13-q13     |
| ADRB3         | Adrenergic, beta-3-, receptor          | 8p12-p11.2   |
| AGT           | Angiotensinogen                        | 1q42-q43     |

| Gene or locus | Name  | Location      |
|---------------|---|---------------|
| AK1           | Adenylate kinase 1  | 9q34.1        |
| ANG           | Angiogenin, ribonuclease, RNase A family, 5   | 14q11.1-q11.2 |
| APM1          | Adipose most abundant gene transcript 1, adiponectin                                    | 3q27          |
| APOA4         | Apolipoprotein A-IV   | 11q23         |
| APOB          | Apolipoprotein B (including Ag (x) antigen)   | 2p24-p23      |
| APOD          | Apolipoprotein D  | 3q26.2-qter   |
| ASIP          | Agouti (mouse) signaling protein  | 20q11.2-q12   |
| ATP1A2        | ATPase, Na <sup>+</sup> K <sup>+</sup> transporting, alpha 2 (+) polypeptide            | 1q21-q23      |
| ATP1B1        | ATPase, Na <sup>+</sup> K <sup>+</sup> transporting, beta 1 polypeptide                 | 1q22-q25      |
| ATRN          | Attractin (with dipeptidylpeptidase IV activity)  | 20p13         |
| B, C          |   |               |
| BBS2          | Bardet-Biedl syndrome 2 gene  | 16q21         |
| BBS4          | Bardet-Biedl syndrome 4 gene  | 15q22.3-q23   |
| BF            | B-factor, properdin   | 6p21.3        |
| BSCL2         | Berardinelli-Siepp congenital lipodystrophy 2 gene                                      | 11q13         |
| CART          | Cocaine- and amphetamine-regulated transcript   | 5q            |
| CAV2          | Caveolin 2  | 7q31.1        |
| CBFA2T1       | Core-binding factor, runt domain, alpha subunit 2; translocated to, 1; cyclin D-related | 8q22          |
| CCKAR         | Cholecystokinin A receptor  | 4p15.2-p15.1  |
| CCKBR         | Cholecystokinin B receptor (or gastrin receptor)  | 11p15.4       |
| CD36L1        | CD36 antigen (collagen type I receptor, thrombospondin receptor)-like 1                 | 12q24.1-q24.3 |
| CPE           | Carboxypeptidase E  | 4q32          |
| D-F           |   |               |
| DRD2          | Dopamine receptor D2  | 11q23         |
| ESD           | Esterase D/formylglutathione hydrolase  | 13q14.1-q14.2 |

| Gene or locus | Name   | Location      | Gene or locus | Name   | Location      |
|---------------|--|---------------|---------------|--|---------------|
| ESR1          | Estrogen receptor 1  | 6q25.1        | HTR2A         | 5-hydroxytryptamine (serotonin) receptor 2A                      | 13q14-q21     |
| FABP2         | Fatty acid binding protein 2, intestinal   | 4q28-q31      | HTR2C         | 5-hydroxytryptamine (serotonin) receptor 2C                      | Xq24          |
| FBS           | Fanconi-Bickel syndrome  | 3q26.1-q26.3  | IGF1          | Insulin-like growth factor 1 (somatomedin C)                     | 12q22-q23     |
| FGR3          | Fibroblast growth factor receptor 3 (achondroplasia, thanatophoric dwarfism)             | 4p16.3        | IGF1R         | Insulin-like growth factor 1 receptor                            | 15q25-q26     |
| FGF13         | Fibroblast Growth Factor 13  | Xq26          | IGF2          | Insulin-like growth factor 2 (somatomedin A)                     | 11p15.5       |
| G-I, K<br>GCK | Glucokinase (hexokinase 4, maturity onset diabetes of the young 2)                       | 7p15.3-p15.1  | IGKC          | Immunoglobulin kappa constant                                    | 2p12          |
| GHRH          | Growth hormone releasing hormone   | 20q11.2       | INS           | Insulin  | 11p15.5       |
| GHRHR         | Growth hormone releasing hormone receptor  | 7p14          | INSR          | Insulin receptor   | 19p13.3-p13.2 |
| GLO1          | Glyoxalase I   | 6p21.3-p21.1  | IRS           | Insulin Resistance syndromes                                     | 19p13.3       |
| GNAS1         | Guanine nucleotide binding protein (G protein), alpha stimulating activity polypeptide 1 | 20q13.2-q13.3 | IRS1          | Insulin receptor substrate 1                                     | 2q36          |
| GNB3          | Guanine nucleotide binding protein (G protein), beta polypeptide 3                       | 12p13         | ISL1          | ISL1 transcription factor, LIM/homeo-domain (islet-1)            | 5q22.3        |
| GPC3          | Glypican 3   | Xq26.1        | KEL           | Kell blood group   | 7q33          |
| GPC4          | Glypican 4   | Xq26.1        | L             |  |               |
| GRL           | Glucocorticoid receptor  | 5q31-q32      | LDLR          | Low-density lipoprotein receptor (familial hypercholesterolemia) | 19p13.3       |
| GYPA          | Glycophorin A (includes MN blood group)  | 4q28.2-q31.1  | LEPR          | Leptin receptor  | 1p31          |

## Molecular Genetics of Rodent and Human Single Gene Mutations Affecting Body Composition

**Streamson Chua, Jr., Kathleen Graham Lomax, and Rudolph L. Leibel**

Columbia University College of Physicians and Surgeons, New York, New York, U.S.A.

### I INTRODUCTION

The existence of a biological basis for the regulation of body composition was established by the characterization of rodent models of obesity caused by single gene mutations and experimental hypothalamic lesions (1). Obesity induced by hypothalamic lesions clearly demonstrated the major impact of the central nervous system and the neuroendocrine system in regulating ingestive behavior and energy expenditure. The identifications of the leptin/leptin receptor and the melanocortin systems by molecular genetics and positional cloning methodologies provided clear molecular and cellular substrates for the interactions between peripheral tissues (adipocytes in the case of leptin, and pancreatic beta cells in the case of insulin) and the brain. Other elements of the neuroendocrine system such as growth hormone, cortisol, thyroid hormone, and sex steroids/gonadotropins influence the disposition of ingested calories toward expenditure or storage in various tissues as specific molecules ("partitioning"). This chapter reviews the insights regarding the control of energy homeostasis that have come from the identification and functional characterization of the monogenic mouse obesities and their human orthologs.

Obesity is the presence of excessive adipose tissue. The excess can be absolute, relative to lean tissue,

or (in most clinical instances) both. Excess absolute fat mass can be achieved only by a chronic positive imbalance between energy intake and expenditure. In humans and animals in which such imbalance is induced by manipulation of diet or the central nervous system (CNS), the increments of body fat are usually greater (out of proportion) to gains in lean body mass, resulting in increased absolute and relative fat mass. It is possible, however, to preferentially affect body composition (vs. mass) by metabolic shunting (partitioning) of ingested calories to fat (by virtue of metabolic "steal" or deficient fatty acid oxidation in muscle), hyper- or hypoplastic development of adipose tissue (SREBP) or muscle (myogenin). Rodent obesities due to primary derangements of energy intake, expenditure, and partitioning have been identified and are described below. Our discussion of rodent obesities is focused primarily on those occurring as a result of spontaneous mutations in single genes. Induced mutations and studies of quantitative trait loci (QTLs) modifying body composition have been extremely important in helping to understand the molecular physiology of weight regulation. Several of these are discussed here when they shed light on major pathways affected by the spontaneous mutations. Otherwise, these genes are described elsewhere in this handbook.

## II NATURALLY OCCURRING SINGLE GENE OBESITY MUTATIONS IN RODENTS

### A Agouti-Yellow (Dominant Yellow Allelic Series)

The yellow mutation ( $A^y$ ) is a dominant allele, as are the other alleles that produce yellow pigmentation and obesity (MGI accession ID 87853). The original yellow mutation is descended from a mutation that arose in the so-called Japanese “mouse fancy” that involved collection and display of unusual-looking mice. Other dominant yellow mutations have been collected as part of an interesting allelic series. Mice carrying any one of these dominant yellow mutations are obese (2). The degree of obesity correlates with the amount of yellow pigmentation, suggesting that the degree of expression of the agouti protein is directly responsible for producing obesity. The yellow obese mice exhibit increased linear growth, reflecting an auxotrophic effect of their increased caloric intake. Obesity is not clearly manifest until the mice are adults (6–8 weeks), although hyperphagia is present prior to the development of obesity. The hyperphagia is a major factor in the development of obesity since pair-feeding yellow mutant mice to wild type mice produces yellow mice of near normal body fat content (3). Diabetes and glucose intolerance are associated with the obesity of yellow mice. The yellow mice are mildly insulin resistant, with elevated fasting insulin levels. The diabetes syndrome is clearly regulated by other genetic factors, as genetic background controls diabetes risk. On the C57BL/6J background, obese yellow mice are nearly euglycemic and mildly glucose intolerant. With the yellow mutation on the KK background, obese yellow mice are hyperglycemic (4). Both sexes of the yellow mice are fertile, although fertility is reduced as the obesity increases (Table 1).

The original  $A^y$  mutation is due to a large deletion of the 5' region of the agouti gene and a neighboring gene, *Raly* (hnRNP-associated with lethal yellow). The deletion juxtaposes the ubiquitously and strongly expressed *Raly* promoter to the agouti coding sequence, causing expression of agouti mRNA in all tissues (5,6). The other dominant yellow alleles arise owing to insertion of retroviral sequences (6,7) that juxtapose the promoter elements of their long terminal repeats (LTRs) to drive expression of the agouti coding sequence. Presumably, either the specific LTR sequence or the insertion site determines the strength of expression of the agouti allele. Indeed, the  $A^{vy}$  allele displays variable expression such that pseudo-agouti individuals are observed that

are lean and nonyellow. Whereas the  $A^y$  mutation is lethal in the homozygous state because the *Raly* gene product is required during embryogenesis, the other yellow alleles are viable in the homozygous state since the *Raly* locus has not been affected.

A large number of dominant yellow mutations have been described, and almost all are due to retroviral insertions between the agouti coding sequences and its various promoters. The large (>100 kbp) distance, between the proximal hair cycle-specific promoters and the ventral hair-specific promoter is probably responsible for the frequency of insertional mutations within the agouti gene. The agouti gene's large size also makes it a good target in x-irradiation mutagenesis screens that have produced numerous agouti alleles. In fact, it was the availability of numerous deletions and rearranged alleles of agouti that aided in its initial identification by positional cloning.

#### 1 Molecular Clues to the Identification of *Agouti* (agouti signaling protein = ASP)

The large number of dominant and recessive alleles, comprising deletions, insertions, and inversions, were extremely helpful in the eventual cloning of *Agouti* (8,9). At the time of agouti's identification, genomics tools such as detailed chromosomal maps and large insert clone libraries were either crude or nonexistent. The task was made easier by fortuitous events, such as the discovery of a large inversion that simultaneously produced two new alleles of *Agouti* and *limb deformity*. This allele provided a molecular breakpoint that was within the *Agouti* gene and allowed the accurate mapping of molecular probes to *Agouti* and the eventual realization that the  $A^y$  mutation was due to a large deletion. The application of electrophoretic separation of DNA fragments in the 100 kbp to 1 Mbp by pulsed-field gel electrophoresis was instrumental in this discovery. However, most deletions result in a loss-of-function mutation, and further work was needed to account for the dominant nature of some agouti mutations. The eventual identification of the molecular basis of the gain-of-function mutation was foreshadowed by the identification of a ubiquitously expressed fusion transcript that was the result of splicing the 5' untranslated region of an ubiquitously expressed gene (*Raly*) to a gene that was normally expressed exclusively in skin (*Agouti*) (10,11) (Fig. 1).

Ectopic Agouti (ASP) overexpression causes obesity mainly by causing hyperphagia. ASP is an antagonist of melanocortin receptors with an affinity in the nanomolar range (12). The melanocortin receptors are

a family of G protein coupled receptors that cause intracellular accumulation of cAMP upon binding of melanocyte-stimulating hormone (MSH). ASP inhibits the accumulation of cAMP by MSH stimulation. Since the loss of melanocortin receptor 4 (MC4R) causes hyperphagia and obesity (13), ASP overexpression in the brain leads to inhibition of MC4R, simulating the syndrome of MC4R deficiency. Single ICV injections of agouti-related protein (AGRP) increase food intake for up to 7 days (14), indicating the powerful antagonistic effect of this protein on MC4R activity. In addition, the relative binding affinities of agouti and MSH for MC4R differ by nearly an order of magnitude: ASP binds to MC4R in the low nanomolar range while MSH binds to MC4R between 20 and 40 nM (15). This discrepancy highly favors the inhibitory effect of agouti on MC4R and the induction of hyperphagia.

It has been suggested that ASP acts as an inverse agonist at the melanocortin receptors. Inverse agonists are ligands that suppress spontaneous receptor signaling. In the case of inducing hyperphagia, it is possible that ASP acts by suppressing spontaneous activity of melanocortin receptors, MC3R and MC4R, in addition to antagonizing MSH stimulation.

## 2 Normal Action of *Agouti* and Various Alleles of *Agouti*

The agouti gene (ASP) is normally expressed only in the skin, acting as a paracrine factor on melanocytes. The intermittent expression of ASP and the continuous expression of MSH are responsible for the alternate bands of eumelanin (black pigment produced during MSH action) and pheomelanin (yellow pigment under ASP control/lack of MSH stimulation) on hair follicles of agouti-pigmented rodents (16). Eumelanin is a brown/black pigment produced by the combined action on tyrosine of at least three enzymes: tyrosinase, TRP1 (tyrosinase-related protein 1), and TRP2 (17). Pheomelanin is a yellowish pigment also derived from the action of tyrosinase on tyrosine. Only tyrosinase, in the presence of cysteine, is required to produce pheomelanin. ASP action reduces total melanin content through inhibition of tyrosinase, and near complete inhibition of TRP1 and TRP2 activity. The actual ratio of eumelanin to pheomelanin is altered by ASP such that more pheomelanin than eumelanin is produced. This is an important point to consider since reductions of tyrosinase activity, as seen in hypomorphic mutations of tyrosinase, result in a reduction of eumelanin content without significant alterations in pheomelanin content.

An understanding of this capacity of agouti could be relevant to the various actions of ASP, AGRP (see below), and MSH within the hypothalamus and their effects on food intake and energy balance.

In the *A<sup>w</sup>* (Agouti white belly) allele, an upstream skin-specific promoter causes increased ASP expression in ventral (abdominal) skin which causes a further decrease in pigment deposition, resulting in a light cream to white pigmentation (16). Interestingly, black mice of the C57 strains and other derivatives are due to a retroviral insertion before the first coding exon of agouti such that no Agouti mRNA is detected (7). It has not been determined whether the inserted VL30 element interferes with transcription of the agouti gene or splicing of the agouti transcript, or both. Several embryonic lethal *a* alleles are the result of large deletions that span the *Agouti* and *Raly* genes. Agouti expression is normally restricted to skin in rodents, although human adipocytes express ASP at low levels.

## 3 Pigmentation Phenocopies of Agouti Alleles Generated by Alleles at *Mclr*

So-called recessive yellow is another mutation in mice that produces yellow fur. It is a recessive allele of an allelic series at the *Extension* locus that encodes a skin-specific MSH receptor, MC1R. The recessive yellow allele inactivates the *Mclr* gene, producing a pigmentation phenocopy of the dominant yellow mutation, without producing obesity (18). This observation also suggested that the brain melanocortin receptors were primarily responsible for the obesity resulting from ectopic overexpression of agouti. Interestingly, semi-dominant point mutations that produce constitutively active MC1R alleles of *Mclr* produce darkening of pigmentation such that homozygotes are indistinguishable from nonagouti mice (*a/a*).

## 4 Modifiers of *Agouti* Action—*Mahogany* (*Attractin*) and *Mahoganoid* *Mahogunin*

Two genes modifying Agouti action have been identified by virtue of their ability to darken agouti pigmentation—*mahogany* and *mahoganoid*. Both of these loci appear to act as codominants; homozygosity produces a dark coat that is dissimilar to pure black (*a/a*) coloration due to the persistence of yellow pigment (19). The *mahogany* locus results from inactivating mutations of *Attractin* (20), whereas *mahoganoid* remains to be characterized in molecular terms. Attractin was initially described as a human serum glycoprotein that caused the spreading of monocytes that attract nonproliferat-

| Gene   | Gene product                   | Location/mouse and human  | Nature of mutation   | Knockout model, rodent phenotype  | Human phenotype  | Ref's.       |
|--|--------------------------------|---|--|---|--|--------------|
| <i>ASIP</i> (mouse: <i>Agouti</i> , <i>A<sup>y</sup></i> ) | Agouti signaling protein       | Mouse: 2 at 89; human: 20q11.2  | Deletion   | In mice with "lethal yellow" <i>A<sup>y</sup></i> and "viable yellow" <i>A<sup>y</sup></i> mutations, agouti is ectopically overexpressed; yellow coat, obesity, hyperphagia, hypereinsulinemia, increased linear growth.   | None reported  | (11,49)      |
| <i>BRS3</i>  | Bombesinlike receptor 3        | Mouse: X; human: Xq26-q28   | Generated <i>Brs3</i> -null mice by rendering male mice hemizygous for deletion of <i>Brs3</i> by homologous recombination in embryonic stem cells | Mice without <i>Brs3</i> develop obesity due to hyperphagia and have slight decrease in physical activity and reduced metabolic rate.   | None reported  | (273)        |
| <i>CCKAR</i>   | Cholecystokinin receptor       | Mouse: 5 at 34; human: 4p15.2-p15.1   | Deletion of, promoter and 1st 2 exons, prevents synthesis of mature transcript   | Spontaneously mutant OLETF rat with adult-onset obesity, hyperphagia, males with impaired glucose tolerance.  | 1. het Gly21Arg in obese, NIDDM African-American; 2. Val365Ile obese African-American; 3. aberrant splicing of exon 3, predicted to result in a nonfunctional receptor, in 1 obese patient with cholesterolgallstone disease | (274,275)    |
| Callipyge locus  |                                | Not reported locus/gene   | Polar overdominance where paternally imprinted mutant allele only produces effect in heterozygous state  | Spontaneous mutation in sheep associated with increased muscle mass in hindquarters of sheep  | None reported  | (276)        |
| <i>CEBP</i> ( <i>alpha</i> , <i>beta</i> , <i>gamma</i> )  | CCAAT/enhancer binding protein | <i>Cebpa</i> : mouse: Chr. 7 at 12; human: 19q13.1<br><i>Cebpb</i> : mouse: Chr. 2 at 95.5; human: 20q13.1<br><i>Cebpg</i> : mouse: not reported<br><i>Cebpe</i> : mouse: Chr. 14 at 20.5; human: 14q11.2 | Targeted deletions   | <i>Cebpa</i> homozygous KO mice die hours after birth. Mice doubly homozygous for KO of <i>Cebpb</i> / <i>γ</i> also have increased neonatal mortality and reduced fat pad weight. Decreased fat content likely due to impaired differentiation of preadipocytes. | None reported (mutations in <i>CEBPα</i> have been found in humans with acute myeloid leukemia)  | (277)        |
| <i>CPE</i>   | Carboxy peptidase E            | Mouse: Chr. 8 at 32.6; human: 4q32  | S202P mutation abolishes activity of enzyme  | Knockout mice have misrouting and unregulated secretion of POMC; late-onset, moderate obesity, early and severe hyperproinsulinemia, transient hyperglycemia.   | None reported with <i>CPE</i> . See <i>PCSK1</i> (i.e., <i>PC1</i> ) that acts just proximal to CPE in posttranslational processing of proinsulin, POMC, GH, CCK, neurotensin, MCH, and gastrin.                             | (49,149,278) |

|              |  |                                  |  |  |  |           |
|--------------|--|----------------------------------|--|--|--|-----------|
| <i>DGAT</i>  | Diacylglycerol acyltransferase (i.e., <i>ARGPI</i> )                         | Mouse: 15 at 46.9; human: 8qter  | Targeted disruption  | <i>Dgat</i> -deficient mice are viable and still synthesize triglycerides; are lean and resistant to diet-induced obesity. The obesity resistance involved increased energy expenditure and increased activity.  | None reported  | (279)     |
| Dopamine     |  |                                  |  | Selective loss of DA only w/in DA neurons obtained by knock-in using homologous recombination. 1st: TH locus inactive by homologous recombination; TH activity reconstituted in noradrenergic cells by insertion of functional TH construct within DBH locus   |  |           |
| <i>DBH</i>   | Dopamine beta hydroxylase  | Mouse: 2 at 15.5; human: 9q34    | Targeted gene inactivation (unable to synthesize noradrenaline or adrenaline)  | DA-deficient mice hypoactive, aphagic, adipsic several weeks after birth; similar to aphagic/adipsia syndrome caused by bilateral lesions of lateral hypothalamus. Near-normal growth achieved with L-DOPA treatment. These mice were cold intolerant (impaired peripheral vasoconstriction); unable to induce thermogenesis in BAT (brown adipose tissue) through uncoupling protein (UCP); increased food intake but not obese because BMR (basal metabolic rate) was also elevated. (Increased BMR not due to hyperthyroidism, compensation by UCP2, or shivering.) | Similar phenotype in subjects with bilateral lesions of lateral hypothalamus   | (280)     |
|              |  |                                  |  | None reported  | None reported  | (280,281) |
| <i>FGF13</i> | Fibroblast growth factor 13 (i.e., FHF2)                                     | Mouse: X at 18; human: Xq26.3    | Gene within duplication breakpoint interval  | None reported.   | Borjeson-Forsman-Lehmann: mental retardation, obesity, short stature, epilepsy   | (232)     |
| <i>GNAS1</i> | Guanine nucleotide-binding protein, alpha stimulating activity polypeptide 1 | Mouse: 2 at 104; human: 20q13.2  | 16 Mutations described in AHO patients; some create premature stop codons, others increase GDP (guanosine diphosphate) release | Homozygous deficiency is lethal in embryonic period. Evidence for imprinting as heterozygotes with maternal null allele have different phenotypes from heterozygotes with paternal null allele.  | 1. Albright Hereditary Osteodystrophy (AHO): skeletal and developmental abnormalities, mental retardation, obesity; 2. McCune Albright syndrome; 3. pituitary tumors | (282)     |
| <i>GPC3</i>  | Glypican 3   | Mouse: not reported; human: Xq26 | 1. 13 bp del NT391<br>2. exon 2 del<br>3. Trp296Arg<br>4. IVS5, G-T, + 1 (premature stop)<br>5. Arg199Ter                      | None reported.   | Simpson-Golabi-Beihel 1: obesity, X-linked overgrowth syndrome with associated visceral and skeletal abnormalities   | (253)     |
| <i>GPC4</i>  | Glypican 4   | Mouse: X at 16; human: Xq26      | Deletion of last 2 exons <i>GPC3</i> and entire <i>GPC4</i> gene   | None reported.   | Simpson-Golabi-Beihel 1: obesity, X-linked overgrowth syndrome with associated visceral and skeletal abnormalities   | (283)     |

Table 1 (continued)

| Gene         | Gene product                              | Location/mouse and human         | Nature of mutation   | Knockout model, rodent phenotype  | Human phenotype   | Refs.                    |
|--------------|---|----------------------------------|--|---|---|--------------------------|
| <i>GHRHR</i> | Growth hormone-releasing hormone receptor | Mouse: 6 at 26; human: 7p15-p14  | Spontaneous mutation in “lit” mice; inactivating mutation                              | <i>lit/lit</i> mice have increased adipose tissue at weaning despite normal intake—partitioning preferentially into fat.  | Glu72TER and IVS1, G-A, +1; in 2 first cousins from a consanguineous Indian Muslim family; extremely short and no GH secretion in response to provocative stimulation | (284–287)                |
| <i>HMGIC</i> | High mobility group protein isoform I-C   | Mouse: 10 at 67.5; human: 12q15  | Inactivation in pygmy mice   | Homozygous KO mice have dwarfing phenotype corresponding to reduced cell replication during fetal development; partially resistant to obesity-inducing effects of leptin deficient and high fat diet.   | Mutations found in several benign and malignant tumors; especially found in lipomas   | (288–290)                |
| <i>IGF2</i>  | Insulin-like growth factor 2              | Mouse: 7 at 69.1; human: 11p15.5 | Transactivation in mouse model of Sun; targeted disruption in mouse model of DeChiara  | <b>Sun model:</b> mice with overexpression of <i>Igf2</i> developed most of the signs of Beckwith-Wiedemann syndrome, including prenatal overgrowth, polyhydramnios, fetal/neonatal lethality, disproportionate organ overgrowth (including tongue) and skeletal abnormalities.<br><b>DeChiara model:</b> Transmission paternally: heterozygotes were growth deficient. When transmitted maternally, heterozygotes phenotypically normal. Only the paternal allele was expressed in embryos (except in the choroid plexus and leptomeninges) where both alleles transcribed). | Overexpressed in Wilms’ tumor and in some cases of Beckwith-Wiedemann syndrome; regulated by genomic imprinting, with maternal allele inactive in most normal tissues | (291,292)                |
| <i>LEP</i>   | Leptin                                    | Mouse: 6 at 10.5; human: 7q31.3  | 1. guanine deletion, codon 133 (G <sub>398</sub> )<br>2. C→T, codon 105, exon 3; R105W | <i>Lepr<sup>ob</sup></i> mice; early-onset, severe obesity, hyperphagia, hypercortisolemia, defective thermogenesis.  | Early-onset, severe obesity, hypogonadotropic hypogonadism in 4 individuals (2 consanguineous families each with 2 affecteds)   | (49,166,170,278,293,294) |

|              |   |  |  |   |  |                                 |
|--------------|---|--|--|---|--|---------------------------------|
| <i>LEPR</i>  | Leptin receptor                                       | Mouse: 4 at 46.7; human: 1p31  | G→A in 3' splice donor site of exon 16   | <i>Lep<sup>ob</sup></i> mice; early-onset, severe obesity, hyperphagia, hypercortisolemia, defective thermogenesis.   | Early-onset, severe obesity, hypogonadotropic hypogonadism moderately growth hormone deficient, central hypothyroidism in 3 sisters of highly consanguineous family  | (49,180,278,293,294)            |
| <i>MCHR</i>  | Melanocortin 4 receptor                               | Mouse: not reported; human: 18q21.3  | 27 Different mutations in humans published; most are missense (for example Ser30Phe) with 2 frameshift (GATT insertion in codon 244; CTCT deletion codon 211), 1 nonsense (Tyr35 STOP), 1 loss of function (deletion of 18q) | <i>Mchr</i> <sup>-/-</sup> mice; late-onset dominant obesity, hyperphagia, hyperinsulinemia, hyperglycemia; <sup>-/-</sup> mice don't respond to anorectic actions of MSH agonist; do not respond to inhibitory effects of leptin on feeding. Do respond to orexigenic actions of NPY and PYY and to anorectic actions of CNTF and CRF. | Majority of reported cases in morbidly obese subjects with childhood onset hyperphagia. In some studies, up to 5% of subjects with BMI > 40 were heterozygous for <i>MCHR</i> mutations.                           | (13,49,189,190,192,278,293,294) |
| <i>MCH</i>   | Melanocyte concentrating hormone (i.e., <i>PMCH</i> ) | Mouse: Chr. 10 at 47; human: 12q23-q24   | Targeted deletion  | MCH-deficient mice had reduced body weight and leanness due to hypophagia, inappropriately increased metabolic rate, reduced amount of both leptin and arcuate nucleus POMC mRNA. MCH is critical regulator of feeding and energy balance, acts downstream of leptin and the melanocortin system.                                       | None reported  | (295)                           |
| <i>MKKS</i>  | McKusick-Kaufman syndrome gene                        | Mouse: not reported; human: 20p12 BBS6 mutations: compound heterozygote for Leu277Pro and 280delT; cnp'd het for Gly52Asp and 1679T→A, Tyr264toTer, Y264STOP; homo for 2 deletions 1316delC and 1324-1326 delGTA; Tyr264Ter; lbp del, 280T; Thr57Ala | <b>Bardet-Biedl syndrome type 6:</b> patients with complete loss of function mutations: <b>MKKS</b> subjects with variety and missense mutations   | None reported.  | <b>BBS6:</b> mental retardation, obesity, postaxial polydactyly, retinopathy, renal malformations<br><b>MKKS:</b> developmental anomalies include hydrometrocolpos postaxial polydactyly, congenital heart disease | (223,224,228,296-299)           |
| <i>MYO9A</i> | Myosin IX A   | Mouse: 9 at 33; human: 15q22-q23   | None reported, but gene within region of BBS4  | None reported.  | Bardet-Biedl syndrome type 4 ( <b>BBS4</b> ): mental retardation, obesity, postaxial polydactyly, retinopathy, renal disease   | (300)                           |

Table 1 (continued)

| Gene                          | Gene product  | Location/mouse and human                  | Nature of mutation  | Knockout model, rodent phenotype   | Human phenotype | Refs.     |
|-------------------------------|---|---|---|--|-----------------|-----------|
| <i>MYOD1</i>                  | Myogenin (MYOD regulates skeletal muscle differentiation; essential for repair of damaged tissue) | Mouse: 7 at 23.5; human: 11p15.4          | KO  | Myogenin-deficient mice are born alive but immobile; die perinatally due to lack of skeletal muscle.   | None reported   | (301,302) |
| <i>GDF8</i> / aka <i>MSTN</i> | Growth differentiation factor 8; i.e., Myostatin  | Mouse: 1 at 27.8; human: 2q32.1           | Gene targeted disruption; deletion (double muscled cattle); autosomal recessive ( <i>cmpt</i> mice) | <b>Gdf8-null mice</b> are significantly larger than wildtype or with large and widespread increase in skeletal muscle mass; (individual muscles of mutants weigh 2–3× more than wt), and the increase in mass appears to result from a combination of muscle cell hyperplasia/hypertrophy— <i>Gdf8</i> may function as a negative regulator of skeletal muscle growth.<br><br>-‘compact’ ( <b>cmpt</b> ) mice are hypermuscular; caused by deletion in the myostatin gene.<br><br>- <b>double muscled cattle</b> have 20% increased muscle mass due to general skeletal muscle hyperplasia—mutation in <i>Gdf8</i> .<br><br>Homozygotes exhibit progressive adult-onset obesity and hypogonadism; male <i>Nhlh2</i> –/– mice are microphallic, hypogonadal, and fertile. Female <i>Nhlh2</i> –/– mice reared alone are hypogonadal; when reared with males, their ovaries and uteri develop normally and they are fertile. | None reported   | (303–305) |
| <i>Nhlh2</i>                  | Nescient helix-loop-helix 2; also known as <i>HEN2</i> and <i>NSCL2</i>                           | Mouse: Chr. 3 (syntenic); human: 1p12-p11 | Targeted deletion   | None reported  | None reported   | (306)     |
| <i>NPY</i>                    | Neuropeptide Y/receptors  | Mouse: Chr. 6; human: 7p15.1              | Double mutant mice; NYP-null, leptin-null   | <i>ob/ob</i> mice deficient in NPY; mice were less obese due to reduced food intake and increased energy expenditure, and were less severely affected by diabetes, sterility, and somatotropic defects.  | None reported   | (307)     |

|                     |  |   |  |  |   |               |
|---------------------|--|---|--|--|---|---------------|
| <i>PCSK1</i>        | Proprotein convertase subtilisin/kexin type 1; also known as PC1 | Mouse: 13 at 44; human: 5q15-q21                | Compound heterozygote: Gly483Arg. A→C <sup>+</sup> 4, exon 5 donor splice site   | None reported.   | One woman with extreme childhood-onset obesity, hypogonadotropic hypogonadism, low ACTH/low cortisol  | (293,308)     |
| <i>PLIN</i>         | Perilipin  | Mouse: Chr. 7 is syntenic; human: 15q26         | Targeted disruption; KO  | <p>None reported.</p> <p><b>Pin null mice</b> consumed more food than controls but were leaner, more muscular and had normal body weight. Also, null mice were resistant to diet-induced obesity.</p> <p><b>KO mice:</b> 30% less adipose tissue mass in null mice than wt with equal food intake; isolated adipocyte of perilipin null mice exhibited elevated basal lipolysis and dramatically attenuated stimulated lipolytic activity; plasma leptin in null animals greater than expected for the reduced fat mass. Null mice had greater lean body mass and increased metabolic rate but they also showed an increased tendency to glucose intolerance and peripheral insulin resistance. When fed high-fat diet, the perilipin null mice were resistant to diet-induced obesity but not to glucose intolerance.</p> | None reported   | (309,310)     |
| <i>PMM2</i>         | Phosphomannomutase 2   | Mouse: Chr. 16 (syntenic); human: 16p13.3-p13.2 | Nearly 60 mutations described, most in exons 5 and 8; 90% accounted for by F119L and R141H   | None reported.   | Congenital disorder of glycosylation type Ia: psychomotor retardation, growth retardation, moderate obesity, serum glycoprotein abnormalities | (311)         |
| <i>POMC</i>         | Pro-opiomelanocortin   | Mouse: Chr. 12 at 4; human: 2p23.3              | 16 Published mutations in humans; half are silent  | Hyperphagia, obesity, hypoplastic adrenal cortex due to low ACTH, light skin and hair pigmentation.  | 3 yo female, 30 kg; 7 yo boy, 50 kg; early-onset obesity, red hair pigmentation, ACTH deficiency  | (40,194)      |
| <i>PPAR gamma 2</i> | Peroxisome proliferator activated receptor gamma 2               | Mouse: Chr. 6 at 52.7; human: 3p25              | 5 Published mutations related to obese phenotype: Pro115Gln missense mutation; Pro12Ala; His478His; helix 12 destabilizing mutations | <p><i>Pparg2</i> heterozygote mice (homozygous KO is lethal) have improved insulin sensitivity, overexpress and hypersecrete leptin, have smaller adipocytes and reduced fat mass.</p>   | 4 cases of Pro115Gln mutation in adults with marked obesity   | (278,293,312) |

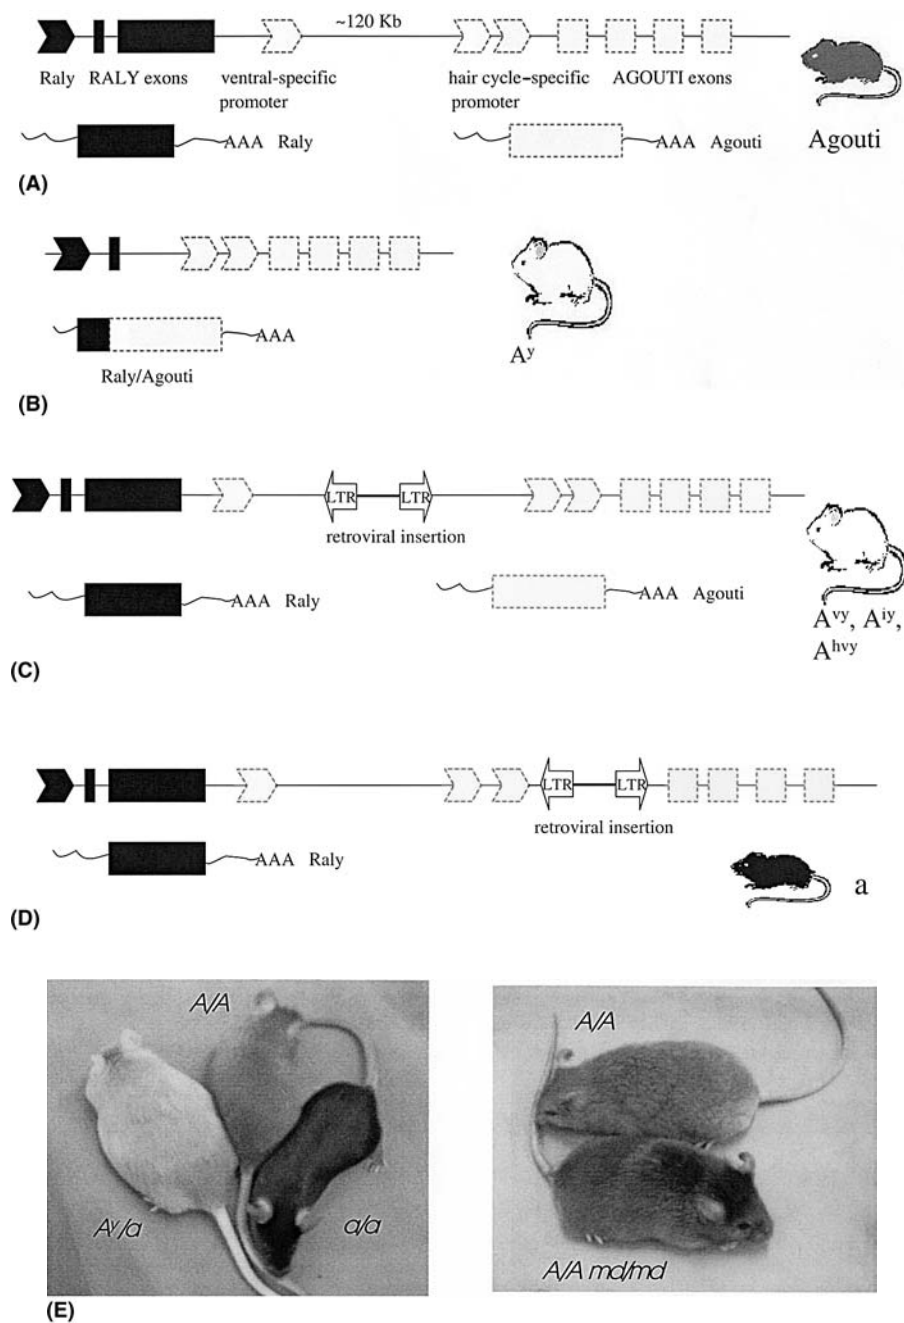

Table 1 (continued)

| Gene                                       | Gene product   | Location/mouse and human  | Nature of mutation  | Knockout model, rodent phenotype   | Human phenotype  | Refs.     |
|--|--|---|---|--|--|-----------|
| Prader-Willi syndrome (PWS)                |  |   |   |  |  |           |
|  |  | Mouse: P: 7 at 28 <i>Ipw</i> : Chr. 7 at 28; <i>Surpm</i> : Chr. 7 at 28; <i>Ndn</i> : Chr. 7 at 28; human: 15q11.2-q12 | PWS is a contiguous gene syndrome presumably resulting from deletion or disruption of the paternal copies of the imprinted <i>SNRPN</i> gene, the <i>necdin</i> ( <i>NDN</i> ) gene, and possibly other genes. PWS can also be caused by maternal uniparental disomy. | <b><i>Surpm</i> KO:</b> mice with only intragenic deletion—normal. Mice heterozygous for paternally inherited deletion (putative imprinting center [ <i>Ipw</i> ]) appeared normal at birth except underweight and unable to support selves on hind feet; these mice died as neonates.<br><b><i>Ndn</i> KO:</b> postnatal lethality associated with loss of paternal gene strain dependent; viable mice had reduced oxytocin and LHRH neurons. | Severe early-onset obesity (from ~ 1–2 years of age), hypotonia, mental retardation, short stature, hypogonadotropic hypogonadism  | (313–318) |
| <i>SIM1</i> (dimerizes with <i>ARNT2</i> ) | <i>SIM1</i> is human homolog of <i>Drosophila</i> <i>Sim</i> : (“single-minded”), bHLH-PAS transcription factor involved in midline neurogenesis | Mouse: Chr. 10 at 26.5; human: 6q16.3-q21   | Translocation which disrupts <i>SIM1</i> gene on 6q   | Haploinsufficient mouse is obese (mouse <i>Sim1</i> is expressed in developing kidney and CNS; is essential for development of several neuroendocrine lineages in supraoptic and PVN nuclei of the hypothalamus [arginine vasopressin, oxytocin, corticotropin-releasing hormone, thyrotropin releasing hormone]).   | One young girl with early-onset obesity (67 months, 47.5 kg), normal energy expenditure; translocation between 1p22.1 and 6q16.2. Phenotype resembles heterozygous <i>MC4R</i> mutation. | (218–220) |
| <i>SOX3</i>                                | SRY-BOX 3  | Mouse: Chr. X at 24.5; human: Xq26-q27  | Deletion  | None reported.   | Borjeson-Forsman-Lehman: mental retardation, obesity, short stature, epilepsy  | (233)     |
| <i>STAT5A</i>                              | Signal transducer and activator of transcription 5A  | A and B: mouse: Chr. 11 at 60.5; B: human: 17q11.2  | KO  | <b><i>Stat5a/5b</i> KO:</b> small, not fat, severely anemic.<br><b><i>Stat5a</i></b> : small, fat.<br><b><i>Stat5b</i></b> : similar to GHR-deficient subjects; proportionate dwarfism, obese, elevated GH, low IGF1.  | None reported  | (319)     |

|              |                                     |  |  |  |   |                   |
|--------------|-------------------------------------|--|--|--|---|-------------------|
| <i>TBX3</i>  | T-box 3                             | Mouse: Chr. 5 at 65;<br>human: 12q24.1 | 1. 1-bp del 227T, premature stop codon; 2. IVS 2ds, G-C, +1; predicted to alter gene splicing  | None reported.   | Ulnar mammary syndrome: complex malformations of ulnar ray, teeth, axillary apocrine glands, urogenital system; obesity                   | (256)             |
| <i>THRβ</i>  | Thyroid hormone receptor beta       | Mouse: not reported; human: 3p24.3     | Nearly 40 documented mutations leading to generalized thyroid hormone resistance   | Resistant to thyroid hormone, severe dysfunction of pituitary-thyroid axis, impaired growth/weight gain, advance bone age. | Many cases of generalized thyroid hormone resistance, for example: 15 yo female, BMI 26.3; combined hypothyroid and hyperthyroid symptoms | (165,320)         |
| <i>TUB</i>   | Tubby transcription factor          | Mouse: Chr. 7 at 51.5; human: 11p15.5  | Larger transcript in tubby mice due to G- to T-transversion in single splice donor site, leading to substitution of 44 amino acid C-terminus         | Tubby mice: late-onset, mild obesity, hyperinsulinemia, retinal degeneration, progressive deafness.                        | None reported, see <i>TULP1</i>   | (153,157,158,321) |
| <i>TULP1</i> | Tubby-like gene expressed in retina | Mouse: not reported; human: 6p21.3     | Compound heterozygotes, 3 mutations in conserved carboxy terminal region; 4th mutation affects donor splice site upstream of carboxy terminal region | Tulp1 -/- mice have early-onset retinal degeneration but normal hearing and normal body weight.                            | Recessive retinitis pigmentosa  | (155,322)         |

<sup>a</sup> Single-gene mutations that produce obesity in humans are well documented: e.g., Bardet-Biedl, and more recently, genes that are components of the "leptin axis." Intensive screening of human populations for mutations in orthologs of the spontaneous rodent obesity mutations have shown that such mutations (*LEP*, *LEPR*) exist, thereby confirming the role(s) of these genes in the control of human body weight. However, such mutations are extremely rare in humans. Other genes, known by virtue of physiology or the phenotypes of knockout animals to participate in energy homeostasis, have been implicated in human obesity: pro-opiomelanocortin (*POMC*), melanocortin-4 receptor (*MC4R*), and prohormone convertase 1 (*PCSK1*). Of these, *MC4R* mutations are highly prevalent, and are found in 3–5% of patients with BMI > 40. However, not all individuals with these mutations are obese, suggesting that obesity is contingent on the presence of genetic variation in other genes in these individuals and/or on specific developmental or environmental factors. For rare types of "syndromic" human obesity (e.g., Prader-Willi, Bardet-Biedl, Alstrom, Biemond, Cohen), specific regions of the genome have been implicated.

**Figure 1** Structure of Agouti locus. (A) Gene structure of Raly and Agouti in normal mice, including resulting transcripts and appearance of mice with normal brown coat color. (B) Structure of Agouti locus in *A<sup>y</sup>* mice, with altered transcript and obese mice with yellow coat color. (C) Structure of Agouti locus, transcripts, and mouse appearance for *A<sup>vy</sup>*, *A<sup>iy</sup>*, *A<sup>hvy</sup>* mice. (D) Structure of Agouti locus, transcripts, and mouse appearance (normal weight, black coat color) for *a* mice. (E) Photographs of wild-type mice (*a/a*), agouti mice (*A/A*), heterozygous mouse for yellow mutation (*A<sup>y</sup>/a*), and double homozygous mouse for agouti and mahoganoid (*A/A md/md*).

ing T-lymphocytes (21). The two mRNA species, 8.5 kb and 4 kb, correspond to proteins that encode membrane-bound and soluble forms of attractin. The membrane-bound form is found in the brain, skin, heart, kidney, liver, and lung, while the soluble form is specific to hematopoietic tissues. The protein has several putative motifs: serine protease, EGF-like regions, a CUB domain, c-type lectin domain, and a ligand-binding domain for gamma chain cytokines. Mahogany mouse mutants are hyperphagic but remain lean, perhaps owing to increased energy expenditure. The mahogany mutation was also able to prevent the obesity and the yellow pigmentation caused by the dominant Yellow mutation. Surprisingly, *mahogany* is unable to prevent the obesity resulting from transgenic overexpression of AGRP, a peptide clearly related to ASP (see below). However, the identification of an *Attractin* mutation in the rat neurological mutation *zitter* suggests that a reassessment of the *mahogany* phenotype may be necessary (20,22,23). Transgenic complementation with the membrane bound form of attractin corrected the neurological defect as well as the abnormal pigmentation of *zitter* rats, whereas the soluble attractin did not affect either phenotype. All of the rodent *Attractin* mutations cause spongiform encephalopathy and hypomyelination. Thus, the lean phenotype of *Attractin* mutants might be due to a wasting syndrome caused by encephalopathy and/or the movement disorder caused by hypomyelination rather than being due to a specific effect on Agouti (ASP) or AGRP action.

The *mahoganooid* mutation was recently cloned and identified as a 54 kDa RING-containing protein with E3 ubiquitin ligase activity. The gene has been named Mahogunin (gene symbol, *Mgrn1*). The allelic series is due mostly to spontaneous IAP (intracisternal particle) insertions; the *Mgrn1<sup>nc</sup>* (*nonagouti curly*), a chemically-induced mutation, may be due to a T→A mutation in intron 9. Based on the failure of overexpression of *Attractin* (*Atrn*) to rescue the phenotype of *md* animals, *Atrn* is placed proximal to *Mgrn1* in a pathway that operates at or proximal to the melanocortin receptor 1 and possibly 3/4. Levels of *Mgrn1* expression are not affected by *Atrn*, and vice versa. Like *Atrn*, *Mgrn1* is widely expressed in adult tissues, with similar expression patterns throughout the brain. The patterns of spongiform degeneration in brain (hippocampus, thalamus, stem and cerebellum) are similar in *md* and *mg* affecteds, and are proportionate to the apparent degree of inactivation of gene expression. For example, both *Atrn<sup>mg-L</sup>* and *Mgrn1<sup>md</sup>* mutants (apparent hypomorphic alleles) show no evidence of brain degeneration up to 8 and 12 months, respectively, whereas the *Mgrn1<sup>md-nc</sup>*, *Atrn<sup>mg</sup>*,

and *Atrn<sup>mg3J</sup>* (putative nulls) do (23a; 23b). The mechanisms by which *mg* and *md* rescue the obesity phenotype of *A<sup>y</sup>*, may be related to anatomic effects within the hypothalamus and/or to effects on increased energy expenditure due to tremor. However, neither *mg* (23c) or *md* (unpublished data) appears to rescue the obese phenotype of the *Lep<sup>ob</sup>* mouse, creating the possibility that, as implied by the coat color effects conveyed via MC1R, that the *mg* and *md* mutations are quite specific to the melanocortin pathway with regard to effects on energy homeostasis, and/or that the magnitude of the aberration in the *Lep<sup>ob</sup>* overwhelms any compensation provided by *md* or *mg*.

## 5 Agouti Gene-Related Peptide (*Agrp*) [Agouti Related Transcript (*Art*)]

The cloning of the agouti gene and understanding of the effects of its protein product, ASP, on food intake led to the proposal that an endogenous ligand/receptor system existed that was being modulated by the overexpression of ASP. As agouti protein is not normally expressed within the brain, an endogenous ligand(s) and its cognate receptor(s) was postulated to mediate the obesity-producing effects of agouti overexpression. Homology searches through a cDNA database and an actual cDNA library identified a transcript that is expressed in the ventral hypothalamus and adrenal gland, as well as in testis and kidney (24,25). The gene, "agouti-related peptide" (*Agrp*), encodes a peptide that has 25% overall homology to agouti protein, with a higher degree of homology within the carboxyl terminus. The bioactive peptide may be a smaller cleavage product of AGRP, as the peptide derived from the carboxyl terminus (26) is equipotent to the full-length AGRP in evoking feeding, and hypothalamic extracts contain this smaller peptide rather than the full-length AGRP. The putative protease and the steps in processing and secretion of AGRP remain to be elucidated.

## 6 Regulation of *Agrp* Expression by Fasting and Leptin

AGRP mRNA concentrations in the hypothalamus are regulated by nutritional state: fasting increases AGRP mRNA (about four- to 10-fold increases in the mouse and about two- to four-fold increases in the rat), and refeeding promptly reduces these levels to the basal state. These nutritional effects may be mediated partially by leptin since, ad libitum-fed leptin- and leptin receptor-deficient mice have elevated concentrations of AGRP in the hypothalamus. This may not be a univer-

sal phenomenon, however, since leptin receptor-deficient rats do not show the elevated hypothalamic AGRP mRNA levels seen in mice. Since nonmutant rats do show fasting-induced increases in AGRP mRNA, it is possible that other factors influence AGRP expression. Since AGRP/NPY neurons bearing MC3R are responsive to melanocortins, it is probable that *Agrp* expression is regulated by melanocortin agonists, such as MSH peptides, and antagonists, such as AGRP itself. In *A<sup>y</sup>* mice, hypothalamic AGRP mRNA is considerably suppressed, presumably due to the inhibitory effect of high levels of ASP on melanocortin receptors. It is quite possible that there exists an ultrashort feedback autoregulatory loop for *Agrp* expression. For example, AGRP, upon its release and inhibition of melanocortin

receptors on AGRP/NPY neurons, inhibits its own synthesis and release (Fig. 2).

Overexpression of an *Agrp* transgene behind an actin promoter for ubiquitous expression simulates the obesity (24) produced by overexpression of agouti (ASP) as well as the obesity syndrome of melanocortin receptor-4 deficiency (see MC4R below). Both ASP and AGRP are antagonists of MSH peptides at the melanocortin receptors. However, AGRP does not bind to MC1R, the MSH receptor in skin, explaining the inability of AGRP to affect pigmentation. AGRP and ASP bind well to melanocortin receptors found in the brain (both MC3R and MC4R), and both prevent the accumulation of intracellular cAMP that normally occurs with binding of MSH.

**Figure 2** Genes regulating body fat. This figure includes only some of the genes known to participate in regulating body fat. The genes in **boldface** have been shown by mutation and pedigree analysis to be capable of causing human obesity. See Table 1 for other candidate genes (272): ARCuate, ParaVentricular Nucleus, Lateral Hypothalamus. The receptors for the various peptides are not shown, but are also candidate genes in the context of this proposal. For example, **POMC** is processed to **aMSH**, ACTH, and various opioid peptides. aMSH is a ligand for the **MC4 receptor (MC4R)** that it engages to reduce food intake and energy expenditure. **AGRP** interferes with the action of aMSH at this receptor, and hence has the effect of increasing food intake and energy expenditure. **PCSK1** is a processing enzyme for many of these peptides, and **PPARG** is a transcription factor that affects adipocyte differentiation. Genes such as the *ADRB3* and members of the *UCP* family may play roles in energy expenditure. *Symbols*: aMSH (a melanocyte stimulating hormone); *ADRB3* ( $\beta$  3 adrenergic receptor), *AGRP* (agouti-related peptide); ARC (arcuate nucleus); BBB (blood-brainbarrier); *CART* (cocaine-amphetamine related transcript); *CRH* (corticotropin releasing hormone); *HCRT/orexin* (hypocretin); *LEP* (leptin); *LEPR* (leptin receptor); LHA (lateral hypothalamus); *MC4R* (melanocortin 4 receptor); *MCH* (melanocyte-concentrating hormone); *NPY* (neuropeptide Y); *PCSK1* (pro-protein convertase); *POMC* (pro-opiomelanocortin); *PPARG* (peroxisome proliferator activated receptor gamma); PVN (paraventricular nucleus); *TRH* (thyrotropin-releasing hormone); *UCP* (uncoupling protein).

### 7 Modifier of AGRP Action—Syndecan-3

Obesity was present in a transgenic mouse expressing syndecan-1 (27). Syndecans are extracellular heparan sulfate glycoproteins that bind a variety of macromolecules, including extracellular matrix proteins and cytokines (28). Transgenic syndecan-1 expression was found within the brain and hypothalamus, and binding studies showed a strong interaction between syndecan-1 and AGRP. As syndecan-3 is expressed within the brain, whereas syndecan-1 is not found in the brain, the role of syndecan-3 in energy balance and ingestive behavior was tested. Syndecan-3 protein is induced in the hypothalamus severalfold by a prolonged fast. Syndecan-3 knockout mice were tested for abnormal energy homeostasis. The mice had normal body weights and appeared to be healthy. However, when challenged with a prolonged fast, the syndecan-3 mutants did not show the anticipated hyperphagic response. Thus, it is likely that syndecan-3 modulates AGRP action and ingestive behavior within the brain.

### 8 Coexpression of AGRP with Neuropeptide Y in the Arcuate Nucleus of the Hypothalamus

The discrete expression of AGRP within the medial area of the arcuate nucleus in the rodent hypothalamus led to the finding that two orexigenic peptides, AGRP and NPY, were coexpressed, defining a unique population of neurons (29). This finding is remarkable since NPY was the most potent orexigenic neuropeptide known until the characterization of AGRP. Neuropeptide Y was initially isolated from pig brain extracts as an amidated peptide of unknown function and high abundance (30). Intracranial injections of NPY into male rats resulted in increased food intake and a decided preference of the rats to ingest chow, even when exposed to sexually receptive females (31). Neuropeptide Y has been shown to elicit ingestive behavior in numerous mammalian and avian species. In a manner similar to *AgRP*, *Npy* gene expression in the hypothalamus is regulated by nutritional state and overall energy balance; increases of hypothalamic NPY or its mRNA are observed during fasting (32), insulinopenic diabetes (33), pregnancy/lactation (34), and cold exposure (35). The correction of the negative energy balance restores NPY mRNA concentrations to the basal state. These alterations are probably mediated by ambient leptin concentrations since leptin receptor-deficient ad libitum-fed rats and mice show equivalent increases in hypothalamic NPY mRNA (36,37), unlike the situation for *AgRP* (38) in rats. However, NPY is widely distributed in neural tissues, as well as the adrenal

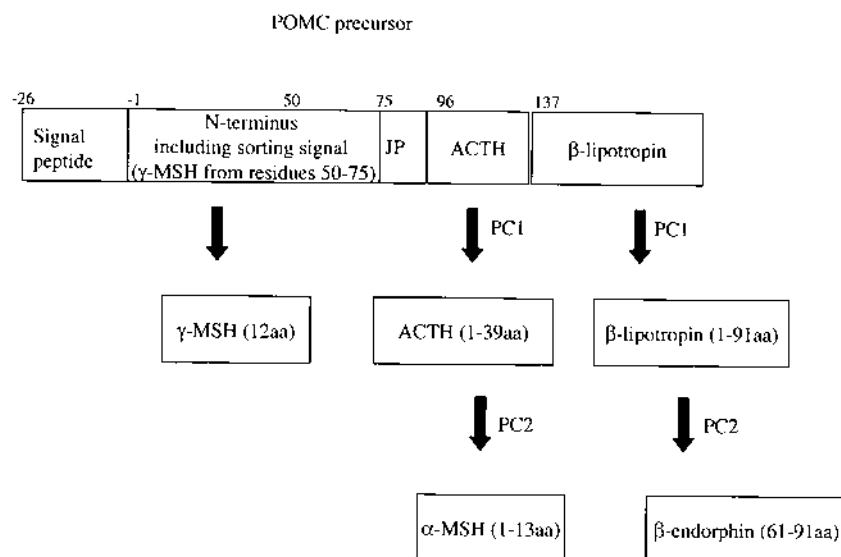

medulla and vasa vasorum, unlike the discrete neuro-anatomical localization of *AgRP* expression in the medial arcuate hypothalamus.

### 9 Proopiomelanocortin (POMC)

The function of POMC-derived peptides in ingestive behavior and energy balance was not well appreciated until the characterization of naturally occurring and induced obesity-producing mutations of genes within the melanocortin system and the development of potent agonists and antagonists for melanocortin receptors. Well known as the precursor for adrenocorticotropin, endorphin, and melanocyte-stimulating hormone, *Pomc* expression in the hypothalamus results primarily in the synthesis and release of alpha MSH, gamma MSH, and endorphin as the processing enzymes cleave the ACTH sequence to produce alpha MSH (39). Inactivation of *Pomc* using gene-targeting methodology produced homozygous mutant mice unable to produce POMC and its peptides (40). The mutation acted as a recessive allele. The initial report describes the effects of POMC deficiency on energy balance and pigmentation. Surprisingly, the mutant mice did not exhibit a lethal phenotype, given the predicted lack of ACTH and adrenal steroid secretion. However, some early mortality was described, presumably due to adrenal insufficiency. Indeed, the mutants have aplastic/hypoplastic adrenal glands, suggesting a critical role for POMC peptides in adrenal development. The surviving mutant mice exhibited hyperphagia and early onset obesity. The mutants, bearing agouti coloration, exhibited a somewhat lighter coat (less eumelanin) than wild-type agouti controls and the pigmentation could be darkened by MSH injections (Fig. 3).

The phenotypes of the *Pomc* knockout mouse can be understood through analysis of the various melanocortin receptors: (1) MC1R, the MSH receptor found in skin; (2) MC2R, the ACTH receptor in the adrenal cortex; (3) MC3R, a brain melanocortin receptor; (4) MC4R, a brain melanocortin receptor; and (5) MC5R, a melanocortin receptor in exocrine glands (including lacrimal and sebaceous) (41,42). The loss of alpha MSH causes a decrease in stimulation of MC1R and increased synthesis of pheomelanin. However, the mice are not completely yellow, as is the case with inactivating mutations of MC1R, and as might have been expected by the intermittent expression of agouti during mouse hair follicle development. The adrenal aplasia is a somewhat unexpected phenotype, considering the lack of proliferation induced by ACTH on adrenal cortical cells. However, gamma MSH stimulates adre-

**Figure 3** POMC posttranslational processing. POMC is a 267–amino acid length precursor molecule which is processed in the pituitary to several peptides, the major peptides being ACTH (39 amino acids),  $\alpha$ -MSH (13 amino acids), and  $\beta$ -endorphin (30 amino acids). The POMC precursor has basic residue cleavage sites listed above the diagram showing sites at which processing of the prohormone occurs. PC1 cleaves POMC into ACTH and  $\beta$ -lipotropin, whereas PC2 cleaves POMC into  $\beta$ -endorphin and  $\alpha$ -MSH. Carboxypeptidase E (CPE) is a proprotein processing exopeptidase, cleaving at C-terminal basic residues, and may function as a regulated secretory pathway sorting receptor, using a sorting signal sequence in the N-terminal region of the POMC precursor molecule. JP, joining peptide.

nal cortical cells to proliferate and an adrenal secretory protease that specifically cleaves gamma MSH from the POMC precursor has been identified. Moreover, expression of adrenal secretory protease is induced in the proliferative zone of the adrenal cortex after unilateral adrenalectomy. However, there may be an unidentified member of the MC receptor family since knockout alleles of MC1R to MC5R have been generated but none have the phenotype of adrenal aplasia. The lack of MSH stimulation at MC3R and MC4R is responsible for the obesity and hyperphagia of POMC-deficient mice since mice deficient for either MC3R or MC4R exhibit obesity. The POMC-deficient mouse was not tested for the exocrine gland secretory deficiency of MC5R-null mice.

#### 10 Melanocortin Receptors—MC4R and MC3R

The discovery of melanocortin receptors unique to the brain provided strong evidence for functions of melanocortins that were mediated via the central nervous system. The melanocortin receptors form a gene family that encodes G-protein coupled receptors that are coupled to Gs, having the traditional seven transmem-

brane domains. However, at the time of their discovery, the nature of these functions was unclear. There were some indications that MSH and melanocortin receptors might be involved in regulating ingestion, based on the information about agouti and the dominant yellow mutation. The task of providing conclusive evidence regarding the functions of central melanocortin receptors fell to mice with targeted mutations of *Mc3r* (43,44) and *Mc4r* (13). Mice that are homozygous for the knockout allele of *Mc4r* develop adult onset obesity accompanied by diabetes, a phenotype very similar to the obesity/diabetes syndrome observed in dominant Yellow mice. The mutants also have increased linear growth as seen in  $A^y$  mice. Indeed, heterozygous *Mc4r*<sup>+/-</sup> mice have a mild degree of obesity, suggesting a degree of haploinsufficiency that may be considered a semidominant phenotype.

Mice that are homozygous for the knockout allele of *Mc3r* develop late onset, mild obesity that appears to be mediated by metabolic aberrations rather than changes in ingestive behavior. The obesity is exacerbated by providing a high fat diet that is calorically denser than regular chow, and the increased adiposity is attained without an apparent increase in caloric intake. Therefore, metabolic alterations mediated by the loss of

MC3R are responsible for the obesity of the mutant mice. It remains to be determined whether the alteration is mediated via a specific expansion of adipose tissue or differential utilization of caloric stores ("partitioning").

As both of these receptors bind MSH and AGRP, it is reasonable to propose that both of these receptors mediate the functions of MSH and AGRP. The exact nature of the interactions between the receptors and their ligands remains to be fully explored. Since the melanocortin receptors are found presynaptically and postsynaptically, short and long feedback loops must be present that are made more intricate by the reciprocal innervations of NPY/AGRP and POMC/CART neurons (45) (see Fig. 2).

Superpotent agonists (NDP-MSH and Melanotan II/MTII) and antagonists (SHU9119) are relatively poor discriminators between MC3R and MC4R, and the results of intracranial injections of these compounds reflect this nondiscriminatory behavior. Effects are observed on both ingestive behavior as well as nutrient partitioning (46,47). The data are also consistent with the phenotypes of the two knockout mouse models, showing that obesity is produced via hyperphagia as well as preferential fat deposition, although the metabolic effects result in much smaller amounts of excess fat accumulation.

### III LEPTIN (*OBESE*)

The *obese* mutation was initially identified in an outbred colony of mice ("stock V") carrying the waltzer (*v*) mutation (48). The recessive mutation causes hyperphagia with early-onset obesity, insulin resistance with glucose intolerance, cold intolerance, and infertility (49). Almost all of these phenotypes are modified by other downstream effectors and have proven to be an extremely rich area of investigation (see Fig. 1). Positional cloning of the *obese* mutation revealed a gene, later called *Leptin*, that encodes a novel, adipocyte-specific hormone (50) that belongs to the cytokine superfamily. The hormone is processed to a mature form that circulates in a form bound to serum proteins that include a soluble form of the leptin receptor (51). The concentrations of leptin in blood are directly related to the amount of fat in the body and show an extremely good correlation to total fat mass (52). Most of the leptin found in blood is derived from white adipose tissue; smaller amounts of leptin are derived from brown adipose tissue. In neonatal rodents, initially all circulating leptin comes from BAT since rodent pups have no white adipose tissue at birth.

### A Mechanisms Causing Obesity in Leptin Deficiency

#### 1 Hyperphagia and Obesity

Leptin-deficient mice (*Lep<sup>ob</sup>*) exhibit early-onset hyperphagia and obesity, being obese to inspection at the time of weaning at postnatal day 21 or up to a week later. After weaning, the mutant mice ingest up to twice the calories of lean littermates and rapidly gain weight and adipose tissue. On the C57BL/6J strain, mutant mice of both sexes are twice the weight of lean siblings at 8 weeks. The mutants maintain this extreme adiposity as long as circulating insulin concentrations are sufficiently elevated above physiological concentrations. In some strains of mice (such as C57BLKS/J), leptin deficiency leads to insulinopenia and severe hyperglycemia with persistent insulin resistance (53). In this state of absolute and relative insulin deficiency, the mutant mice rapidly lose weight and adipose tissue. The importance of hyperphagia in the development of the obese state is shown by pair-feeding studies in which *obese* mice are fed the amount of food taken spontaneously by genetically lean mice. In such studies, the *obese* animals still gain slightly more weight than the lean animals, but a much higher fraction of the additional weight is adipose tissue (54). Thus, the increased body fat of the *obese* mice reflects the confluence of leptin's effects on energy intake, expenditure and partitioning.

#### 2 Glucose Intolerance

Leptin-deficient mice are glucose intolerant and this is readily evident upon weaning onto standard laboratory chow that is carbohydrate rich (55). The mutant mice develop hyperglycemia when ingesting standard rodent chow; a prolonged fast reduces blood glucose concentrations to the normal range. The hyperglycemia is caused by insulin insensitivity, probably due in part to hypothalamic defects in the regulation of autonomic nervous system outflow.

As the tissues of mutant mice are insulin resistant, it is counterintuitive to think that adipose tissue, which is dependent on insulin for its growth and maintenance, would be greatly expanded. However, the insulin concentrations that are attained in mutant mice can be > 100-fold elevated over lean mice, providing sufficient stimulation of insulin pathways to maintain adipose tissue mass. This proposition is supported by the extreme fat mass loss of mutants that are insulinopenic, for example, C57LBKS/J mice. Furthermore, the loss of calories by glycosuria is probably offset by the massive caloric intake of these mutants.

The role of leptin in modulating carbohydrate metabolism remains to be fully described. While humans with leptin and leptin receptor deficiencies do not show overt glucose intolerance, humans and mice with lipodystrophy show extreme glucose intolerance and diabetes. Moreover, in some lipodystrophic mice, diabetes is reversed by transplantation of adipose tissue, leptin injections, or expression of a leptin transgene (see Modifiers of Leptin Action).

### 3 Cold Intolerance

In rodents, leptin deficiency results in hypothermia and cold intolerance (56). Mutant mice usually display basal hypothermia when raised under standard vivarium temperatures ( $\sim 22^{\circ}\text{C}$ ). The mutant mice are also unable to maintain core temperature during a moderate cold challenge ( $4^{\circ}\text{C}$  over 1–2 hr). This thermal defect can be partially corrected by prolonged rearing under mild cold challenges ( $12\text{--}14^{\circ}\text{C}$ ) over a period of several weeks (57,58). Upon examination of the physiological response to a cold challenge, the leptin deficient mice are able to shiver but fail to activate brown adipose tissue via the sympathetic nervous system. Prolonged cold rearing allows a direct trophic effect on BAT since BAT from mutants raised under cold thermal challenge is nearly normal in mass and function. In conventionally reared mutants, the BAT is atrophic with a severe reduction in mitochondrial content and uncoupling protein 1, showing morphology reminiscent of white adipose tissue. Therefore, there appear to be two deficiencies in the mutants—an acute inability to activate BAT via the sympathetic nervous system (SNS), and the absence of a trophic stimulation on BAT. The prolonged cold rearing probably activates BAT via direct stimulation from cold sensitive neurons in the peripheral nervous system.

Rearing *obese* mice at thermoneutrality ( $\sim 35^{\circ}\text{C}$ ) does not prevent the appearance of obesity (59). In addition, as mentioned above, cold rearing to induce the development of BAT in *obese* mice does not significantly affect the development of obesity. Thus, the thermogenic defect does not contribute substantially to the obesity of these mice.

### 4 Caloric Partitioning

Hyperphagia per se should not lead to obesity in a continuously growing animal such as mice and rats during their rapid postweaning growth phase. Increased caloric intake can lead to symmetric expansion of all body compartments, leading to a larger organism. There are apparent developmental and genetic factors

in the regulation of growth of various tissue compartments, such as preferential expansion of white adipose tissue, to lead to obesity. Body composition analyses in mice consistently show that leptin deficiency causes an excessive absolute and relative accumulation of white adipose tissue, with a reduction in skeletal muscle, diminished linear growth, and reduced brain weights. There are several candidate mechanisms for this effect, each of which has been observed in leptin deficient mice: (1) defective growth hormone axis; (2) defective thyroid hormone axis; (3) hypothalamic hypogonadism; and (4) reduced physical activity. The caloric partitioning effect is dramatically demonstrated during pair-feeding studies in which the ingested calories of mutant mice are yoked to genetically lean control mice (60). After a period of such restricted feeding, the mutant mice attain slightly greater body weights than lean mice. However body composition analysis shows that the mutant mice have increased absolute fat content (about twofold) (55). Therefore, the obesity of leptin deficiency is due to both hyperphagia and to preferential deposition of stored calories as fat.

### 5 Infertility and Hypothalamic Hypogonadism

It is well known that hypogonadism alters body composition and increases fat accumulation in both sexes. Leptin deficiency, in most of the strains tested (C57BL/6J, C57BLKS/J, DBA/2V, and V), causes hypothalamic hypogonadism and infertility (53). The low sex hormone levels probably contribute to the adiposity of the mutant mice. However, the original strain of leptin receptor deficient rats (Zucker fatty strain) can be selected for fertility in mutant males. Recently, the *Lep<sup>ob</sup>* mutation has been transferred to the BALB/cJ strain (61). Both male and female mutants of this strain are obese, yet fertile and produce normal pups. This striking strain difference between C57BL/6J, the standard obese inbred strain host, and BALB/cJ could be utilized to identify allelic variants of genes that modify leptin effects on the integrity of the gonadal axis.

## B Leptin Effects on Normal and *obese* Mice

The production of synthetic leptin led to the rapid evaluation of leptin's actions on normal and mutant mice (62–64). When injected either into the periphery or into the brain, leptin can correct all of the abnormalities of obese mice. Indeed, if treated for a sufficient period of time, the mutant mice become phenotypically lean and reproduce in a normal fashion. Treatment of rodents with leptin that maintains leptin concentrations in the

high physiological range actually depletes adipose tissue depots, resulting in leaner animals (65). Similar responses occur if leptin is delivered either via an adenovirus (66) or a transgene (67), indicating that normal mice can respond to elevations in leptin concentrations and reduce adipose depots. In addition, these results indicate that it is unlikely hyperleptinemia per se causes leptin resistance. However, diet-induced obese rodents are hyperleptinemic and resistant to the effects of leptin. Therefore, the hyperleptinemia of diet-induced obesity may reflect effects of increased adiposity as well as leptin insensitivity. The factors that are involved in causing the leptin resistance of diet-induced obesity should prove to be an interesting area of research.

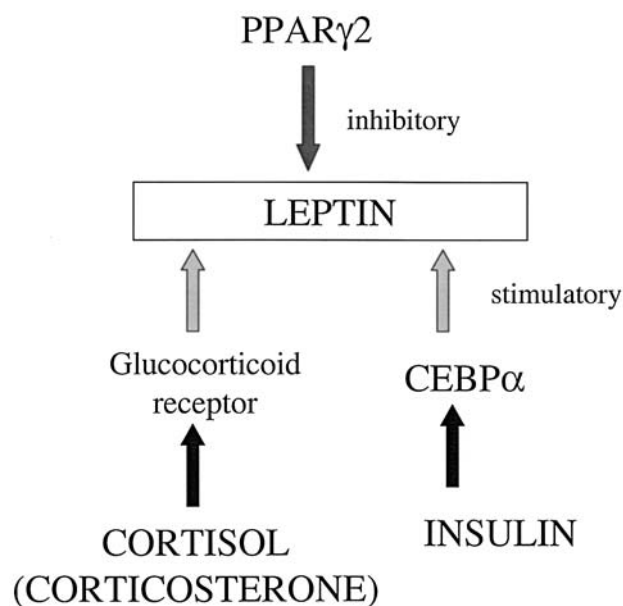

### C Regulation of Leptin in Adipose Tissue

Leptin secretion and blood levels are regulated by nutritional factors, in addition to their correlation to fat mass. Leptin is secreted via the constitutive synthetic and secretory pathway that is highly sensitive to adipocyte volume (68). The mechanism for this sensitivity to adipocyte volume is not known, but provides an explanation for the correlation of circulating leptin concentrations with adipose tissue mass. Insulin has a stimulatory effect on leptin gene transcription and translation, and causes release of a leptin from a pool of stored leptin (69). Glucocorticoids have a similar

stimulatory effect on leptin gene transcription and synthesis of leptin, although glucocorticoids do not stimulate the release of stored leptin.

The insulin-mediated stimulation of leptin transcription could be mediated directly, via stimulation of the phosphorylation cascades initiated by the insulin receptor, or indirectly, via metabolites produced during glucose metabolism, such as UDP-glucosamine (70). Initial characterization of the leptin promoters from man and mouse indicated the presence of a CCAAT enhancer-binding protein (C/EBP) site (71) that could stimulate transcription in preadipocytes and that C/EBP alpha could stimulate leptin transcription (72). Subsequent studies have indicated that C/EBP alpha is downregulated during insulin treatment of fully differentiated adipocytes, suggesting that stimulation of C/EBP alpha activity is not the mechanism for insulin-mediated stimulation of leptin transcription (73). These results need to be more fully explored in order to reconcile the discrepancies (see Fig. 4).

Treatment of rodents and adipocytes with a class of drugs called thiazolidinediones (TZDs; used as insulin-sensitizing agents in type 2 diabetes mellitus) have been found to suppress leptin gene expression. In addition, TZDs can increase fat accumulation, probably by stimulating adipocyte proliferation and differentiation. TZDs activate PPAR gamma, a transcription factor that positively regulates adipocyte differentiation.

**Figure 4** Regulation of leptin synthesis. Insulin and glucocorticoids stimulate leptin gene transcription and synthesis, whereas fatty acids that activate PPAR $\gamma$  are inhibitory to leptin synthesis.

However, in contrast to its stimulatory effect on some adipose-specific genes, PPAR gamma inhibits leptin gene transcription (74). While PPAR gamma does not appear to bind directly to the site of the leptin promoter responsible for the inhibitory effect of TZDs on leptin transcription nor to C/EBP alpha, it is possible that the two transcription factors compete for a critical cofactor (75).

#### D Leptin Expression in Nonadipose Tissues

Leptin has been reported to be expressed in numerous tissues in addition to adipose tissue. Leptin mRNA and/or protein have been reported in the stomach (76), skeletal muscle (70), and the trophoblast of the developing embryo (77). Leptin secreted from the stomach during or after a meal might contribute to inhibit further feeding. Among other postulated roles of gastric leptin is a cytoprotective effect against the formation of mucosal ulcers (78). Within skeletal muscle, leptin gene expression is induced by increased leptin concentrations and glucosamine, a metabolic intermediate of a proposed nutrient-sensing pathway in skeletal muscle and adipose tissue. Leptin has been found in the preimplantation embryo, and it is derived from maternal leptin mRNA. Leptin is found in a gradient and eventually localizes to outside cells of the morula that are destined to become trophoblastic cells. However, leptin is not absolutely necessary for ontogenesis since embryos from leptin-deficient dams develop into normal fetuses and pups.

#### E Circulating Leptin and Soluble Leptin Receptor

Leptin circulates in a bound form in most lean individuals. The leptin binding protein in humans is probably a proteolytically shed form of membrane bound leptin receptor since the 3' terminal exon for the soluble leptin receptor isoform is nonfunctional in humans, due to absence of a polyadenylation signal (79). In rodents, a transcript (LEPR-E) directly encodes a soluble leptin receptor. In obese individuals, circulating leptin concentrations are higher and the ratio of bound leptin to free leptin is altered in favor of free leptin, presumably due to independent mechanisms that modulate leptin and soluble leptin receptor (51,80).

Leptin is cleared primarily by the kidneys. In end stage renal disease, leptin concentrations are elevated, owing to diminished leptin clearance (81). These elevated leptin levels could be partially responsible for the

anorexia and wasting associated with renal failure. Interestingly, the kidneys and the lungs are organs with high levels of expression of LEPR-A isoform, suggesting that LEPR-A might be involved in leptin clearance and degradation.

Circulating leptin is extremely elevated during pregnancy in the mouse (82), whereas a modest twofold elevation is seen during pregnancy in rats (83,84) and humans (77,85). In the mouse, the soluble leptin receptor is produced via a placental-specific promoter driving synthesis of the soluble LEPR-E isoform. This increase in LEPR-E leads to increased amounts of LEPR-bound leptin and diminished clearance of leptin. An interesting difference between the hyperleptinemic states of pregnancy and obesity accounts for the increased leptin concentrations. Increased adipose tissue mass produces increased amounts of leptin, leading to increased free leptin. During pregnancy, the increased amounts of soluble leptin receptor bind leptin, increasing the amount of bound leptin and decreasing the clearance of leptin. The evolutionary advantage of such leptin accumulation could be related to the extreme energy demands of gestation and lactation in a small homeotherm, the mouse. Maintaining the health of the pregnant dam and the developing fetuses requires a constant, high level of caloric intake and prolonged caloric deficits would be deleterious to both the dam and the developing pups. Therefore, it is reasonable to argue that the decreased availability of free leptin during pregnancy is a mechanism to drive feeding even in the face of increasing adipose depots and increased leptin biosynthesis. Apparently, the rat and human *LEPR* genes do not have such a strong placental promoter, leading to the much more modest increases in circulating leptin during gestation in rats and humans.

#### F Effects of Leptin Outside of the Brain and Neuroendocrine System

Leptin receptors are found in numerous tissues outside of the brain. Leptin receptors, particularly LEPR-B, are found in abundance in developing long bones and cartilage (86). Moreover, leptin-deficient mice have increased cortical bone thickness and leptin treatment of *ob/ob* mice normalizes bone thickness (87), although it has also been reported that leptin promotes bone growth in *ob/ob* mice (88). Moreover, leptin deficiency causes mild growth hormone deficiency with associated decreased linear growth. Thus, the effects of leptin on the skeletal system remain to be further elucidated.

Leptin-deficient mice have a mild immune system deficiency, and LEPR-B is expressed in lymphocytes at levels equivalent to the hypothalamus (89). Because leptin is a cytokinelike molecule, it is not surprising that immune cells respond to leptin (90). Since fasting and caloric restriction produce a mild repression of immune function, it is possible that the decreased leptin concentration associated with negative energy balance is partly responsible. High turnover of circulating immune cells is energy costly and might be dispensable under conditions of nutritional deficit and might have evolved as a means of maximizing metabolic fuel efficiency.

Leptin has angiogenic properties, stimulating the growth of new capillaries (91). LEPR-B is expressed in human endothelial cells, and the control of capillary growth could be important to the delivery of metabolic substrates to various tissues—in particular, adipose tissue. It is possible that differential blood flow to various adipose depots could be responsible for the substantial metabolic differences between subcutaneous and visceral adipose depots.

### G Mutant Alleles of Leptin

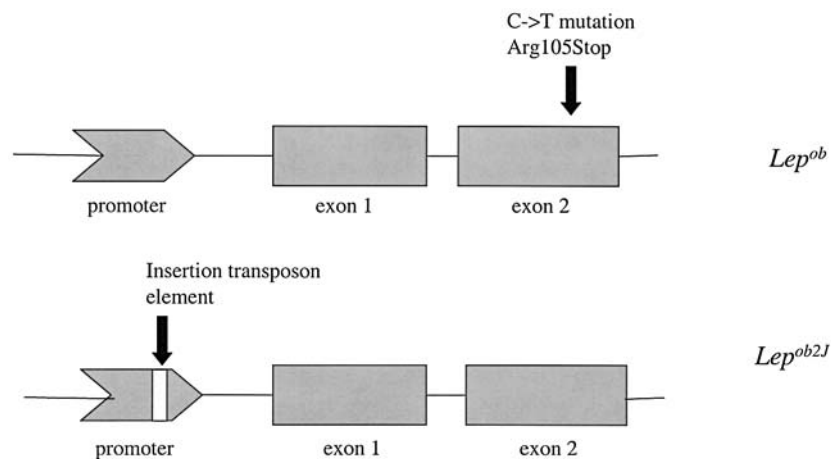

The leptin transcript is remarkable for a long 3' untranslated region. The transcript comprises two exons, and the first *Lep<sup>ob</sup>* mutation is a point mutation in the second exon that generates a premature termination codon (50). Since the mutation occurs in the 3' terminal exon, the mutant transcript is not susceptible

to nonsense-mediated mRNA decay and accumulates at much higher concentrations than the wild-type allele. Although cytoplasmic concentrations of *Lep<sup>ob</sup>* leptin have not been measured, the protein is certainly not secreted from the adipocyte. In humans, a similar mutation generating a premature termination codon has been described. In these individuals, mutant leptin remains within the cytoplasm of adipocytes and is not secreted (see below). While such accumulation might be attributable to high levels of stimulation due to high concentrations of insulin, it is also possible that there is an autoregulatory feedback loop for leptin gene expression in the adipocyte and that the lack of leptin auto-inhibition leads to increased leptin gene transcription.

The *Lep<sup>ob2J</sup>* mutation is due to an insertion of a transposon element within the proximal promoter of the leptin gene (92). Very little if any leptin transcript is observed with this mutation. The mutation arose on the SM/J strain and the mutant mice of this strain are not severely hyperglycemic, suggesting the presence of alleles that are protective against type 2 diabetes (see Fig. 5).

### H Mediators and Modifiers of Leptin Action in the Hypothalamus

The proximal mediators of leptin action relevant to energy balance are leptin-sensitive neurons within the hypothalamus and their constituent neurotransmitters (93). This is highlighted by the fact that intracerebroventricular injections of small doses of leptin are

**Figure 5** Genetic structure of the *Lep<sup>ob</sup>* and *Lep<sup>ob2J</sup>* loci. *Lep<sup>ob</sup>* contains a point mutation in the second exon, R105X, that leads to premature chain termination. *Lep<sup>ob2J</sup>* has a transposon element inserted into the promoter. This transposon element is from the ETn family of transposons and contains multiple splice-acceptor sites that interfere with normal splicing.

sufficient to correct the obese phenotype, as noted previously (62). In addition, these leptin injections into the brain can correct the glucose intolerance prior to the appearance of the effects on feeding (94), suggesting that there may be different thresholds for the various actions of leptin. A large number of leptin-sensitive neurons have been identified, and each type contributes to the obesity/diabetes syndrome of leptin deficiency. Upon binding to its receptor, activation of the JAK/STAT pathway is responsible for leptin's effects (89,95,96), although the stimulatory and inhibitory effects on specific neuropeptide genes remain to be fully explained. The genes encoding orexigenic peptides (NPY, AGRP, MCH [melanocyte-concentrating hormone]) are downregulated by leptin while the genes encoding anorectic peptides (POMC and CART [cocaine- and amphetamine-regulated transcript] in arcuate nucleus neurons) are upregulated [reviewed by Spiegelman and Flier (93)]. Leptin also can hyperpolarize hypothalamic neurons (97), an effect perhaps mediated by the activation of ATP-sensitive potassium channels, probably contributing to decreased release of the orexigenic peptides. However, this action would not be expected to be correlated with leptin's effect on POMC neurons since hyperpolarization would inhibit release of POMC-derived peptides. Indeed, leptin depolarizes POMC neurons directly and relieves GABA-mediated inhibition (45). Thus, leptin can have directly opposite actions on resting potential, depending on neuronal cell type. This action will require much farther investigation to elucidate its mechanism.

These actions of leptin appear to orchestrate a coordinated response to alterations in circulating leptin concentration. Under conditions of negative energy balance and decreased leptin concentrations, the neurons secreting orexigenic peptides, such as NPY (98) and MCH, are activated and increase release of their orexigenic peptides. Simultaneously, the decreased leptin concentrations stimulate the transcription of the same neuropeptide genes to allow for increased synthesis of the neuropeptides being released. The POMC/CART neuron is controlled in a reciprocal fashion to maximize the drive to feed. Decreased leptin concentrations decrease POMC and CART synthesis (99–101). Correction of the leptin concentrations to the basal state normalizes neuronal activity and neuropeptide gene transcription/translation.

In normal rodents, exogenous leptin administration via leptin infusion or gene transfer techniques (viral vectors or transgenes) causes hypophagia and diminished adipose tissue mass. Leptin infusions that

increase leptin concentrations at the high end of physiological concentrations (10 ng/mL) do not appear to cause alterations in NPY mRNA, but other neuropeptides remain to be studied. It is remarkable that the lack of adipose tissue in these leptin-treated animals does not lead to insulin resistance and diabetes usually associated with lipodystrophy, a syndrome characterized by diminished adipose depots. In fact, leptin transgenic mice are exceptionally lean and have increased glucose tolerance, implying that high leptin concentrations in normal lean organisms cause enhanced glucose metabolism. The paradox remains as to the lack of efficacy of leptin in correcting obesity and insulin resistance in diet-induced obesity.

#### IV LEPTIN RECEPTOR (*DIABETES AND FATTY*)

The *diabetes* mutation arose in the C57BLKS/J strain; obese mice of this strain are susceptible to developing insulinopenia and severe diabetes (102). The phenotypes of young *db/db* mice are strikingly similar to that of young *ob/ob* mice: early-onset hyperphagia and obesity with the attendant thermogenic defect. In addition, both mutations cause early onset hyperglycemia and hyperinsulinemia that diverge only later in life, with *db* C57BLKS/J mice developing severe insulinopenia and early mortality. When the *ob* and *db* mutations were both transferred to the C57BL/6J strain, the two mutations showed identical phenotypes, suggesting that the diabetes susceptibility of C57BLKS/J *db* mice was due to a strain-specific combination of allelic variants (103,104). These similarities in phenotypes led Douglas Coleman to perform parabiosis studies to test the hypothesis that the normal *ob* and *db* gene products constituted a ligand-receptor system (105). Coleman found that *ob:ob* pairs and *db:db* pairs showed no differences in the partners of the pairs. However, in *ob:db* pairs, the *ob* partners lost weight and occasionally succumbed to starvation. While this might be a strong indication that the *ob* gene product was a diffusible substance and that the *db* gene product was its receptor (as later shown by molecular cloning of both genes), parabiosis between *ob* and lean animals did not produce such clear-cut results. Both partners of the *ob:lean* pairs thrived and gained weight in nearly the same fashion as singleton animals of the same genotypes. One would have predicted that the *ob* partners of *ob:lean* pairs should have lost weight upon exposure to the diffusible substance provided by the lean partner.

Remarkably, two rat mutations, *fatty* [Zucker (106)] and *fatty-f* [Koletsky (107)], caused a nearly identical obesity/diabetes phenotype as *obese* and *diabetes* mouse mutants. The mutations were recessive and caused early onset obesity with hyperphagia, cold intolerance, hyperglycemia and insulin resistance, and infertility. The similarities of the phenotypes suggested that diabetes and fatty might be molecular orthologs. This was confirmed upon the mapping of the *fatty* mutation to a segment of rat chromosome 1 (108) that was orthologous to a segment of mouse chromosome 5 that contained *diabetes*.

### A Molecular Clues to the Identification of *diabetes*

Various approaches were combined to provide the conclusive evidence that mutations of the leptin receptor gene and *diabetes* and *fatty* alleles were one and the same. Mapping studies had shown that the mouse *diabetes* mutations and the rat *fatty* alleles were orthologs. A positional cloning approach by two groups had narrowed the critical chromosomal interval to ~1 Mbp (109,110). A leptin-binding protein expression cloned from the choroid plexus mapped to this critical interval (111). However, analysis of the most frequently studied alleles of *diabetes* and *fatty* initially proved to be uninformative in terms of providing the evidence that mutations were present in the leptin receptor gene. It fell to the infrequently studied *db<sup>Pas</sup>* allele to provide the proof. Genomic analysis of the leptin receptor in *db<sup>Pas</sup>* showed the presence of a partial duplication, eventually shown to be a duplication of four exons, which eliminated all leptin receptor transcripts (110,112). While the original *db* allele was found to have a mutation that generated a new splice donor site in one of the alternative 3' terminal exons (109,113), preventing the translation of one of the isoforms ("Rb"), the mutation did not eliminate three other membrane-bound leptin receptor isoforms, providing a puzzle that could only be explicated with further studies of the molecular properties of the leptin-leptin receptor signaling system.

The homology of the leptin receptor to cytokine receptors was not surprising, given the structural similarity of leptin to cytokines (111). Given this structural similarity, the *diabetes* mutation's elimination of the STAT signaling-competent isoform, LEPR-B, proved to be a critical element in highlighting the importance of LEPR-B function and the hypothalamus in the obesity/diabetes syndrome (89,95), given the normal expression of the other LEPR isoforms in *db/db* mice.

### B Alternative 3' Terminal Exons Provide a Variety of Leptin Receptor Isoforms

The leptin receptor gene has multiple 3' terminal exons (79) that may be alternatively spliced in a tissue-specific manner (89) (Fig. 6). Each of these 3' terminal exons contains a stop codon and a polyadenylation signal. Two of the exons, 14' and 17', are extensions of the preceding exons and start with a canonical splice donor site, an arrangement for 3' terminal exons that is not uncommon in genes that are differentially spliced in cells that undergo differentiation and maturation, such as the gene encoding the heavy chains of immunoglobulins. The presence of multiple 3' terminal exons was a complication in the initial identification of disruptive mutations of *Lepr* (109,110,113). However, the identification of the single nucleotide alteration for *Lepr<sup>db</sup>* was highly instructive regarding the singular critical role of the membrane-bound B isoform of LEPR. Analysis of cDNA clones indicated that there was heterogeneity in the 3' terminus of transcripts that *Lepr* encoded. All of the transcripts contain the same ligand-binding domain (present in exons 8, 9, 10, and 11) so that all of the LEPR isoforms should bind leptin equally. There is a short transcript that includes coding exons 1–14 and the 3' terminal exon that has been called exon 14'. This soluble receptor (LEPR-E) is found in the circulation and its production is strikingly increased during pregnancy in the mouse due to a placenta-specific promoter (82), resulting in extreme hyperleptinemia (10-fold elevation of total leptin in the blood). However, the hyperleptinemia in pregnant rats or humans is only twofold, suggesting that any advantages conferred by the extreme hyperleptinemia of pregnancy in the mouse may not be necessary for satisfactory gestations in other species (114). In fact, the human gene does not contain a functional exon 14', since it lacks a polyadenylation site. The human *LEPR* does not produce LEPR-E mRNA although there is soluble LEPR in the circulation. Human LEPR-E is produced by proteolytic cleavage of membrane bound LEPR isoforms; this phenomenon is seen frequently amongst members of the cytokine receptor superfamily (79).

There are several membrane-bound LEPR isoforms, all of which include coding exons 1–17 and one of several 3' terminal exons. Exon 16 encodes the transmembrane domain while exon 17 encodes a membrane proximal segment containing the JAK activation region to which JAK and SOCS3 bind. Two of the alternative terminal exons, 17' and 18a, encode short cytoplasmic tails that do not appear to have functional motifs. The number of these 3' terminal exons and LEPR isoforms

**Figure 6** Genomic structure of *Lepr* and alternative transcripts. (A) Genomic structure of *Lepr*. Coding exons are in blocks and numbered. Terminal exons are denoted by numbers under the exons while coding exons are numbered above the exons (exon 16 bears a transmembrane domain). Colored blocks within exons represent sequence motifs: yellow represents a JAK box, white represents a STAT box, while a black block represents the single transmembrane domain. (B) Alternative transcripts of *Lepr*. Four isoforms of LEPR are represented. LEPR-E is a soluble receptor, terminating at exon 14' and excluding the transmembrane domain (black) in exon 16. All of the membrane bound receptors (LEPR-A, LEPR-B, LEPR-C) include exon 17, which has a JAK box. The LEPR-B isoform is the sole receptor that contains the STAT box.

is species dependent; rats and humans have at least four of membrane-bound isoforms (rat LEPR-D and human B219, in addition to the ones described in detail) as opposed to the three isoforms in the mouse. Interestingly, only one LEPR isoform, LEPR-B, has a long cytoplasmic tail (accounting for its common designation as the “long-form” leptin receptor) that can activate STAT (signal transduction and transactivation) proteins. The sole loss of LEPR-B caused by the *Lepr<sup>db</sup>* mutation produces an obesity/diabetes/infertility syndrome that is identical to the loss of all LEPR isoforms by the other *Lepr* mutations (112,115), such as *Lepr<sup>dbPas</sup>* and *Lepr<sup>db3J</sup>*, indicating the crucial role performed of STAT activation by the LEPR-B isoform. LEPR-B is the major isoform only in some tissues, such as in neurons of the hypothalamus and lymphocytes (89). The nature of the tissue specificity of splicing of the terminal exons remains obscure, although any investigations that suggest regulation of specific LEPR isoforms need to address this issue. Specific alterations in the ratios of LEPR isoforms are probably mediated via splicing rather than regulation via effects on transcription rates.

Another surprising aspect of LEPR isoforms is that studies have failed to detect heterodimer forma-

tion in cells transfected with two different membrane-bound LEPR isoforms—LEPR-A and LEPR-B. LEPR appears to form homodimers prior to ligand binding (116), and one can postulate that the cytoplasmic tails of the isoforms dictate preferential self-dimerization or differential sorting to various subcellular compartments.

### C LEPR-B, a STAT-Competent Signaling Isoform, Is Critical for Leptin Signaling

Complete loss of LEPR mRNA results in an obesity/diabetes syndrome that is identical to that produced by the loss of the LEPR-B mRNA. This finding indicates that LEPR-B is necessary and sufficient to mediate all of leptin's actions regarding energy regulation. However, the other LEPR isoforms may perform functions outside of this context that remain to be more fully explored. LEPR-B is the only isoform that bears a STAT-activating motif (111), indicative of the critical function of STAT3 in transducing leptin receptor activation. All membrane-bound LEPR isoforms (A, B, C, and D) can bind and activate JAK. Interestingly, leptin activates

STAT3 within the hypothalamus (95), whereas leptin can activate STAT3 and STAT5 in vitro (89).

#### D Alleles of *Lepr* in Mice and Rats

Several additional diabetes alleles have been detected since the initial identification of *db*. The large size of *Lepr* (> 100 kbp) and easy phenotypic discrimination (severe obesity) may produce an ascertainment bias contributing to the apparent high frequency of mutations. All of the *Lepr* mutations are recessive and cause a similar phenotype, minor differences being attributable to the strain on which the specific allele is characterized. The variety of the nature of the mutations also suggests that the size of the gene provides a large target for mutational mechanisms. A relatively large number of potentially significant sequence variants have also been described in humans (see below).

##### 1 *db*

The nature of the *db* allele has been described above. The molecular consequences of this allele are relatively minor in terms of its effects on amount of RNA. The mutation's major impact lies in the prevention of the translation of the LEPR-B isoform through the interposition of the 3' terminal exon for the LEPR-A isoform in the LEPR-B transcript. Originally arising in the C5BLKS/J strain, this allele has been subsequently transferred to multiple strains (117). The variation in severity of diabetes in obese animals of different strains has been exploited to look for modifiers of diabetes.

##### 2 *db<sup>3J</sup>*

A 17-bp deletion within an exon disrupts the reading frame (118,119). As the exon is within the middle of the coding sequence and prior to the transmembrane spanning region, any leptin receptor that is produced is found as a soluble protein. Owing to the premature termination, a considerable reduction in LEPR mRNA results. The *db<sup>3J</sup>* mutation arose on the 129/J strain and showed a unique phenotype of extreme hyperinsulinemia so severe that older mutant mice were found to be hypoglycemic.

##### 3 *db<sup>Pas</sup>*

A large interstitial duplication exists of coding exons 3, 4, 5, and 6 (112,120). The disruption of the coding sequence probably leads to an unstable transcript and a significant reduction in LEPR mRNA. The duplication occurs prior to the putative ligand-binding domain and any LEPR produced would be predicted to be

unable to bind leptin. This allele was discovered in the DW strain maintained at the Pasteur Institute.

##### 4 *db<sup>NCSU</sup>*

A single basepair deletion in an exon reduces LEPR mRNA and shifts the reading frame of all LEPR isoforms (121). No membrane bound isoforms are expressed by this mutant allele. This mutation occurred in an outbred population of CD1 mice maintained at North Carolina State University. The stock is directly descended from Swiss albino mice and is genetically unrelated to most of the mouse stocks on which *ob* and *db* have been analyzed. The severe diabetic phenotype of these mice highlights the importance of strain background in determining diabetes susceptibility in rodents.

##### 5 *Lepr<sup>Tg(Mth11)1Aig</sup>*

This is a mutation due to a transgenic insertion coupled with deletion of all exons 3' to coding exon 17' (122,123). This mutation illustrates some of the difficulties encountered with molecular analysis due to transgenesis. The insertion of the transgene would probably have been sufficient to inactivate *Lepr* transcription. However, additional molecular events, such as large-scale deletions or rearrangements, are possible and compound the analysis of the effects of the mutational event.

#### E Extinct *Lepr<sup>db</sup>* Mutations

Two documented alleles for *db* were described although no DNA is available for molecular analysis. The two alleles are *db<sup>ad</sup>* and *db<sup>2J</sup>*. The *db<sup>ad</sup>* allele was described in 1959 and demonstrated to be allelic to *db* (124). Interestingly, this allele was also discovered in mouse lines that were being selected for large size and increased growth, similar to the background for discovery of *fatty* and the *Socs2<sup>hg</sup>* mutations. The *db<sup>2J</sup>* mutation was discovered at Jackson Laboratories as indicated by its allelic designation and found to be allelic to the first *db* mutation (104). This was the mutation with which some of the initial comparisons of strain effects on the obesity-diabetes syndrome were performed.

##### 1 *fatty*

The *fatty* mutation arose in an outbred population of rats that had been generated to study genetic effects on nutrition and body weight regulation (106). The 13M stock was made heterogeneous by outcrosses of at least four different rat strains at the outset of the

experiment to maximize diversity in the gene pool. The spontaneous recessive *fatty* mutation produced the obese phenotype. Obese rats of the outbred Zucker stock are obese and mildly glucose intolerant but never develop overt hyperglycemia and glycosuria. In keeping with the minimal pathology associated with obesity in the Zucker stock, obese males are occasionally fertile. This trait can be selected for and the proportion of fertile obese males can be significantly enhanced by this procedure. This is in contrast to two inbred rat strains derived from the original 13M fatty stock—the Zucker Diabetic Fatty [ZDF (125)] and the Wistar Diabetic Fatty [WDF (126,127)]. The ZDF rats were derived by initial selection of the 13M stock for pairs that produced obese diabetic progeny, and subsequent inbreeding to fix the diabetic trait. The WDF rats were produced simply by transferring the *fatty* mutation to the WKY/N inbred strain. The resulting co-isogenic WDF strain produced obese rats with severe diabetes. Obese males of the ZDF and WDF strains are much more severely affected in terms of diabetes than obese females, following a trend of some protective effect of female sex found in most obese mice. It has been proposed that sulfurylation of estrogens by sulfotransferases differentially expressed between the sexes might be responsible for this effect (128).

The *fatty* mutation is a point mutation that substitutes a proline for glutamine at residue 269 (129,130). The effect of this mutation on RNA abundance and protein abundance is negligible. In fact, the mutant protein binds leptin with an affinity equal to the native receptor. Thus, the mutation was not helpful in the initial attempts to show that leptin receptor mutations were responsible for the obese phenotype. However, the mutant protein fails to be expressed at the cell surface, presumably owing to misfolding and inappropriate subcellular sorting. Thus, the mutation abrogates leptin-dependent STAT3 activation. However, the mutant protein has constitutive STAT activating activity, although at a much lower level than the native receptor.

## 2 *fatty*<sup>f</sup>

This mutation arose in a cross between Sprague-Dawley and spontaneously hypertensive rats (SHR). The mutation was given a provisional symbol “f” by its discoverer, Koletsky (107). The stock has been maintained as such and has been duly named the Koletsky mutation (*fa*<sup>K</sup>). Owing to the SHR background, obese rats showed profound pathology associated with obesity, hyperglycemia, hyperlipidemia, and hypertension. Subsequently, the mutation was transferred to two other

inbred strains (131,132), LA/N and SHR/N, and was given another name, *corpulent*. The obese LA rats are mildly hyperglycemic and are quite similar in phenotype to obese C57BL/6J mice, whereas obese SHR rats are obese and overtly hyperglycemic, suffering early mortality due to the diabetes and hypertension imposed by the strain background. In order to limit the profusion/confusion of names, and to comply with terminology precedents, it is preferable to use the initial symbol given, *fatty*<sup>f</sup>.

The *fatty*<sup>f</sup> mutation is a single base substitution that generates a premature termination codon prior to the transmembrane domain (133,134). The amount of LEPR mRNA is greatly reduced by the mutation, probably due to degradation of the mutant transcript by nonsense-mediated decay. However, sufficient amounts of LEPR mRNA remain to permit amplification and subsequent sequence analysis as the mutation was identified from amplified cDNA.

## F Critical Tissues and Cells That Mediate Leptin's Actions

All of leptin's actions on hyperphagia and glucose metabolism appear to be mediated by the brain since small intracranial infusions of leptin can normalize ingestive behavior and glucose tolerance in *ob* mice. However, it remains to be determined whether all of leptin's actions on metabolism and ingestion are mediated by the brain. Due to the specific actions of leptin on lymphocytes and vascular endothelium, which are not mediated by the brain, it is possible that adipocytes, hepatocytes, pancreatic beta cells, and muscle cells can be directly affected by leptin. However, these extrahypothalamic contributions toward energy homeostasis must be of a small magnitude since LEPR-B expression within the brain is sufficient to correct most or all of the obesity/diabetes syndrome of leptin receptor deficiency (135).

LEPR-B is expressed in many of the critical hypothalamic neuronal populations that regulate energy balance—NPY/AGRP, POMC/CART, TRH, CRH, and MCH. Moreover, leptin regulates the expression of these neuropeptide genes (via STAT-mediated transcription effects) and modulates their release (probably by effects on membrane potential). These effects of leptin occur over a longer time interval than most effectors, taking ~20–30 min to attain maximal effect (45,97). However, these effects are also long-lasting and take up to an hour to dissipate after the initial stimulus. While the stimulatory effect of leptin on POMC activity

can be explained by stimulatory effects of STAT3 on *Pomc* transcription, it is more difficult to relate STAT3 activation to the suppression of *Npy* and *Agrp* transcription. There is no doubt regarding the effects of leptin on these genes (136) since leptin can reverse the fasting-induced changes in *Pomc* (leptin reverses fasting-related inhibition) and *Npy* (leptin reverses fasting-related induction).

Since it has been identified that leptin, upon binding to its receptor, activated STAT3 in the hypothalamus, it was interesting to note that ciliary neurotrophic factor (CNTF), another cytokine, could mimic the anorexiogenic effects of leptin (137). Similar to leptin, CNTF and its analogs activate STAT3 within the hypothalamus by a mechanism that is not dependent upon LEPR, since the effect is seen in *db/db* animals. Presumably, there is considerable overlap between the distributions of LEPR and CNTFR, although this has not been directly determined. The drug axokine, which activates CNTFR, is under trial as a weight-reducing agent.

#### G Modulation of the Hyperglycemia and Insulinopenia of C57BLKS-*db* Mice

The severe diabetic syndrome of *db/db* C57BLKS/J mice is not an irremediable phenotype. Food restriction can ameliorate the diabetes and prevent early mortality although the mutant mice still develop hyperglycemia (138). The diabetes is not an autoimmune phenomenon although some autoimmune markers can be observed, such as islet immunoreactive antibodies (139). An intact immune system, either T-cells, B-cells, or both, is not necessary for the development of the diabetes. However, a simple nutritional modification, substitution of all carbohydrate sources in the diet with protein, can prevent the development of hyperglycemia, insulinopenia, and pancreatic beta-cell loss (138). There appears to be a critical period for this protective effect of dietary manipulation since it is most effective within the first 1 or 2 weeks after weaning. Mutant mice that are older cannot be rescued by this diet, suggesting that there has been a depletion of precursor stem cells or that a block in capacity for differentiation has occurred. The molecular bases of this diabetes susceptibility remains to be further explored since there are numerous well-characterized inbred strains that differ in their diabetes susceptibility. While it is possible that a simple two-allele system is responsible for this diabetes susceptibility, it is just as likely that a large set of genes and their allelic variants are responsible for differential diabetes susceptibility among different rodent strains. These genes

may affect beta-cell development and function, and insulin sensitivity in muscle, liver, and adipose tissue.

#### H Adrenal Steroids Affect the Progression of Obesity

Adrenalectomy can halt or reverse the development of obesity in virtually all genetically obese rodents. Obese *ob* and *db* mice have supraphysiological circulating concentrations of corticosterone, the main glucocorticoid in rodents (140,141). After adrenalectomy, subphysiological replacement doses of corticosterone allow the full expression of the obesity (142). Thus, these mutant animals are apparently hypersensitive to these effects of corticosterone. The full physiological impact of glucocorticoids requires further exploration. However, it has been shown that many of the neuropeptide genes within the hypothalamus are modulated by glucocorticoids. Whether it is all of these genes that are affected by adrenal steroids or a select few remains to be determined.

#### V CARBOXYPEPTIDASE E (*fat*)

The *fat* mutation was identified in a colony of HRS/J mice (carrying the *hairless* mutation) and subsequently transferred to the C57BLKS/J strain for ease of propagation and comparative studies with other obesity mutations (143). The obesity develops in adult animals and is obvious at approximately a similar age as in *A<sup>y</sup>* mice. Mutant mice of both sexes are infertile, as has been found for many of the recessive obese mutations maintained on the C57BL strains. The mutants are also glucose intolerant with hyperinsulinemia of a sort that is unlike that seen in any of the other mouse obesity mutants. The insulin found in the blood is primarily proinsulin produced from the two insulin genes of the mouse genome (144). This remarkable observation, coupled with the chromosomal mapping of the mutation, was crucial to the eventual identification of the *fat* mutation.

The gene that is mutated in *fat* mice was, at the time of the identification of the mutation, a well-characterized enzyme, carboxypeptidase E, a member of a family of carboxypeptidases that have similar and overlapping activities (145). The carboxypeptidases cleave the carboxyl residues from proteolytically cleaved substrates of proprotein convertases. Some substrates can be cleaved by multiple carboxypeptidases, such as carboxypeptidase D cleaving similar substrates as CPE. CPE

is found in many secretory tissues (islet beta cells and salivary glands among them) as well as the brain and neuroendocrine organs. While the activity of CPE was well known, it remained for studies of the CPE mutation to highlight the central role of CPE in processing of many hormones and neuropeptides.

#### A Molecular Clues to the Identification of the *Cpe<sup>fat</sup>* Mutation

As previously mentioned, Ed Leiter had observed the profound hyperproinsulinemia of *fat* mutants. He had also mapped the *fat* mutation to chromosome 8 within an interval that contained the *Cpe* locus. Further characterization of the nature of the circulating proinsulin indicated that the proinsulins were extended by an amino acid at the carboxy terminus, a defect that was consistent with a lack of carboxypeptidase processing. The identification of the *fat* mutation highlights the value of key observations regarding the basic pathological processes affected by a mutation combined with relatively crude genetic mapping—an excellent candidate gene was immediately identified.

#### B Nature of the *fat* Mutation

These observations led to the direct test for mutations of the *Cpe* gene in *fat* mutants and the identification of a point mutation in the *Cpe* coding sequence that causes a Ser202Pro substitution. Although the mutation did not alter mRNA abundance or protein levels, there was a complete loss of CPE enzymatic activity. The simple amino acid substitution would not be predicted to alter transcript size or abundance or to affect translation. However, the amino acid substitution presumably affects the three dimensional structure of the protein so that the protein is misfolded leading to either an inactive conformation or defective sorting to the appropriate subcellular compartments.

#### C CPE Functions as a Sorting Enzyme in the Regulated Secretory Pathway

A characterization of the proteolytic products and the secretory pathways of protein in CPE-deficient cells and tissues led to discovery of another previously unknown function of CPE. There are two major cellular pathways for protein secretion: the constitutive secretory pathway, and the regulated secretory pathway (146). The constitutive pathway secretes proteins continuously and these proteins are mainly minimally processed in terms of proteolytic cleavage and other posttranslational

modifications. The regulated secretory pathway is used by many secretory cells, including neuroendocrine cells, to control the timing and rate of secretion of many extensively processed hormones and neuropeptides, e.g., POMC (147) and preproinsulin. CPE-deficient cells constitutively secrete neuropeptides and hormones in their partially processed states that are usually inactive or retained only partial activity (148). It was discovered that CPE has a membrane-bound form that is the sorting protein that funnels prohormones to the regulated secretory pathway by recognizing sequence motifs within the prohormones. This function could be the major defect in *fat* mice, since other carboxypeptidases could compensate for proteolytic deficiency. The inability to sort most peptide hormones and neuropeptides to the appropriate secretory pathway would effectively inactivate regulated secretion of neurons, neuroendocrine and endocrine cells, preventing effective regulation of the intricate networks that rely on cosecretion and feedback stimuli (both positive and negative).

#### D Defective Neuropeptide Processing Probably Underlies the Obesity of *fat* Mutants

As would be expected, the brains of *fat* mice show numerous abnormalities in neuropeptide content. Almost all neuropeptides are processed via the regulated secretory pathway and require CPE function, both for proteolytic cleavage and for sorting (149). Chief among these defects are deficiencies in the processing of POMC and CCK (150) that might be predicted to lead to a loss of inhibition of food intake. Orexigenic peptides such as MCH are also improperly processed in *fat* mice, perhaps muting somewhat the increase in food intake that might occur if only anorexiant peptides were affected. However, the action of the extremely potent orexiant, AGRP, may actually be enhanced by CPE deficiency. In the AGRP transgenic mouse, constitutive expression of unprocessed AGRP is sufficient to promote hyperphagia and obesity. Thus, the net effect of CPE deficiency on anorexigenic and orexigenic peptides and neurons could result in obesity.

## VI *TUBBY*

The *tubby* mutation was identified as a recessive allele that produced mild, late onset obesity in C57BL/6J mice (143). Subsequently, the mice were also found to suffer from vision and hearing loss, owing to retinal degeneration and the loss of cochlear hair cells, respectively, by apoptosis (151). The identification of the gene and the

mutation were achieved through positional cloning approaches by two groups (152,153). The gene encodes the founding member of a novel gene family that includes TULP1, TULP2, and TULP3. TULP1 mutations are responsible for some forms of retinitis pigmentosa in nonobese humans (154), suggesting that there may be common features and functions between members of this family. The *tubby* mutation alters 3' splice donor site causing the loss of 44 carboxyl terminal amino acids and their replacement by 22 intron-encoded amino residues. Thus, the carboxyl terminus is essential for the function of tubby protein.

#### **A Molecular Clues to the Identification of the *Tubby* Mutation**

The *Tubby* gene was isolated by positional cloning (152,153). A physical contig was generated that was analyzed by exon trapping and direct sequencing. Putative exons were found that hybridized to a transcript that was increased in size by ~ 400 bp (7.5 kb in *tubby* brain vs. 7 kb in normal brain) and was increased in amount in the mutant. The eventual identification of the splice donor site mutation in the penultimate exon (exon 11 of a total of 12 exons) fully explained the anomalous mutant transcript's size and quantity. The loss of the donor splice site prevented the excision of the last intron (~ 400 bp in length), leading to the increased transcript size. The increased transcript amount could be explained by lack of possible feedback inhibition, and the premature termination codon in the now terminal exon that protected the mutant transcript from nonsense-mediated mRNA decay that usually acts on mutations occurring prior to the terminal exon.

#### **B *Tubby* Encodes a Transcriptional Transactivator Activated by Gq-Coupled Receptors**

The tubby protein is expressed in neural tissues, primarily in the hypothalamus (arcuate, PVN, and VMN) and other regions of the brain, as well as the retina and cochlea. Within neuronal cells, the tubby protein is localized to the nucleolus (155). While increased apoptosis has been implicated as a causal mechanism for the loss of hearing and vision, this is unlikely to be the case for the obesity and hypothalamic neurons. Expression studies show that *tubby* mRNA is increased in the hypothalamus of mutant mice. This would be unlikely to be the case if neurons were being eliminated via apoptosis. A selective reduction of a subpopulation of neurons is possible since there is a small reduction of

NPY mRNA in the arcuate nucleus of *tubby* mice with a concomitant induction of NPY expression in the VMN and the DMN (156). This is very similar to the pattern of expression of NPY mRNA in *A<sup>y</sup>* mice, suggesting that altered neuropeptide gene expression, as a result of faulty TUBBY transactivation, might be the responsible obesity-producing mechanism. Also, POMC mRNA is greatly reduced in mature, obese *tubby* mutants although this has not been observed in young, preobese mutant mice. In favor of selective apoptosis of a neuronal subpopulation is that a similar phenomenon of ectopic induction of NPY mRNA is observed in mice with lesions of the hypothalamic arcuate nucleus generated by gold thioglucose (GTG treatment of adult mice) and glutamate (MSG treatment of neonates). Therefore, the mechanism causing obesity in *tubby* mice remains to be determined, at both the molecular and cellular levels.

In a novel approach to understanding the function of tubby protein, structural analyses were conducted to determine the conformation of the protein (157,158). The amino terminus has a simple sequence that is a characteristic of transactivating domains while the carboxyl terminus bears a large groove lined with positively charged amino acids that binds and bends double stranded DNA, a characteristic of DNA binding domains of transcriptional transactivators. An interesting feature of the tubby protein is its dual localization to the plasma membrane and the nucleus, having a sequence motif in its carboxyl terminus that binds phosphatidylinositides, anchoring it to the plasma membrane as well as a nuclear localization sequence near the carboxyl end.

Tubby is functionally coupled to Gq protein and Gq-coupled receptors. HTR2C is such a receptor (see below). Activation of HTR2C and Gq-coupled receptors causes the release of tubby protein from its plasma membrane anchor resulting in translocation into the nucleus, presumably to function as a transcriptional transactivator of target genes that remain to be identified. Given the similarities in the obese phenotypes of *tubby* and *Htr2c* knockout mice, it is quite possible that the functional coupling described in vitro faithfully reflects the situation in the brain.

There have been no studies of the ingestive behavior of *tubby* mice, and it remains to be resolved whether the mild obesity is due to hyperphagia or increased metabolic efficiency. However, the late-onset obesity and degree of adiposity are similar to the phenotype of *Htr2c* knockout mice, which have been reported to be purely hyperphagic. One can surmise that tubby mutant mice develop obesity due to mild hyperphagia, but it

remains to be determined whether there is a metabolic component to the weight gain.

### C Modifier of Tubby Hearing—*Moth1*

In outcross progeny, Tubby homozygotes are not uniformly deaf. A modifier gene, *moth1*, for modifier of tubby hearing, was localized to chromosome 2 (155). Analysis of the mode of inheritance indicated that the B6 allele was recessive suggesting that a loss-of-function mutation is present in the C57BL/6J strain that is only manifest in the absence of tubby protein. Because no other phenotypes were analyzed, it is not known whether the modifier affects the degree of obesity and the retinal degeneration. However, since retinal degeneration due to *TULP1* mutations (humans and mice) is the only phenotype, and the mutations do not produce obesity or deafness, it is quite possible that tissue-specific expression of *moth1* would only manifest as an effect on hearing.

## VII CCK AND CCK RECEPTORS

Cholecystokinin has satiety-producing effects during the ingestion of a meal (159). Exogenous CCK will limit meal size, and the prevention of intestinal CCK release will lead to continuous ingestion, as modeled in rats with gastric cannulae during sham-feeding studies. The action of intestinal CCK appears to be mediated by CCK receptors on afferent vagal neurons, although a direct action of CCK in the brain has also been suggested.

A spontaneous mutation of the CCK-A receptor has been identified in a rat model of adult-onset obesity and diabetes, the Otsuka Long-Evans Takashima Fatty rat (OLETF) (160). The recessive mutation is due to a deletion of a large segment of the *CCKAR* gene. The affected rats ingest larger meals, consistent with a defect in satiation mediated by the CCK receptor (161,162). However, mutant mice with a knockout of the *Cck* (163) or the *Cckbr* (164) genes do not develop obesity, although they are resistant to the satiety effects of CCK. In addition, humans with apparent inactivating mutations of *CCKAR* are not obese.

It appears that the role of CCK differs among mice, rats, and humans. CCK appears to play a more central role in satiation in rats. Alternatively, the OLETF rat may have another mutation in another locus that interacts with the *CCKAR* deficiency to produce obesity. This is quite possible since a diabetes phenotype in OLETF rats is dependent on two loci. This rat obesity model suggests that mutations at multiple loci can

interact to produce an obese phenotype that mimics the effects of single gene mutations.

## VIII HUMAN SINGLE-GENE OBESITIES

Human orthologs for all of the spontaneous rodent single gene obesities have been identified. Mutations in human orthologs of *Lep*, *Lepr*, and *Cpe* (*PC1* in human) that result in obesity have been described (see below). These important instances confirm the role of these genes and their constituent pathways in the regulation of body fat in humans. However, such mutations, and other single-gene obesities, account for only a small number of instances of human obesity (165). Association and linkage studies, as well as physiological data, indicate that most instances of human obesity are not due to mutations in a single gene. However, such instances are of great importance for the insights they provide with regard to the molecular physiology of weight regulation.

### A Orthologs of Single-Gene Obesities in Rodents

#### 1 Leptin. *LEP* (7q31.3)

##### a. *LEP* G398→Del

Montague et al. (166) reported a consanguineous Pakistani family with two children who were homozygous for an inactivating G398→Del leptin mutation. The children (8-year-old girl, BMI 45.8; 2-year-old boy, BMI 36.6) were identified because of their extreme obesity and hyperphagia; both had heights at the 75th centile for their ages. The mutation creates a frameshift resulting from the deletion of a guanine nucleotide at position 398, codon 133. Fourteen amino acids are introduced into the reading frame of the mutant protein, followed by a premature stop codon. Transient transfection experiments of CHO cells with the mutant protein demonstrated the presence of mutant leptin in the cell lysates but none was secreted, suggesting abnormal protein transport within the cell. Western blot analysis of the sera of the affected children showed no serum leptin, supporting the prediction that the mutation prevented protein secretion. In this sense, the functional effect of this human mutation closely resembles that of *Lep<sup>ob</sup>*.

Similar to *ob/ob* mice with inactivating leptin mutations, these children developed early-onset, severe hyperphagia and obesity. These children had few associated endocrine abnormalities, mainly mild euglycemic

hyperinsulinemia. The older child had much higher insulin concentrations than the younger child, suggesting an increase of insulin resistance with age. Of note, however, the mild hyperinsulinemia was much less than the striking elevations seen in *ob/ob* mice. The young children also had gonadal axis profiles consistent with a pre-pubertal state. In distinction to the *ob/ob* mice, both children had normal plasma cortisol and body temperature; the older child responded normally to a 1-mg dexamethasone suppression test. Both children showed slight elevations of TSH, in contrast to the mild hypothalamic hypothyroidism of the *ob/ob* mouse. Growth hormone was not studied, though the older child's growth velocity was normal and she had an advanced bone age (at age 9 years, bone age was 12.5 years) (167). As indicated earlier, *ob/ob* mice display hypogonadotropic hypogonadism, as have human subjects found to have inactivating *LEP* and *LEPR* mutations. However, at least one female with an inactivating *LEPR* mutation has entered spontaneous puberty at age 21 years (personal communication, K. Clement). Thus, as for the effects of *ob* on sexual maturation in mice (see above) (168,169), there may be important genetic modifiers of leptin actions on the gonadal axis in humans. The older child was subsequently treated with a 12-month course of daily subcutaneous recombinant leptin, 0.028 mg/kg lean body mass (167). This dose was chosen to achieve peak serum leptin concentrations of 10% of the predicted normal leptin for this obese child (70 ng/mL). She experienced a 16.4-kg weight loss during the 12-month treatment period; 95% of the weight loss was due to loss of body fat. She also had a significant and rapid change in her eating behavior (within 1 week of initiating leptin injections): she ate much less food, at a slower rate, and did not seek or request food between meals. The reduction in food intake was sustained throughout the study. She had similar total energy expenditure before and after 12 months of therapy, so the leptin therapy primarily affected her energy intake, not her energy expenditure. At the start of therapy, the subject had endocrinologic studies consistent with a prepubertal state; after 1 year of therapy (at age 10), she had a profile consistent with early puberty: nocturnal, pulsatile gonadotropin secretion.

#### b. *LEP* Arg105Trp C→T

A second family with an inactivating missense leptin mutation was described by Strobel et al. (170). Two homozygous subjects were members of a highly consanguineous Turkish family. The mutation was a C→T missense mutation leading to Arg105Trp, which is

similar to *ob* mice that have an Arg105STOP mutation. COS-1 expression studies showed the presence of immunoreactive protein in cell lysates but no secretion, similar to the G398→Del mutation in the Pakistani kindred. One subject was a 22-year-old male, BMI 55.8, and the second was a 24-year-old female, BMI 46.9. Both had early-onset hyperphagia and obesity. The affected woman had primary amenorrhea, and the male had evidence of hypothalamic hypogonadism. The adult male subject also had evidence of reduced sympathetic autonomic nervous system tone (low systolic blood pressure in response to cold pressor test, reduced sympathetic skin response, and mild orthostatic hypotension). The homozygous Arg105Trp C→T mutation was found in three additional obese relatives of these individuals. Family members heterozygous for the *LEP* mutation were said to be of normal body weight and to have normal plasma leptin concentrations. Subsequent studies of three nominally unrelated Pakistani families segregating for a del G133 (glycine deletion) mutation in *LEP* have found increased body fat and low circulating leptin in heterozygous individuals (171). These findings are remarkably similar to those reported earlier in mice heterozygous for the *Lep<sup>ob</sup>* and *Lep<sup>db</sup>* mutations (172), and support the idea that moderate deficiency of leptin may have physiological consequences (173). While several large studies have demonstrated the rarity of major *LEP* mutations in obese humans (174,175), minor differences in *LEP* coding or regulatory sequences could contribute to variation in body fat in humans (Table 2). As possible evidence of such effects, among humans with the same body fat, serum leptin concentrations vary considerably, either higher or lower than expected given the subject's degree of adiposity (176,177). Also, molecular markers in the region of *LEP* (7q31.3) have been linked to skinfold thickness using a sibship database of Mexican-American probands with type 2 diabetes (178), and a *LEP* polymorphism (A19G in first [untranslated] exon) has been associated with severe obesity in some studies (179). And, finally, that humans, mice, and rats heterozygous for mutations in leptin or the leptin receptor are fatter than wild-type individuals indicates that the systems regulating body composition are sensitive to partial deficiencies of these molecules (173).

#### 2 Leptin Receptor. *LEPR* (1p31-p22)

Clement et al. (180) described three sisters from a consanguineous Algerian family (Berbers) who were homozygous for an inactivating *LEPR* mutation: IVS16, G→A, +1. The mutation is in the 3' donor splice site

**Table 2** *LEP* Mutations in Human Subjects

| Mutation                  | Association with obesity   | Refs.     |
|---------------------------|--|-----------|
| G398→Del                  | Yes  | (166)     |
| Arg105Trp C→T             | Yes  | (170)     |
| A19G                      | Variable association   | (323–325) |
| –2548 G→A                 | Effects on BMI in response to diet;<br>polymorphism more frequent in<br>obese population | (323,326) |
| –2437 T→G                 | Effects on BMI in response to diet   | (323)     |
| –1887 C→T                 | Effects on BMI in response to diet   | (323)     |
| –1823 C→T                 | Effects on BMI in response to diet   | (323)     |
| –1387 G→A                 | Effects on BMI in response to diet   | (323)     |
| –633 C→T                  | Effects on BMI in response to diet   | (323)     |
| –188 C→A                  | Effects on BMI in response to diet   | (323,327) |
| Gln25Gln (nucleotide 131) | None   | (328)     |
| G144A                     | Decreased leptin concentration in 2 subjects   | (324)     |
| G328A; Ala110Met          | Decreased leptin concentration in 2 subjects   | (324)     |
| C538T                     | None; silent mutation  | (324)     |

of exon 16 and results in skipping of this exon. The resulting protein is truncated (831 amino acids) and lacks the transmembrane and intracellular domains. Accordingly, the long form of the leptin receptor (1162 amino acids with STAT binding domain) is completely absent in these subjects, similar to the *db/db* mouse. The three affected sisters had early-onset obesity and severe hyperphagia. At ages 13, 19, and 19 (now deceased) years, they had BMIs of 71.5, 65.5, and 52.5, respectively, and had heights considered low for their degree of obesity (25–50th centile for age) (181). Leptin concentrations were much higher than predicted based on their degree of adiposity (670 and 600 ng/mL, respectively). The five heterozygous family members had intermediate levels of circulating leptin and were moderately obese (BMI range 26.5–31). Interestingly, in both homozygous and heterozygous individuals, 80% of circulating leptin was in a high molecular weight (MW) complex (~450 kDa), whereas in nonmutant individuals, only 5–20% of circulating leptin is present in the high MW form (51,182).

Endocrine studies of the surviving homozygous subjects showed absence of a nighttime GH surge with reduced GH release in response to secretagogues. IGF-1 concentration was low, but increased after GH administration, a response also characteristic of GH-deficient subjects. The affecteds had no physical changes suggestive of puberty and had low estradiol, LH, and FSH levels consistent with central hypogonadism. However, as indicated above, one of the females has entered puberty spontaneously at age 21 years.

Besides this Berber family reported by Clement et al. (180), several studies of obese humans have found a high frequency of sequence variation in the coding sequences of *LEPR* but none which unequivocally lead to obesity (183). Also, several association studies showed no connection between *LEPR* allelic variation and adiposity (184–186), and a Danish study found no association between *LEPR* variations and early-onset obesity (187). A recent meta-analysis of data from nine independent studies (3263 individuals) also showed no significant linkage of these sequence variants to BMI (188) (Table 3).

### 3 Melanocortin 4 Receptor. *MC4R* (18q21.3-q22)

The molecular physiology of the melanocortin system is described above. Inactivating *MC4R* mutations were originally described in two nonconsanguineous families; all subjects were heterozygous for mutations that segregated in a dominant fashion (189,190). These are the only reported cases of dominantly expressed obesity in humans, similar to the codominant obesity of *Mc4r* null mice. One family had a 4-bp deletion at codon 211 (4-BP DEL, NT631), and the second family had a 4-bp insertion at codon 244 (4-BP INS, NT732). In both cases, these frameshift mutations led to truncation of the protein in either the fifth or sixth transmembrane region, respectively. Since the transmembrane regions are critical for obtaining proper receptor conformation, mutations affecting/obliterat-

**Table 3** *LEPR* Mutations in Human Subjects

| Mutation           | Association with obesity                | Ref.                          |
|--------------------|---|-------------------------------|
| Lys109Arg          | Variable                                | (183,185,187,329,330)         |
| Lys204Arg          | No association with obesity             | (187,331)                     |
| Gln223Arg          | Variable                                | (183,185–187,329,330,332–335) |
| Ser343Ser          | No association with BMI                 | (185)                         |
| Lys656Asn          | Variable                                | (183,185–187,330)             |
| Ser675Thr          | Found in 2 subjects                     | (331)                         |
| Pro1019Pro         | Variable                                | (185,332)                     |
| Codon 986 (silent) | Associated with BMI among lean subjects | (185)                         |
| IVS16, G→A, +1     | Found in 3 subjects                     | (180)                         |

ing specific transmembrane regions would be predicted to significantly affect receptor functioning. The affected subjects had childhood-onset hyperphagia and obesity with elevated leptin concentrations consistent with their level of adiposity.

To date, 27 mutations have been described in *MC4R*, the majority of which are associated with obesity. However, for some apparently significant deletions (191) and missense mutations (192), variable or no phenotypic impact has been reported. In some studies, 5% of morbidly obese subjects have been reported to be heterozygous for *MC4R* mutations (193).

#### 4 Pro-opiomelanocortin. *POMC*(2p23.2)

POMC is synthesized as a large precursor molecule, pre-POMC, that is processed in the pituitary into several transcripts, including ACTH,  $\alpha$ MSH,  $\beta$ -lipotropin, and  $\beta$ -endorphin (see Fig. 3). PC1 cleaves POMC into ACTH and  $\beta$ -lipotropin, whereas PC2 cleaves POMC into  $\beta$ -endorphin and  $\alpha$ MSH (see Fig. 3). Krude et al. (194) described two unrelated children with inactivating *POMC* mutations. Both had severe, early-onset obesity, adrenal insufficiency, and red hair. The phenotypes are consistent with absence of the pre-POMC cleavage products: ACTH and  $\alpha$ MSH. The functional consequences of absence of ACTH and  $\alpha$ MSH ligand/receptor activity are discussed with regard to the relevant mouse mutations above. The light skin and hair of the children with these mutations are due to reduced MSH activity at MC1R.

One patient was a 3-year-old girl who weighed 32 kg and was a compound heterozygote for mutations in exon 3: G7013T and C7133Del (194). Both mutations in the 3-year-old led to premature termination of POMC, at codons 79 and 131, respectively, and absence of ACTH,  $\alpha$  MSH, and  $\beta$ -endorphin. She had no detectable circulating ACTH or cortisol after CRH stimula-

tion, but the other anterior pituitary hormones were in the normal range. Her older brother, who had died at 7 months, was found on autopsy to have bilateral adrenal hypoplasia, which led to recognition of his sister's similar status at 23 days of life. His newborn screening filter paper blood specimen was located after his death and used for *POMC* mutation analysis; he had the same *POMC* genotype as his sister.

The second subject was a 5-year-old boy who weighed 48 kg, had adrenal insufficiency and red hair, and was homozygous for C3804A which is 11 bp 5' of the normal start site of the 5'UTR in exon 2 (194). This mutation adds an out-of-frame start codon within a consensus sequence for translation initiation and is thus predicted to abolish *POMC* translation. Consistent with this prediction, the subject had no detectable circulating ACTH. The obligate heterozygote parents were described as having normal body weight and dark hair.

There have been at least 14 other *POMC* mutations described, but none with complete loss of POMC cleavage products, though most are associated with obesity (except for several silent mutations) (192) (see Table 4). Linkage studies have shown that a region on chromosome 2 that includes *POMC* accounted for 32% of variation in fat mass and 47% of variation in serum leptin concentration (195,196).

#### 5 *PC1* (5q15-q21)

Prohormone convertase 1, also called PCSK1 or PC3, is a member of the family of serine proteases of the subtilisin family that are located in acidic secretory vesicles (197). PC1 acts just proximal to carboxypeptidase E (CPE) in the posttranslational processing of many prohormones and proneuropeptides, including insulin. Specifically, PC1 cleaves proinsulin at a dibasic peptide, Arg31-Arg32, joining the B-chain and C-peptide. Thus,

**Table 4** *POMC* Mutations in Human Subjects

| Mutation in <i>POMC</i> ;<br>location                                   | Mechanism (Ref.)   |

| Glu188Gly   | Missense (337)   |
| G7016A, Asp80Asn  | Missense (337)   |
| C6982T, C7285T  | Silent (337)   |
| C3832T  | Silent (337)   |
| C7111G  | Silent (337)   |
| G7316T, Glu180Stop  | Premature stop codon within<br>$\gamma$ -LPH sequence (337)                    |

PC1 is crucial to the regulation of insulin biosynthesis. In the *fat* mouse (see above for details), CPE deficiency leads to altered processing of proinsulin, POMC, GH, CCK, neurotensin, MCH, and gastrin. The *Cpe<sup>fat</sup>* mice display a late-onset, moderate obesity (198–202).

While no *CPE* mutations leading to obesity have been described in humans, there has been one instance of obesity associated with mutations in *PC1* (203). O'Rahilly et al. (203) described a morbidly obese 43-year-old woman (89.2 kg) with childhood-onset extreme obesity (36 kg by age 3 years). She was found to be a compound heterozygote for mutations in *PC1*: G483R and A→C +4 at the donor splice site of exon 5 (IVS5DS, A-C, +4) (203). G483R prevents processing of the proPC1 molecule, and the second mutation (IVS5DS, A-C, +4) causes a frameshift and a premature stop codon. The patient's endocrine phenotype was characterized by extremely high circulating proinsulin

concentration, nearly undetectable insulin, hypocortisolism, and hypogonadotropic hypogonadism, all consistent with impaired processing of the respective prohormones. Interestingly, the *Cpe<sup>fat</sup>* mice display hyperproinsulinemia, consistent with their more distal enzymatic defect in carboxypeptidase E.

## 6 PPAR $\gamma$ (3p25)

PPAR $\gamma$ 2 is specifically expressed in adipose tissue, is induced early in adipocyte differentiation, and, when experimentally expressed in fibroblasts, induces the fibroblasts to differentiate into adipocytes. Since PPAR $\gamma$ 2 leads to adipocyte differentiation and thus fat cell accumulation, the more active the PPAR $\gamma$ 2 protein (activating mutations), the higher the BMI and the higher the risk for insulin resistance. Similarly, the less active the PPAR $\gamma$ 2 molecule is at inducing adipocyte differentiation (inactivating mutations), the lower the BMI with improved insulin sensitivity. When activated by agonists such as thiazolidinediones, PPAR $\gamma$ 2 acts an insulin sensitizer in adipose tissue, liver, skeletal muscle, and kidney. There have been six mutations described in PPAR $\gamma$ 2 with inconsistent associations with obesity.

In expression studies, Pro12A1a decreases TZD-mediated transcriptional activation and adipogenesis (204). Pro12A1a was associated with higher insulin sensitivity and reduced BMI (205,206), but the apparent effect on insulin sensitivity was eliminated by correction for BMI. Other studies have found an association with an increased BMI (207,208), while two studies have not found such an association (209,210). Meta-analysis indicated that Pro12A1a was associated with a decreased risk for type 2 diabetes mellitus (211). A potential explanation of these conflicting findings comes from the recent paper of Hastedt et al. (212), in which Pro12A1a was found to act as a recessive mutation with effects on many traits associated with the insulin resistance syndrome (including BMI, blood pressure, triglyceride levels, and glucose tolerance), and had a homozygote frequency of 1–2% of the population. The varying associations with Pro12A1a found in the literature could be due to population differences in the frequency of the mutation (212).

Meirhaeghe et al. (213) examined whether a relatively common, silent polymorphism (C161T in exon 6) was associated with phenotypes related to obesity. The authors found no association between the polymorphism and BMI, body weight, leptin concentration, waist-hip ratio, but did find a statistically significant interaction

between the polymorphism, BMI, and plasma leptin. At any given leptin concentration, obese subjects (BMI > 30) who were heterozygous or homozygous for the polymorphism had relatively lower BMIs than obese wild-type subjects (213). A study of the same mutation by Wang (214) also showed no association with obesity but did find a decreased risk of cardiovascular disease in heterozygous and homozygous subjects.

A Pro115Gln mutation affects phosphorylation at the adjacent Ser114, accelerating adipocyte differentiation and possibly reducing insulin responsiveness (215). Pro115Gln was studied in a cohort of 358 Germans (mean age 59 years) (215). Four markedly obese subjects were heterozygous carriers of the mutation, which was not found in any nonobese individuals. Of note, the four carriers of the mutation had BMIs greater than the obese (BMI > 29) noncarriers of the mutation: affected BMIs ranged from 37.9 to 47.3; obese, noncarriers mean BMI 33.6.

A silent mutation, C1431T in exon 6, has been linked to severe overweight and increased fat mass in obese women (207). Postmenopausal Japanese women who were either heterozygous or homozygous for the mutant T-allele were also shown to have reduced bone mineral density in comparison to individuals with the C allele (216). The same mutation was also weakly associated ( $P < .03$ ) with circulating leptin concentration in 820 French subjects (213).

Barroso et al. (217) described two mutations, Val290Met and Pro467Leu, which destabilize helix 12 in the ligand-binding domain and lead to transcriptional impairment by apparent dominant negative effects on the nonmutant transcripts. A mother and her son were identified who were heterozygous for Pro476Leu. Both subjects had type 2 diabetes and hypertension, but were not obese (55-year-old woman, BMI 24.9; 31-year-old male, BMI 25.9). A 15-year-old girl was identified who was heterozygous for Val290Met. She also had type 2 diabetes and hypertension, and was not obese (BMI 25.6) (Table 5).

## 7 *SIM1* (6q16.3-q21)

*SIM1* is the human ortholog of the *Drosophila Sim* ("single-minded") transcription factor that is involved in midline neurogenesis and is essential for development of several neuroendocrine lineages in the supra-optic nuclei and PVN in the hypothalamus, including arginine vasopressin, oxytocin, corticotropin-releasing hormone, and thyrotropin-releasing hormone (218). Haploinsufficient mice have a reduction in cell number in the PVN, and are obese (219). Holder et al. (220) described a girl with a balanced translocation between 1p22.1 and 6q16.2 that disrupted *SIM1*. She displayed hyperphagia and early-onset obesity (weight 47.5 kg at age 5 years), and had normal energy expenditure.

**Table 5** *PPAR $\gamma$*  Mutations in Human Subjects

| Mutation in <i>PPAR<math>\gamma</math></i> ; location | Mechanism (reference)  |
|---|--|
| Pro12Ala exon B (unique to PPAR $\gamma$ 2) C→G       | Missense C→G; expression study (204) showed mutant with decreased ability to mediate transcriptional activation and adipogenesis induced by TZDs; Ala allele has decreased binding affinity to cognate promoter elements and decreased ability to transactivate responsive promoters (206); less active PPAR $\gamma$ : decreased BMI, improved insulin sensitivity (208,211). |
| C161T; exon 6 (ligand-binding domain)                 | Ligand-binding domain (213).   |
| Pro115Gln; exon 6 (ligand-binding domain)             | Overexpression in fibroblasts produces a protein with defective serine phosphorylation at position 114, accelerated adipocyte differentiation greater triglyceride accumulation than wildtype. More active PPAR $\gamma$ may result in increased BMI and increased insulin resistance (214,215).   |
| Val290Met   | Mutations destabilized helix 12 in the ligand-binding domain leading to transcriptional impairment by dominant negative effects on non-mutant transcripts (217).   |
| Pro476Leu   |  |
| His478His, C1431T, exon 6                             | Silent; association between this SNP, RFLP, and bone mineral density in postmenopausal Japanese women (216).   |

Holder suggested that her obesity could be due to *SIM1* haploinsufficiency.

## IX HUMAN GENETIC OBESITIES WITHOUT MOUSE HOMOLOGS

### A Obesity Syndromes with Single or Oligo/Contiguous Gene Basis

#### 1 Albright Hereditary Osteodystrophy

Albright hereditary osteodystrophy (AHO) (pseudo-hypoparathyroidism) is a genetically heterogeneous syndrome (generally autosomal dominant) characterized by skeletal and developmental abnormalities (short stature, brachydactyly, subcutaneous ossifications), mental retardation (in some cases), and obesity. Some instances are due to mutations in the *GNAS1* gene, a complex locus that encodes several overlapping transcripts. AHO has resulted from heterozygosity for inactivating mutations in the alpha subunit of a stimulatory G protein [G(s)alpha] encoded by *GNAS1*. Mutations in Gs may lead to obesity based on reduced function of this stimulatory G-protein in the lipolytic pathway, where Gs transduces lipolytic signals through the  $\beta$ -adrenergic receptor. There is evidence for genomic imprinting at the *GNAS1* locus. When the mother transmits the mutation, the phenotype is usually PHPIa (pseudo-hypoparathyroidism type Ia) with low serum calcium and elevated PTH, whereas paternally transmitted mutations lead to PPHP (pseudo-pseudo-hypoparathyroidism) with normal calcium levels and no generalized hormone resistance; all patients manifest osteodystrophy. In both PHPIa and PPHP patients, levels of Gs $\alpha$  expression and activity are 50% normal in the affected tissues. Almost 40 different inactivating mutations distributed throughout the *GNAS1* gene have been described in association with AHO; most are either frameshift mutations, creating premature stop codons, or missense mutations (221).

Of note, several activating mutations in *GNAS1* have also been described in association with McCune-Albright syndrome and several endocrine tumors (such as pituitary adenomas, pheochromocytomas, and thyroid carcinomas; the *GNAS1* gene is designated “gsp oncogene” in tumor tissues). Patients with McCune-Albright are somatic mosaics for gain-of-function *GNAS1* mutations and have abnormalities in bone, skin, and endocrine tissues, with widely varying symptoms depending on the tissue expressing the mosaicism. Common findings in this autosomal dominant, embryonic lethal (unless mosaic) condition include polyostotic fibrous dysplasia, large café au lait spots (irregular

margins, “coast of Maine”), hyperthyroidism, and precocious puberty (due to constitutively activated gonadal LH and FSH receptors) (222).

#### 2 Bardet Biedl Syndrome 1–6 (BBS)

BBS is a heterogeneous autosomal-recessive disorder with six different chromosomal regions implicated, termed BBS types 1–6: 11q13, 16q21, 3p12, 15q22.3-q23, 2q31, 20p12. Three genes have been identified to date as causative: *BBS2*, which encodes a protein of unknown function; myosin IX A (*MYO9A*) for BBS4; and *MKKS*, a putative chaperonin, for BBS6. A recent report (223,224) described triallelic inheritance for BBS. They screened 163 BBS families for mutations in *BBS2* and *BBS6* and found three mutant alleles in 4 pedigrees of affected individuals. In one family, affected subjects had 3 mutant alleles: homozygous *BBS6* mutation, heterozygous *BBS2* mutation. In a second family, affected subjects were heterozygous for two different *BBS2* nonsense mutations and also were heterozygous for a single *BBS6* nonsense mutation. However, several pedigrees with *BBS2* mutations in this report do have a classic recessive segregation pattern, so some cases of *BBS* 2 or 6 may be due to alterations in a single gene.

The phenotype does not differ substantially among the different BBS types, and includes mental retardation, obesity, postaxial polydactyly, hypogonadism (apparently at both the hypothalamic and gonadal level), pigmentary retinopathy, and renal disease. The incidence of congenital cardiac anomalies (wide variety of lesions) is increased (225,226), as is that of type 2 diabetes mellitus and hepatic fibrosis (227). BBS1 and 4 are more prevalent in European populations while BBS2 and 3 are typically found in Arab-Bedouin families. Of note, obesity, pigmentary retinopathy, and renal disease are present in almost all patients, while polydactyly and mental retardation are present in only one-third to one-half of patients.

Myosin IX A (*MYO9A*) is implicated in BBS4. *MYO9A* is expressed throughout the nervous system, neural layer of the retina, inner ear, kidney, thyroid, and teeth. The mechanism(s) by which loss of function of this molecule produces the BBS phenotype are unclear.

The *MKKS* (BBS6) predicted protein has amino acid sequence homology to the chaperonin family of proteins that are involved in protein folding and assembly (228). Chaperonins share a common ring structure with a central cavity where incorrectly folded proteins bind (not in a sequence-specific manner), and via ATP-hydrolysis, the chaperonin enables the misfolded protein to achieve its native shape. The well-studied eukaryotic cytosolic chaperonin, CCT, is composed of

two rings, each with eight dissimilar units, in a cylindrical assembly. Inactivating mutations of *MKKS* lead to BBS6, whereas less severe mutations (missense, frameshift) result in the McKusick-Kaufman syndrome (hydrometrocolpos, postaxial polydactyly, and congenital heart disease). It is possible that inactivation of *MKKS* leads to misfolding of target proteins whose resulting malfunction results in BBS. Alternatively, *MKKS* may be part of an oligomeric protein whose function is disrupted by the absence or aberrant sequence of *MKKS*.

Heterozygosity effects have been described for BBS. Croft found that heterozygous BBS subjects (type unspecified) had increased frequency of obesity, hypertension, diabetes mellitus, and renal disease (229). In a study of 34 heterozygotes, again without specifying BBS types (230), the proportion of overweight (defined as BMI > 31.1) male heterozygotes (26.7%) was significantly higher than age-matched U.S. white males (8.9%).

### 3 Borjeson-Forssman-Lehmann Syndrome (BFLS) (Xq26.3)

BFLS is an X-linked syndrome with incompletely recessive inheritance characterized by obesity, hypometabolism, hypogonadism, characteristic facies (swollen subcutaneous facial tissue, deep-set eyes, narrow pal-prebral fissures), epilepsy, and mental retardation. Although BFLS is primarily manifest in males, there have been a few cases described in females. One female with BFLS had extremely nonrandom X-inactivation, which accounted for the manifestation of this X-linked disorder (231). Gecz et al. described a male infant with BFLS-like features and a duplication: 46,Y, dup(X)(q26q28), with the duplication breakpoint containing the fibroblast growth factor-13 gene (*FGF13*) (232). In 10- to 12-week human fetal tissue, *FGF13* showed maximal expression in brain and skeletal muscle.

Another gene that localizes to the same region, *SOX3*, is also a candidate for causing BFLS. *SOX3*, SRY-related HMG-box 3, is a member of a family of genes that are related to *SRY*, the testis-determining gene. The homology between *SOX3* and *SRY* is in the region of *SRY* encoding the HMG-box class DNA-binding motif. *SOX3* is expressed in the human fetal brain and spinal cord, and the murine homolog is expressed at very high levels in neuronal tissues during development. Thus, mutation or deletion of *SOX3* could conceivably result in hypothalamic and CNS cortical dysfunction, consistent with the BFLS phenotype. Rousseau et al. described a male patient with

*SOX3* deletion who had hemophilia and mental retardation, and partial primary testicular failure, recapitulating several features of BFLS (mild mental retardation, small testes) (233).

### 4 Congenital Disorder of Glycosylation Type 1a (CDG1a) (16p13.3-p13.2)

The CDG1a syndrome, also known as Jaeken syndrome, is a severe, multisystemic, autosomal-recessive disorder that usually presents in the neonatal period and is characterized by the defective glycosylation of glycoconjugates (especially asparagine-N-linked oligosaccharides in the ER) (234). The syndrome includes severe encephalopathy, axial hypotonia, abnormal eye movement, pronounced psychomotor retardation, peripheral neuropathy, and serum glycoprotein abnormalities. Patients have a peculiar distribution of subcutaneous fat (fat pads above buttocks, lipodystrophy), moderate obesity, and hypogonadism. *PMM2*, phosphomannomutase 2, has been implicated as the responsible gene, which is required for the synthesis of GDP-mannose (converts mannose 6-phosphate to mannose 1-phosphate). Nearly 60 mutations have been described, mostly in exons 5 and 8, with 90% accounted for by two mutations: F119L and R141H (not seen in homozygous state, mutant protein with zero activity in *in vitro* assay).

### 5 Prader-Willi Syndrome (15q11.2-q12)

Prader-Willi syndrome (PWS) is a contiguous deletion/disruption defect involving the region between 15q11.2-q12, likely due to the disruption of *SNRPN*, *necdin*, and potentially other genes (235). This region of chromosome 15 is imprinted. Maternal uniparental disomy (UPD) for these genes results in PWS; paternal uniparental disomy and disruption of the E6-associated protein, ubiquitin-protein ligase (*UBE3A*), results in Angelman syndrome (236).

PWS is characterized by diminished fetal activity, failure to thrive in infancy, hypotonia, followed by the onset of hyperphagia with rapid weight gain after 1 year of age, leading to massive obesity. Body composition is altered, however, even before the subjects develop obesity: PW infants have increased fractional body fat content even during their period of slow postnatal growth (237). Mental retardation, short stature, hypogonadotropic hypogonadism, relative pain insensitivity, and thick saliva are other characteristic features. Most of the features are consistent with CNS effects, but not all (narrow bitemporal diameter, almond eyes, small narrow hands, small feet, skin depigmentation) (238).

Most cases of PWS are sporadic, resulting either from spontaneous interstitial deletions (often microdeletions), de novo unbalanced translocations, or maternal uniparental disomy. Seventy percent of instances are due to microscopic 15q11 deletions, 25% to maternal UPD (often with balanced translocation), <5% to imprinting center mutation and transmitted unbalanced translocation (235). There have been familial cases of PWS, but these are very rare. The recurrence rate in siblings of affected patients is ~1:1000, versus a population risk of ~1:25,000. Most of the instances of maternal UPD result from meiosis-1 errors, whereas paternal UPD cases of Angelman syndrome usually result from meiosis-2 or mitotic errors (239).

There are slight phenotypic differences among patients with different molecular defects leading to PWS. For example, subjects with paternal deletions manifest the classic PWS phenotype, whereas subjects with maternal UPD generally manifest a milder phenotype and have better cognitive function. Subjects with both maternal UPD and mosaic trisomy 15 are the most severely affected and also have a high incidence of congenital heart disease. Maternal age is higher in patients with disomy, in line with the expected findings of a nondisjunction event (240). Depigmentation is more frequent in subjects with deletions (77%) than in those with UPD (39%). Also, female subjects with UPD have slightly milder phenotype than those with deletions (241). The differences in phenotype point to underlying differences in the respective regions and amounts of chromosome 15 that are affected.

*SNRPN* (15q12) has been implicated in the pathogenesis of PWS. *SNRPN* encodes small ribonucleoprotein polypeptide N, a protein found in spliceosomes, and possibly has a role in mediating alternative splicing of CNS mRNA transcripts. Reed et al. showed there is maternal imprinting of *SNRPN* and that the maternal allele is not expressed in the human fetal brain (242). Ishikawa et al. reported two siblings with PWS who had deletions in *SNRPN* by FISH (243). Sun et al. described another PWS patient with a paternal balanced reciprocal translocation t(15; 19)(q12; q13.41) with the breakpoint occurring between exons 0 and 1 of *SNRPN* (exons numbered -1 to 8) (244). No complete *SNRPN* mRNA transcript was identified in this patient. Similarly, Kuslich et al. described a PWS patient with a de novo balanced translocation (4; 15)(q27; q11.2) between *SNRPN* exons 2 and 3 (245). The reports by Sun and Kuslich support the inference that the region between *SNRPN* exons 2 and 3 is critical, and that mutations affecting this region contribute to the major phenotypic manifestations of PWS.

Dittrich et al. described a model involving an imprinting center mapping to 15q11-q13 (246). Their model proposed that the imprinting center (IC) contained an imprintor and an imprint switch initiation site (involving exon 1 of *SNRPN*), and that the imprintor is transcribed only from the paternal chromosome. There are numerous transcripts encoded in the IC that are alternatively spliced and that are only expressed from the paternal chromosome. Since some subjects with PWS (and Angelman's) have mutations affecting the IC, the transcripts are not expressed. Thus, the IC may be critical in regulating alternative RNA splicing in the *SNRPN* transcripts. Lyko et al. studied this region in *Drosophila* and showed that a 215-bp region containing the *SNRPN* promoter region has a silencer of maternal *SNRPN* (247). Lyko suggested that this silencer element may play a role in the imprinting of 15q11-13 and may repress *SNRPN* expression from the maternal allele.

Bressler et al., however, showed that a deletion of exon 1 of mouse *Snrpn* (~1 kb) did not elicit any obvious phenotypic change, while a 4.8-kb deletion including the same region led to a partial imprinting defect and perinatal lethality when paternally inherited (248). Also, Schulze et al. reported a PWS patient with a balanced 9:15 translocation whose breakpoint was between *SNRPN* and an adjacent gene, *PARI*, with *SNRPN* unaffected by the translocation (249). This patient met formal criteria for PWS, including obesity (moderate), hypopigmented in relation to his family, PWS facies, and delayed puberty, but he displayed no hyperphagia (250). These data suggest that *SNRPN* may play a role in regulation of food intake, but not in the other somatic and endocrine phenotypes associated with PWS.

It is unlikely a single gene will be implicated as the cause of the diverse range of PWS phenotypic features given the sizeable deletion in most PWS patients and the number of genes (at least two) in that interval (251). *Drosophila* or mice harboring *Snrpn* deletions and contiguous gene interruptions may help to clarify the molecular pathogenesis of the PWS.

## 6 Simpson-Golabi-Behmel 1 Syndrome (SGBS) (Xq26)

SGBS is an X-linked overgrowth-obesity syndrome. Affected subjects have weights and heights over 97th centile at birth, and manifest postnatal overgrowth, cardiac abnormalities (conduction defects, ventricular septal defects, pulmonic stenosis, transposition of the great vessels, and cardiomyopathies), risk for embryonal tumors, and in general, show significant pheno-

typic overlap with Beckwith-Wiedemann syndrome (neonatal exomphalos, macroglossia, and gigantism).

Two genes have been implicated, glypican 3 and 4 (*GPC3*, 4). Pilia et al. reported two SGBS patients with X/autosome translocations with breakpoints near the ends of the 500-kb *GPC3* gene at Xq26 (252). In three families, microdeletions in *GPC3* cosegregated with SGBS. Veugelers et al. reported on one of the patients initially described by Pilia and found a deletion of the last two exons of *GPC3* as well as the entire *GPC4* gene (253).

*GPC3* and *GPC4* are members of a family of cell surface proteoglycans that appear to control growth and cell division, especially of embryonic mesodermal tissues. *GPC3* seems to act by forming a complex with IGF2. This is reminiscent of another overgrowth syndrome, Beckwith-Wiedemann, which appears to be caused by overexpression of *IGF2* (254).

#### 7 Ulnar Mammary Syndrome (UMS) (12q24.1)

UMS is an autosomal-dominant syndrome characterized by obesity; delayed growth and puberty; and complex malformations of the ulnar ray, teeth, axillary apocrine glands, and urogenital system. The *TBX3* gene (12q24.1) has been implicated as causative by Bamshad et al. (255). *TBX3* encodes a transcription factor that seems to be critical to the morphogenesis of several organs. Mutations in a related gene, *TBX5*, are associated with anterior limb malformations in the Holt-Oram syndrome; *TBX3* appears to be associated with the posterior limb malformations of UMS. The affected subjects were doubly heterozygous for mutations predicted to alter DNA binding: 1 bp del 227T leading to a premature stop codon; IVS 2ds, G→C, +1. Further study by Bamshad found additional novel *TBX3* mutations in families with UMS, but identified no obvious phenotypic differences between those with missense mutations, frameshifts, or deletions (256). The molecular mechanism for the obesity in this syndrome is unknown.

#### 8 Human Alleles of UCPs

The role of allelic variation/mutation in UCPs in human energy homeostasis remains unclear. A number of studies have reported associations with allelic variants of *UCPI* (4q31) with obesity-related phenotypes in humans (some in interaction with an allele of *B3AR*) (257) (258), while others have not found such associations (259). Because BAT is apparently not an important thermogenic organ in humans outside of the neonatal period, *UCPI* is not a particularly strong

candidate for a role in human obesity. *UCP2* and *UCP3* are adjacent to each other on chromosome 11q13. Microsatellites in the region of *UCP2/UCP3* have been associated with aspects of metabolic rate and body composition (260). Three alleles of *UCP2* or *UCP3* have been associated with measures of metabolic rate in Pima Indians (261), and Esterbauer et al. (262) reported an association between a promoter polymorphism in *UCP2* (11q13) and obesity in adults. Because of its primary expression in skeletal muscle, *UCP3* is perhaps the best candidate for effects on energy expenditure in humans. Homozygosity for a V102I mutation in *UCP3* was associated with obesity in three Gullah-speaking African-Americans, and compound heterozygosity for an R143X mutation and a splice junction mutation eliminating the terminal (6) exon (IVS6, G-A, +1) was found in a morbidly obese 16-year-old with type 2 diabetes (263). However, homozygosity for the splice mutation was detected in obese and lean African-Americans, and was not associated with any abnormality in metabolic rate or skeletal muscle mitochondrial coupling (264). No association of this allele with BMI or diabetes was detected in an analysis of a large group of African-Americans (264). An Arg70Trp mutation was found in a severely obese, diabetic 15-year-old Chinese male (265,266).

### B Lipodystrophy Syndromes with Single-Gene Basis

These mutations are included in this discussion because of their profound effects on adipose tissue mass. The genes and pathways involved may also have roles in obesity by virtue of reciprocal effects.

#### 1 Berardinelli-Seip Congenital Lipodystrophy Syndrome (BSCL) (9q34)

During the neonatal period affected patients manifest generalized lipodystrophy, low fat mass, insulin-resistant diabetes mellitus, acanthosis nigricans, elevated basal metabolic rate, and hypertriglyceridemia. Some patients subsequently develop polycystic ovaries and muscular hypertrophy. BSCL is caused by mutations in *BSCL2* (11q13) and *RXRA* (9q34) (267). *BSCL2* is highly expressed in most regions of the central nervous system. All affected subjects with *BSCL2* mutations have been either homozygous or compound heterozygous for mutations that severely disrupt the protein structure (usually frameshifts with premature termination). *RXRA* encodes a nuclear receptor that can

function as either a homodimer or as a heterodimer (RXRA/RAR) and has a crucial role in adipocyte differentiation. A mouse model lacking functional hepatic *Rxra* (via CRE-mediated recombination) had wide-ranging hepatic metabolic abnormalities, showing the importance of intact *Rxra* function to the regulation of cholesterol, fatty acid, bile acid, and steroid metabolism (268). As there are two genetic loci implicated in cases of BSCL, it is possible that each encodes a protein with effects on the same pathway, possibly affecting G proteins or transcription factors involved in activating genes involved in the fatty acid synthetic pathway.

## 2 Familial Partial Lipodystrophy Dunnigan (FPLD) (1q21.2)

Mutations in the lamin A/C gene (*LMNA*; 1q21.2) lead to an autosomal dominant form of insulin resistant diabetes mellitus. Affected patients often manifest acanthosis nigricans and pubertal-onset lipoatrophy. Once puberty commences, the patients experience a slow loss of subcutaneous fat from the extremities, buttocks, and truncal areas while simultaneously accumulating fat tissue on the face and neck, leading to a cushingoid appearance. Lamin A and Lamin C are both encoded by *LMNA*, with alternative splicing of exon 10 leading to two different transcripts for A and C. Lamins A, B, and C comprise the nuclear lamina in mammals and are highly conserved throughout evolution. The nuclear lamina is a protein-rich layer that is juxtaposed to and interacts with proteins in the inner nuclear membrane. Cao and Hegele described an *LMNA* Arg482Gln mutation in five Canadian FPLD families (269). Mutations in *LMNA* also lead to muscle wasting in the autosomal-recessive and -dominant forms of Emery-Dreifuss muscular dystrophy (270) as well as a familial dilated cardiomyopathy with conduction defects (CMD1A). Mutations in the globular C-terminal domain have been found in subjects with FPLD, mutations in the head or tail domains have been found in cases of Emery-Dreifuss muscular dystrophy, and mutations in the rod domain have been found in CMD1A subjects (271). Possibly mutations at each of the aforementioned domains uniquely alters *LMNA* interactions with different components of the inner nuclear membrane, leading to the disparate disease phenotypes.

## X SUMMARY

Human obesity is an apparently simple convergent phenotype that actually resolves extremely complex

genetic, developmental, and environmental processes. None of these is sufficiently well understood to be able to “fix” it experimentally in efforts to understand the others. It is now clear that the genetic contribution to human obesity is substantial, but, in most instances, strongly dependent for expression upon the other two factors. The single-gene obesities in humans and mice are the exception to this general principle, because they are phenotypically apparent in virtually all environmental and developmental circumstances. The inactivating mutations of these genes account for only a small fraction of human obesity, but the pathways that they affect must be crucial in the regulation of body fat. For this reason alone these mutations (and those yet to be identified) are of critical importance to our understanding of human energy homeostasis. And, it remains a formal and likely possibility that subtle variation in expression/function of these genes may account for much or all of the genetic contribution to body weight regulation (173).

## Rodent Models of Obesity

**David A. York**

Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

### I INTRODUCTION

Since publication of the initial chapter on animal models in 1998 (1), there has been an explosive increase in the number of animal models in mice. This has arisen from two major avenues of research—the use of transgenic and gene-targeting approaches for proof of function for several genes that were thought to alter energy balance or through the use of similar approaches to study genes that had not previously been associated with obesity but in which a phenotype of altered body composition and/or food intake has emerged. These genes (Table 1) have a wide range of functions including effects on food intake, energy expenditure and physical activity, tissue metabolism, and adipose tissue differentiation. Further important developments have been the identification of the tub gene as an insulin-signaling molecule expressed in the nervous system and the elucidation of the signaling pathways associated with leptin activation of its long form of receptor in the hypothalamus. Thus, the identity of all of the spontaneous single gene mutations that cause obesity is now known. While these models were a major focus of the previous review, this chapter will concentrate on new information that has been published in the interim period. Readers are referred to the original chapter (1) and other chapters in the present edition of the Handbook of Obesity for more detailed information on the single gene models and other nonrodent models of obesity.

Until the recent past, the animal models that were available for the study of obesity either were of spontaneous origin or were the result of experimental manipulation of the environment or the hypothalamic centers that regulate food intake and energy balance (2–4). Much emphasis has been placed recently on dietary obesity in which a wide species-dependent variability has been described. Indeed, body weight gain when fed a high-fat diet has become a standard “test phenotype” for mice with experimentally altered gene expression. Interest in virally mediated obesities has also been renewed in recent years.

The research to date with animal models has provided substantive insight into the hypothalamic control systems and physiological disturbances that can lead to obesity. However, the recognition that so many gene manipulations can alter body composition and energy balance emphasizes the complexity of the systems involved and the research effort needed to obtain a fuller understanding of the role each of these genes play. Nevertheless, we can be encouraged by the human research that is establishing the relevance of many of the genes identified from studies of rodent models to human obesity.

Historically, the animal models have been subdivided into three groups, genetic, dietary, and neuroendocrine, according to the origin of the disorder. The explosion of information that has come from genetic and molecular studies of the obese models has emphasized the inappropriateness of this classification

**Table 1** Transgenic (Tg) and Gene Knockout (KO) Models That Affect Energy Balance and/or Body Composition

| Gene                             | Name              | Position<br>(Chr, cM) | Transgenic (Tg) or<br>knockout (KO) | Comment   | Effect  |
|----------------------------------|-------------------|-----------------------|-------------------------------------|---|---|
| <b>I. Receptors/transporters</b> |                   |                       |                                     |   |   |
| MC3                              | Mc3r              | 2, 100                | KO                                  |   | Obesity without hyperphagia, hyperactivity                        |
| MC4                              | Mc4r              | unknown               | KO                                  |   | Hyperphagia and obesity   |

as we have identified the peripheral and central mechanisms for controlling energy balance and their interdependence. While identification of the five single genes ( $A^y$ ,  $lep^{ob}$ ,  $lepr^{db}$ ,  $lepr^{fa}$ ,  $Cpe^{fat}$ , and  $tub$ ) that cause obesity in rodents provided the catalyst that promoted the research focus on obesity, the wide range of experimental genetic manipulations that have been shown to alter the susceptibility to develop obesity emphasize the multicausal nature of the disease. While the spontaneous single gene rodent models emphasize the overriding effects of single genes, numerous experimental genetic manipulations have been shown only to cause obesity with the appropriate environment, such as a high-fat diet. Rat and mouse strains vary greatly in their sensitivity to this form of obesity (5), and this characteristic has facilitated genomewide linkage studies of this response. Another example is the obesity that develops in desert rodents when they are fed a laboratory chow diet.

The animal models also vary in the age of onset and in the severity of the obesity. More importantly, they illustrate the importance of the background genome on the phenotype that results from any particular gene mutation. Likewise, within primate colonies there are wide-ranging individual differences in responses (6). The multigenic factors that predispose animals to this form of obesity make them probably the closest models for the study of human obesity.

The neurochemical explanations for the hyperphagia and obesity that results from lesions of the ventromedial hypothalamus and the paraventricular nucleus and for the aphagia and leanness that follows lesions of the lateral hypothalamus (3,4,7) has become apparent in recent years. Studies with these models have illustrated the inextricable links between regulation of feeding behavior and autonomic regulation of peripheral metabolism and endocrine activity. The effects of these lesions may now be mimicked by infusions of specific neuropeptides or manipulations of the expression of specific genes. This provides the functional neurochemical links to the anatomical circuitry that had been previously identified. The mechanisms through which endocrine, e.g., insulin and leptin manipulations, alter feeding behavior and body composition are also now becoming clearer as their interactions with the central neuropeptide circuits are identified. Finally, it is becoming evident that the natural seasonal and migratory changes observed in several species may well be explained by changes in the activity of the peripheral and central pathways that have been identified from studies of laboratory animal models (8).

## A Advantages and Disadvantages of Animal Models for the Study of Human Obesity

The advantages and disadvantages of animal models for the study of human obesity were discussed in our previous review (1). What has become evident in the intervening years is the relevance of these animal models to human disease. Thus while mutations in the leptin gene or leptin receptor gene are rare, linkages of several indices relating obesity to chromosomal regions of these genes have been documented (9). Further, a number of mutations in either the pro-opiomelanocortin gene or in the melanocortin receptors have been linked with morbid obesity in humans (10), emphasizing the importance of this system to human energy balance. We are confident that, as the polygenic nature of the susceptibility of human subjects to obesity (9) is further explored, many of the genes that have been shown to cause or prevent animal obesity will also be implicated in human obesity.

In this chapter, we shall review the recent developments in our understanding of obesity that has been obtained through the study of the wide range of rodent models and review the many new experimental genetic manipulations that have provided insight into the function of known, or heretofore unknown gene products. The chapter will not be a comprehensive review of the literature in this field, but rather an update of animal models with a focus on the genetic basis of obesity.

## II GENETIC MODELS OF OBESITY

### A Single-Gene Obesities

#### 1 Genes of the Leptin Signaling Pathway

Mutations in both the leptin gene and the leptin receptor gene underlie the phenotype of three single-gene obesity models. The obese mouse ( $lep^{ob}/lep^{ob}$ ) inherits its obesity as a result of a C428T mutation of the leptin gene which changes an arginine codon (CGA) to a stop codon (TGA) at codon 105, resulting in a shortened nonfunctional product (11). Despite very high levels of expression of the  $lep^{ob}$  gene in adipose tissue of the  $lep^{ob}/lep^{ob}$  mouse, no leptin can be detected in the serum of these mice. A second mutation  $ob^{2j}/ob^{2j}$  has been mapped 7 kb upstream of the 4.5-kb *ob* RNA start site and is assumed to be the result of a structural alteration or a mutation in the promoter region.

As predicted from the classical parabiotic studies of Coleman (12) and Hervey et al. (13), the mutations responsible for the obesity phenotype of the diabetes mouse ( $lepr^{db}/lepr^{db}$ ) and the Zucker fatty ( $lepr^{fa}/lepr^{fa}$ ) rat are both in the leptin receptor. The long intracellular

signaling domain of the leptin receptor is not translated in  $\text{lepr}^{\text{db}}/\text{lepr}^{\text{db}}$  mice since a G-to-T mutation (14,15) introduces a novel consensus splice donor site (AGG-GAAA sequence to an AGGTAAA sequence). As a result of this mutation, a 106-base sequence of the terminal exon of the short form of the receptor is spliced into the long form of the receptor mRNA. This introduces a stop codon that prevents translation of the long intracellular domain of the receptor. In contrast the mutations in the Zucker rat (16,17) and the Koletsky rat (18) are both in the extracellular domain of the leptin receptor; in the  $\text{lepr}^{\text{fa}}/\text{lepr}^{\text{fa}}$  rat an A880C (G1n269Pro) mutation reduces the localization of the receptor in the cell membrane (19), whereas in the Koletsky rats a T2349A nonsense mutation results in no expression of the gene (18).

It is thus not surprising that these animals share a similar phenotype, the variation appearing to result mainly from the background genome on which the mutation is expressed. The phenotype is of an early-onset form of obesity associated with hyperphagia, impaired sympathetic activation of brown adipose tissue (BAT) thermogenesis, an enhanced insulin secretory activity, overactivity of the hypothalamic-pituitary-adrenal axis, decreased growth hormone secretion, stunted growth, impaired thyroid hormone metabolism, and infertility together with some immune function deficits. The reader is referred to our previous review for a fuller description (1). The phenotype of  $\text{lepr}^{\text{db}}/\text{lepr}^{\text{db}}$  mice can be partially corrected by transgenic expression of the long form, but not the short form, of the leptin receptor (20).

The severity and temporal characteristics of diabetes vary with the background strain in these obese mice models; hyperglycemia and hypertension are significant phenotypic variations across the rat mutations with strain. By introducing the Koletsky ( $\text{fa}^{\text{cp}}$ ) gene onto an inbred strain of rats derived from the hypertensive Okamoto strain (SHR/N) and further crossing onto other strains, e.g., LA/N, a variety of strains exhibiting various aspects of the Syndrome X metabolic profile have been developed (21). By transferring the  $\text{lepr}^{\text{fa}}$  gene from its Brown-Norway background strain, on which diabetes is normally absent, to other backgrounds, long-lasting severe diabetes may become characteristic, e.g., diabetic fatty (ZDF/Drt-fa), the Wistar Kyoto fatty (WKY/NDrt-fa), or the Wistar Kyoto diabetic (WDF/TA-fa). Transgene insertion to prevent the expression of the long form of the leptin receptor in an outbred strain of mice led to wide divergence in the diabetes phenotype and provides another model for studies of the interactions of the leptin system with the background genome (22).

The other major difference across these models is the obvious one that those with mutations in the leptin receptor are partially or totally resistant to the effects of leptin whereas the obese mouse has a supersensitivity to exogenous leptin (23–25). Treatment of the  $\text{lep}^{\text{ob}}/\text{lep}^{\text{ob}}$  mouse with leptin reverses all of the phenotypic characteristics, reducing body fat, food intake, insulin secretion, and corticosterone levels and restoring sympathetic activity and brown adipose tissue thermogenesis to yield a lean mouse that is also fertile (23–25). Likewise, transgenic overexpression of leptin in normal mice leads to a very lean animal (26).

## 2 The Fat Mouse ( $\text{fat}/\text{fat}$ or $\text{Cpe}^{\text{fat}}/\text{Cpe}^{\text{fat}}$ )

The fat mouse, unlike the  $\text{lep}^{\text{ob}}/\text{lep}^{\text{ob}}$  and  $\text{lepr}^{\text{db}}/\text{lepr}^{\text{db}}$  mice and the  $\text{lepr}^{\text{fa}}/\text{lepr}^{\text{fa}}$  rat, is an example of a late-onset form of obesity (27). The obesity may be severe (60–70 g body weight at 24 weeks) and is expressed in all adipose depots. In this mutant the obesity is not normally evident until 8–12 weeks of age and is not pronounced until 16–20 weeks of age. It arose out of an inbred HRS/J strain of mice and has been crossed onto the C57BLKS/J background strain to facilitate comparison with the obese and diabetes mutations. The fat mouse is characterized by massive hyperinsulinemia without significant hyperglycemia from weaning, suggestive of extreme insulin resistance, but does not display the pancreatic failure and severe diabetes that are evident in older  $\text{lep}^{\text{ob}}/\text{lep}^{\text{ob}}$  and  $\text{lepr}^{\text{db}}/\text{lepr}^{\text{db}}$  mice (27). When the mutation is transferred to the C57BLKS/J(HKS) background strain, the fat/fat mouse is diabetic, but the diabetes is still less severe than that seen with  $\text{lep}^{\text{ob}}/\text{lep}^{\text{ob}}$  and  $\text{lepr}^{\text{db}}/\text{lepr}^{\text{db}}$  mice on the same background. Indeed, the mouse remains extremely sensitive to exogenous insulin. This paradox has been explained by the recognition that the apparent hyperinsulinemia is in fact a hyperproinsulinemia (2). The fat gene, located on chromosome 8 codes for carboxypeptidase E (2). A single base mutation that results in a ser202pro substitution severely reduces or completely abolishes the activity of carboxypeptidase E in the pancreatic islet, hypothalamus, pituitary, gastrointestinal tract, and other tissues (28). The functional effect of this mutation was confirmed by site-specific mutagenesis of the Cpe gene and its expression in a baculovirus system. Indeed immunoreactive carboxypeptidase E protein is undetectable in pancreas and pituitary of fat/fat mice, suggesting that the mutation affects either transcriptional or translational activity or stability of the mRNA or protein.

Carboxypeptidase E (also known as carboxypeptidase H) is required for cleavage of two arginine

residues from the B-chain of insulin during its processing from proinsulin. The impairment in enzyme activity in  $Cpe^{fat}/Cpe^{fat}$  mice explains their 10-fold increased proinsulin to insulin ratios in the pancreas and the very high level of proinsulin rather than insulin in the circulation. The obesity, however, results from the role of carboxypeptidase E in the posttranslational processing of numerous neuropeptides including pro-opiomelanocortin to  $\alpha$ -MSH,  $\beta$ -endorphin and  $\beta$ -lipotropin, proenkephalins, preproNPY, vasopressin, oxytocin, gastrin, and CCK. While Naggert et al. (2) suggest that the obesity of  $Cpe^{fat}/Cpe^{fat}$  mouse is likely to result from a complex pattern of alterations in neuropeptide activity and secretion within the hypothalamic-pituitary system rather than the hyperproinsulinemia, it is not surprising that it has many similarities to the obesity of the MC4 receptor knockout mouse (29). The mutation also appears to have differential effects on postranslational processing in the CNS and the periphery. The processing of procholecystokinin provides an example of this. In  $Cpe^{fat}/Cpe^{fat}$  mice bioactive CCK was reduced in neural tissue but not in gastrointestinal endocrine cells, although the level of the enzyme substrate glycylarginine-extended CCK was greatly elevated in both tissues (30).

### 3 Tubby (*tub/tub*) Mouse

This mutation was first reported by Coleman and Eicher in 1990 (27). It is an autosomal-recessive mutation on chromosome 7 in the gene coding for the tubby protein, one of a family of four proteins that also includes TULPs 1–3. A characteristic of these proteins is the ~260–amino acid domain at the carboxyl terminus that forms a helix barrel structure that binds avidly to DNA. The tubby mutation introduces a splice site at the junction of the 3'-coding sequence that leads to the loss of this carboxyl terminus domain (31). Knockout of *tub* confirmed that the tubby gene mutation is a loss of function mutation (32).

The wild-type tub protein is expressed in the hypothalamus and other brain regions, where it is localized to plasma membranes, released by activation of  $G\alpha_q$  protein, and translocated into the nucleus (33). This process may be activated by 5HT<sub>2c</sub> receptor activity. Studies of CHO cells expressing the human insulin receptor have shown an insulin-dependent phosphorylation of tyrosine residues on the tub protein. This has led to the suggestion that tub acts as an adapter protein linking the insulin receptor to protein tyrosine kinases and may function as part of a neural insulin signaling mechanism (34).

On the C57BL/6J background, Tubby mice are phenotypically very similar to 5HT<sub>2c</sub> receptor knockout mice and to fat mice except that the obesity in fat mice develops more slowly, not being visually apparent until 9–12 weeks of age. All fat depots are enlarged. The tub mutation is associated with distinct sexual dimorphism in blood glucose, serum insulin, islet hypertrophy and hyperplasia, and  $\beta$ -cell degranulation, all changes being more pronounced in male mice. The hyperinsulinemia, mild at weaning, progressively increases with age. Morphological changes in the pancreatic islets occur earlier and are more pronounced in males. However, the tub mice remain mildly hypoglycemic, indicating the absence of the pronounced insulin resistance common to other mouse models of obesity. This insulin resistance appears to be centrally expressed since NPY mRNA levels are massively elevated in *tubby* mice (35). Infertility is also a feature of this mouse when severe obesity develops.

### 4 The Yellow ( $A^y/a$ ) Obese Mouse

The agouti gene of the Yellow ( $A^y/a$ ) obese mouse was the first single-gene mutation for obesity to be identified in mice (see (36) for review). The Yellow ( $A^y/a$ ) obese mouse and the KK mouse (37) discussed below are the only models of dominant inheritance of obesity so far described. The obesity of the yellow mouse is inherited as a mutation in the agouti protein coded on chromosome 2, and is associated with a moderate obesity and a high incidence of tumor growth. Although the homozygous ( $A^y/A^y$ ) mouse is lethal in utero, there are a number of different alleles ( $A^{vy}/A^{vy}$ ,  $A^{iy}/A^{iy}$ ) at the agouti locus in which the defects are less severe and in which the degree of obesity is linked directly to the level of yellow pigmentation in the coat (38). The obesity of the yellow mice is less pronounced than in the obese and diabetes mice and is of later onset (8–12 weeks of age). While these animals share many of the characteristics common to all rodent obesities, they do differ in the clear sexual dimorphism of the associated hyperglycemia (39) and in the apparently normal activity of the hypothalamic-pituitary-adrenal axis (39,40). The  $A^y/a$  mouse is extremely leptin resistant. This appears to be mainly of central focus since transgenic overexpression of leptin in  $A^y/a$  mice improves the diabetes but does not ameliorate the obesity (24).

The agouti (a) gene encodes a 131–amino acid protein that is normally uniquely expressed in the hair follicle where it acts to inhibit eumelanin synthesis in response to stimulation by  $\alpha$ -melanophore-stimulating hormone ( $\alpha$ -MSH). In the Yellow mouse exon 1 of the agouti gene is replaced by a unique sequence, but exons

2–4, which contain the full coding sequence, are normal. The result of this mutation is the ubiquitous expression of the agouti gene in a wide range of tissues including white adipose tissue and brain (41). Transgenic mice expressing agouti unregulated and ubiquitously driven by the human  $\beta$ -actin promoter also develop yellow coat color and become obese (42–44), confirming that ectopic expression of normal agouti protein results in the obese yellow phenotype.

Two potential actions of agouti protein have been identified. Its ability to increase intracellular calcium levels may promote insulin resistance (45). Intracellular calcium levels are related to the level of expression of agouti protein and to body weight and degree of coat color. Using a murine melanoma cell line, Lu et al. (46) were able to demonstrate that agouti protein inhibited the stimulation of adenylyl cyclase by  $\alpha$ -MSH, shifting the dose required for half-maximal stimulation from 1.7 to 13.4 nM by acting as a potent antagonist of the melanocortin-4 receptor (MC4-R). However, agouti had no effects on MC1, MC2, MC3, or MC5 receptors.

Identification of agouti and its interactions with the melanocortin 4 receptor led to the cloning of a natural MC4 receptor antagonist, agouti-related protein (AgRP) (47) that is expressed in the hypothalamus. Transgenic and gene-knockout studies have provided new insight into the role of this melanocortin pathway in regulating energy balance. A fuller description is provided in Section B.1.

## 5 KK Mice

Since the original description of the KK mouse (48), several different strains have been identified (see 19, 35 for review). While the obesity and diabetes were originally thought to be inherited as a polygenic trait, the KK gene is now regarded as a dominant gene with low (25%) penetrance (37). The obesity and hyperinsulinemia are relatively mild, although the hyperglycemia may be severe. The KK mice are, however, very sensitive to diet, and obesity may be prevented by dietary restriction. The temporal changes in this mouse are also very different from the other mouse models in that changes to or toward normality of body composition, insulin secretion, and insulin resistance may be evident in older (>6 months) animals. In these mice the pancreas appears to have the ability to increase insulin secretion without the subsequent necrosis seen in ob/ob and db/db mice. Once again there are major variations across the different strains of KK mice.

## B Transgenic and Gene Knockout Models

During the past four years extensive use of transgenic and knockout approaches has identified 60 genes that modulate energy balance, either increasing energy storage and obesity, or reducing or eliminating energy storage in white adipose tissue (Table 1). While many of these studies have aimed to substantiate a function which prior experimental data had suggested for the gene product on energy balance, other studies were designed primarily to identify a function for the specific gene.

To help in reviewing the large number of animal models, I have subdivided the genes into those that can be related to receptors and transporters, hormone and neuropeptide systems, metabolic genes, signaling proteins, transcription factors/nuclear proteins, and finally to structural genes.

### 1 Hormones and Neuropeptide Systems

#### *a. The Melanocortin System*

Studies of the Yellow obese syndrome ( $A^y/a$ ,  $A^{vy/a}$ , etc.) led to the identification of the important role of  $\alpha$ -MSH, an anorectic peptide (49) derived from the precursor pro-opiomelanocortin (POMC), and the antagonist AgRP peptide as the major regulators of this system (47, 50–52), which affects feeding behavior, energy expenditure, and insulin secretion. Several genetic models have been used to illustrate the functionality of this system. Transgenic mice ectopically expressing agouti recapitulate the obese yellow syndrome of the  $A^y/a$  mouse (43). Likewise, expression of the hypothalamic homolog protein AgRP produces a similar obesity but without the coat color changes associated with antagonism of the MC1 receptor (53).  $\alpha$ -MSH, a product cleaved from the POMC precursor protein, is an agonist for all melanocortin receptors except MC2. Knockout of the precursor POMC gene produces obesity (54). Knockout of the 7B2 gene (Sgnt1), which prevents the production of proconvertase 2 and the cleavage of ACTH and  $\alpha$ -MSH, also produces obesity (55). The effect of  $\alpha$ -MSH on energy balance appears to result from actions at both the MC4 and MC3 receptors. MC4 receptor knockout mice (29) are hyperphagic and obese, whereas MC3 receptor knockout mice become obese in the absence of significant hyperphagia (56) while exhibiting decreased locomotor activity and an atypical increase in respiratory quotient on a high fat diet (57). These observations suggest that  $\alpha$ -MSH may primarily inhibit feeding through MC4 receptors and enhance energy expendi-

ture and influence energy partitioning through MC3 receptors. Indeed, the double knockout  $Mc3r^{-/-}/Mc4r^{-/-}$  becomes more obese than either of the individual receptor knockouts.

The expression of the agouti gene in humans differs from that in mice, where it is only transiently expressed in hair follicles. In humans, agouti is also expressed in a variety of peripheral tissues, including adipose tissue. To develop a model of human agouti, Mynatt and colleagues (58,59) have created transgenic mice expressing agouti in adipose tissue. These transgenic mice develop a mild obesity and show an enhanced sensitivity of adipose tissue to insulin.

Neural tracing and immunohistochemical approaches have been used to identify the functional neuroanatomy of the melanocortin system. Two subsets of neurons in the arcuate nucleus, coexpressing either POMC and CART or NPY and AgRP, send axonal projections to both the PVN and LH to synapse with cell bodies that express either MC3 or MC4 receptors, and may regulate secretion of melanin-concentrating hormone and orexin. The presence of leptin receptors on the arcuate POMC and AgRP neurons provides the link among leptin, the melanocortin system, feeding behavior, and energy expenditure. Of all the animal models, the natural mutations and the experimental manipulations of this melanocortin system appear to be most relevant to human obesity, where a number of mutations have also been linked to severe obesity and changes in hair color (9,10).

In addition to the agouti mutation, two other genes, mahogany (mg) and mahoginoid (md) (60) have effects on both body weight and coat color. Several mutations have been identified at the mg locus giving total or partial loss of function but, to date, only a single md mutation has been reported. The phenotypes of these mutant animals are similar, although the degree of obesity is variable. Both md and mg mutations inhibit agouti-related obesity and its associated changes in linear growth and insulin secretion, but do not alter the hyperphagia. Mg and md (*Atrn*) mutations appear to enhance food intake, and mg also increases physical activity.

Mahogany, a transmembrane protein, has been identified as a member of the Attractin (*Atrn*) gene family (61). It is expressed widely in the CNS, including the major regions known to be important for the regulation of energy balance (62). The site of action of mg is unknown. Since the mg mutation has no effect on energy balance in MC4R knockout mice or in  $lepr^{db}/lepr^{db}$ ,  $tub/tub$ , or  $Cpe^{fat}/Cpe^{fat}$  mice, it is

thought to act upstream of the MC4 and MC1 receptors. However, mg can suppress diet-induced obesity (63).

#### b. *The Syndecans*

Syndecans are a family of cell surface heparin sulphate proteoglycans that show differential tissue distribution. The extracellular domains of the syndecans are released from the cell surface and may act as either positive or negative paracrine regulators. Transgenic overexpression of Syndecan I (*Sdc1*) using the CMV promoter (64) led to a maturity-onset type of obesity that was phenotypically very similar to the obesities associated with agouti or agouti-related protein. While Syndecan I is not normally expressed in the brain, Syndecan III null mice (a neural syndecan), while of normal body phenotype, show an impaired feeding response to fasting (64). Reizes et al. (64) propose that the released ectodomains of the syndecans modulate the interactions between  $\alpha$ -MSH and agouti-related protein with the MC4 receptor, and that the hypothalamic Syndecan III levels are physiological modulators of feeding behavior.

#### c. *The NPY System*

Neuropeptide Y (NPY) is recognized as the most powerful orexigenic peptide yet to be identified. Physiological and pharmacological evidence support a role for NPY in the regulation of feeding behavior. However, experimental genetic manipulations of the NPY system have failed to show that it is essential for normal feeding. Recently, however, NPY knockout mice have been shown to have an attenuated response to fasting (65). When obob mice are made  $Npy^{-/-}$ , there is an attenuation of the level of obesity (66). However,  $Npy^{-/-}$  mice grow normally, and knockout of NPY1, Y2, and Y5 receptors does not attenuate food intake or weight gain as would have been predicted from pharmacological studies. Indeed, surprisingly, both Y1 and Y5 receptor-deficient mice develop a mild obesity with aging, and Y2 receptor-deficient mice become obese when provided with a high-fat diet.

Pancreatic polypeptide, another member of the NPY family, is expressed at high levels in the pancreas and gut. Overexpression regulated by a cytomegalovirus  $\beta$ -actin promoter was lethal to many of the transgenic mice, but surviving animals were characterized by reduced growth, lower body fat, and lower food intake and oxygen consumption (67).

#### d. *The CRH/Urocortin-Glucocorticoid System*

In addition to a role in regulation of pituitary-adrenal function, CRH and Urocortin inhibit food intake and promote energy expenditure, particularly the sympathetically mediated BAT thermogenesis. Numerous models, targeting specific components of this system, have identified the ability to alter homeostasis. These models generally produce a cushingoid-type of central adiposity. The models include the transgenic overexpression of antisense cDNA to the brain type II glucocorticoid receptor (GR) (68,69), knockout of the brain type II GR, and transgenic expression of CRH (70,71). The concentration of free CRH in the CNS is affected by the levels of the CRH-binding protein. Knockout of this gene results in a hypophagic small mouse whereas overexpression regulated by the metallothionin promoter caused obesity (72,73). Despite these effects, knockout of CRH1 and CRH2 receptors does not have any major phenotypic effects on body weight or food intake although the response to exogenous urocortin or CRH may be absent or diminished (74–77).

#### e. *Melanin Concentrating Hormone (MCH)*

This peptide is synthesized in lateral hypothalamic neurons that are innervated by POMC/CART or NPY/AgRP axons from the arcuate nucleus. Although MCH has only a modest orexigenic effect when given intracerebroventricularly, MCH knockout mice have reduced body weight and are hypophagic and lean (78). Absence of MCH release could explain the effects of lateral hypothalamic lesions. In contrast, transgenic overexpression of MCH increases body weight of mice fed a chow diet and induces obesity in mice fed a high fat diet (79).

#### f. *Orexin*

Orexin is also expressed in the LH. While orexin appears to have moderate orexigenic effects, mutations in this receptor appear to be related to narcolepsy (80), suggesting that orexin has a primary role in arousal rather than energy homeostasis. However, ablation of orexigenic neurons by specific expression of a truncated Machado-Joseph disease product Ataxin-3 produced a late-onset obesity in addition to a narcoleptic phenotype (81).

#### g. *Insulin/Insulinlike Growth Factor (IGF)-1 and Amylin*

Like leptin, insulin has been proposed as a long-term signal to the brain on the status of the energy

reserves of the body. When given ICV, it may reduce food intake and body weight, although, like leptin, this effect is absent in obese rats. Strong evidence for the importance of this regulatory system comes from the neuron-specific knock out of the insulin receptor. These mice become obese when given a high fat diet and develop mild insulin resistance and hypertriglyceridemia. Hyperphagia was only evident in female mice (82). The importance of insulin sensitivity in muscle for the prevention of obesity is emphasized by the observation that transgenic overexpression of dominant-negative insulin receptors in muscle, which causes muscle insulin resistance, results in a major increase in body fat (22–38%) and a loss of lean body mass (83).

Amylin is a 361-amino acid protein cosecreted with insulin from pancreatic  $\beta$ -cells. It has been shown to have multiple effects including suppression of food intake and inhibition of gastric emptying. Amylin knockout mice of both sexes show an approximate 20% increase in body weight and body fat (84).

Transgenic mice overexpressing the IGF-1-binding protein in adipose tissue have been used to explore the effects of IGF-1 on adipocyte differentiation (85). IGF-1-binding protein overexpression attenuated the weight gain and increase in adipose tissue mass and fat cell size of mice provided a sucrose-enriched diet. These data, together with some in vitro studies, suggest that IGF-1 has a critical role in the differentiation of preadipocytes and in the development of obesity.

#### h. *Cholecystokinin (CCK)*

CCK is expressed both in the gastrointestinal tract and in the CNS. When given both peripherally and centrally, CCK inhibits food intake through actions mediated by CCKA receptors (86). A natural mutation which prevents the expression of CCKA receptors has been identified in OLETF rats (87). These are hyperphagic and heavier than the wild-type LETO rats. Further, they fail to suppress food intake normally in response to a dietary supplement of fat (88). In contrast, knockout of CCKA receptors in mice does not appear to have any effects on energy balance (89,90).

#### i. *Bombesin*

Bombesin is one member of a family of peptides that are also expressed widely in the CNS and GI tract. They inhibit food intake and stimulate sympathetic-related energy expenditure. Of the three receptors identified, the bombesin receptor subtype 3 (BRS-3) appears to be important for energy balance, since BRS-3 knockout mice develop mild obesity, hyper-

tension, and impaired glucose tolerance (91). BRS-3-deficient mice also show changes in sensitivity to nutrient stimuli, showing an enhanced preference for saccharin solutions but also a stronger aversive response to LiCl (92).

*j. Growth Hormone (GH)*

Both overexpression and knockout approaches have been used to study the effects of GH on energy balance and body composition. GH deficiency, as in “little” mice, is associated with decreased somatic growth but increased body fat (93) despite normophagia (per gram body weight). In contrast, overexpression of GH is associated with increased somatic growth and decreased body fat (94), which has been related to a severe insulin resistance of adipose tissue (95). Overexpression of an ovine GH transgene driven by a metallothionein promoter (96) leads, as expected, to larger mice. However, when expression of this transgene is switched off by removal of dietary zinc, significant obesity results, suggesting downstream effects in the GH pathway. Overexpression of GHRH, which results in elevated GH levels, results in hyperphagic mice of increased body mass but, unexpectedly, also increased body fat (97). The reason for the increased body fat is unclear but may be related to a dysregulation of the leptin receptor system in the hypothalamus.

*k. TNF $\alpha$  and Other Cytokines*

With the recognition of adipose tissue as an endocrine organ and the suggestion that TNF $\alpha$  secretion was linked to insulin resistance (98), attention has focused on the possibility that TNF $\alpha$  and other cytokines may have an important role in the physiological control of energy balance as well as their pathological role in cancer cachexia. Divergent results have been reported. TNF $\alpha$ -null mice either may be of normal weight or even gain weight normally when fed a high-fat diet (99) or they may be characterized by a significant reduction in body weight (100). To date, two receptor subtypes (P55 and P75) have been identified. Mice that are P75 $^{-/-}$  have lower body weight than wild type mice (101) when fed a high fat diet whereas P55 $^{-/-}$  mice exhibit an attenuated cachectic response to tumors (102). Similarly, mice lacking the IL6 gene do not exhibit the tumor related reduction in food intake (103). Genetic studies in which the expression of IL1 receptor antagonist (Il1ra) is manipulated also suggest a role for IL1 in energy regulation and cancer cachexia. Transgenic overexpression of IL1ra, which blocks the binding of IL1 to its receptor, promotes weight reduction as would be anticipated (104).

*l. Adrenergic Receptors ( $\beta_3$ AR and  $\alpha_2$ AR)*

$\beta_3$ -AR knockout mice do not become obese despite the role of this receptor in signaling sympathetically mediated BAT thermogenesis (105). This may result from a number of compensatory changes. However, of particular interest with these mice has been the ability to show, using tissue-specific knockins of  $\beta_3$ AR in  $\beta_3$ -AR knockout mice, that the  $\beta_3$ -adrenergic suppression of food intake is mediated by white adipose tissue  $\beta_3$ ARs (106). The chemical mediator(s) of this response have yet to be identified. Transgenic overexpression of  $\alpha_2$ -adrenergic receptors in  $\beta_3$ -AR-null mice leads to obesity and adipocyte hyperplasia in mice fed a high-fat diet (107). This model emphasizes the importance of  $\alpha_2$ ARs in the stimulation of adipocyte hyperplasia.

*m. Neurotransmitters*

The anorectic response of 5HT is diminished in both 5HT2c and 5HT1b receptor knockout mice. This suggests that both receptor subtypes are necessary for this activity. The 5HT2c knockout mice become obese with age and show a greater sensitivity to high-fat diets than wild-type mice (108,109). These mice also appear to have an enhanced preference for dietary fat (Brenda Richards, personal communication). However, 5HT1b null mice are indistinguishable from wild-type mice in body weight and daily food intake.

Dopamine appears to be essential for the motor components of feeding. Knockout of tyrosine hydroxylase (an enzyme necessary for dopamine and norepinephrine synthesis) is lethal (110). However, when norepinephrine synthesis is restored, the dopamine-deficient mice live to ~4 weeks of age. They are aphagic and hypoactive (111). Both D1 receptor and D2 receptor knockout mice have reduced body weight, and the latter mice are hypoactive (111–113). In contrast, the D3 receptor knockout mouse is hyperphagic on a high-fat diet and becomes obese (Stephen Woods, personal communication).

Histamine also appears to be an important neurotransmitter for feeding behavior. Knockout of the H1 receptor has no effect in mice fed a regular chow diet, but is associated with excessive weight gain on a high-fat diet and a reduced response to ICV leptin (114). Acetylcholine is widely distributed in the central and autonomic nervous systems. Mice that are deficient in the M3 muscarinic receptors are hypophagic and have a reduced body weight (115).

Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter within the CNS. Ubiquitous overexpression of the GABA transporter I gene

caused a moderate obesity that was characterized by an altered feeding pattern and a small reduction in physical activity (116).

#### *n. Other Hormone Receptors*

Estrogens have been recognized to have significant effects in feeding behavior. Knockout of the estradiol  $\alpha$ -receptor is associated with increased white but not brown adiposity, which appears to develop after the onset of puberty (117) in both males and females (118). As in aromatase-deficient mice, the obesity appears to be associated with a decrease in energy expenditure rather than hyperphagia. Similarly, knockout of the FSH receptor, which causes severe estrogen deficiency from an early age, induces obesity and skeletal abnormalities that give a hunchback appearance to the mice (119).

## 2 Metabolic Genes

### *a. Lipid Metabolism*

**1 Acetyl CoA carboxylase 2 (*Acc2*)** *Acc2* is predominantly expressed in heart and muscle as opposed to the hepatic and adipose tissue expression of acetyl CoA carboxylase 1. Knockout of the muscle ACC2 results in lean mice that had reduced tissue malonyl CoA levels and enhanced muscle fatty acid oxidation rates by 30% (120). Adipose tissue depot size of the *Acc2*-null mice was only 50% of that on the wild type. This occurred despite a 20–30% increase in food intake that might be either associated with the low leptin levels or a direct effect of the reduced levels of malonyl CoA in hypothalamic centers (121).

**2 Perilipin** Although only a single gene codes for perilipin, there are multiple tissue-specific isoforms as the result of alternative splicing. Perilipin A coats the triglyceride droplets in adipose tissue, where it protects the lipid from hydrolysis by hormone sensitive lipase. Activation of perilipin by protein kinase A is necessary for hormone-sensitive lipase activity. The perilipin (*plin*)-null mice have enhanced basal lipolysis but severely impaired stimulated lipolytic activity. Perilipin-null mice have normal body weight but a greatly reduced adipose tissue mass, an increased lean body mass, an increased metabolic rate, and a tendency to develop insulin resistance (122,123). Food intake may be normal or increased, and the mice are resistant to high-fat diet-induced obesity. A similar phenotype has been reported for the protein kinase A RII $\beta$  subunit (*Pkar2b*) null mouse (124), suggesting that failure to

activate perilipin might also explain the phenotype of this mouse, although PKA activity is increased. Transferring the perilipin (*plin*)-null mutation into the diabetes mouse (*Lepr<sup>db</sup>/Lepr<sup>db</sup>*) dramatically attenuates their obesity (122,123).

**3 Hormone-sensitive lipase (*Lipe*)** This enzyme catalyzes the initial stage of the hydrolysis of stored triglycerides to fatty acids and glycerol. Its activity is regulated by numerous endocrine and neural inputs to the adipose tissue. *Lipe*-null mice did not become obese, although fat cells in white and brown adipose tissue were significantly enlarged by two- and fivefold, respectively (125). Brown adipose tissue mass was increased. No differences in metabolic rate or response to a cold environment could be detected in *Lipe*-null mice where the major phenotype was male sterility.

**4 Adipocyte binding protein (*aP2*; *Fabp4*)** This protein is expressed mainly in adipose tissue and binds intracellular fatty acids. Its promoter is frequently used to target gene expression to adipose tissue. *Fabp4*-null mice grow normally but show an exaggerated obesity when placed on a high-fat diet. This obesity is unique in that insulin resistance does not develop (126). Transfer of the *Fabp4* null allele onto the *lep<sup>ob</sup>/lep<sup>ob</sup>* mouse increases its level of obesity yet enhances the insulin sensitivity compared to *lep<sup>ob</sup>/lep<sup>ob</sup>* mice expressing the *Fabp4* gene (127).

**5 Acyl CoA: diacylglycerol acyl transferase (*Dgat*)** This enzyme transfers a fatty acid to convert diglycerides into triglycerides. *Dgat*-null mice have normal body weight, but lower body fat when fed a standard chow diet. Despite the absence of enzyme activity, the *Dgat*-null mice gain significant weight and body fat when fed a high-fat diet to reach levels similar to those in wild-type mice (128).

### *b. Carbohydrate Metabolism*

**1 Glucose transporters** *Glut4* is an insulin-regulated glucose transporter expressed in adipose tissue and muscle. In adipose tissue glucose carbon is required for glyceride synthesis and for fatty acid synthesis. Overexpression of the *Glut4* gene (*Slc2a4*) in adipose tissue using the *aP<sub>2</sub>* promoter results in an obese mouse with enhanced glucose clearance that is not further exaggerated by feeding a high-fat diet (129). Expressing *Glut4* in muscle with the myosin light chain promoter has no effects on body weight or body composition, but does again improve insulin-stimulated glucose disposal (130,131). In contrast, *Glut4* (*Slc2a4*)-null mice have little white adipose

tissue and have a lower body weight but decreased sensitivity to insulin (132).

**2 Glutamine:fructose-6-phosphate amidotransferase (GFAT)** GFAT is the rate-limiting enzyme for hexosamine synthesis in the liver. Transgenic overexpression of the GFAT gene (*Gfptl*) using the PEPCK promoter resulted in mice that appear to have enhanced or normal insulin sensitivity and elevated hepatic glycogen when young, but which become obese when old (133).

### c. Converting Enzymes

**1 Aromatase** Aromatase is responsible for the final step in estrogen biosynthesis from C<sub>19</sub> steroids. Human mutations in the aromatase gene have been associated with visceral obesity, insulin resistance, and the metabolic syndrome. The aromatase gene (*Cyp19*) knockout mouse of either sex likewise accumulates excess abdominal fat deposits. This phenotype occurs despite a reduction in food intake and normal metabolic rate, and reflects the 50% reduction in the level of spontaneous physical activity (134).

**2 Interleukin 1 $\beta$  converting enzyme** This enzyme is responsible for the production of biologically active IL1 $\beta$ . Mice lacking the enzyme fail to demonstrate the hypophagic response to lipopolysaccharide (135).

**3 7B2** The 7B2 protein is necessary for the expression of proconvertase 2. Obesity that occurs in 7B2 (*Sgne*)-null mice probably reflects their inability to process POMC into  $\alpha$ -MSH (54).

### d. Thermogenic Pathways

**1  $\alpha$ -Glycerol phosphate dehydrogenase ( $\alpha$ GPDH)** This enzyme forms part of a substrate cycle that effectively shuttles protons from NADH to FADH so releasing the equivalent of 1ATP energy as heat, in addition to its role in the supply of glycerophosphate for triglyceride synthesis. Over-expression of the  $\alpha$ GPDH gene (*Gapd*) at high levels leads to a lean mouse devoid of white adipose tissue (136) and resistant to both dietary-induced obesity and gold thioglucose-induced obesity (137). Knockout of the  $\alpha$ GPDH gene also leads to a small mouse, possibly by impairing lipid deposition and phospholipid biosynthesis (138).

**2 Uncoupling proteins (UCPs)** Multiple approaches have been used to alter the expression of

genes coding for UCPs. Targeted expression of a diphtheria toxin A chain gene has been used to selectively knock out tissue functional activity. By coupling the gene to uncoupling protein gene expression, brown adipose tissue thermogenic function was abolished, and mice became obese (139) and developed hyperphagia. This model not only illustrates the importance of BAT thermogenesis to energy balance in rodents but also emphasizes that BAT may reciprocally affect food intake (140), probably through a sympathetically mediated signal, e.g., heat (141). This approach appears to be more successful than knock-out of the  $\beta_3$ -adrenergic receptor gene in white and brown adipose tissue (142), as this yields only a moderate form of obesity in which BAT remained morphologically normal and responded normally to cold acclimation. This questions the relationship between BAT thermogenesis and feeding behavior proposed by Himms-Hagen (141). Surprisingly, however, *Ucp1* knockouts do not induce obesity although they do induce an impaired thermogenic response to a cold environmental stimulus (143). This suggests that other thermogenic mechanisms can replace the dietary thermogenic needs but not the greater thermogenic requirement imposed by cold temperatures.

Targeted overexpression of *Ucp 1* to adipose tissue using the *aP<sub>2</sub>* promoter had no phenotypic effect until mice were placed on a high-fat diet on which they were resistant to becoming obese (144). Likewise, targeting *Ucp1* gene expression to muscle with the rat myosin light chain 2 promoter reduces body size and confers resistance to high-fat dietary obesity (145), but the physiological significance of high expression of this gene in muscle has to be questioned.

The identification of other members of the uncoupling family of genes promised the possibility of multiple approaches to manipulate thermogenesis. This promise is largely unfulfilled and it does not appear that the major physiological role of UCP2 and UCP3 is regulation of body temperature or diet induced thermogenesis. *Ucp2* knockout mice do not become obese and have a normal response to both cold exposure and high-fat diets (146).

*Ucp3* gene expression is primarily in muscle. However, while knockout of the *Ucp3* gene reduces the mitochondrial proton leak in muscle, null mutation mice remain lean (147), and the double-null mutation of *Ucp1* and *Ucp3* retains the phenotype of the UCP1 knockout mouse. While massive overexpression of *Ucp3* in muscle induces hypophagia and leanness (148), it is doubtful that this reflects any physiological role of UCP 3 on energy balance.

e. *Other*

1 *Metallothionein I and II (MtI and MtII)*

Targeted disruption of both MtI and MtII genes leads to a moderate obesity that first becomes evident at 5–6 weeks of age (149). However, the mechanism through which proteins associated with copper and zinc homeostasis and free radical metabolism induce changes in energy balance is not clear at this time.

2 *Acylation-stimulating protein (ASP)*

This protein is a product of the cleavage of complement C3. ASP gene (C3) null mice exhibit sexual dimorphism in body weight, male null mice being of normal weight whereas female null mice are smaller than wild-type females. Body fat is reduced in both sexes but food intake is increased, suggesting that there is also an increase in either basal metabolic rate or physical activity (150).

3 Signaling Proteins

a. *PKARII $\beta$*

Protein kinase A (PKA) is a multiunit complex enzyme consisting of two catalytic and two enzymatic subunits. Mice lacking the PKARII $\beta$  subunit, normally expressed in both white and brown adipose tissue, have greatly reduced levels of white adipose tissue when fed a normal chow diet. Additionally, PKARII $\beta$  (Pkar2b) null mice are resistant to the development of obesity when placed on a high-fat diet (151,152). The lean phenotype may arise from multiple effects that include enhanced brown adipose tissue thermogenesis (124) and enhanced basal levels of lipolysis (153). In contrast, targeted knockout of protein kinase B $\beta$  or the Pkakt gene has no apparent effect on growth and development but induces an insulin resistant state (154).

b. *G Protein Alpha Subunit (Gnas)*

Previously known as Gs $\alpha$ , Gnas is a stimulatory G protein linked with receptor-mediated activation of adenylyl cyclase and other membrane-related proteins. The phenotype associated with knockout of the Gnas gene depends on the parental origin of the mutation. Homozygous null mice die in utero. Obesity is associated with maternal origin of the heterozygote null allele, but leanness is the result with paternal origin of the mutation. The changes in body composition are related to alterations in energy expenditure rather than food intake. Male Gnas $-/+$  mice have increased basal metabolic rate and physical activity whereas female Gnas $-/$

+ mice have low metabolic rate and decreased physical activity (155).

c. *Protein Tyrosine Phosphatase 1B (PTRB)*

Activity of this enzyme appears to attenuate the metabolic response to insulin. The mice null for the PTRB gene (Ptrb) mutation have increased insulin sensitivity of muscle and liver but not adipose tissue, and are resistant to development of a high-fat diet-induced obesity (156). Both heterozygote Ptrb $-/+$  and homozygous null Ptrb $-/-$  mice are similarly resistant to the development of obesity, indicating the need for full activity of PTR1B for the development of obesity. Food intake is unaltered in  $-/-$  mice suggesting that the obesity of the knockout mice results from changes in energy expenditure.

d. *Signal Transducers and Activators of Transcription (STATs)*

The STATs are a family of proteins that mediate the transcriptional responses to cytokines such as growth hormone and leptin. STAT5 is phosphorylated in response to numerous signals including growth hormone, prolactin, and IL2. Knockout of the STAT5 gene (Stat5) results in a phenotype of growth hormone deficiency that includes reduced longitudinal growth, decreased adiposity in young, but obesity in older mice (157).

4 Transcription Factors

a. *Lipin (fld)*

Lipin is an 891-amino acid protein predominantly localized in the nucleus that appears to be necessary for adipose tissue development and metabolism.

Natural mutations in the gene (Lpin 1) that encodes the protein have been described in BALB/c and C3H mouse strains and are associated with a lipodystrophic phenotype, fatty liver, and neuropathy of peripheral nerves (158).

b. *PPAR $\alpha$*

The peroxisome proliferator-activated receptors (PPARs) are a family of transactivating proteins related to the steroid/thyroid/retinoid receptors. PPAR $\gamma$  is essential for adipose tissue development (159). PPAR $\alpha$  gene (Ppara)-null mice develop a late-onset obesity that shows a sexual dimorphism in the temporal development, females becoming obese at a much younger age than males (160). The cause of this obesity remains

unclear since investigators have been unable to identify changes in either food intake (160) or metabolic rate (161). Pparb null mice also have reduced adipose tissue stores (162).

#### c. *SREBP-1c*

The sterol regulatory element binding proteins (SREBPs) are expressed in multiple tissues. Overexpression of a truncated form of the adipose tissue form (SREPB-1c) gene (*Srebf1*) from the aP2 promoter leads to a mouse of similar phenotype to the A-ZIP/F-1 mouse described below, with a general lipodystrophy, severe diabetes, and liver engorged with lipid (163). Leptin treatment normalizes insulin and glucose levels (164). Transgenic overexpression of the liver form protein (SREBP-1a) gene (*Srebf2*) on the PEPCK promoter results in a similar but less severe phenotype (165).

#### d. *A-ZIP/F-1*

A-ZIP/F is a protein that prevents the binding of B-ZIP transcription factors to both C/EBP and Jun DNA binding sites. Transgenic expression of the A-ZIP/F gene under the control of the aP2 promoter results in a mouse devoid of white adipose tissue that is severely diabetic, has enlarged internal organs and reduced fecundity, and often dies prematurely. Body weight is normal (males) or increased (females) despite the absence of white adipose tissue (166). It has been proposed as a model of human lipodystrophic diabetes. Transplantation of adipose tissue and transgenic leptin overexpression reverses the metabolic phenotype (167,168), illustrating again the role of adipose tissue and or leptin in the control of insulin sensitivity and glucose metabolism.

#### e. *C/EBP*

The CCAAT enhancer-binding proteins (CEBPs) are a family of transcriptional regulator proteins. At least two of these, CEBP $\alpha$  and CEBP $\beta$ , are thought to be important regulators of preadipocyte differentiation. CEBP $\alpha$  gene (*Cebpa*) knockout has high lethality, but surviving mice are devoid of white adipose tissue (169), consistent with the observations described above for the transgenic overexpression of A-ZIP-F. Further, mice with the double knockout of *Cebpa* and *Cebpb* genes also have a partial lipodystrophy (170).

#### f. *Nhlh2*

This transcription factor gene is expressed in neural tissue particularly in those hypothalamic areas that

have been implicated in the regulation of energy balance, the arcuate nucleus, and the ventomedial and lateral hypothalamus. Both homozygous and heterozygous knockout mice develop a severe maturity-onset obesity yet do not develop diabetes on the 129  $\times$  C56BL/6J background. Hypogonadism is also characteristic (171).

#### g. *Vgf*

The function of the protein encoded by the *Vgf* gene is unknown at this time. However, it is expressed in neural tissue and particularly in the hypothalamus. Null mutations of this gene are particularly interesting since they cause a phenotype of increased physical activity, increased basal metabolic rate, relative hyperphagia related to their reduced body weight and decreased adipose tissue stores (172).

### 5 Structural Genes

#### a. *Hmgic*

Hmgic are a family of 3 proteins that function as structural components of the enhancosome. Hmgic is expressed in undifferentiated cells during proliferation, and is expressed highly and selectively in adipose tissue. Both heterozygote Hmgic gene (*Hmga2*) $-/+$  and null mutant *Hmga2* $-/-$  are completely resistant to obesity induced by a high-fat diet, while Hmgic deficiency attenuated the obesity of obese *lep<sup>ob</sup>/lep<sup>ob</sup>* and diabetes *lepr<sup>db</sup>/lepr<sup>db</sup>* mice in a gene-dosage-dependent manner (173). This effect results from an inability of Hmgic-deficient preadipocytes to differentiate into mature adipocytes.

#### b. *Intercellular adhesion molecule 1 (ICAM-1)*

ICAM-1 is a membrane protein that interacts with  $\beta$ -integrins to facilitate the migration of leucocytes. ICAM-1 gene (*Icam1*)-null mice develop a late-onset moderate form of obesity, where excess adipose tissue is predominantly deposited in subcutaneous depots (174). Food intake appears to be similar to that of wild-type mice.

### C Obesity and Related Phenotypes Associated with Multiple Genes

The polygenic forms of obesity provide a particular challenge to identify the individual genes and their contributions to the phenotype. In general, polygenic obesity has been related to those mouse strains that will develop obesity either spontaneously or in response to a

dietary influence, although there are also numerous examples in rats and other animal species (175). The Sand Rat (*Psammodromus obesus*) becomes obese when it is transferred from its usual herbivorous desert diet to a high-carbohydrate laboratory chow. A similar murine obesity and diabetes has been reported in the Spiny Mouse (*Acomys cahirinus*) (176). There is a relatively low frequency of diabetes and large variance in the severity of the syndrome in those animals affected. The NZO mouse, originally described by Bielschowsky and Bielschowsky (177), develops a moderate form of obesity from early life and has many of the features of the metabolic syndrome (hypertension, elevated blood lipids, hyperglycemia) (178). While these mice have a variant leptin receptor (A720T/T1044I), that alone does not explain the obesity. However, interaction with other genes (eg *Nob1* on chromosome 5) may be a significant contributor to the obesity (179).

More recently, the variation in susceptibility to become obese in the offspring of crosses of individual inbred strains that differed in their propensity to become obese, has become a popular form of polygenic obesity to study. BSB mice, derived from a backcross of *Mus spretus* and C57BL/6J strains, have a body fat content that shows individual variation from 1% to 50% (180,181). Backcrosses between AKR/J and C57BL/J mice likewise give a variation in body fat that has allowed the identification of linked chromosomal regions (182). The full range of linkages gained from genomewide scans in crosses of different mouse strains has been summarized elsewhere (9,10).

The susceptibility to dietary-induced obesity has been a popular model for the identification of genetic linkages. We described the wide range of dietary manipulations that can induce the development of obesity in our previous review (1). A prominent feature of all of the dietary manipulations is the variability of response across individuals and strains of rodents (5,183,184), indicating a strong interaction between genotype and diet. This characteristic may be particularly relevant to the current epidemic of obesity in humans. The strain variability also provides the experimental opportunity for genetic analysis of these differences (185,186).

Several laboratories have mapped quantitative trait loci (QTLs) that influence body fat, particularly after feeding a high-fat diet. Numerous linkages on multiple chromosomes have been identified, many in regions not known to contain an obesity gene (180–182,185–187). Congenic mice or radiation-induced chromosomal deletions have been used to try to narrow the DNA region and identify the specific gene. This approach has successfully identified a novel ATPase coded on chro-

sosome 7 as a potential obesity-related gene (188), although no functional studies have yet been made for proof of function.

## D Hypothalamic Obesity

The use of animal models to study the causes and consequences of obesity really began with the destructive lesioning of specific hypothalamic areas (3,4). Since that time a wide range of methods have been used to damage or activate specific brain sites including selective knife cuts and electrical, chemical (gold thioglucose, bipiperidyl mustard, monosodium glutamate, ibotenic acid, neurotransmitters, neuropeptides), or viral routes. These models were reviewed extensively previously (1,3,4). During the past few years, the possibility of a viral cause of obesity has received increased attention.

Four animal viruses and one human virus have been shown to induce obesity or some degree of additional adiposity in animal models. These are the canine distemper virus in mice (189), the Rous-associated virus in chickens (190,191), the Borna disease virus in rats (192), the adenovirus SMAM-1 in chickens (193), and the related human adenovirus Ad-36 in chicken and mice (194). These have been reviewed recently (195).

In general, there is variability in the level of obesity and the metabolic changes that depend on the age of infection and the animal model. The demonstration that a human adenovirus can induce obesity has raised interest particularly since antibodies to the virus have been reported to be linked to higher body weight in small numbers of humans (196). However, the effect size is small, and has been linked with an atypical reduction in serum cholesterol, making it unlikely to be a major cause of human obesity. Similarly, in mice and chicken the increase in body fat in response to adenoviral infection is small, < 10% (194). While the mechanisms of action of all of the viruses has not been demonstrated, evidence of neuronal damage supports the hypothesis that the virus may have their effects through changes in the activity of the hypothalamic neuropeptide circuits that are modulated by leptin (197,198).

The hypothalamic models of obesity have led to the recognition of the different but overlapping functions of specific hypothalamic regions in the control of energy balance. The VMH is recognized as a primary center regulating the autonomic outflow in response to dietary related signals (3,4,199). The lateral hypothalamus has opposing actions to the VMH on the autonomic nervous system, but also is responsible for feeding behav-

ior. In contrast the PVN region has less to do with sympathetic regulation of brown adipose tissue and vagal regulation of insulin secretion, but is a powerful site for the regulation of feeding behavior. It is only in recent years, with the benefit of molecular and genetic studies, that the neurochemical basis for the activities of these centers has been identified. In particular, the two subpopulations of neurons in the arcuate-PVN pathway (NPY/AGRP neurons and POMC/CART neurons) and the identification of MCH and Orexin (hypocretin) in LH neurons have provided neurochemical insight into function of these sites.

### **E Endocrine Obesity**

Endocrine manipulations have long been known to influence feeding behavior and body composition (1,3,4). These include peripheral injections of insulin (200), excessive glucocorticoid activity (70), and ovariectomy (201–204). The use of transgenic and gene knockout approaches (see Sec. B above) to manipulate hormone and receptor levels has helped to study the role of insulin, adrenal, and gonadal steroids. In addition, these approaches have identified effects of numerous other endocrine influences including pancreatic polypeptide, amylin, IGF-1, CRH, growth hormone, and CCK on energy balance.

### **F Features Common to Many Models of Obesity**

In our previous review we identified numerous features that were common to virtually all animal models of obesity. These included the hypersecretion of insulin and the development of insulin resistance, the hyperphagia and/or autonomic dysfunction, and the glucocorticoid dependence of the obesities (1). It is not our intent to review these characteristics again. However, it is appropriate to identify some significant advances in these areas.

Serum leptin levels are closely related to body fat. Increased levels of leptin gene expression have been reported in all obese models, including the Zucker fa/fa rat (205,206), the diabetes db/db mouse (11), and rats made obese by VMH lesions (207), in rats fed a high-fat diet (208), in the obesity associated with aging (209), and in nonhuman primates (207). The coincidence of hyperleptinemia and obesity is indicative of a failure of leptin to modulate food intake and energy expenditure appropriately, a state of leptin resistance.

A number of studies have sought to identify the site of this leptin resistance by comparison of the responses

to peripheral and centrally administered leptin. The loss of response to peripheral leptin, but not to central leptin, has been noted in high-fat diet-induced obesity in both mouse and rat models (210–213) and in CCKA receptor-deficient rats (214), suggesting that transport of leptin across the blood brain barrier is reduced in obesity. This has been confirmed by direct measurement of leptin transport in high-fat-fed obese mice (215). However, this effect may be related to the dietary fat rather than the obesity, since we (216) have shown that the response to peripheral leptin is lost within 24 hr of feeding a high-fat diet. It is likely, though, that the temporal sequence and magnitude of this response are variable across animal models (212).

Leptin resistance is probably manifest at multiple sites in addition to transport across the blood brain barrier. It is now clear that there are significant changes within the signaling pathways in the hypothalamus that also contribute to leptin resistance. Leptin appears to express its biological activity through regulation of the expression and release of several neuropeptides within specific hypothalamic neurons known to affect energy balance. This includes NPY,  $\alpha$ -MSH, AgRP, CART, and CRH. The reduced inhibition of arcuate neurons by leptin in overfed rats has been directly demonstrated by electrical recording of nerve activity (217). Decreases in either message or protein levels of the long form of the leptin receptor have been documented (208,218,219), including attenuated transport of leptin across the blood brain barrier as well as reduced activity of the signaling pathways (JAK-STAT, MAP kinase, K-dependent ATPase) or enhanced activity of the suppressors of cytokine signaling (SOCS3) that regulate the release and synthesis of these neuropeptides (210,220). This central leptin resistance might result from effects of leptin itself (221), from downregulation in response to insulin (222), or from the effects of glucocorticoids (223). Readers are referred to other chapters for a full description of these signaling pathways.

## **III SUMMARY**

Obesity is now recognized as the major nutritionally related disease in the Western world. The rapid development in our understanding of the causes and consequences of obesity owes much to the intensive studies of a wide range of animal models, ranging from rodents to nonhuman primate colonies. In rodents, the application of transgenic and gene knockout technologies has created many new models and provided the tools for proof

of function of particular genes in causing obesity, affecting adipocyte development or altering feeding behavior and energy expenditure. These models have provided tools for investigation and identification of the hypothalamic pathways and neuropeptidergic systems that regulate feeding behavior and the autonomic nervous system control of energy expenditure. Genetic studies increasingly show the relevance of these animal models to human obesity.

The genes causing a number of spontaneous obesities have been identified; identification of the agouti gene in the Yellow Obese mouse has led to the discovery of the melanocortin pathways; identification of the carboxypeptidase E gene mutation in the Fat ( $Cpe^{fat}/Cpe^{fat}$ ) mouse has identified the importance of posttranslational processing of peptides; and the identification of the mutations in the Obese and the Diabetes mice and in the Zucker rat led to the discovery of leptin and its signaling pathway. The interaction of environment and genes and its importance for the development of obesity has been studied in crosses of mouse strains and after genetic manipulations that enhance or attenuate the sensitivity to induction of obesity on a high-fat diet. Linkage analysis has identified other gene loci that can be linked to obesity. Age and sex may also be important factors in determining the degree of obesity and the intensity of the associated disorders, particularly diabetes. The possibility of a viral cause of obesity has also been raised.

The application of imaging systems to identify specific mRNA or proteins has linked the genetic and molecular studies to the neuroanatomical networks that had previously been demonstrated to regulate feeding behavior and autonomic control of thermogenesis and insulin secretion. They have also identified abnormalities in these systems that promote obesity.

By study of such divergent experimental models, it has become clear that there may be many different causes of the obesity, but also that there are a number of features that are common to all obesities. Further, it has illustrated the potential for significant gene  $\times$  gene interactions to enhance or reduce the susceptibility to obesity. The new insight that has been gained from genetic manipulations in mice and from the identification of the function of those genes responsible for the genetically inherited obesities has led to the identification of new targets for the therapeutic prevention and treatment of obesity. The continuing use of genetic manipulations in animals and the identification of genes responsible for linkage traits in animals and humans is likely to identify even more genes that will affect energy balance. Understanding

the interactions of these multiple systems is a challenge for the next decade.

## Primates in the Study of Aging-Associated Obesity

Barbara C. Hansen

University of Maryland, Baltimore, Maryland, U.S.A.

### I AGING-ASSOCIATED NATURALLY OCCURRING SPONTANEOUS OBESITY IN NONHUMAN PRIMATES

Within the class Mammalia, obesity has been identified in a number of orders, including the Rodentia, the Carnivora (e.g., dogs, bears), the Artiodactyla (pigs, cattle), and the order Primates (which includes, for example, lemurs, monkeys, apes, and humans, a total of ~200 primate species), as well as in other orders which include such mammals as the whale, walrus, manatee, hedgehog, and rhinoceros. Within the sub-order Anthropoidea, obesity has been described in two of three superfamilies: Cercopithecoidea (Old World monkeys, including many species of macaques) and Hominoidea (including orangutans, chimpanzees and gorillas—with specimens of this last sometimes found to weigh >180 kg 400 lb). Obesity may also occur in the third superfamily Ceboidea (New World monkeys); however, to date it has not been well documented. Most commonly, within the genus *Macaca*, obesity has been described in the species *Macaca fascicularis* (cynomolgus monkeys), *Macaca nigra* (misnomered the Celebes ape), and most of all, in *Macaca mulatta* (rhesus monkeys)(1–3).

Spontaneous, naturally occurring obesity is common both in free-ranging and in laboratory or zoo-maintained nonhuman primates and has been described in a wide range of primate species. In addition, primate models of obesity have been experimentally induced.

Previous reviews have described the various measures used to produce experimental obesity in primates (4,5), including the production of hypothalamic lesions to induce weight gain and diabeteslike syndromes, drug and hormonal approaches, and diet manipulations (6) or forced overfeeding (7,8) to produce weight gain. These methods have received little use in the past 10 years, probably because, as monkeys have been held longer under laboratory conditions, well into middle age, more and more spontaneously obese animals have been identified, thus reducing the need to experimentally create obese primate models. Further, the induced obese models may deviate significantly from the “normal” naturally occurring form(s), both in underlying mechanisms and in responses to treatment. The present review will, therefore, focus on spontaneous obesity in both free-ranging and laboratory-maintained monkeys.

One of the first surveys aimed at identifying the prevalence of obesity in a colony of group-housed monkeys examined the medical records of >800 pig-tailed macaques (*Macaca nemestrina*) in a large breeding facility (9). Tritiated water was then used to determine the relative body composition of those selected on the basis of heavy body weight for age. Several spontaneously obese individuals were identified; however, the incidence appeared to be very low. Retrospective consideration of this study, based on further understanding of obesity in primates gained over the past 20 years, suggests that the reason for the finding of a very low

number of obese animals was the relatively young age distribution of the breeding colony. It is, in fact, unusual to find monkeys of either sex over the age of 15 years in a breeding colony, as they are usually moved before reaching such an age.

The obesity of nonhuman primates is clearly of adult onset, with no cases of obesity having yet been identified in an animal under the age of 7 years. For reference, sexual maturity is reached in the female between 3 and 5 years (10) with completion of growth at 6–7 years of age, while in the male the corresponding ages are 4–6 years (11) and 8 years. The obese monkeys, identified in a survey of a free-ranging chow-provisioned colony living on the island of Cayo Santiago, ranged in age from 9 to 16 years (12,13). Peak body weight on average is reached around the age of 15 years in *Macaca mulatta*.

Obesity in male monkeys has been associated with abnormal androgen metabolism, with obese males having lower serum testosterone and lower dihydrotestosterone than leans (5). Females had lower serum androgen levels than males, but there were no differences between obese and lean females. Gonadectomy in male and in female monkeys reduced body weight relative to intact animals; however, replacement therapy with testosterone propionate or dihydrotestosterone propionate resulted in an increase in lean body mass, but not in adiposity (14).

No early markers for the propensity to develop obesity at a later age have yet been found that could be used to identify in young adult monkeys (or in, for that matter, humans) the predisposition toward obesity—with the exception of family history (and an unconstraining environment).

## II DIET, FOOD INTAKE, ACTIVITY, AND ENERGY EXPENDITURE IN NONHUMAN PRIMATE OBESITY

In spontaneously obese male rhesus monkeys ranging from 10 to 17 kg, no differences in food intake were observed between the most obese and the least obese groups, suggesting that differences in energy expenditure may contribute principally to the development of obesity. Obese animals showed reduced physical activity (15); however, it has not been possible to document reduced activity in advance of the development of obesity (16). In some studies obese monkeys have been found to ingest fewer calories than lean monkeys (17), thus providing no evidence for hyperphagia as an important contributor to the development of obesity or its sustaining. Prevention of obesity by restraint of

calories neither increased nor decreased physical activity relative to similar-weight animals (15). Energy expenditure per kg lean body mass was significantly reduced by a degree of calorie restriction sufficient only to prevent the development of obesity (15).

Although several studies have involved dietary manipulations thought to facilitate the development of obesity, where these dietary regimens have been tested in young animals, obesity has not developed (18). Some very high fat diets, for example, 60% fat, have been found to produce weight gain in young monkeys. High-fat diets have been used to alter lipoprotein composition (19). The usual dietary regimen of laboratory monkeys, primate chow, would be expected to be optimal in the prevention of obesity, as it is high in fiber, low in fat (17%), and relatively low in caloric density (4 kcal/g). In colonies where the calorie allocation to each monkey is strictly controlled, that is, restricted below ad libitum levels, obesity does not develop. Under conditions of ad libitum feeding (food continuously available for 8–24 hr/d), obesity will eventually develop in perhaps 50% or more of the laboratory-maintained animals, despite the presumed optimal diet composition. As discussed below, long-term experimental limitation of calories, adjusted on an individual basis to prevent body weight increase, can prevent the development of this middle-age-onset obesity (20).

## III MEASUREMENT OF ADIPOSITY IN MONKEYS

The assessment of obesity in monkeys can be made by body weight alone, since, in adult animals, body weight and percent fat are highly correlated (within each sex) ( $r = .62, p < .01$ ) (21). The body mass index, or Quetelet index ( $\text{weight}/\text{height}^2$ ), was adapted for use in monkeys by substitution of the crown-rump length (in cm) for height (21). This body mass index, termed the Obesity Index Rh (for rhesus monkeys), was shown to be highly correlated with percent weight as fat ( $r = .80, p < .01$ ), midgirth circumference ( $r = .82, p < .001$ ), and body weight ( $r = .80, p < .001$ ), but not with height, and is therefore the best simple measurement of body fatness in monkeys. Total height is not readily or accurately measured in monkeys, particularly as they age, and thus the usual body mass index used for humans is not sufficiently reliable. All rhesus monkeys over the body weight of 15 kg had >25% of weight as fat. In obese male rhesus monkeys, body fat can reach 50% of body weight. The tritiated water dilution method has also been reliably used to estimate total body fat content,

and is highly correlated with the body mass index for monkeys.

Computed tomography has been used to assess abdominal fat distribution, with the observation in *Macaca fascicularis* of very strong positive correlations between body mass index and intra-abdominal fat, subcutaneous fat, and total abdominal fat ( $r$ 's  $> .89$ ) (22). Sharma et al. (23) compared magnetic resonance imaging (MRI) and various anthropometric measures in *Macaca fascicularis*, and found significant heterogeneity in the amounts of intra-abdominal and subcutaneous fat. Body weight correlated with intra-abdominal fat in these male cynomolgus monkeys. Although little has yet been published on the use of the DXA (dual-energy x-ray absorptiometry) method in non-human primates, it is likely with careful standardization to become the "gold standard" for assessing body composition. Female cynomolgus monkeys have been examined by DXA for body composition against a standard, with the observation that percent body fat of soft tissue mass is a better index of obesity than body weight and/or anthropometry (24).

#### IV FEATURES COMMON TO MANY PRIMATE MODELS OF OBESITY

Obese rhesus monkeys, followed longitudinally, show a gradual slow decline in glucose tolerance, many years before the development of overt diabetes (25), and this has been observed in cynomolgus monkeys as well (26–29). This deterioration takes place at the same time as pancreatic insulin output is increased both basally and under stimulated conditions.  $\beta$ -cell hyper-responsiveness to a glucose load has been shown to be a very early defect in obesity, possibly preceding the development of significant insulin resistance and hyperinsulinemia (30). In obese monkeys, prior to the development of overt diabetes, deKoning et al. (31) found beginning changes in pancreatic  $\beta$ -cells, with proliferation of  $\beta$ -cell mass, and small deposits of islet-associated polypeptide as islet amyloid, as also noted in cynomolgus (28).

The insulin resistance is not a requirement for the development of obesity in rodents or primates. Furthermore, the hepatic insulin resistance as evidenced by the failure of insulin to suppress hepatic glucose production is not associated with obesity per se, but has been directly related to the subsequent development of overt type 2 diabetes mellitus in monkeys (32).

Reduced hepatic extraction of insulin has also been shown to be involved in the sustaining of hyperinsuli-

nemia (33). Nevertheless, this reduction does not appear to be primary, occurring only as insulin levels increase above a portal insulin level of 700–1000 pmol/L (peripheral insulin level of  $> 350$  pmol/L). Thus at the early stages in the development of both obesity and hyperinsulinemia, there appears to be no defect in hepatic insulin uptake (34).

#### V IN VIVO METABOLIC AND ENDOCRINE DEFECTS ASSOCIATED WITH OBESITY AND DIABETES IN PRIMATES

Abdominal obesity in humans, as well as in monkeys, has been shown to be associated with diabetes mellitus. Monkeys with central or abdominal obesity could be classified as insulin-sensitive or insulin-resistant and showed a strong linear relationship between abdominal circumference and fasting plasma insulin and an inverse relationship with insulin resistance. Within the obese group there was, however, a diversity of degrees of insulin resistance (33).

In primates, spontaneous obesity has been shown to be associated with an increased frequency of dyslipidemia. Monkeys, like humans, show individual variability in susceptibility to diet-induced or spontaneous atherosclerosis (35), and these primates develop atherosclerotic lesions similar to humans (36). There was, however, no significant relationship in this study between abdominal circumference and various lipoprotein fractions. Hannah et al. (37) showed that obese hyperinsulinemic normoglycemic monkeys have beginning increases in VLDL triglycerides, small reductions in HDL cholesterol, and no change in LDL cholesterol. This dyslipidemia was significantly exacerbated in those monkeys with type 2 diabetes mellitus.

As previously described, many but not all obese monkeys go on to develop impaired glucose tolerance and then progress to overt type 2 diabetes mellitus (4,20). This longitudinal process was first described by Hamilton and Ciaccia (38) as a period of middle-aged obesity and normal glucose tolerance associated with hyperinsulinemia, followed by glucose intolerance and frank diabetes. The progressive process was further defined as a series of successive phases leading from normal lean young animals to older monkeys with or without obesity (39). Among the obese, some then progress through successive phases of increasing hyperinsulinemia and insulin resistance, progressive impairment of glucose tolerance, and finally overt diabetes (39). Glucose tolerance, one measure of this progressive

process, has been calculated using a number of different formulas, the optimal of which is defined by the slope of the time points 5 and 20 min of an IV glucose tolerance test using a glucose load of 0.25 g/kg body weight. This time period was determined to be optimally applicable to monkeys across the entire range of tolerance from young normal to severe diabetic (12). Kemnitz et al. (5,14) showed that during pregnancy, a deterioration of glucose tolerance and an increase in fasting plasma insulin levels occur in the rhesus monkeys in the highest preconception tertile of adiposity. Wagner et al. (40) also showed a similar effect in cynomolgus monkeys.

## VI GENETICS OF OBESITY IN PRIMATES

### A Gene-Environment Interactions

Nonhuman primates provide excellent models for examining gene-environment interactions and for seeking the mechanisms underlying the development of aging-associated non-dietary-induced obesity, and possible mechanisms for its mitigation (41). Both the induction and the remission of obesity require cellular events involving overall energy balance (42). As in humans, several studies have documented a familial association in the development of obesity. A mother and daughter pair was identified in the 1977 survey of *Macaca nemestrina* mentioned above (9), and Schwartz et al. (13,43,44) noted several primary familial relationships among the obese animals of the Cayo Santiago colony. Environmental factors, principally ready access to food, also influence the incidence of obesity, which has been reported to range from 7% among the free-ranging Cayo Santiago troops ranging up to age 16, to 50% or more in individually housed animals in an age range up to 40 years.

Further support for a genetic basis of nonhuman primate obesity comes by inference from studies of groups of *Macaca mulatta* held under identical and constant environmental and dietary conditions, in which some animals have become significantly obese, while others have remained lean throughout their lives (44a).

### B Candidate Genes for Obesity

No single-gene induced cases of obesity have been reported in nonhuman primates. Examination of the genetics of obesity in nonhuman primates has, to

date, focused on a wide range of candidate genes, some specific to adipose tissue, and others potentially involved in insulin action and insulin sensitivity. Several candidate genes have, however, recently received special attention for their possible roles in obesity. Both human and mouse sequence data have assisted in the characterization of the molecular features of nonhuman primate obesity, and physiologic and molecular data from monkeys have assisted in the evaluation of the relevance of these genes and their products to human obesity. Although many candidate genes have been considered, we will deal specifically here with leptin and the *ob* gene, adiponectin, the  $\beta$ -3 receptor, the peroxisome proliferator-activated receptors, insulin and its insulin receptor, and the newest adipose specific protein, galectin-12.

Adipose tissue is now known to be the largest of the endocrine organs, secreting many different products into the circulation, including, for example, leptin, adiponectin, interleukin-6,  $\text{TNF}\alpha$ , angiotensinogen, plasminogen activator-inhibitor 1 (PAI-1), adipsin (complement factor D), sex steroids, and glucocorticoids. In addition, some adipocyte products apparently act in a paracrine manner. Prior to 1994, several such products were known, but despite efforts to do so, they were not successfully connected to the pathophysiology of obesity or to causal mechanisms (45). Recent reviews have summarized the expanding knowledge of adipose tissue as an endocrine organ and its role in the regulation of energy balance and obesity (42,46).

### C Leptin, the Circulating Protein, the OB Gene, and the OB Receptor

Evidence for the existence of one or more circulating factors emanating from adipose tissue and playing a role in regulating body weight came first from the parabiosis experiments of Coleman and colleagues more than 30 years ago (47,48). Mice with genetic forms of diabetes (47) and with genetic forms of obesity (48) were parabiosed with normal mice, with the results suggesting that the obese mice lacked a substance secreted by normal mice and that the diabetic mice lacked the ability to respond to this factor. Much later the *ob* gene was cloned and characterized by Zhang et al. (49), and shown to be located on human chromosome 7q31.3. The product of this gene, leptin, is an adipocyte-derived 16-KDa circulating protein that clearly is involved in body weight regulation. Administration of this product, now called leptin, to obese *ob/ob* mice reversed many of the consequences of the *ob/ob* gene mu-

tation, including reducing food intake and decreasing body weight (50). The *db* gene was subsequently shown by Tartaglia et al. to encode the ob receptor, OB-R, which is the receptor for leptin (51,52), and was found to be highly expressed in the central nervous system.

With the discovery of the gene responsible for obesity in the *ob/ob* mouse, and the identification of the circulating protein that it encodes (leptin) and its receptor, exploration of the possible role of leptin in the spontaneous obesity of monkeys was pursued. Interestingly, cross-circulation experiments in monkeys (53), carried out about the same time as the parabiosis studies in mice, did not lead to a prediction of any abnormal circulating factor or receptor regulating short-term feeding behavior in the monkey. The absence of such an abnormal gene or gene product in monkeys was subsequently proved to be true (see below). Cross-circulation studies in nonhuman primates accurately predicted the absence of a powerful circulating factor controlling short term energy regulation and short-term food intake (53). In these studies, various paradigms were tested, but the most informative one was the sustaining of pairs of monkeys for 4+ days in complete rapid cross-circulation, with one but not the other of the pair of monkeys allowed free access to food. It was anticipated that, in making the equivalent of one monkey "pregnant" with a whole second monkey's body, that the first monkey would regulate to "eat for two." This did not happen, despite the lack of any gastrointestinal limitations on increased chow consumption. On the contrary, the "feeding" monkey ate normally, ignoring the presence of the second monkey in his circulatory bed. (And by short-term tests, the non-feeding monkey remained acutely hungry, even during the postmeal period of its partner.) This cross-circula-

tion was engineered to be femoral artery to femoral vein, and thus, only the GI tract and the liver of the feeding monkey "saw" a different environment (the absorption of nutrients). The neural signals to the CNS from the gut of the feeding monkey undoubtedly differed from those of the parabiosed monkey, while the circulating signals were undoubtedly shared by both. We interpret this to mean that the humoral signals, whatever they may be, are relatively weak in controlling short-term feeding. Alternatively, those humoral or bloodborne signals must be received in the CNS in concert with the gut neural signals. Given contradictory information (fed state in the circulation and fasted state in the gut), the humoral signals were insufficient to produce satiety in the nonfeeding monkey. Further, in the feeding monkey, the signals (both humoral and neural) from the GI tract and liver were strong enough to overcome any such signals. The feeding animal lost a small amount of weight, but despite this, did not increase feeding to "eat for two."

The *ob* cDNA of the monkey was cloned from adipose tissue and shown to have at least 47 bp of 5' noncoding region, 501 bp of coding region, and 219 bp of 3' noncoding region (54). The *ob* mRNA is 0.8 kb long, which is shorter than that of rodents or humans due principally to a shorter 3' noncoding region. The *ob* protein is 167 amino acids in length, as in humans and rodents, and has 91% amino acid similarity to the human *ob* protein. The *ob* mRNA was only expressed in adipose tissue (55).

Among a group of normal weight 7-year-old monkeys, the level of *ob* mRNA in adipose tissue was correlated to body weight and body fat. In a larger group of older animals, plasma leptin levels were correlated to obesity (% body fat), as shown in Figure 1;

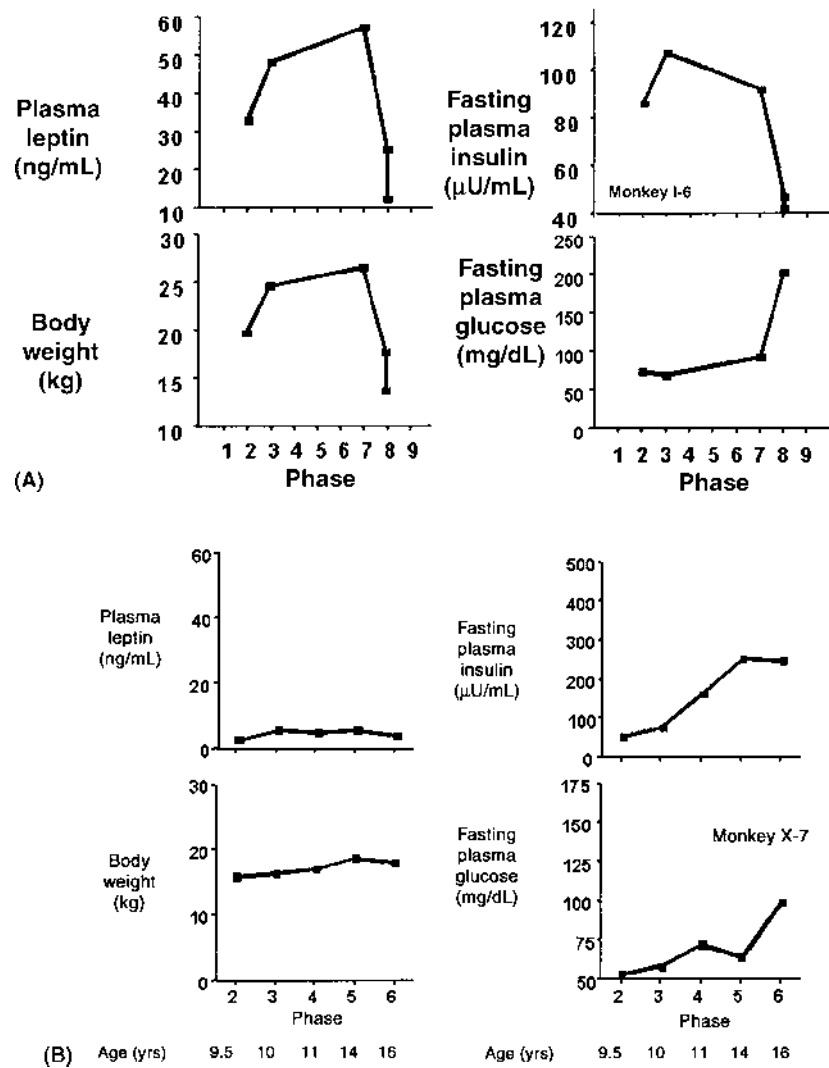

**Figure 1** Relationship between fasting plasma leptin levels and percent body fat in rhesus monkeys varying in degree of adiposity. (From Ref. 56.)

however, this association was found to be reduced due to a subgroup of animals showing no relation between body weight and leptin. In 10 of 13 older monkeys examined during the development of increasing body weight and increasing adiposity, an increase in circulating leptin was positively associated with the increase in body weight (56). There was a tendency for ob mRNA to be increased in the hyperinsulinemic obese group of monkeys and reduced relative to normals in a group of diabetic animals that had previously lost body weight.

Figure 2 shows leptin levels across a longitudinal study period for two monkeys. The data shown in the

top 4 panels represent a monkey that “tracked” body weight with leptin level changes very closely. On the bottom 4 panels, however, is another example, a monkey that, despite a similar degree of obesity, showed no elevation of leptin at all. These extremes are also seen across humans (57) and suggest that leptin is not solely an indicator of the amount of adipose tissue, but that other factors must also significantly alter its levels. Since the two animals shown in Figure 2 were maintained and studied under identical laboratory, diet, and environmental conditions, one must speculate on other genetic influences as contenders for inducing such differences.

**Figure 2** Longitudinal changes in plasma leptin levels compared to changes in plasma insulin, plasma glucose, and body weight in two monkeys. Panel A shows a monkey in which leptin and body weight changes are highly related, while panel B shows a monkey that is equally obese but shows no elevation in plasma leptin levels.

Indeed, we now know that leptin plays a role in a wide range of physiologic processes, and that while its absence (no leptin production or no functional receptor) has profound effects to increase body fatness in rodents and in humans, its presence in varying amounts in individuals with normal receptors appears to be without consequence. It has been suggested that leptin may play a role in puberty; however, a longitudinal analysis of male rhesus monkeys found no significant fluctuations in leptin levels prior to or during the puberty associated rise in testosterone secretion (58).

The ob or leptin receptor, primarily acting through its obRb form in the arcuate nucleus, seems to transduce leptin signals to two sets of neurons—one set with properties leading to feeding inducing (which are reduced by leptin), and another set with appetite suppressing properties (which are induced by leptin) (42). The monkey leptin receptor cDNA has been cloned and its sequence analyzed (59). Two alternatively spliced variants were identified, one with homology to the mouse obRb (long form) and the other a short form homologous to the mouse obRa. The long form in the rhesus monkey was found to be 96% homologous to the human long form (59). The receptor was expressed in liver and in kidney as in humans, suggesting that leptin may act not only through the CNS, but also through various peripheral tissues. The mRNA levels of the leptin receptor in the monkey were not related to obesity, hyperinsulinemia, or type 2 diabetes.

#### D Effects of the Administration of Leptin

The pharmacokinetics of human leptin administered to monkeys indicates a half-life of  $\sim 96$  min after IV administration, and  $> 8$  hr after SC dosing, and was similar to that observed in humans (60). Attempts to alter feeding regulation and fatness via peripheral administration of leptin to monkeys (61,62) and to humans (63) had little if any effect on body weight. Although there was no acute effect of centrally administered leptin to lower food intake in monkeys, a day after the central leptin administration, food intake was reduced by 40–50% (61). The cause of this effect was not readily discerned.

The failure of peripheral leptin administration in monkeys and humans to alter food intake and body weight significantly may be due to the absence of a defect in the leptin molecule of these subjects. Clearly in children with congenital leptin deficiency, leptin treatment can reduce body weight and adiposity and improve reproductive hormone activity (64). Leptin administration to monkeys had no effect on the

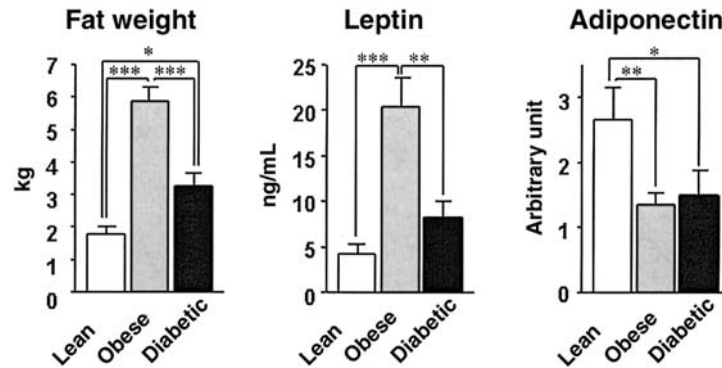

fasting-induced acute changes in growth hormone, luteinizing hormone, or cortisol secretion, although the fasting-induced fall in leptin was prevented (65). Leptin also did not have effects to acutely regulate either basal or ACTH-stimulated adrenal cortisol secretion (66). During food restriction, leptin levels (67) and reproductive hormones (68) are acutely suppressed. Replacement of leptin, however, had no effect on the other hormones; therefore, leptin does not mediate the effect of food deprivation on reproductive hormones (68).

What, if any, physiological signal is produced by the relatively high leptin levels frequently seen in obese humans and in obese monkeys is unknown. Further, while the concept of “leptin resistance” has been proposed, there is, to date, no evidence to support such a phenomenon other than its inference from the absence of apparent consequences of high leptin. Thus, the original view of leptin as the “adipostat,” sensing the amount of adipose tissue in the body and signaling that information to the brain, thus acting as a mediator of food intake and body weight, does not appear to be the case.

We conclude that the leptin pathway may not serve as a simple “servomechanism/feedback loop” for regulating obesity or food intake, and should be considered not for a primary role in obesity for most humans, but as a far more complex hormone interacting with many systems, as yet not fully understood.

#### E Adiponectin (Acrp3, AdipoQ, apM1, GBP 28)

In searching an adipose specific cDNA library for novel genes expressed abundantly in fat tissue, Maeda et al. (69) identified an adipose specific collagenlike factor that was termed apM1 for AdiPoseMost abundant gene transcript 1. The protein expressed by this gene was separately identified in plasma by Nakano et al. (70) as GBP28, a novel gelatin-binding protein of 244 amino acids with a secretory signal sequence at the amino terminal. The gene was located on chromosome 3q27 and consists of three exons and two introns. Two polymorphisms have been identified in humans, but neither was associated with obesity (71). This protein, specifically secreted by adipose tissue, was subsequently named adiponectin, and was initially thought to function in lipid metabolism and fat storage. Unlike leptin, adiponectin is lower in obesity. In cultured cell lines, adiponectin inhibits the phagocytic activity of macrophages and the production of  $\text{TNF}\alpha$ , thus raising the possibility that adiponectin plays a role in ending inflammatory responses (72).

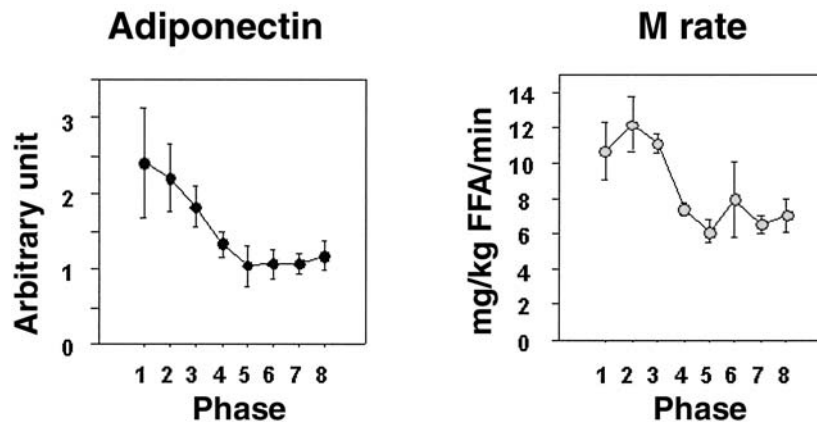

**Figure 3** Comparison of fat weight, plasma leptin levels, and plasma adiponectin levels in three groups of monkeys—lean, obese with insulin resistance, and obese with type 2 diabetes. \* $P < .05$ , \*\* $P < .01$ , \*\*\* $P < .001$ . (From Ref. 74.)

Adiponectin also suppressed macrophage to foam cell transformation (73).

Monkey adiponectin was cloned and sequenced and shown to be ~ 96% homologous to human adiponectin and specifically expressed in adipose tissue, as it is in humans (69,74). Body fat weight was determined by the tritiated water method for three groups of monkeys—lean, obese with insulin resistance, and overt type 2 diabetes. Fat weight was then compared to plasma leptin levels and plasma adiponectin levels for the three groups, as shown in Figure 3. We also sought to determine the longitudinal changes in plasma adiponectin levels during the progression from normal to insulin resistant/obese to overtly diabetic in nonhuman primates with a high predisposition to type 2 diabetes and dyslipidemia. Plasma adiponectin levels declined

as insulin sensitivity declined, and then remained at low levels as insulin resistant animals progressed to overt diabetes (74), as shown in Figure 4. The glucose uptake rate during a euglycemic hyperinsulinemic clamp was highly correlated to plasma adiponectin levels ( $r = .66$ ,  $P < .001$ ). There was no clear association between the plasma adiponectin levels and the mRNA expression in adipose tissue, nor were these related to total body fat mass.

Low levels of adiponectin have been associated in humans with cardiovascular disease (75) and with diabetes (76) and insulin resistance (77). Adiponectin has been administered to rodents with promising results; however, there are not yet reports of its administration to nonhuman primates. It is hypothesized that changes in metabolism induced by this hormone would

**Figure 4** Longitudinal changes in plasma adiponectin levels (left panel) and insulin sensitivity as measured by a euglycemic hyperinsulinemic clamp (M rate, glucose uptake rate) as monkeys progress from normal/lean (phase 1) to obese with increasing insulin resistance (phases 3–6), to impaired glucose tolerance (phase 7), to overt type 2 diabetes mellitus (phase 8).

reduce markers of the metabolic syndrome and potentially mitigate the risk of cardiovascular disease and diabetes.

## VII ENERGY EXPENDITURE AND THE ADRENERGIC RECEPTORS IN PRIMATES

### A The $\beta$ -3 Adrenergic Receptor and Agonists

On the energy expenditure side, attempts have been made to increase energy output selectively in the adipose tissue by activation of the  $\beta$ -3 adrenergic receptor. The  $\beta$ -3 adrenergic receptor, which is specifically expressed in adipose tissue, has been sequenced in the rhesus monkey (78). It shows 95% amino acid identity with the human  $\beta$ -3 receptor, differing between the two species in 22 of 408 amino acids. The rhesus monkey receptor contains an arginine at position 64, an amino acid that has been found in greater frequency in several groups of humans with a high propensity to obesity. Because of the similarity of the monkey to the human  $\beta$ -3 receptor, nonhuman primates have been used to examine the potential of  $\beta$ -3-specific agonists to alter the metabolism of adipose tissue, with the goal of producing adipose tissue specific weight loss in humans (79). Early agents, such as BRL-37344, CL-316243, ICI-D7114, and SR58611A, were found to be lipolytic in rat and dog adipocytes, but proved to be only weakly lipolytic or not at all active in baboon, macaque, and human cells. L757,793 and GR5261X are human selective  $\beta$ -3-specific agonists that stimulate lipolysis and show other metabolic effects. In nonhuman primates, chronic dosing produced no change in food intake and no decline in body weight, despite evidence of lowering of nonesterified fatty acids, triglycerides, and plasma insulin levels (79). While the theory remains seductive, as yet, there is no  $\beta$ -3-specific agonist that has been reported to have strong clinical potential for use in humans. Further, it is recognized that with weight loss itself, energy expenditure may be disproportionately reduced, thus potentially limiting further weight loss.

### B Other Means of Sympathetic Activation

Other methods to increase energy expenditure are based on the hypothesis that a contributing factor in obesity is low sympathetic nervous system activity (SNS). One study has attempted to promote weight loss in obese monkeys using this approach (17). The agents used were ephedrine (6 mg) and caffeine (50 mg) three times per day. Food intake was reduced and energy expenditure

increased with the net effect of a reduction in body weight of  $\sim 7\%$  over 8 weeks in the obese monkeys. These effects too may be mediated via the  $\beta$ -adrenergic receptors. Weight was regained within 5 weeks of the end of the study.

## VIII PEROXISOME PROLIFERATOR-ACTIVATED NUCLEAR RECEPTORS AND THEIR AGONISTS

A family of nuclear receptors termed the peroxisome proliferator-activated receptors has been identified, initially on the basis of the identification of pharmacological ligands. They are of three subtypes, PPAR $\alpha$ , PPAR $\gamma$ , and PPAR $\delta$ , and they are the products of different genes on different chromosomes. They were first cloned as "orphan" receptors, but the past 10 years has shown a proliferation of papers on the PPARs, and with those, a growing understanding of their diverse roles, particularly in the areas of insulin sensitizing and amelioration of dyslipidemias. Concerning obesity, these PPARs have not been found to be causally involved; however, the association of obesity with insulin insensitivity and dyslipidemia has made the agonists of these receptors particularly of interest for addressing the pathophysiology associated with obesity. Nonhuman primates have been used effectively in the examination of ligands for each of the three subtypes, and have been shown to be predictive of the effects in humans (80).

Species specificity has proved to be important, since many of the PPAR agonists act at the human and nonhuman primate receptors, but not at the rodent receptors (or have different effects at the rodent receptor). Thus, human cell lines have been used to predict activity in primates.

### A PPAR $\alpha$ Receptor and Agonists

The PPAR $\alpha$  receptor gene has been mapped to chromosome 22q12-q13.1, and its tissue distribution shows increased expression in metabolically active tissues such as heart, liver, kidney, and muscle. No single high-affinity natural ligand for the PPAR $\alpha$  receptor has been found, but this receptor may sense the flux of free fatty acids in the tissues where it is expressed. Among the known activators of this receptor are the fibrates. Although compounds that activate these receptors in rodents induce peroxisome proliferation and hepatomegaly in man following years of extensive use of the fibrates, PPAR $\alpha$  ligands are not believed to have these

effects. Thus, there appear to be functional and physiological differences that are species specific. In humans and nonhuman primates, the PPAR $\alpha$  ligands generally function in lipid and fatty acid homeostasis. In addition to pharmaceutical agents, these receptors are probably activated by fatty acids and their metabolites. Monkeys share with humans 97% cDNA identity, and 99% identity with the putative protein of the PPAR $\alpha$  receptor (81).

The fibrates were developed before the receptor was known, based on their lipid-lowering properties, and include such agents as fenofibrate, clofibrate, and bezafibrate. Fenofibrate, for example, is a dual activator of both PPAR $\alpha$  and PPAR $\gamma$ , but has 10-fold higher selectivity for PPAR $\alpha$ , while bezafibrate acts at all three receptor types. Fenofibrate has been shown to lower triglycerides (50%), to lower LDL cholesterol (27%), and to increase HDL cholesterol (35%). Apoproteins B-100 and CIII were also lowered (70% and 29%, respectively). Elevated plasma insulin levels were reduced by 40% in monkeys, supporting a role as an insulin sensitizer (81). Thus, this PPAR $\alpha$  agent improved features of the metabolic syndrome including reducing the insulin resistance of obesity, but did not produce weight loss.

We have termed another PPAR $\alpha$  activator, BM 17.0744, a calorie restriction mimetic agent as, in obese insulin-resistant monkeys, it appears to exert many of the positive features associated with long-term calorie restriction (see below). This agent is not in the fibrate class [it is 2,2-dichlorophenyl dodecanoic acid, and its general features have been described (82)]; however, it seems to carry significant PPAR $\alpha$  activity, acting as both an antidyslipidemic and antidiabetic agent. In overweight insulin-resistant male rhesus monkeys, body weight was significantly reduced in a dose-related manner across six of six subjects, an effect not observed with other PPAR $\alpha$  agents. Hyperinsulinemia declined, although it was not normalized, and insulin sensitivity was greatly improved. Triglycerides were substantially reduced, particularly the VLDL triglycerides. While total cholesterol and LDL cholesterol were not significantly affected, HDL cholesterol was nearly doubled, suggesting improvement in the lipid profile of these monkeys (83).

## B PPAR $\gamma$ Receptor and Agonists

Since 1994, when a ligand class of insulin sensitizers called the thiazolidinediones were recognized to interact with the PPAR $\gamma$  receptor, and the three classes of

PPARs clearly delineated, great attention has been given to finding better ligands for this receptor (84). The role of PPAR $\gamma$  has been particularly of interest in the field of obesity because this nuclear transcription regulator is essential to adipocyte differentiation. The PPAR $\gamma$  protein is well conserved across species, and its gene has been mapped to chromosome 3p25. There are two principal isoforms, PPAR $\gamma$ 1 and PPAR $\gamma$ 2. This receptor, and particularly its PPAR $\gamma$ 2 isoform, is found primarily in adipose tissue, but also is expressed in the colon and in macrophages. The monkey PPAR $\gamma$ 2 protein showed 99% identity with the human protein. PPAR $\gamma$ 2 is a critical transcription factor in adipose cell differentiation. This adipogenesis appears to require the coordinated expression of other transcription factors including C/EBP and ADD-1/SREBP-1. ADD-1/SREBP-1 are known to control several enzymes of fatty acid metabolism (85). PPAR $\gamma$ 1 mRNA was shown to be most abundant in adipose tissue, but it is expressed in various other tissues, while PPAR $\gamma$ 2 is primarily in adipose tissue. The mRNA levels of C/EBP $\alpha$ , LPL, and GLUT4 were highly correlated to that of total PPAR $\gamma$  mRNA and these appear to be coordinately regulated (86). (Note that Total was not related to the amount of adipose tissue.) The ratio of the expression of the two isoforms apparently changes in obesity, with the ratio of PPAR $\gamma$ 2 to total PPAR $\gamma$  showing a high correlation to degree of obesity both in humans and in monkeys (86,87).

Several polymorphisms have been identified in the PPAR $\gamma$  gene of humans (88), with much attention focused upon the Pro12Ala missense mutation. This mutation may in fact convey some diabetes protective feature, as at least in some human groups insulin sensitivity is improved (89).

The ligands for the PPAR $\gamma$  receptor include fatty acids, especially those of the eicosinoids such as prostaglandin J2, and the glitazones or thiazolidinediones. PPAR $\gamma$  plays an important role in adipogenesis, and, in fact, without PPAR $\gamma$ , no fat cells are made. Separately, and perhaps at another developmental stage, PPAR $\gamma$  agonists show antidiabetic and insulin-sensitizing properties that do not appear to be directly related to the adipogenic properties, probably by influencing the expression of a different cohort of genes.

Several thiazolidinediones have been reported to be active in nonhuman primates. Pioglitazone administration to rhesus monkeys resulted in a reduction in plasma insulin levels of 64% at a dose of 3.0 mg/kg/d. Triglycerides in this study were lowered by 44% (90). Another thiazolidinedione, R-102380, lowered glucose in those

monkeys with moderate increases in plasma glucose, but did not affect glucose in those with initially normal glycemia. Similarly, those with the greatest elevations of plasma triglycerides showed the greatest triglyceride-lowering effects. This agent showed evidence of direct effects on insulin sensitizing of skeletal muscle, even though at the whole-body level, the insulin sensitivity as measured by a euglycemic hyperinsulinemic clamp was not significantly altered (91).

Rosiglitazone (BRL49653) has also been used in nonhuman primates, and is in clinical use in humans as an insulin sensitizer. In monkeys, this PPAR $\gamma$  agonist significantly reduced plasma insulin levels as well as plasma triglycerides, and increased *in vivo* insulin action on skeletal muscle. Rosiglitazone induced an increase in the insulin-induced activation of glycogen synthase, without change in glycogen content (92).

Another PPAR $\gamma$  agonist, GI262570, has been shown to be highly potent in nonhuman primates and in humans. In monkeys, this agent produced a 63% reduction in plasma insulin levels and a 54% reduction in plasma triglycerides, while raising HDL cholesterol by 23% (93).

### C PPAR $\delta$

The PPAR $\delta$  receptor is ubiquitously expressed, and until recently was of unknown function, there being no known ligand for it until the presentation of a highly specific  $\delta$  agonist in monkeys (80). Interestingly, despite its wide tissue distribution, it has shown highly specific lipid regulating properties.

PPAR $\delta$  has been mapped to chromosome 6p21.1-p21.2 and is widely expressed in all tissues that are involved in lipid metabolism (94). The eicosinoid PGA1 and PGD2 have been found to activate PPAR $\delta$ .

New agonists selective for the PPAR $\delta$  receptor subtype are under study in nonhuman primates to examine the potential for development for human applications (80). GW501516 is such an agent, and has been shown in human cell lines to increase the expression of the reverse cholesterol transporter ATP-binding cassette, and to induce apolipoprotein A1-specific cholesterol efflux. Although inactive in rodent models, this agent caused a dose-dependent rise in HDL cholesterol, lowered small dense LDL cholesterol, lowered fasting VLDL triglycerides, and reduced fasting plasma insulin levels (80). These results suggest a potential for addressing the Metabolic Syndrome, and potentially reducing the risk of cardiovascular disease with such a PPAR $\delta$  receptor subtype agonist.

## IX INSULIN AND THE INSULIN RECEPTOR

Defects in the insulin molecule, the insulin receptor, and/or its variants have long been considered possible candidates for the underlying cause of insulin resistance and obesity. The insulin molecule of the monkey is identical in structure to that of human, and the proinsulin differs in only one amino acid (95). The monkey insulin receptor has been cloned and sequenced and found to have 99% amino acid identity to that of human (96). The two identified nonconservative amino acid changes have been examined by site-directed mutagenesis of the human insulin receptor, and found to have no effect on insulin receptor affinity or autophosphorylation, thus indicating that these are not responsible for the heightened insulin resistance of monkeys relative to humans (97).

Since obesity has not been shown to be associated with any defect in the insulin receptor structure, nor with a defective insulin molecule in most humans or monkeys (although there are a few well-documented cases of each of these defects in extreme cases of insulin resistance in humans), the possibility of a defect in expression of the major insulin receptor variants was considered. Differential expression of the two primary naturally occurring variants of the insulin receptor has been proposed to be involved in insulin resistance. Huang et al. (96) studied the relative expression of the type A insulin receptor isoform lacking exon 11 and of the type B isoform containing exon 11 in muscle of monkeys. Increased expression of the type A (higher-affinity) isoform in obese hyperinsulinemic monkeys was observed compared to either normal or diabetic animals, indicating that alterations in the insulin receptor mRNA splicing may be involved in the mechanisms of insulin resistance.

## X GALECTIN-12

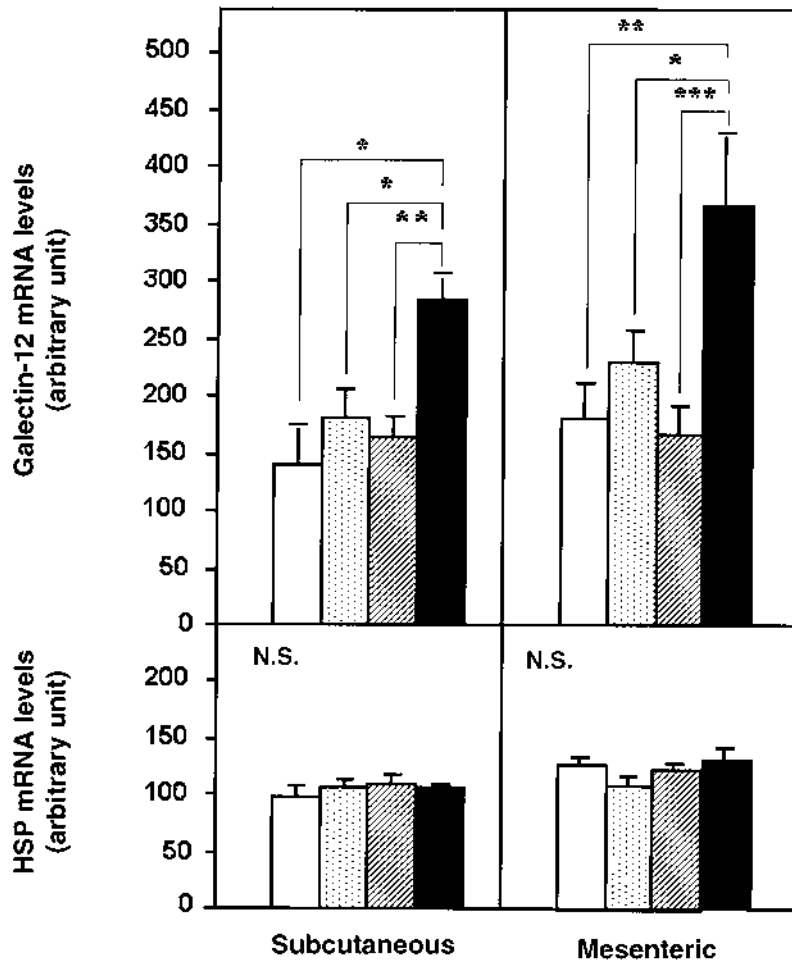

Another new gene that has been recently cloned and sequenced is galectin-12, a member of the galectin family of beta-galactoside-binding lectins. The galectins are involved in the regulation of a variety of processes, including cell adhesion, cell migration, cell growth (98), and apoptosis (99,100). While many galectins are widely expressed, galectin-12 is specifically expressed in adipose tissue. The cDNA coded for a 336-amino acid protein.

Galectin-12 mRNA levels were examined in monkey subcutaneous and omental adipose tissue (100). There were no differences between the mRNA levels of normal, obese, or type 2 diabetic monkeys, nor were there differences between subcutaneous and omental adipose tissue. Galectin-12 expression levels were increased by treatment with troglitazone, an insulin sensitizer. This treatment in rats was paralleled by an increase in the number of apoptotic cells. Another treatment that increases insulin sensitivity in both rodents and monkeys is sustained calorie restriction. Comparison of long-time calorie-restricted monkeys to ad libitum-fed animals showed a significant increase in the number of apoptotic cells, suggesting that galectin-12 may be involved in regulating adipose tissue growth, as shown in Figure 5.

## XI OTHER CANDIDATE GENES

Other specific candidate genes, including adipose-specific genes (101), are being identified and studied in nonhuman primates (102), and their ongoing study in spontaneously obese primates should offer insights into their roles in obesity.

In addition, the development of new antiobesity compounds directed toward new target genes or their receptors suggests further possibilities for the mitigation of obesity. The GLP-1 receptor is one such target, with at least two new long-acting agents having been examined in monkeys (103,104). We had previously shown the ability of GLP-1 to raise insulin levels; however, GLP-1 itself is too short-acting to be considered an attractive therapeutic agent (79).

**Figure 5** Expression of Galectin-12 in the subcutaneous and omental adipose tissue of four groups of rhesus monkeys: lean, obese, type 2 diabetic, and long-time calorie restricted. (From Ref. 100.)

## XII PREVENTION OF OBESITY IN NONHUMAN PRIMATES HAVING A HIGH PROPENSITY TO DEVELOP OBESITY

Obesity is well recognized to be closely associated with the development of type 2 (non-insulin-dependent) diabetes mellitus (NIDDM) in human and nonhuman primates. A long-term study, still ongoing, has attempted to prevent the development of adult-onset obesity in a group of monkeys through a calorie titration regimen in which calories have been adjusted weekly on an individual animal basis to prevent the development of obesity or weight gain. Thus, under this protocol, any gain of weight in fully adult monkeys was met with a reduction in allocated calories, and conversely, weight loss was the trigger for increasing the calories allowed to each adult animal.

Primary prevention of obesity in adult rhesus monkeys has been shown to powerfully and completely prevent the development of type 2 diabetes mellitus (105). At the least, the onset of overt diabetes has been indefinitely delayed. Chronic long-term restriction of calories to prevent the development of obesity appears to have major effects on several metabolic pathways of insulin action. The development of insulin resistance has been shown to be mitigated (105), and plasma insulin levels were reduced by calorie restriction (106). Basal glycogen synthase activity was greatly increased above the levels of normal lean young monkeys, and the normal effect of insulin to activate glycogen synthase was absent in the calorie-restricted monkeys (107). The change in glycogen synthase activity was inversely related to the change in glycogen phosphorylase activity (108). Nevertheless, despite prevention of the development of obesity, calorie restriction appeared to unmask some early defects potentially associated with the propensity to ultimately develop obesity.

### I INTRODUCTION

An animal's brain monitors energy in the environment and within the body and then adjusts eating behavior, energy utilization, and fat stores to maintain a balance. This chapter will discuss how the brain performs this life-giving task. The brain integrates energy-related sensory information from the eyes, ears, nose, tongue, gastrointestinal tract, liver, pancreas, and blood. In many parts of the body and brain, there are specialized receptors to detect nutrient-rich molecules. The hypothalamus is one of the areas that use this information to adjust physiological functions for storing or utilizing energy at appropriate times. The hypothalamus also contributes to the control of food intake by interacting with mechanisms for voluntary behavior that are essential for obtaining food. This physiological and behavioral control involves connections to the pituitary for endocrine regulation and feedback actions of hormones impacting on the brain. It also involves connections to the hindbrain, which subserve essential feeding reflexes and gut responses. The whole system is integrated by circuits extending to forebrain systems for choosing, instigating and reinforcing food choices. These circuits allow the brain to adjust its physiology and behavior to meet the economic demands of the ecological niche in

which the animal lives. This introductory section briefly summarizes the different hormones, neurochemicals and brain areas that are required to perform these functions. These are listed in Table 1, together with the abbreviations used in the sections below.

#### A Hormones

An important function of the hypothalamus is to synthesize neuropeptides, which control hormone secretion from the pituitary that, in turn, influences hormone synthesis in target organs. Hypothalamic neurosecretory cells produce peptides that are delivered to the portal blood vessels and transported to the anterior pituitary. These brain peptides include corticotropin-releasing hormone (CRH), luteinizing hormone-releasing hormone (LHRH), and thyrotropin-releasing hormone (TRH). They regulate the release of three pituitary hormones—adrenocorticotrophic hormone (ACTH), luteinizing hormone, and thyroid-stimulating hormone (TSH). These pituitary hormones, then, travel in the bloodstream and impact on target glands to stimulate the production, respectively, of the adrenal steroid, corticosterone (CORT), the gonadal steroids, estradiol (E<sub>2</sub>), progesterone (P), and the thyroid hormone, thyroxine. In addition, there are other

**Table 1** Abbreviations of Hormones and Neurochemicals Reviewed in This Chapter

---

Hormones involved in eating and body weight regulation

ACTH, adrenocorticotrophic hormone  
 CORT, corticosterone  
 E<sub>2</sub>, estradiol  
 GH, growth hormone  
 Glucose  
 HPA, hypothalamo-pituitary-adrenal  
 Insulin  
 Leptin  
 Lipids  
 P, progesterone

## Peptides that increase eating and body weight

AGRP, agouti-related protein  
 Amandamide  
 Beacon  
 DYN, dynorphin  
 GAL, galanin  
 GALP, galaninlike peptide  
 Ghrelin  
 GHRH, growth hormone–releasing hormone  
 GHRP, growth hormone–releasing peptide  
 GnRH, gonadotrophin-releasing hormone  
 MCH, melanin-concentrating hormone  
 NPY, neuropeptide Y  
 Opioid peptides  
 ORX, orexin  
 PRL, prolactin  
 PYY, peptide YY  
 VGF (nonacronym)

## Peptides that reduce eating and body weight

α-MSH, alpha-melanocyte-stimulating hormone  
 aFGF, acidic fibroblast growth factor  
 Amylin  
 apo A-IV, apolipoprotein A-IV  
 apo D, apolipoprotein D  
 AVP, arginine vasopressin  
 BBS, bombesin  
 Calcitonin  
 CART, cocaine- and amphetamine-regulated transcript  
 CCK, cholecystokinin  
 CGRP, calcitonin gene-related peptide  
 CNTF, ciliary neurotropic factor  
 CRH, corticotropin-releasing hormone  
 Cyclo(his-Pro)  
 Cytokines  
 ENT, enterostatin  
 GLP-1, glucagon-like peptide 1  
 Glucagon  
 IL, interleukin  
 Melanocortins  
 MSH, melanocyte-stimulating hormone  
 NMU, neuromedin U  
 NT, neurotensin  
 OT, oxytocin  
 POMC, pro-opiomelanocortin  
 PrRP, prolactin-releasing peptide  
 TNFα, tumor necrosis factor-alpha  
 TRH, thyrotropin-releasing hormone

## Biogenic amines in the control of eating behavior and metabolism

5HIAA, 5-hydroxy-3-indole acetic acid  
 5HT, serotonin  
 AMPH, amphetamine  
 DA, dopamine  
 Histamine  
 NE, norepinephrine

## Acetylcholine and amino acids in feeding-related circuits

ACh, acetylcholine  
 GABA, gamma-aminobutyric acid  
 GLUT, glutamate

## Receptors

α<sub>1,2</sub> -noradrenergic receptors  
 β<sub>1,2</sub> -adrenergic receptors  
 5HT<sub>1B/2C</sub> receptors, serotonin receptor subtype 1B/2C  
 CCK<sub>A</sub> receptor, cholecystokinin receptor subtype A  
 CRH<sub>1</sub> receptor, corticotropin-releasing hormone receptor subtype 1  
 CRH<sub>2</sub> receptor, corticotropin-releasing hormone receptor subtype 2  
 D<sub>1</sub> receptor, dopamine receptor subtype 1  
 D<sub>2</sub> receptor, dopamine receptor subtype 2  
 GHS receptor, growth hormone secretagogue receptor  
 GALR1 receptor, galanin receptor subtype 1  
 GALR2 receptor, galanin receptor subtype 2  
 H<sub>1</sub> receptor, histamine receptor subtype 1  
 M<sub>5</sub> receptor, muscarinic receptor subtype 5  
 MC1,3,4-R, melanocortin receptor subtype 1,3,4  
 Ob-Ra, short leptin receptor isoform  
 Ob-Rb, long leptin receptor isoform  
 Y<sub>1</sub> receptor, neuropeptide Y receptor subtype 1  
 Y<sub>5</sub> receptor, neuropeptide Y receptor subtype 5

## Signaling factors

ATP, adenosine triphosphate  
 JAK, Janus kinase  
 K<sup>+</sup>, potassium  
 K-ATP, potassium adenosine triphosphate  
 mRNA, messenger ribonucleic acid  
 SHP-2, SH2 domain-containing tyrosine phosphatase type 2  
 SOCS-3, suppressor of cytokine signaling-3  
 STAT, signal transducer and activator of transcription

## Brain areas

ARC, arcuate nucleus  
 DMN, dorsomedial nucleus  
 GP, globus pallidus  
 LH, lateral hypothalamus  
 ME, median eminence  
 MH, medial hypothalamus  
 MPO, medial preoptic area  
 NAc, nucleus accumbens  
 NTS, nucleus tractus solitarius  
 PBN, parabrachial nucleus  
 PFC, prefrontal cortex  
 PFLH, perifornical lateral hypothalamus  
 PVN, paraventricular nucleus  
 SCN, suprachiasmatic nucleus  
 VMH, ventromedial hypothalamus  
 VTA, ventral tegmental area

---

hypothalamic neurons that synthesize the peptides, arginine vasopressin (AVP) and oxytocin (OT), and send axons to the posterior pituitary. Here, they end in close proximity to the vascular bed of the gland to store and release these neurosecretory products directly into the bloodstream.

Each of these hormones, controlled by the hypothalamus and released by the pituitary, has potent metabolic actions in peripheral tissues that affect body fat. In addition, they have direct impact on the brain, where they produce complex behavioral and physiological responses related to the intake and metabolism of nutrients. These responses are believed to be mediated through the feedback actions of these hormones on brain peptides and monoamines. In addition to the adrenal and gonadal hormones, the pancreatic hormone, insulin, and the adipocyte hormone, leptin, also have important effects on central and peripheral neurochemical systems that are involved in energy and nutrient balance.

Section II below, on circulating hormones, provides a general overview of our current understanding of these peptide and steroid hormones. It also includes a discussion of the metabolic fuels, glucose and triglycerides, which like hormones are greatly altered by food ingestion and weight gain and, in turn, have marked effects on both peripheral and central tissues. It is energy-rich molecules such as these that provide the fuel for living. Thus, a major function of the body and brain is to obtain and regulate these metabolites and keep them in balance with other physiological and neurochemical processes.

## B Neurochemicals

Recent investigations of neurochemical mechanisms underlying obesity focus on a variety of peptides that modulate nutrient balance and body weight. As illustrated in Figure 1, these peptides include the original feeding-stimulatory peptides, neuropeptide Y (NPY) and galanin (GAL), which have cell bodies in the hypothalamus.

A newly discovered "feeding peptide," agouti-related protein (AGRP), which colocalizes with NPY, is also depicted with a plus sign in Figure 1. In addition to acting as an agonist for the feeding system, AGRP is an endogenous receptor antagonist, which blocks the inhibitory action of the "satiety peptide," alpha-melanocyte stimulating hormone ( $\alpha$ -MSH). As shown in Figure 1,  $\alpha$ -MSH is colocalized with a more recently discovered satiety peptide, cocaine- and amphetamine-regulated transcript (CART). These "satiety peptides"

**Figure 1** Diagram of selected neurochemical features of the hypothalamus. Note that insulin and leptin have effects in the ARC indicated by plus and minus signs. These hormones are shown as inhibiting (minus sign) feeding-stimulatory peptides, such as GAL and NPY-AGRP pathways in the ARC, which thereby disinhibits the TRH and CRH satiety outputs of the PVN. The  $\alpha$ -MSH-CART pathway, on the other hand, is activated by insulin and leptin (plus sign), which thereby inhibits the ORX-DYN or MCH feeding outputs of the PFLH. Thus, satiation is promoted in both cases. The diagram also illustrates the projection to the PFLH, where AGRP acts as an endogenous receptor antagonist to block  $\alpha$ -MSH and thereby promote feeding. This diagram includes, and the text discusses, additional steroid and protein hormones (Sec. II), peptides for feeding (Sec. III) and for satiation (Sec. IV), the monoamines (Sec. V), acetylcholine and amino acids (Sec. VI), behavioral systems (Sec. VII), and relationships to the autonomic nervous system (Sec. VIII). Abbreviations are given in Table 1.

are shown in Figure 1 as inhibiting a lateral hypothalamic feeding system that uses the feeding-stimulatory peptides, orexin and DYN. Also listed in Figure 1 are additional satiety peptides. The classic example is cholecystokinin (CCK), which inhibits feeding through its actions in the gut as well as the brain. Recent research links both the feeding and satiety peptide systems to the powerful endocrine influences mentioned above: insulin, leptin, CORT, and the gonadal steroids,  $E_2$  and P. The interactions of these hormones with brain neurotransmitters and neuromodulators are critical in determining specific states of nutrient balance and weight gain. This is illustrated in Figure 1, by insulin and leptin inhibiting the production of the feeding-stimulatory peptides, NPY and AGRP, while stimulating the feeding-inhibitory peptides,  $\alpha$ -MSH and CART. These and other neuropeptide systems are reviewed in detail

in Sections III and IV below. These sections summarize our present knowledge of different peptides that stimulate or inhibit eating behavior and body weight.

In addition to these peptides, there is considerable evidence to suggest a role for the biogenic amines, nor-epinephrine (NE), serotonin (5-HT), dopamine (DA), and histamine, in the control of food intake and related behaviors. A DA pathway is illustrated in Figure 2.

In Section V below, these neurotransmitters are discussed in terms of their roles in modulating the peptide

systems as a function of states of sleep, arousal, selective attention, and stress. This is followed by Section VI, which reviews evidence supporting two different roles for acetylcholine (ACh) in the reinforcement of feeding (Fig. 2). Specifically, the release of ACh is necessary to arouse a DA motivation system in the midbrain, whereas ACh interneurons inhibit eating by counteracting DA when it is released in the forebrain. The amino acid neurotransmitters, glutamate and gamma-amino butyric acid (GABA) also have interest-

**Figure 2** Schematic side view of the brain with emphasis on the hypothalamic area (in the expanded cross section) and the two neural circuits (shown with bold arrows). The expanded view of the hypothalamus indicates some of the local feeding and satiety neurons and their inputs (see Fig. 1). The hypothalamus is part of a much larger feeding circuit. Starting in the lower right corner, signals from the tongue and gut enter the brainstem. The hypothalamus also senses chemical information and sends it to the brainstem. The NTS output goes to the PBN and from there, via the thalamus, projects to the areas labeled, sensory cortex, amygdala, and hippocampus. Here chemosensory information is combined with other sense modalities, such as sights, sounds, locations, and codes for safe nutrition vs. toxic foods. The arrows from the hippocampus (place memory), amygdala (emotion memory), and prefrontal cortex (complex choice memory) sweep into the nucleus accumbens (NAc) and hypothalamus on GLUT neurons (input to NAc is shown). The NAc is a sensorimotor interface in the cognitive/limbic loop drawn in bold lines from PFC to NAc then GP and back to the PFC via the thalamus, with commands branching off to motor output circuits. The ACh interneurons in the NAc may act as gates that counteract DA input from the VTA. Other monoamines and opioid peptides that act in this circuit are discussed in the text (Secs. V–VII). The medial and lateral hypothalamus help control the NAc via the pathways shown descending from the hypothalamus to the brainstem, including an ORX/DYN output for feeding and a CRH pathway for satiation. The circuit ascends via cholinergic cell groups 5 and 6, to the VTA where DA cells project to the NAc and to the rest of the limbic system. The NAc projects back to the hypothalamus. By this route, feeding and satiety signals generated in the hypothalamus can influence DA/ACh balance in the NAc to reinforce or inhibit instrumental behavior and motivation.

ing functions, as described in Section VI. Glutamate in the hypothalamus stimulates feeding, whereas GABA rises as the meal progresses and brings it to a close (Fig. 2).

### C Brain Areas

In studying brain neurochemicals that control appetite, it is essential to identify and examine the different brain areas and hypothalamic nuclei that are critical for their effects on eating behavior and body weight regulation. In addition to the hormones and neurochemicals, Table 1 lists the areas and nuclei, together with their abbreviations, that are discussed in the chapter. Studies of the hypothalamus in laboratory animals reveal specific nuclei that have a direct role in maintaining energy or nutrient balance. Figure 1 illustrates a few of these nuclei and gives specific examples of interactions that occur between circulating hormones and hypothalamic neurochemicals. The nuclei in the medial hypothalamus (MH) include the paraventricular nucleus (PVN), arcuate nucleus (ARC), ventromedial hypothalamus (VMH) and dorsomedial nucleus (DMN), which control both nutrient intake and metabolism. The figure displays nerves that synthesize the peptides, OT, CRH, and TRH, which have satiety functions (1). The medial preoptic area (MPO) anterior to the PVN is involved in reproductive physiology, which shifts with metabolic fuels and body weight most notably at puberty and during pregnancy. The suprachiasmatic nucleus (SCN) is the master controller of circadian rhythms for both physiological and behavioral processes. The ARC and median eminence (ME) in the basomedial hypothalamus control the secretion of anterior pituitary hormones in relation to nutrient balance. The ARC and ME also transport leptin and insulin across the blood brain barrier and bring these hormones into contact with hypothalamic peptide systems that control eating and satiety. These hormones, then, inhibit such peptides as NPY and AGRP to reduce the tendency to excite the feeding outputs.

Along with these MH nuclei, there is the lateral hypothalamus (LH), which is like a city train station with a welter of nerve fibers passing through local circuitry and sensory cell groups. The complexity of the LH is reflected in the scientific history of this region, which Stellar characterized as a feeding center (2). The LH contains glucose-sensitive cells, feeding-related neurons with monoamine and peptide receptors, nerve fibers involved in feeding reward, and fibers of passage subserving motive functions. The perifornical (PF) area along the medial aspect of the LH,

together referred to as the PFLH, may be specialized for potentiating feeding reflexes and reinforcing voluntary motor functions of ingestive behavior. Cells that synthesize orexins and MCH lie at the heart of this PFLH area (1), which has long been allied with stimulation-induced eating and a site where self-stimulation varies with appetite (3).

Section VII takes the hypothalamic systems portrayed in Figure 1 and places them in the larger context of the whole brain, as shown in Figure 2. Some LH fibers are part of a reinforcement circuit from the PFLH to brainstem nuclei, such as the parabrachial nucleus (PBN) and nucleus of the solitary tract (NTS). These nuclei integrate descending information with primary taste input and ascending autonomic signals from the gut (4). Part of the brainstem output goes to cortical sensory areas, whereas another part goes to midbrain ACh neurons that connect to midbrain DA fibers in the ventral tegmental area (VTA). These DA fibers ascend forward through the LH on their way to the entire limbic system, including the nucleus accumbens (NAc). The NAc is one of the limbic areas projecting to the LH thus forming the loop through the hypothalamus shown in Figure 2.

Complex “cognitive” sensory information about food is funneled into the NAc from several higher brain regions, such as the cortex, hippocampus and amygdala. These areas also project directly to the hypothalamus, but for the sake of clarity, the diagram is simplified and only depicts the inputs to the NAc. The prefrontal cortex (PFC) takes cortical sensory taste information, transforms it to reflect sensory specific satiety (5), and probably sends it in part to the LH and NAc (6). The anterior piriform cortex has a region specialized to respond to repletion of indispensable amino acid imbalance by sending signals to the LH and NAc (7). The NAc also receives multimodal sensory information from the amygdala and hippocampus, reflecting good and bad experiences with tastes, smells, sights, sounds, and important places in the environment. The NAc output courses its way to motor command systems, with a prominent component for feeding.

As seen in Figure 2, part of the NAc output goes via the globus pallidus (GP), and another part descends to the hypothalamus. The GP instructs the motor system and feeds back in the loop shown going to the PFC. Thus, the NAc lies at the intersection of the hypothalamic and PFC loops. It serves as a sensorimotor interface for appetitive motivation, and it is gated, in part, by signals from the hypothalamus (8).

The NAc is also known to be involved with addiction to drugs of abuse. Since it is at the crossroads of

systems controlling the motivation to eat, there is the hypothetical possibility of becoming addicted to certain foods. In fact, the addiction process may have evolved for that purpose. Various brain opioids are released by starvation and by palatable foods. Thus, intermittent fasting and bingeing may release sufficient endogenous opioids to create signs of addiction in rats, with similarities to human eating disorders. These circuits, together with evidence for sugar dependency, are described in greater detail in Section VII.

Section VIII deals in broad strokes with the peripheral and central components of the autonomic nervous system in regulatory physiology and regulatory behavior. Low sympathetic tone in the system controlling brown adipose tissue, for example, is associated with many types of obesity. Apparently, it causes the potential to overeat until such time as the animal becomes sufficiently obese to counteract the process. Leptin and other adipocyte hormones may play a role in curbing the motivation to eat, by inhibiting the feeding-reinforcement pathway, as the animal gains weight. It is interesting that the sympathetic system, itself, may strongly influence leptin production. This discussion is followed by Section IX, which provides a brief summary and overview of the different systems that are involved in maintaining energy homeostasis.

## II HORMONES INVOLVED IN EATING AND BODY WEIGHT REGULATION

Many peptides, proteins, steroids, metabolites, and other molecules circulating in the blood are likely to have a role in energy balance. There are a few, however, that have received greatest attention, particularly in terms of their impact on neurochemical systems in the brain. These are the pancreatic and adipocyte hormones, insulin and leptin, and the adrenal and gonadal steroids. A subsequent section discusses the metabolites, glucose and lipids, which are also believed to have impact on the brain.

### A Insulin

Insulin is the major hormone that enables tissues to remove glucose from the blood. Thus, its secretion from pancreatic  $\beta$ -cells is directly responsive to circulating glucose levels (9). Insulin secretion also varies in proportion to body adiposity, with a heavier individual secreting proportionally more insulin to a given increase in glucose. Thus, insulin levels reflect both ongoing metabolic needs and level of body fat accrual. The im-

portance of insulin as an adiposity signal to the brain is revealed by evidence that insulin-deficient animals are hyperphagic, an effect reversed by administration of insulin (10–14).

To control body weight, insulin is believed to gain access to the brain through areas with a reduced blood brain barrier and by a saturable, receptor-mediated mechanism that transports insulin through the blood-brain barrier and into the interstitial fluid (14,15). In the brain, it acts as a humoral feedback regulator of food intake and energy balance. Insulin injections into the brain reduce food intake, meal size, and weight gain and stimulate the sympathetic nervous system. Consistent with these observations, the *tubby* mouse, characterized by hyperphagia and obesity, is found to have a mutation in the intracellular insulin-signaling pathway within the ventral hypothalamus (16). One site of insulin's action is the hypothalamus, where insulin receptors and intracellular signaling molecules, e.g., insulin receptor substrate-1, are concentrated and where insulin-specific antibodies have opposite effects to insulin itself.

This metabolic hormone may act, in part, through its effects on the production of brain neurochemicals (10,11,17–19), as described in Sections III and IV. For example, insulin inhibits gene expression of peptides, such as NPY and GAL, that enhance food ingestion and exert anabolic effects. The insulinlike growth factor 2, which has anorexic actions, also reduces NPY release in vitro. Conversely, insulin stimulates the activity of peptides, such as CCK, CRH, and  $\alpha$ -MSH, which have satiety or catabolic actions. Thus, overall insulin secretion may link short-term changes in energy intake and expenditure with long-term body weight regulation (11). Obese states are invariably associated with hyperinsulinemia and insulin resistance, which produce marked disturbances in the expression and production of these hypothalamic peptides.

### B Leptin

Leptin, a product of the *ob* gene, is mutated in the obese *ob/ob* mouse and is produced almost exclusively in fat cells (20). The leptin receptor, found in various peripheral tissues as well as the brain, has also been cloned (21), and a mutation of this receptor produces the syndrome of the diabetic *db/db* mouse (22). This structure belongs to the class I cytokine receptor family, and one of the binding proteins may be the extracellular domain analogous to the growth hormone-binding protein, another member of the cytokine family (23). Leptin produces its biological effects by acting on the

long-form receptor isoform, which contains intracellular motifs required for activation of the JAK-STAT signal transduction pathway (see Table 1). Whereas a primary defect in leptin expression may lead to human disease, as shown in studies of consanguineous kindreds with extreme obesity, mutations of the genes that produce leptin or its receptor are rare in humans (22,24).

Leptin expression is influenced by the status of energy stores in body fat, with adipocyte size an important determinant of leptin synthesis (25). Whereas leptin levels in blood correlate strongly with total body fat stores, it is unknown whether leptin expression is influenced by triglyceride levels, lipid metabolites, or mechanical factors associated with increased adipocyte size (22,23). Since changes in leptin expression after fasting and feeding do not necessarily correspond with changes in body fat, leptin may serve as a mediator of energy balance, as well as an indicator of energy stores. Regulation of leptin expression by nutrition may be mediated, in part, by insulin, which is positively related to leptin levels, and also to glucocorticoids, which are negatively related (22,23,26). Cytokines also stimulate the synthesis of leptin, which may contribute to the anorexia and weight loss in response to inflammation.

Anatomical and functional studies suggest that leptin exerts its effects on energy balance primarily by acting in the brain. This protein is secreted into the circulation and enters the brain through a saturable transport mechanism (9,22,27,28). Peripheral leptin injection activates neurons in hypothalamic feeding-regulatory areas that have dense concentrations of leptin receptors. Peripheral as well as central injection of leptin reduces food intake, insulin secretion and adiposity (28), with centrally administered leptin producing more potent effects. Leptin also increases energy expenditure and normalizes blood glucose concentrations in obese mice (29). Hyperleptinemia, produced in normal-weight rats through adenovirus gene transfer of the *ob* gene, causes loss of virtually all body fat, an effect that is absent in rats with MH lesions (30).

Leptin-sensitive neurons in the hypothalamic nuclei express neuropeptides and neurotransmitters that are implicated in the central regulation of energy balance and, thus, may mediate leptin's actions (1,22,31). The long-form leptin receptor in the ARC is coexpressed with peptides that stimulate feeding, as well as with those that inhibit feeding. In general, the expression or synthesis of neurochemicals that potentiate feeding behavior is inhibited by leptin injection and elevated in leptin-deficient or food-deprived rodents. Diametrically opposite changes, in contrast, are seen with

neurochemicals that suppress food intake. By modulating these peptides in the ARC, leptin may also influence feeding by controlling the expression of orexigenic peptides in other hypothalamic sites, such as the PVN and LH, which are possibly controlled by projections from the ARC. To understand the physiological significance of these findings obtained with leptin injections or gene mutations, further studies of this hormone performed under natural feeding conditions are needed. A fall in leptin levels during fasting, accompanied by a rise in feeding-stimulatory peptides, has been suggested to signal starvation (1). However, a reevaluation of leptin's physiological functions and its relationship to specific peptides has been encouraged by specific evidence, for example, that leptin corrects the neuroendocrine abnormalities of *ob/ob* mice at considerably lower doses than those required to reverse the overeating and obesity (32). Moreover, its effects in intact mice may not be altered by targeted mutations of the feeding-regulatory peptide gene (33).

The evidence that leptin injection produces feeding suppression and weight loss restricted to adipose tissue, while increasing energy expenditure and lipid oxidation (22,34–36), supports a role for this hormone as an antiobesity hormone. However, this is inconsistent with the finding that circulating leptin concentrations rise in direct proportion to the amount of adipose tissue (31). This rise in leptin with obesity has been interpreted as an indication of "leptin resistance" (22), possibly resulting from a dysregulation of leptin synthesis and secretion or from abnormalities of brain leptin transport, leptin receptors, and/or postreceptor signaling. Potential molecular mediators of leptin resistance may include SOCS-3, a member of the suppressors of cytokine signaling family, as well as SH2-containing tyrosine phosphatase, SHP-2, and molecules downstream from the initial step of receptor interaction (see Table 1 for abbreviations). Evolutionarily, it is extremely important to be efficient in the storage of energy when food is available.

Thus, the common occurrence of leptin-resistant obesity suggests that the predominant function of this hormone in energy balance is not to reduce body fat but is to mediate physiological processes of adaptation during fasting and promotion of energy conservation (22,37). Starvation triggers complex neural, metabolic, hormonal, and behavioral adaptations to maintain energy substrates, protect lean mass, and promote survival. This is accomplished by switching from a carbohydrate- to fat-based metabolism, mediated by a decline in insulin and rise in counterregulatory hor-

mones. Starvation also involves suppression of energy utilization, reproductive function, and growth through a decline in gonadal and thyroid hormones and rise in adrenal glucocorticoids. The main effect of these adaptations is to stimulate gluconeogenesis, to supply glucose for vital cellular function and fatty acids for use by skeletal muscle. These endocrine and metabolic adaptations are accompanied by a reduction in leptin caused, in part, by an increase in sympathetic nervous system activity (38). That this decrease in leptin during starvation mediates many of the adaptive responses to fasting is supported by evidence that this state can be reversed or prevented by exogenous leptin, in the absence of a change in adiposity (22). Moreover, leptin restores fertility in female *ob/ob* mice independent of any effect on weight gain, and it advances the time of first estrus in normal mice (39). This may reflect the close relationship between fat accumulation at puberty and activation of the hypothalamic-pituitary-gonadal axis, with leptin informing the brain of the adequacy of fat stores needed for reproduction.

Thus, independent of its role in long-term weight regulation, leptin exerts acute effects on metabolism (22,38,40,41). These include an increase in gluconeogenesis, glucose metabolism, and lipolysis, as well as thermogenesis in brown adipose tissue. Also, leptin prevents triglyceride overload in skeletal muscle and stimulates fatty acid metabolism in liver and sympathetic nervous system activity. Evidence presented in Sections III and IV below provides strong support for the idea that these effects of leptin, while involving direct actions on peripheral tissues, are also mediated through its modulatory actions on the hypothalamic neuropeptide circuitry.

### C Adrenal Steroid Hormones

There is a vast literature on the adrenal steroids and their role in controlling feeding and body weight. This literature, which has been extensively reviewed (42–46), leads to the conclusion that, at normal physiological levels, the steroids CORT and aldosterone have specific functions in maintaining carbohydrate and fat stores across the daily light/dark cycle. This process is accomplished through behavioral and metabolic actions, which involve the mediation of both the type I and type II steroid receptors. These receptors exist in the brain and act, in part, through their permissive interactions with neurochemical systems that modulate nutrient balance. Under conditions of obesity and repeated stress, the adrenal steroids are elevated, resulting in chronic disturbances in the steroid-neurochem-

ical interactions. In the absence of these steroids, such as after adrenalectomy, all forms of obesity are attenuated (46).

#### 1 Type I and Type II Steroid Receptors

Studies of the natural light/dark cycle in normal-weight animals have led to the proposal that distinct functions are performed by the different steroid receptors (42). The type I receptor is activated under conditions of low levels of circulating CORT (0.5–2.0 µg/dL), and it functions tonically throughout the daily cycle to sustain feeding, particularly fat intake, and enhance fat deposition. Fat intake occurs at a fairly constant level across the feeding cycle in almost every meal, although it rises toward the second half of the active phase. This stable behavioral pattern provides a continuous supply of a high-caloric nutrient, which can be readily stored in the gastrointestinal tract or adipose tissue for short- or long-term use, respectively. This tonic control of fat intake, possibly mediated through hypothalamic type I receptors, may be analogous to their function in the basal forebrain for maintaining salt balance (47) and in lower brainstem for monitoring blood pressure (48).

The type II receptor, in contrast, is activated under conditions of somewhat higher or moderate levels of CORT. This receptor may function phasically during the early hours of the active cycle when CORT normally rises to levels of 3–10 µg/dL, and it also comes into play also during periods of stress when even higher levels are achieved (42). A primary function of the type II receptor at the onset of the feeding cycle is to replenish and defend the body's carbohydrate stores through both ingestion and storage. This immediate defense is required to prevent the hypoglycemia that may develop after periods of little eating and continued utilization of carbohydrate stores. This defense provides adequate supplies to the brain to stabilize neuronal processes (49,50). The phasic, anabolic effect of moderate levels of CORT may be contrasted with the type II receptor actions of high CORT levels, such as after severe stress or starvation. In addition to stimulating nutrient ingestion, unusually high CORT concentrations actually have catabolic actions on the body's fat and protein stores to provide additional substrates for maintaining normal carbohydrate balance. Under stable conditions, however, the type II receptor subtype is very likely inactive at times of the circadian cycle or in physiological states when glycogen stores are plentiful, cellular glucose uptake is normal, and circulating CORT levels are low.

Thus, these two receptor subtypes work towards a common goal in maintaining the body's nutrient stores from day to day. Through ingestion and metabolism, they provide the nutrients essential for maintaining the body's carbohydrate stores under different environmental conditions. As circulating CORT levels rise, the priorities of nutrient partitioning favor the actions of type II receptors, which restore carbohydrate through behavioral and metabolic processes. Thus, at any moment across the light/dark cycle, but particularly during the initial phase of the feeding cycle, there exists an inverse relation between the carbohydrate and fat content of a meal (51). The differential functions of the receptor subtypes, however, are most evident under conditions of abnormally high CORT levels, when type II receptor activation exerts catabolic effects on certain tissues to shift essential nutrients towards carbohydrate replenishment and storage. Transgenic mice with disturbed expression of the type II glucocorticoid receptors exhibit increased food intake, weight gain, and body fat accrual and a characteristic phenotype of a hyperactive hypothalamopituitary-adrenal axis (HPA) (52).

## 2 Corticosterone Interactions with Hypothalamic Peptides

Receptors mediating these actions of the adrenal steroids across the circadian cycle are located in the brain (42). As described below, they are particularly responsive in the hypothalamic PVN, which plays a primary role in controlling CORT release as well as nutrient balance. Neurons in the ARC are similarly responsive to CORT. In maintaining carbohydrate stores, the type II receptors act in part through central neurochemical systems that synthesize NPY in the ARC and NE in the brainstem. Circulating CORT enhances gene expression, transport, and receptor activity, ultimately potentiating the action of NPY and NE released in the medial PVN, and it very likely determines the circadian rhythm of endogenous NPY and noradrenergic activity detected in the hypothalamus. Natural rhythms of circulating steroids and their receptor subtypes are critical in maintaining normal control of physiological processes (53,54). These rhythms allow for necessary shifts in phases of priming, activation and rest. Without these rhythms, a chronic state of activation, which constitutes a stress to the organism, will eventually result in pathology. In the control of nutrient balance, the dual-control receptor systems involving type I and type II receptors provide a mechanism that responds to shifts in circulating CORT and assists in coordinating metabolic processes appropriate for specific circadian

periods or environmental challenges. The loss of these rhythms in states of obesity has clear negative consequences on cellular and physiological functions. Evidence indicates that the obesity-promoting effects of NPY require the presence of glucocorticoids (55).

## 3 Corticosterone Interactions with Insulin and Leptin

In evaluating the anabolic and catabolic effects of CORT, it is important to consider its actions in relation to the primary metabolic hormone, insulin (42,43). Corticosterone and insulin are well known for their antagonistic actions, particularly in their effects on glucose uptake and metabolism in the periphery. This antagonism is also evident in their behavioral actions, whereby insulin is released in proportion to the body's fat mass, reduces food intake, and attenuates the steroid's stimulatory action on feeding. This antagonistic interaction between CORT and insulin may occur within the brain as well as in peripheral tissues, possibly involving differential effects on brain neurochemicals, such as NPY. It may differ, however, in other tissues, such as the liver, where CORT and insulin act synergistically to increase lipogenesis and glycogen synthesis. It may also vary at different times of the daily cycle, such as at the onset of the natural feeding cycle when both hormones normally peak, with CORT potentiating eating and insulin allowing efficient postprandial storage of the ingested carbohydrates. In states of obesity, the antagonism between CORT and insulin becomes exaggerated when circulating CORT levels are abnormally and chronically high. There occurs a compensatory rise in insulin secretion along with increased insulin resistance. The resulting chronic hyperinsulinemia and hypercortisolemia increase hepatic lipogenesis, while reducing gluconeogenesis, and they produce catabolic effects within muscle where CORT's actions outweigh those of insulin.

In addition to insulin, there is an antagonistic interaction between leptin and CORT (56,57). Leptin's inhibitory effect on food intake and body weight is markedly enhanced in adrenalectomized rats. Moreover, it is attenuated after glucocorticoid administration. As indicated above, this antagonism between leptin and CORT is evident in terms of their opposing effects on NPY production in the ARC. There is evidence that the obesity syndrome produced by chronic central infusion of glucocorticoids may be attributed, in part, to an increase in hypothalamic NPY, as well as a decline in CRH, effects that may result from a steroid-induced reduction in leptin's actions (57).

## D Gonadal Steroid Hormones

Reproductive physiology and behavior depend on the availability of oxidizable metabolic fuels. Energetic factors that affect reproduction, such as food availability, ambient temperature, exercise, and storage and mobilization of fatty acids, all affect the availability of metabolic fuels (58,59). These changes in metabolic fuels influence reproduction through actions at multiple sites. These include key sites in the brain and involve alterations in the activity of neurons that synthesize gonadotrophin-releasing hormone (GnRH) and growth hormone-releasing hormone (GHRH) or have steroid receptor binding sites. The ovarian steroids,  $E_2$  and P, play a major role in this process, producing changes in nutrient ingestion, partitioning and utilization of fuels that differ markedly from the anabolic actions of testosterone.

Estradiol is associated with a reduction in eating behavior, adiposity, and body weight in adult rats (58). Ovariectomy produces the opposite effect, such that animals gain weight in an  $E_2$ -reversible manner. As described in subsequent sections, these effects of  $E_2$  may be mediated through its influence on hypothalamic peptide systems, such as NPY, CRH, and CCK (60–63). For example,  $E_2$  replacement after ovariectomy reduces NPY gene expression in the ARC and NPY release in the PVN, which is likely to result in a decline in food intake and loss of body weight.

The reverse pattern is seen with steroid effects on CRH and CCK. Estradiol stimulates the production or function of these peptides, which normally act to inhibit feeding and decrease weight gain. This combination of hypothalamic events, enhanced catabolic signaling combined with impaired compensatory activation of anabolic pathways, leads to body weight loss during chronic high levels of  $E_2$  in adults. There is recent evidence that estradiol cyclically increases the activity of the CCK and glucagon satiation-signaling pathways, causing a reduction in meal size and food intake during the estrous phase of the ovarian cycle (64,65).

In understanding the role of gonadal steroids in feeding and metabolism, one must additionally consider the impact of P, which has diverse actions that may involve an early enhancing effect followed by an inhibition. Thus, while  $E_2$  inhibits NPY, P actually stimulates this peptide's production in  $E_2$ -primed animals (66), suggesting an antagonism between the two steroids. In contrast, GAL is activated by  $E_2$  alone, and this effect is enhanced by administration of P (67,68). The resulting pattern, of increased NPY and GAL production under the influence of the two steroids

together, may explain the finding of increased caloric intake and body weight that occurs in females at puberty, when the gonadal steroids and peptides rise to peak levels (69–71). Thus, the role of P contrasts with that of  $E_2$ . It builds energy stores through behavioral as well as metabolic actions, in contrast to the anorexic and lipolytic actions of  $E_2$  (58,59). The precise nature and site of the steroid-neurochemical interactions underlying these physiological effects remain to be characterized.

## E Glucose

The brain is among the most metabolically active tissues. It is dependent almost exclusively on plasma glucose, rather than alternative substrates, such as fatty acids and ketone bodies, and it is responsive to changes in glucose levels (73,713). In the brain, there exist neurons that sense a dangerous decline in circulating glucose levels and utilization and perform the function of reducing neuronal activity and, consequently, metabolic demand. In addition, the brain appears to respond to physiological changes in blood glucose and its utilization. These changes can either stimulate or inhibit the activity of neuroendocrine neurons with integrative metabolic functions, including counterregulatory responses, food intake, and metabolic rate. These neurons, largely confined to the hypothalamus, are referred to as "glucose-responsive" or "glucose-sensitive" if stimulated, respectively, by a rise or fall in glucose levels. The physiological relevance of glucose-responsive neurons is underscored by the observation that they cease firing just before a meal and, then, begin to fire once again as the meal progress (72). It is suggested that local concentrations of glucose to which neuroendocrine hypothalamic neurons are exposed may be higher than those to which other neurons are exposed, owing to the presence of specialized hypothalamic glucose transporters (73).

Evidence has accumulated to suggest that glucose-sensing mechanisms of glucose-responsive neurons and pancreatic endocrine cells share common features. In addition ATP-sensitive  $K^+$  (K-ATP) channels, a key element in this mechanism is the presence of glucokinase (73). This enzyme has properties that allow cells to metabolize glucose in proportion to plasma levels of glucose in the physiological range. It may serve as a glucose transduction mechanism, which links the effects of small changes in glucose to ATP generation. There is recent evidence showing that neurons in the ARC that synthesize the feeding-stimulatory peptide, NPY (see below), colocalize glucokinase mRNA as well as Kir6.2 mRNA, the pore-forming subunit of the

ATP-sensitive  $K^+$  channel (74). The mechanisms underlying the response of glucose-sensitive neurons, which are more concentrated in the LH, remain to be characterized (75).

Both obesity and diabetes are associated with alterations in brain glucose sensing (76). Rats with diet-induced obesity, hyperinsulinemia, or insulin-dependent diabetes have abnormalities in glucose-responsive neurons. These include disturbances in neurotransmitter systems, specific peptides, monoamines, and amino acids that are involved in glucose sensing. A functional relationship between circulating glucose and central neurochemical systems is suggested by the finding that glucose-responsive neurons in the ARC are hyperpolarized by the actions of both leptin and insulin on the K-ATP channel (76). Further, the expression and production of brain peptides, such as NPY in the ARC, or ligand binding to specific  $\alpha_2$ -noradrenergic receptors in the PVN, for example, are stimulated by the injection or ingestion of glucose (77,78), suggesting the involvement of glucose-responsive neurons.

## F Lipids

In addition to glucose, there is evidence that circulating lipids have impact on the brain (79). Except for adipose tissue, the brain has a higher lipid content and greater diversity of lipid species than any other organ. Although many fatty acid constituents of the brain can be synthesized *de novo*, essential fatty acids must be transported into the brain from the plasma. Albumin is considered the physiological vehicle for taking fatty acids into target tissues. Ingested fatty acids bind to albumin in several forms, including triglycerides, which are incorporated into chylomicrons or are bound to lysophosphatidylcholine.

In order to enter the brain, triglycerides are rapidly hydrolyzed in capillary endothelial cells. They are transported, possibly via specific transporters, to astrocytes surrounding the endothelium and, then, to neurons and other cells. Brain microvessel endothelial cells, astrocytes, and neurons readily take up polyunsaturated fatty acids. Radiolabeled lipids injected into the carotid artery are found in the brain within 15 mins, and they remain for up to 17 days (80). Ingested fatty acids are also found in the adult brain (81). Whereas lipids can enter the brain through passive diffusion, protein-mediated transport mechanisms have also been proposed (79). This latter model implies that lipid membranes introduce permeability barriers to fatty acids and that selective transport of fatty acids into brain is accomplished by specific protein transporters.

There is evidence that extracellular fatty acids affect neuronal function in the brain. For example, they inhibit the reuptake of glutamate in synaptosomes (82). They also activate a novel type of  $K^+$  channel in neurons (83). Consumption of a high-fat diet is found to stimulate the expression and production of the feeding-stimulatory peptide, GAL, in the PVN (84), in addition to the opioid peptide, DYN (85). Recent evidence demonstrates a strong, positive correlation between PVN GAL mRNA and circulating triglyceride levels in several different animal models (86). Thus, in addition to certain hormones, circulating lipids may have impact on neurochemical systems in the hypothalamus that control eating and body weight.

## III PEPTIDES THAT INCREASE EATING AND BODY WEIGHT

Through pharmacological and biochemical studies, specific peptides and neurotransmitters have been identified within the hypothalamic areas and implicated in physiological and behavioral processes that impact on body weight. It is now clear that there is great redundancy involving multiple neurochemicals and actions, both stimulatory and inhibitory, on eating and metabolism. These systems are activated under diverse physiological states and environmental conditions that affect an organism during its lifetime. This section reviews evidence obtained with peptides that have stimulatory effects on eating behavior and weight gain and are implicated in the development of obesity (Table 1).

### A Neuropeptide Y

Neuropeptide Y (NPY) is a 36-amino acid member of a highly conserved group of peptides. It is one of the most abundant peptides in the mammalian brain and a very potent stimulator of feeding that, with repeated injection, stimulates weight gain (31,57,87). The available evidence demonstrates that NPY neurons are highly responsive to states of energy deficiency, increased metabolic demand, and disturbed glucoregulation (88). When enhanced, this peptide helps to reverse these disturbances and maintain glucose homeostasis by stimulating processes of carbohydrate ingestion and utilization that gear substrates toward fat synthesis (69,89,90). The neurocircuit underlying this neurochemical action involves a dense NPY projection, which originates in neurons of the ARC, projects to the PVN and PFLH (Fig. 1), and function through NPY

receptors of the  $Y_1$  and  $Y_5$  subtype that are concentrated in these areas (31,91).

The effects produced by hypothalamic NPY injections support the proposed role of this peptide in maintaining carbohydrate balance. These actions of exogenous NPY, summarized in greater detail in various reviews (69,89,90,92), include a stimulatory effect on feeding behavior, with a preferential effect on carbohydrate intake. The endocrine effects of NPY (56,93,94) involve enhanced release of CORT, which favors the availability and utilization of glucose, and increased pancreatic secretion of insulin, which functions together with CORT to promote lipogenesis (95). These behavioral and endocrine effects of NPY are accompanied by metabolic changes effecting enhanced parasympathetic nervous system activity and reduced sympathetic activity (93,96). The effects include a reduction in energy expenditure and thermogenesis, decreased glucose uptake in muscle, and a diversion of excess energy and glucose towards fat synthesis in white adipose tissue.

Pharmacological and anatomical studies (31,91) suggest that these effects of NPY, involving the neurocircuit from the ARC to the PVN, may be mediated, in part, through connections with other neural systems involved in energy homeostasis (Fig. 1). These include reciprocal connections with systems that inhibit feeding, such as CRH in the PVN, melanocortin neurons in the ARC, and 5HT in the midbrain. They also involve peptides that stimulate feeding, including MCH and orexin in the PFLH. The demonstration that NPY neurons in the ARC also express the peptide AGRP, an endogenous antagonist of the feeding-inhibitory melanocortin system, provides evidence for another avenue of communication between NPY and other neuropeptides modulating feeding (91,97–99).

Endogenous NPY has a role in mediating natural feeding. With acute administration, injections of NPY antisera, receptor antagonists, and antisense oligodeoxynucleotides to NPY mRNA invariably reduce food intake (100–102). Moreover, with repeated injections, NPY produces overeating, obesity, and related endocrine and metabolic disturbances (56,87). Antisense oligodeoxynucleotides to NPY mRNA reduce endogenous NPY levels in the ARC and suppress body weight gain (102). In light of these findings, it was surprising that NPY knockout mice and NPY overexpressing mice showed little change in eating or body weight (33,88). The ability of NPY-deficient mice to maintain normal eating patterns may be attributed, in part, to a compensatory increase in the production of other peptides, such as AGRP and GAL, which also enhance food intake and weight

gain (103). There is evidence, however, that a knock-out of the NPY gene can reduce weight gain in mice that have a mutation of the leptin gene or diabetes, indicating a role for endogenous NPY in mediating some effects of leptin or insulin deficiency (104). Moreover, a recent genetic study demonstrates that, in homozygous mice, NPY overexpression in the brain leads to an obese phenotype on a sucrose-loaded diet, accompanied by overeating, hyperglycemia, and hyperinsulinemia (105).

A variety of endocrine signals feed back to regulate NPY synthesis in the ARC-PVN neural projection. This is reflected in measures of gene expression or translation, in addition to peptide synthesis, transport, release, and receptor activity. In these hypothalamic areas, the adrenal steroid CORT acts through glucocorticoid type II receptors to stimulate NPY gene expression, synthesis, and receptor activity (42,106–109). Moreover, the behavioral action of NPY is similarly enhanced by CORT, while antagonized by a glucocorticoid receptor blocker. These effects of CORT on NPY may be direct as well as indirect via the CRH system (109). This suggests that NPY helps to integrate the activities of the hypothalamic feeding systems and the HPA axis, which are important for the circadian rhythmicity of physiological processes (109). A different pattern becomes evident with the gonadal steroids,  $E_2$  and P. Administration of  $E_2$  inhibits NPY gene expression in the ARC and its release in the PVN, and  $E_2$  deficiency increases NPY in the PVN. This suggests a role for this peptide in the anorexic action of  $E_2$  (31). In contrast, administration of P has a stimulatory effect on NPY in  $E_2$ -primed animals (60,110–112). This evidence obtained with P, similar to CORT, suggests that both steroids promote weight gain and body fat accrual through their stimulatory effect on NPY in the ARC (108,113).

In contrast to these steroids are the hormones insulin and leptin, which are released in relation to the amount of body fat. These hormones have a potent, inhibitory effect on NPY gene expression in the ARC, NPY peptide levels in the PVN, and feeding induced by NPY injection (1,114). These suppressive effects may explain the enhanced expression of NPY after food deprivation, which reduces levels of insulin and leptin and, conversely, the satiety-producing effects seen with injections of these hormones (11). Further support for this close relationship between NPY neurons and the circulating hormones is obtained from the findings that leptin and insulin receptors are densely expressed in the ARC. A subpopulation of NPY neurons coexpresses the leptin receptor. The expression of NPY in these

neurons is invariably elevated in rats deficient in insulin, leptin, or the leptin receptor (31,91,97).

Studies of physiological or pathological states reveal associations between dietary macronutrients, circulating hormones, metabolic processes, and hypothalamic NPY (10,115–118). For example, the relationships among carbohydrate intake, circulating CORT levels, lipogenic processes, and NPY levels are evident in adult rats given a choice of macronutrient diets. They exhibit strong, positive correlations among NPY, CORT levels, and spontaneous intake of carbohydrate, as opposed to fat or protein (42,51,108,119,120). These relationships are seen at the start of the active feeding period. Carbohydrate is the preferred dietary nutrient at this time, when CORT levels and NPY gene expression naturally peak, and both gluconeogenesis and glycogenolysis are elevated to support the utilization of carbohydrate. Dietary and pharmacological manipulations also reveal enhanced NPY expression and CORT under conditions of diet-induced insulin resistance or after 2-deoxy-D-glucose blockade of glucose utilization (121–123). In fact, in weanling animals, both the NPY system and the HPA axis reach peak development at an age when carbohydrate accounts by choice for >65% of the animals' diet and lipogenesis is elevated (70,71,124,125).

Similar to CORT, a possible stimulatory effect of P on NPY is evident across the 4-day female cycle. Proestrus reveals peak levels of NPY in the MPO, as well as the ARC and PVN. This occurs with a rise in circulating levels of P, subsequent to E<sub>2</sub> priming, and an increase in lipogenesis (112,126,127). The inhibitory relationship between NPY and both leptin and insulin is clearly evident in studies of obesity-prone rats (128–130). In a preobese state, when leptin and insulin levels are relatively low, NPY mRNA is elevated in the obesity-prone subjects, suggesting a role for this peptide in the early stages of weight gain. This is in contrast to a reduction in NPY detected in the postobese state, when leptin and insulin levels rise significantly with body fat accrual in the obesity-prone subjects. A strong, inverse relationship between NPY and circulating leptin or insulin is underscored by the findings that NPY is reduced in a variety of obese states, such as those produced by a high-fat or high-energy diet, VMH lesions, neurotoxins, or a mutation of the *tubby* gene (131–134). These findings lead one to question the function of NPY in the maintenance of obesity and contrast with those obtained for other feeding-stimulatory peptides, such as GAL and the endorphins. These latter peptides are elevated in different states of obesity and are less responsive or even stimulated

by the elevation of leptin or insulin, suggesting their role in promoting obesity in already obese subjects (31,88,132,135).

## B Galanin and Galaninlike Peptide

Galanin (GAL) is widely distributed through the brain and has a number of physiological and behavioral effects that are mediated via distinct GAL receptor subtypes (136). Similar to NPY, GAL stimulates feeding behavior and has a variety of endocrine and metabolic effects. Although these peptide systems may overlap anatomically (31), an abundance of evidence indicates that they are functionally distinct (69). In addition to the ARC where NPY neurons are concentrated, GAL-expressing neurons also exist in the PVN, in both its medial parvocellular and lateral magnocellular areas, and in the PFLH and MPO (Fig. 1). The behavioral, endocrine, and metabolic actions of GAL in the PVN, mediated by two receptor subtypes, GALRI and GALR2, are very different from those of NPY (69,137–140). The GAL-induced feeding response is smaller and shorter-lasting than that of NPY, although it may involve the release of endogenous NPY (141).

Although GAL has little effect on an animal's preference for carbohydrate or fat, a variety of evidence links this peptide's feeding-stimulatory response to dietary fat (142–144). In contrast to NPY, GAL-elicited feeding is stronger and more prolonged in subgroups or strains of rats that naturally prefer fat or in subjects maintained on a high-fat compared to low-fat diet. Further, GAL but not NPY is suppressed by the pentapeptide enterostatin, which selectively reduces the consumption of fat (145). It is also blocked by the GAL antagonist M40, which reduces fat intake (146,147). Repeated PVN injections of antisense oligonucleotides to GAL mRNA produce a marked reduction in fat ingestion and weight gain, in conjunction with a decline in PVN GAL levels (148,149). Whereas both GAL and NPY reduce energy expenditure and inhibit sympathetic nervous system activity (150,151), GAL's endocrine and gastrointestinal effects are, in some cases, diametrically opposite to those of NPY (42,152,153). They include a suppression of CORT, insulin, and AVP release, and an increase in gastric acid secretion. In contrast to NPY, GAL has little impact specifically on carbohydrate or fat metabolism (150).

Differences between these two peptide systems are also evident in their responsiveness to endocrine and physiological feedback signals. In contrast to the robust stimulatory effect of CORT on NPY expression and feeding response, this steroid has little impact or tran-

siently inhibits GAL gene expression in PVN neurons, and has no effect on GAL's feeding behavioral action in this nucleus (42,154,155). Moreover, E<sub>2</sub> alone or in combination with P has a potent stimulatory effect on GAL in the PVN, MPO, and ME (67,156–158), which is not seen with NPY in the ARC. Insulin suppresses both GAL and NPY (18), but these peptides in the ARC show a markedly different response to leptin. This hormone has a potent inhibitory effect on NPY but produces no change in basal GAL expression in the ARC, only a small suppression of PVN GAL, and little change in GAL-induced release of CRH (141,159). This differential responsiveness to leptin, possibly due to the low concentration of leptin receptors on GAL neurons (159), may explain their different responses to food restriction, which reduces leptin levels and markedly enhances NPY in the ARC while having little impact on GAL (160). It may also be related to the finding that GAL, but not NPY, is suppressed by an inhibitor of fat oxidation (161), and NPY but not GAL is stimulated by an antagonist of carbohydrate oxidation (162).

These differences between NPY and GAL, in both their physiological actions and feedback regulation, suggest that they may function through distinct mechanisms and in different physiological states or conditions. The clearest finding, demonstrated in a number of studies and animal models (143,163–165), is that GAL gene expression and peptide production in the PVN, but not the ARC, are positively related to amount of dietary fat, and they also rise in direct proportion to body fat. This is in contrast to NPY, which is reduced by fat consumption and declines in relation to body fat, possibly owing to an increase in leptin to which GAL is less responsive (128,166). In recent studies, GAL in the PVN is strongly, positively related to circulating levels of triglycerides, in addition to measures of fat oxidation in muscle (86). This relationship is robust, seen in different models of dietary obesity but also under conditions of acute exposure (2–24 hr) to a high-fat diet, indicating its independence of changes in body fat and leptin (86). Fat-preferring, obesity-prone rats exhibit higher levels of GAL mRNA and production in the PVN, while NPY in the ARC is reduced (128,142). They are also more responsive to the feeding-stimulatory effects of GAL, but not NPY (167). Circulating levels of GAL are found to be significantly elevated in obese women (168).

The biological rhythms of GAL also differ from NPY (69,137). Across the light/dark cycle, PVN GAL neurons show peak levels during the middle of the feeding cycle, when fat ingestion spontaneously rises. Levels of GAL also rise during proestrous in the MPO

and PVN, in association with a rise in circulating E<sub>2</sub> and P and a preferential increase in fat ingestion (126,156,158,169). A marked increase in GAL is also seen at puberty, specifically in the ARC of male rats, possibly attributed to a rise in testosterone and growth hormone (GH). An increase occurs in the PVN and MPO of females, attributed to an elevation of E<sub>2</sub> and P levels and accompanied by a rise in fat ingestion and body fat accrual (70,71,170–172). A genetic study shows that GAL-deficient mice feed and grow normally and have unaltered NPY in the hypothalamus (173), suggesting that GAL is not an essential peptide in the early stages of development.

A 60-amino acid, GAL-like peptide (GALP), was recently isolated from the porcine hypothalamus (174). This peptide shares sequence homology with GAL and binds with high affinity to GAL receptors. However, studies to date reveal clear differences between these two peptides. In contrast to GAL, GALP is expressed almost exclusively in the ARC (175), and these GALP-synthesizing neurons do not project to the ME (176). Whereas GAL mRNA in this nucleus is not altered by leptin administration, GALP mRNA in the ARC is markedly reduced in leptin-deficient *ob/ob* mice, while stimulated by intracerebroventricular infusion of leptin (177). Moreover, GALP is similarly decreased by fasting, an effect reversed by leptin injection (177). While GAL acts via both receptor subtypes, GALR1 and GALR2, GALP appears to be selective for GALR2 (175). Further studies are needed to determine the physiological effects and hormone regulation of this peptide.

### C Agouti-Related Protein

Agouti-related protein (AGRP) is a naturally occurring antagonist that binds to a receptor to prevent its response to another molecule (178). This protein inhibits the activity of melanocortins, small peptides derived from a large precursor, pro-opiomelanocortin (POMC), which also gives rise to  $\beta$ -endorphin. As described in Section IV, the melanocortins have an inhibitory effect on feeding and body weight, and AGRP, while having little intrinsic signaling activity, binds directly to melanocortin receptors primarily to inhibit melanocortin binding.

A variety of evidence suggests a close relationship between AGRP and the NPY neurocircuit. AGRP colocalizes almost 100% with NPY in neurons of the ARC (98,179). As with NPY, AGRP is a very potent stimulant of feeding behavior, and it promotes body fat accrual. In fact, this peptide is even more potent than

NPY over the long term, because its actions outlast the drug itself and increase eating for days (180). The endocrine profile for AGRP is similar to that for NPY, including an increase in insulin levels (181,182). There is evidence that AGRP and NPY send similar types of signals that reinforce one another, possibly through the inhibition of a Gs-coupled receptor by AGRP and the activation of Gi-coupled receptor by NPY (183). The possibility that these two peptides represent redundant components of a parallel circuit may help to explain why NPY-deficient animals show only minor defects in eating behavior and leptin signaling (33). However, some differences between the AGRP and NPY neurocircuits appear to exist. The stimulatory effect of AGRP on food intake is longer-lasting than, and additive with, that of NPY, and it is accompanied by a somewhat different pattern of c-Fos immunoreactivity in extrahypothalamic areas (184,185).

That the endogenous peptides function in a similar manner is supported by evidence revealing similar changes in endogenous AGRP and NPY expression under physiological conditions (186,187). For example, both peptides in the ARC are stimulated by conditions of negative energy balance and reduced leptin levels. This is evident in leptin-deficient or streptozotocin-induced diabetic mice, after food deprivation or on a carbohydrate-rich diet, and in response to glucopenia induced by 2-deoxy-D-glucose (122,181,188,189). Further, these peptides are both suppressed under conditions of positive energy balance or enhanced leptin levels. This is evident in obese or leptin-injected rodents (187,188), in adrenalectomized rats with reduced glucocorticosteroid levels (190,191), or after insulin injection in streptozotocin-induced diabetes (189). As described in sections below, these patterns observed with endogenous NPY and AGRP expression are opposite to those seen with measurements of POMC and  $\alpha$ -MSH. This supports the idea that the NPY/AGRP and melanocortin systems interact antagonistically in the control of eating and body weight.

## D Orexins

The orexins are a recently identified class of neuropeptides, also described as hypocretins (192,193). Orexin A and orexin B, sharing 46% identity, are coded by the same gene, and are localized in neurons of the PFLH. Administration of orexin A stimulates feeding behavior more effectively than orexin B, possibly through activation of orexin-1 and orexin-2 receptors (192). This effect, localized to the PFLH and PVN (31), is considerably smaller and of shorter duration than that pro-

duced by NPY or AGRP. In addition to this feeding-stimulatory effect, orexin A injection increases energy metabolism and vagal nerve-dependent gastric acid secretion (194,195). The importance of the orexins in feeding behavior is suggested by evidence from genetic studies, revealing an increase in food intake in orexin-overexpressing mice and a decrease in orexin-deficient mice (196).

Neuroanatomical studies demonstrate reciprocal synaptic contacts between orexin cells in the PFLH and leptin-responsive neurons in the ARC that express NPY, AGRP, POMC (197–199). This suggests that orexin may function as a downstream effector molecule of these peptide systems. Orexin-containing axons also contact other orexin cells that express leptin receptors, indicating possible autoregulation of orexin function (199). These orexin-expressing neurons in the PFLH lie adjacent to, but do not overlap, another cell population, described below, that produces a different feeding-stimulatory peptide, melanin-concentrating hormone (197,198,200).

Despite their close anatomical relationship, it is clear that the orexins in the PFLH function differently from other feeding-stimulatory systems in the ARC, suggesting that the regulatory mechanisms of these peptides differ (201). Whereas the PFLH and ARC systems may be upregulated by food deprivation (192,202,203), diametrically opposite results are obtained in genetically obese mice, which show a decrease in hypothalamic orexin mRNA (204,205) but an increase in NPY and AGRP (204,205). Further, in contrast to the ARC peptides that are inhibited by leptin and invariably elevated when leptin is low (see above), functional evidence for a direct interaction between leptin and orexin neurons in the PFLH is lacking, despite the presence of leptin receptors (199,201). Orexin mRNA or peptide level is reduced both when leptin is deficient and when it is injected (204,206). Moreover, the orexins remain stable in conditions or states with markedly altered leptin levels, including overfeeding, dietary obesity, or food restriction with leptin treatment (203, 205–207).

Whereas leptin may not be a key regulator of the orexins, there is evidence suggesting that the orexin neurons are controlled by changes in circulating glucose and may stimulate feeding specifically under conditions of hypoglycemia. Prepro-orexin mRNA in the PFLH is elevated when plasma glucose falls and food is withheld (203,208), and it is reduced by food ingestion (209), suggesting a role in short-term feeding behavior. Some neurons in the LH are known to be glucose sensitive, that is, stimulated by a decline in glucose (75). These

glucose-sensitive cells include orexin neurons, which are stimulated by insulin-induced hypoglycemia (208,210). Recent evidence (211) indicates that the orexin neurons are the same as those identified as containing "prolactinlike immunoreactivity" that are also activated by hypoglycemia. In addition to being stimulated by hypoglycemia following insulin injection, the orexin neurons are inhibited by signals related to nutrient ingestion and are functionally linked to neuronal activity in the hind-brain (209).

It is unclear whether the orexin neurons have a role in obesity. Knockout of the orexin gene, while reducing food intake, actually leads to obesity (196). This may reflect an underlying reduction in energy expenditure due to decreased motor activity, lower basal metabolic rate, or both. That the orexins have a role in controlling energy metabolism is suggested by studies showing that orexin A injection stimulates metabolic rate in mice independently of an increase in food intake or activity (194). In freely feeding mice, this orexin-induced increase in metabolic rate is accompanied by a decrease in respiratory quotient, indicating the use of lipids as energy substrates. This is in contrast to the increase in respiratory quotient and carbohydrate metabolism produced by food deprivation. Consistent with a role for the orexins in lipid metabolism, recent findings show that orexin gene expression is stimulated by consumption of a high-fat diet compared to a low-fat diet, and orexin mRNA rises even further in association with obesity on a high-fat diet. This increase in orexins is closely associated with circulating triglycerides, leading to the proposal that the orexins, like GAL, belong to a class of fat-stimulated peptides (212,213).

In addition to controlling feeding and energy homeostasis, the orexins act at different levels of the neuroaxis to modulate hypothalamic regulatory systems involved in arousal, neuroendocrine, and autonomic processes. This is supported by the extensive projections of orexin fibers to many areas of the brain and spinal cord (200,214–216). The importance of the orexins in the sleep-wake cycle is underscored by the discoveries that a knockout of the mouse *orexin* gene or a mutation affecting the *orexin-2 receptor* gene in dogs induces narcolepsy (196,217–219). Moreover, orexin injections produce an increase in locomotor activity, grooming, and searching behaviors, suggesting a role for the orexins in vigilance and regulation of arousal states (220). A possible relationship between these effects and those of orexin on energy balance is supported by evidence showing obesity in narcoleptic animals (201). Orexin is localized with DYN in neurons that may perform a function in feeding behavior based on opioid effects in the PBN. This is discussed in

the opioid peptide section below and is illustrated in Figures 1 and 2.

There is further evidence indicating the involvement of an orexin peptide system in neuroendocrine and autonomic functions. This is demonstrated by the stimulatory effect of orexin A injection on blood pressure and heart rate, on autonomic efferent nerve activity and gastric acid secretion, and on luteinizing hormone secretion, at lower doses than those required to stimulate feeding (221–223). This pressor response to orexin A is accompanied by an increase in renal sympathetic nerve activity and plasma catecholamines in conscious rats (224). The finding that orexins act on medullary neurons to increase sympathetic nerve activity to the heart and blood vessels (225) raises the possibility that this peptide system underlies the increased sympathetic activation and risk of high blood pressure associated with obesity (226).

## E Melanin-Concentrating Hormone

In addition to the orexins, other neurons in the LH and zona incerta produce melanin-concentrating hormone (MCH), a cyclic 19-amino acid neuropeptide originally isolated from salmon pituitaries (227,228). This peptide acts via a specific receptor with a typical seven-transmembrane domain region seen with G-protein-coupled receptors (229,230). The involvement of MCH in the control of feeding behavior was first suggested by studies showing that central administration of MCH potentiates food intake (231,232). This MCH-induced feeding response is relatively small and of short duration compared to the responses induced by NPY and AGRP. Also, long-term administration of this peptide has little effect on daily food intake and body weight (232).

Studies of endogenous MCH provide support for its role in feeding and body weight regulation. The expression of MCH is stimulated by fasting, augmented in *ob/ob* mice with leptin deficiency, and decreased by leptin (56,231,232). This peptide is potentiated by insulin-induced hypoglycemia, similar to the orexins in the PFLH but contrary to the ARC NPY/AGRP system, as described above. MCH is also increased by compounds that block glucose and fatty acid oxidation, suggesting that it responds to changes in the availability of immediate fuel sources, perhaps by stimulating food intake. Further, the expression of MCH is responsive to  $E_2$ , which inhibits hypothalamic MCH expression in ovariectomized rats and blocks deprivation-induced increase in MCH (233,234). This suggests that decreased MCH signaling may contribute to the pathogenesis in certain types of anorexia.

A physiological role for MCH in energy homeostasis is strongly supported by genetic studies. For example, targeted ablation of the MCH gene leads to a thin phenotype associated with hypophagia and an inappropriate increase in metabolic rate (235). Moreover, transgenic mice that overexpress MCH in the LH exhibit hyperphagia, hyperleptinemia, hyperglycemia, and insulin resistance on a high-fat diet compared to wild-type animals (236). The finding that MCH-deficient mice show low levels of leptin and POMC mRNA is unexpected, given the anorexia in this strain. The leanness in mice with deletion of the MCH gene, despite other intact orexigenic systems, suggests that this peptide acts downstream of leptin as well as the NPY/AGRP and POMC/melanocortin signaling cascades. This is supported by the immunohistochemical demonstration of a projection from the ARC neurons, which synthesize NPY/AGRP or melanocortins, to MCH neurons in the LH (197,198). It also agrees with the finding that leptin administration decreases MCH expression as well as MCH-induced feeding (56,237).

## F Opioid Peptides

The opioid system is composed of three families of biologically active peptides—DYN,  $\beta$ -endorphin, and enkephalin. One of the many functions of opioid peptides is their role in mediating the component of food intake control that is enhanced by both food palatability and food deprivation. Therefore, opioid systems may be important in binge eating and diet-induced obesity. Systemic morphine increases food ingestion, and the opioid receptor antagonist naloxone reduces intake of palatable food (238,239). When macronutrient diets are available, opioid agonists preferentially enhance ingestion of fat-rich diets (240). Patterns of ingesting sweet solutions under the influence of morphine or naloxone suggest that opioids inhibit aversive components of overeating and, thereby, increase the amount of food ingested (241–243). Opioids released in the nervous system by eating palatable food can also cause analgesia in rats and humans (244–246). Therefore, eating may occur to suppress pain or discomfort.

### 1 Opioid Subsystems

It has been difficult using systemic injections to unravel the roles of various mu, kappa, and delta systems and their multiple receptors. Progress is being made, however, as summarized in several reviews (238,247–249). The opioid peptides DYN,  $\beta$ -endorphin, and enkephalin act primarily via kappa, mu, and delta receptors,

respectively (238,250–253). When labeling the brain for opioid peptides and their receptors, the regions involved with taste, autonomic control, feeding, and reward stand out. Evidence suggests that mu<sub>1</sub> receptors affect body weight and alter physiological responses of the glucostatic and lipostatic systems, whereas some of the kappa receptor systems stimulate food palatability and promote feeding by blocking satiety (254,255).

Early work involving local brain injection in the PVN-MH region showed that  $\beta$ -endorphin, DYN, or an enkephalin analog each induces feeding (256,257). If one starts with the hypothalamus in Figure 2 and follows the hypothalamic loop to the PBN, NTS, VTA, and back to the hypothalamus, there are opioid influences at each step of the way and in the amygdala as well. There may be a specific opioid pathway involved in feeding and its reinforcement (250). The threshold for feeding induced by LH stimulation is raised by specific antibodies against DYN-A (258). Naloxone also raises the threshold for stimulation-induced eating, and this effect, unlike the classic anorexic action of amphetamine (AMPH) and phenylpropanolamine, is potentiated by eating. A site where naloxone exerts its anorexic effect via kappa or mu receptors lies in the PBN, a brainstem region that relays taste and vagal information to and from the forebrain. Thus, an identified DYN path from LH to PBN may potentiate eating for taste and by inhibiting satiation (250,259,260). In addition, food intake and decreased sympathetic activity produced by PVN injection of NPY is blocked by naloxone in the NTS. Thus, NPY-induced feeding depends, in part, on opioids in the NTS (238,261). One or more opioid systems may be involved in GAL-induced eating as well (262). In the VTA, local injection of morphine has a potent feeding-stimulatory effect that is mimicked by DYN (263). A mu opioid antagonist injected in the VTA blocks food-induced release of DA in the NAc, but not in the PFC, and it reduces the animal's appetite (264). This result may depend on the palatability of the food (265). In the NAc, a specific mu opioid agonist induces eating of preferred foods (266,267). A mu agonist in the amygdala also stimulates eating, and this effect is blocked by an opiate antagonist in the NTS (239,268). Studies of feeding with transgenic animal models of opioid abnormalities have also been reviewed (56,97,269).

### 2 Opioid Reward and Eating

The next question is whether the LH-PBN opioid-related path is involved in self-stimulation and feeding reinforcement, as well as in the prolongation of a meal. In support of this proposal electrodes in the LH that

induce feeding also support self-stimulation (3). Opiate antagonists sometimes decrease self-stimulation (270). The self-stimulation rate at eating sites in the LH is inhibited by a meal. This clearly reflects loss of appetite, as long as control is used for motor effects on bar press rate (3,270–272). In a majority of such studies, the converse is also true, whereby food deprivation increases the LH self-stimulation rate or lowers the threshold (250,273). This effect is reversed by ventricular infusion of naltrexone (250). Therefore, opioids potentiate the behavior reinforcement system, which is defined by LH self-stimulation in the PFLH, when it is a stimulation-induced eating site.

It is hypothesized that a natural incentive mechanism for eating is stimulated by palatable tastes via an opioid system, which is sensitized by the metabolic needs imposed by weight loss (250). This appetite enhancement mechanism seems to involve several limbic regions, including the DYN pathway that starts in or near the PFLH and projects to the PBN (259). This may be part of the feeding reinforcement system that is modulated by food intake, food deprivation, and insulin (271). It is potentiated by DYN release and sensitized by an opioid process in response to weight loss or diabetes (250). Therefore, DYN can be envisioned in Figure 2 as part of the feeding and reinforcement system drawn from the LH to the PBN. In light of recent evidence for orexin-expressing cells in the PFLH region that project axons to the hindbrain as well as the prefrontal cortex (216), the orexins may also be excellent candidates for part of the feeding reinforcement circuit. In fact, DYN and orexin coexist in cells of the LH (274).

Opiates are behavior reinforcers in the VTA, as shown by morphine self-injection, conditioned place preference, and potentiation of self-stimulation (270, 275–278). In the NAc, rats self-inject morphine or enkephalin (279,280). From a clinical point of view, it is conceivable that this feeding reinforcement system depicted in Figure 2 is the metabolism-modulated, taste-activated appetitive system that drives bingeing behavior (281). Enterostatin, a peptide released by a fatty meal, may suppress food intake by inhibiting a kappa opioid feeding component (282), which may also be linked to GAL. Logically, enterostatin may inhibit the LH-PBN orexin/DYN pathway of the feeding reinforcement system, but this is yet to be demonstrated.

### 3 Inhibition of Opioid Reward and Feeding

Kappa agonists have either stimulatory or inhibitory effects on feeding in different parts of the brain. As

reviewed above, food deprivation potentiates behavior in part by releasing DYN-A in the PBN (250). On the other hand kappa agonists in the VTA or NAc inhibit the mesolimbic DA system (283) and may play a role in stopping food intake or generating aversion. Thus, there seems to be more than one kappa opioid system involved in the circuitry for eating (284). Naloxone injected locally in the NAc to block opioid receptors, probably the mu subtype, can release ACh, and the ACh can inhibit feeding. Naloxone works in the NAc when something has been done to release endogenous opioids, such as food deprivation or morphine treatment (285). After a week of daily morphine injections, local or systemic naloxone precipitates withdrawal, and in the NAc, the release of DA decreases while ACh increases (285). The same response occurs with systemic naloxone injection after a few weeks of drinking excessive amounts of sugar in the binge-eating model described in Section VII below.

### G Amandamide

The endogenous cannabinoid, amandamide, can induce eating and may interact with opioid systems (286). Tetrahydrocannabinol (THC) induces accumbens DA release that can be blocked by an opioid antagonist in the VTA. Thus, marijuana reinforces behavior, in part, by releasing DA via an opioid system. This may also be the mechanism through which marijuana induces appetite for food (287). A cannabinoid receptor antagonist reduces food intake in rats (288). The same drug causes a small but significant decrease in body weight in people (289).

### H Growth Hormone-Releasing Hormone

Growth hormone regulates overall body and cell growth, in addition to nutrient metabolism (290). Its release is stimulated by GHRH, while inhibited by somatostatin. Evidence suggests a stimulatory role for GHRH in feeding behavior (Fig. 1) (291–294). Central injections of GHRH enhance food intake in rats and sheep. The hypothalamic regions most responsive to this peptide effect are in the area of the MPO and SCN, which have a high concentration of GHRH-containing terminals. This feeding-stimulatory action is centrally mediated and independent of the growth hormone-promoting properties.

From injection studies at different times of the circadian cycle, it seems that endogenous GHRH may contribute to the burst of feeding exhibited at the start of

the active cycle (292–294). This proposal receives support from experiments with antiserum raised against GHRH, which suppresses spontaneous feeding. Injections of GHRH stimulate intake of protein, having little impact on carbohydrate or fat intake. Moreover, an antiserum against GHRH preferentially inhibits protein consumption at the onset of the natural feeding cycle. This may reflect a role for endogenous GHRH, in the MPO/SCN area, in stimulating both growth and the ingestion of the nutrients important for growth.

There is evidence that growth hormone–releasing peptides (GHRP), acting within the brain, mimic an unidentified native GH-releasing hormone-amplifying hormone. Systemic administration of GHRP-6 induces *c-Fos* protein in the ARC (295). Further, intracerebroventricular administration of low doses of the GHRP, KP-102, stimulates feeding in rats, while having no effect after systemic administration, and it amplifies the feeding-stimulatory effect of GHRH through a specific GHRP receptor, possibly in the hypothalamus (296). There is also evidence that GHRH may interact with other neurochemical systems in the brain to control eating and body weight. For example, the GHRH system is closely associated with, and may depend on, the opioid system in the PVN. Opiate agonists stimulate the ingestion of protein as well as fat, an effect blocked by GHRH antiserum, and the action of GHRH is antagonized by PVN injections of opioid receptor antagonists (291,297). Also, GHRH-expressing neurons in the ARC coexpress GAL, which stimulates feeding and increases adiposity after chronic administration (see above). Studies demonstrate that, in these ARC neurons, GAL expression is induced by GH and reduced in the absence of GH, suggesting that the pattern of GHRH and GH release may, in turn, be shaped by GAL (172). In a recent study, double-labeling immunohistochemistry indicates that orexin-containing, but not MCH-containing, neurons in the LH are activated by central administration of GHRP-6 (298).

In obesity, GH secretion is impaired, secondary to the rise in body fat and circulating lipids, and treatment with GH decreases adiposity, reduces triglyceride accumulation, and enhances lipolysis (290,299). A role for GH in body fat accumulation is confirmed by the observation that mice overexpressing GH have increased abdominal fat (300). They are larger and exhibit hyperphagia and increased levels of insulin and leptin, in association with reduced responsiveness of the leptin receptor to fasting. Whereas the physiological mechanisms underlying this obese state remain to be defined, this mouse model points to the importance of GHRH in the regulation of body composition.

## I Ghrelin

Recent evidence suggests that, in addition to GHRH, there exists another peptide, ghrelin, which stimulates the release of GH (301). Ghrelin is a 28–amino acid peptide, and its mRNA is expressed in the stomach. It is secreted into blood vessels to act directly on pituitary cells to stimulate GH release (302). Although ghrelin content in the brain is low, a population of ghrelin-containing neurons exists in the ARC. In addition to producing a dose-dependent rise in GH, intracerebroventricular administration of ghrelin potentiates food intake (303–306) and stimulates gastric acid secretion and motility (307). In contrast to the other feeding-stimulatory peptides described above, ghrelin also stimulates eating when administered peripherally, although the response is not as strong or sustained as that seen with central ghrelin. Antighrelin antibodies suppress feeding behavior with central as well as peripheral administration, supporting a role for endogenous ghrelin in this behavioral response. The feeding-stimulatory effect of ghrelin is independent of this peptide's ability to stimulate GH secretion (305). Ghrelin may stimulate feeding to ensure the provision of calories that GH requires for growth and repair (308).

Ghrelin acts through the growth hormone secretagogue (GHS) receptor. This receptor is expressed at high levels in the ARC. Systemically administered ghrelin increases the electrical activity and *c-fos* gene expression in ARC neurons (309), suggesting that it reaches these receptors through the general circulation. The GHS receptor mRNA is found in essentially all neurons expressing NPY, but it exists in only a small percentage of POMC- or GHRH-expressing neurons. Ghrelin injection increases NPY as well as AGRP mRNA, while having no effect on POMC mRNA (303,304,306,310). Further, NPY antagonists inhibit ghrelin-induced feeding (298). Whereas these findings suggest a role for NPY in mediating ghrelin's action, this peptide is not essential, since ghrelin can increase feeding and body weight in NPY-deficient mice (305).

There is some evidence indicating the involvement of ghrelin in obesity. With chronic subcutaneous injections in mice, ghrelin increases body weight, with a significant gain in fat mass but no change in lean body mass (305). This is accompanied by an increase in respiratory quotient, reflecting a decrease in fat metabolism. Whereas one study shows that ghrelin mRNA in the stomach is stimulated by chronic administration of leptin (311), other evidence reveals a competitive interaction between ghrelin and leptin. Ghrelin concentrations in the blood and mRNA in the stomach are

increased by fasting that reduces leptin, and ghrelin is suppressed by feeding (303,305). Further, ghrelin mRNA is elevated in leptin-deficient *ob/ob* mice and reduced by acute leptin injection (308). The role of ghrelin in weight gain is suggested by evidence that the obese phenotype of *ob/ob* mice is partially reversed by antighrelin antiserum (303). Also, the reduction in weight gain induced by a pro-inflammatory cytokine is attenuated by ghrelin administration (303). Circulating ghrelin levels are decreased in states of obesity in humans (308). Ghrelin is also reduced by carbohydrate diets and glucose in rodents (303,305). This suggests the involvement of this peptide in physiological mechanisms of glucose homeostasis.

### J Beacon

The *beacon* gene was recently identified by differential display polymerase hypothalamic mRNA from a polygenic animal model of obesity and type II diabetes (312). This gene is overexpressed in the hypothalamus of obese animals, and its mRNA level is positively correlated with body fat content. Immunohistochemical studies localize beacon mRNA to the retrochiasmatic area of the hypothalamus. Central administration of beacon stimulates food intake and increases NPY expression in the ARC (312). Repeated injections of beacon increase feeding behavior and weight gain, primarily owing to an increase in body fat accrual (313). With no detectable effect of beacon on nutrient partitioning, physical activity, or energy expenditure, the accumulation of body fat is attributed primarily to the changes in food ingestion (313). This contrasts with other feeding-stimulatory peptides, described above, which have potent and diverse effects on metabolic processes.

### K VGF

VGF was originally identified as a nerve growth factor-regulated transcript, which is rapidly stimulated by neurotrophins (314). Its mRNA and encoded protein are selectively synthesized in neuroendocrine and neuronal cells, and VGF is stored and released from dense core vesicles through the regulated secretory pathway. The VGF polypeptide sequence is rich in paired basic amino acids, potential sites for proteolytic processing. A range of low-molecular-weight VGF peptides have been identified that are preferentially released by nerve terminals upon stimulation (315). This suggests that VGF is the precursor of one or more biologically active peptides and that it may play a role in the regulated release of other peptides from secretory vesicles (314).

While widely expressed through the central and peripheral nervous systems, VGF mRNA is particularly abundant in the hypothalamus (316). In the suprachiasmatic nucleus, VGF mRNA is induced by light and exhibits a circadian rhythm in animals kept in constant light (314). An investigation of VGF knockout mice (317) suggests the involvement of VGF in energy homeostasis. Mice lacking the protein display markedly reduced body weight, body fat, and leptin, indicating a possible stimulatory role for this protein in weight regulation. The major defect in these mice is excess energy expenditure and locomotor activity, rather than reduced food intake. Fasting stimulates VGF mRNA in the ARC (314). Further, the VGF knockout mice exhibit altered expression of hypothalamic peptides in the ARC that affect feeding and metabolism. Whereas VGF-deficient mice have elevated NPY and AGRP mRNA, they show a reduction in POMC expression. Thus, VGF's mechanism of action may involve an effect on the synthesis and release of these peptides known to be involved in energy homeostasis.

### L Prolactin

Prolactin (PRL) is a peptide hormone, which is elevated during lactation, a physiological culmination of the reproductive cycle in female mammals (58). This hormone is synthesized in the anterior pituitary gland but is also expressed, albeit in low concentrations, by cells in the brain, notably the medial basal hypothalamus (318). As the mammary tissue develops the capacity for milk production, there occurs an increase in demand for nutrients, leading the lactating female to look to both metabolic and behavioral adaptations to meet these demands (58). These adaptations include hyperphagia, conservation of energy by reduced activity, decreased rates of nonshivering thermogenesis, lipid synthesis, triglycerol turnover, and more efficient use of nutrients through a change in insulin responsiveness.

Injection studies reveal multiple behavioral as well as physiological actions of PRL related to reproduction. In addition to its well-known actions of enhancing milk production and stimulating growth, PRL acts on behavioral systems. It increases grooming, facilitates sexual receptivity, and promotes maternal behavior (319). Prolactin also stimulates eating behavior in mammals and birds. Lactation in rodents is characterized by marked hyperphagia. Prolactin levels and hyperphagia are directly proportional to litter size, suggesting a causal relationship (58,320,321). An increase in food intake is also seen after systemic administration of PRL in female rats. Interestingly, a

protein-rich diet is preferred after PRL injections, as well as during lactation (58,320,322). Prolactin is effective when administered into the brain, where it functions independently of ovarian hormones (323). Sites of action include nuclei of the MH where PRL receptors are concentrated (319,324). A feedback loop may involve the eating-stimulatory peptide GAL, which is synthesized in PVN neurons and stimulates the release of PRL from the pituitary (325). A hypothalamic  $\beta$ -endorphin-containing circuit may also play a role (326).

The possibility that PRL controls fat synthesis is suggested by the findings that the PRL receptor exists in mouse adipocytes (327) and that DA-induced inhibition of PRL secretion decreases fat stores and blocks lipogenic responsiveness to insulin (328). In addition, fat deposition in migrating species is promoted or inhibited in close relation to circulating levels of PRL as well as CORT. An increase in plasma prolactin is seen in females following puberty, a time of fat deposition (329). Responses to PRL and the circadian rhythm of PRL release are altered in adult obesity, perhaps owing to hyperinsulinemia, and these disturbances are normalized by weight reduction. In obese men, a strong, positive correlation is evident between fasting levels of leptin and prolactin (330).

#### IV PEPTIDES THAT REDUCE EATING AND BODY WEIGHT

Many peptides have been discovered that have inhibitory effects on feeding and weight gain (Table 1). An important question addressed in the investigation of these substances is whether their behavioral or physiological effects are both specific and meaningful in the overall control of energy balance. Discussed below are most of the satiety peptides that have sufficient evidence to support their role in the control of feeding and metabolism. In most cases, the peptides are synthesized in the brain to act through local neurocircuits. In others, these substances are synthesized in peripheral organs and send signals to the brain via the circulation, vagus nerve, or sympathetic afferents.

##### A Melanocortins

Pro-opiomelanocortin (POMC) is a 267-amino acid precursor protein that is synthesized in the ARC as well as the anterior pituitary. The posttranslational processing of POMC results in a number of peptides with very different biological activities. In the anterior

pituitary, it is processed predominantly to ACTH as well as to  $\beta$ -lipoprotein. In the ARC, ACTH is further processed to produce  $\alpha$ -MSH, whereas  $\beta$ -lipoprotein is cleaved to  $\beta$ -endorphin. Pharmacological studies show that central injections of  $\alpha$ -MSH and other MSH agonists suppress food intake and reduce body weight (331). Mice with a mutation in the coding region for the POMC-derived peptides have defective adrenal development and lack corticosteroids (332). They also develop hyperphagia and obesity, which are reversed by injections of  $\alpha$ -MSH (332). A similar phenotype is seen in humans with a genetic POMC mutation resulting in a deficiency of  $\alpha$ -MSH (333).

The biological actions of the MSH peptides are mediated by interactions with at least five G-protein-coupled receptors, with the MC3-R and MC4-R heavily expressed in the brain. Whereas the MC3-R is localized to the hypothalamus and limbic system and is richly expressed in the ARC including in POMC neurons, the MC4-R is more widely distributed throughout the brain and, within the hypothalamus, is highly expressed specifically in the PVN and PFLH (334). Pharmacological blockade or targeted disruption of MC4-R in rodents produces hyperphagia, increased fat mass, and hyperinsulinemia (24,335,336), and spontaneous MC4-R mutations have been linked to morbid obesity in humans (24,337). The additional importance of the MC3-R in energy homeostasis is indicated by the finding that mice lacking this receptor have increased fat mass but not hyperphagia, whereas mice lacking both the MC3-R and MC4-R weigh more than mice lacking only the MC4-R (338). A recent study in MC4-R-null mutant mice suggests a role for this receptor, independent of leptin, in mediating high-fat diet-induced thermogenesis and increase in physical activity (339).

Two naturally occurring MSH antagonists, agouti protein and AGRP (see Section III), have been identified. Agouti, which is normally expressed in hair follicles, antagonizes the effects of  $\alpha$ -MSH at the MC1-R and, consequently, blocks the synthesis of pigments, resulting in a lighter coat color (334). Ectopic expression of agouti seen in the yellow mouse obesity syndrome, similar to that seen with targeted disruption of the MC4-R (340), leads to the blockade of MC4-R in the brain, and this causes a phenotype of hyperphagia, hyperinsulinemia and obesity (341). In transgenic mice, the overexpression of AGRP in ARC neurons also causes hyperphagia, hyperinsulinemia, and obesity (178,182). Injections of AGRP, as well as other synthetic melanocortin receptor antagonists, can block the inhibition of food intake induced by  $\alpha$ -MSH and, by themselves, can stimulate feeding, indicating a role for endogenous  $\alpha$ -

MSH in food intake control (342). The interaction of these melanocortin antagonists with the melanocortin receptors may be mediated or facilitated by the protein mahogany. This neuroactive protein may increase the concentration of agouti/AGRP antagonists in the vicinity of the MC1-R or MC4-R or affect the process of receptor desensitization via posttranslational modifications or cellular internalization (343).

A complex neuronal system involves a variety of downstream MC4-R- and MC3-R-containing neurons in the ARC. The endogenous antagonist AGRP is expressed in separate neurons medial to those expressing POMC, and AGRP-immunoreactive fibers form a projection that is separate from, but overlaps, the  $\alpha$ -MSH fibers (183). This indicates that the melanocortin system may function either through agonists released by POMC neurons or through an endogenous antagonist released from non-POMC neurons (Fig. 1). Despite this dissociation, the  $\alpha$ -MSH and AGRP peptides very likely interact at the hypothalamic MC4-R in their role in maintaining energy homeostasis. These peptides are modulated in a reciprocal fashion by various manipulations, such as leptin or food deprivation, and also in obese, leptin-deficient, or leptin receptor-deficient mice (183,344). Although this reciprocal relationship between the agonist and antagonist is not apparent under all conditions (344), the evidence generally suggests that leptin can regulate the melanocortin system either by increasing levels of the agonist,  $\alpha$ -MSH, or by decreasing levels of the antagonist, AGRP. The importance of the melanocortin system in the signaling cascade of leptin in the brain is further revealed by evidence that antagonists of the melanocortin receptor block the feeding-inhibitory and metabolic-stimulatory actions of leptin (345,346). There is electrophysiological evidence that leptin increases the frequency of action potentials in the anorexigenic POMC neurons, either by depolarization or by reducing the inhibitory effect of local orexigenic NPY neurons (347).

As indicated above, the melanocortin system and NPY neurocircuit are closely related. The POMC and NPY neurons are concentrated in the ARC and project to similar nuclei of the hypothalamus, including the PVN where MC4-R immunoreactivity is dense (334). Moreover, pharmacological studies demonstrate a complete suppression of NPY's orexigenic effect with injection of the melanocortin agonist, MTII (348). Electrophysiological studies provide evidence supporting a cellular basis for this interaction (24). The melanocortin antagonist, AGRP, which colocalizes with NPY in ARC neurons (98,179), is a potent stimulant of feeding behavior. As described in Section III, injection

of AGRP, like NPY, promotes body fat accrual and increases insulin levels (181). Moreover, measurements of endogenous NPY and AGRP expression reveal opposite patterns to those detected with measurements of POMC and  $\alpha$ -MSH (349). This evidence supports the idea that the melanocortin and NPY systems interact antagonistically in the control of eating and body weight.

## B Cytokines

Cytokines are protein molecules released by lymphocytes and/or monocyte macrophages during various disease states, such as infection and cancer. Several proinflammatory cytokines, most notably tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), interleukin (IL)-1, IL-6, and ciliary neurotrophic factor (CNTF), induce anorexia and body weight loss (88,350,351). Evidence suggests that the anorexia is mediated by central neural mechanisms, most notably in the hypothalamus where the receptors for most cytokines are particularly dense (352). Peripherally administered TNF $\alpha$  and IL-1B produce anorexia in rats at doses estimated to yield pathophysiological concentrations in the cerebrospinal fluid of animal models or patients with wasting disorders (353). These peripheral cytokines are released into the circulation and, through the blood brain barrier and circumventricular organs, are transported into the brain, where they exert their effects via the vagus nerve or second messengers, such as nitric oxide and prostanooids in the brain vasculature. Cytokines are also produced by neurons and glia within the brain, including the hypothalamus, in response to microbial and inflammatory products or peripheral cytokines. Whereas the absence of TNF $\alpha$  does not prevent the development of obesity, targeted mutation of the TNF $\alpha$  gene or its type 1 and 2 receptor subtypes improves insulin sensitivity, supporting a role for TNF $\alpha$  as a mediator of insulin resistance in obesity-diabetes models (88,354). Furthermore, IL-1B and IL-6 mutant mice resist anorexia, body weight loss, and fever caused by inflammatory-inducing agents, and IL-1 receptor antagonist-null mice have reduced body weight (88).

The idea that circulating signals generated in proportion to body fat mass influence appetite and energy expenditure through central mechanisms has been clearly demonstrated with the cloning of the leptin gene (20) and the finding that leptin, which is positively related to body fat mass, reduces food intake through leptin receptors in the hypothalamus (22). Leptin is a member of the IL-6 superfamily of proteins, with many biochemical features of a cytokine molecule (20),

and the leptin receptor is most closely related to glycoprotein 130, a common signal transducer among receptors for members of the IL-6 superfamily (355,356). Evidence suggests that leptin increases hypothalamic production of cytokines (357) and activates cytokinelike signal transduction pathways, by stimulating JAK-STAT via the leptin receptor (358–360) (see Table 1 for abbreviations). Leptin also activates SOCS-3, which reduces intracellular signaling by inhibiting JAK activity, a potential mechanism underlying leptin resistance (360). Thus, excessive leptin or leptinlike signaling, resulting from increased inflammatory cytokines in overlapping and redundant cytokine networks, may contribute to the anorexia and weight loss in wasting illnesses (361), although it is not essential to this response (362).

In light of the inhibitory effect of leptin on NPY expression in the ARC described above, it is not surprising to find a similar relationship between circulating cytokines and the NPY feeding system in the development of anorexia (361). Cytokines such as IL-1 and CNTF antagonize NPY gene expression in the ARC and reduce NPY-induced feeding as well as  $Y_1$  receptor abundance (363,364). Whereas this effect may occur indirectly via stimulation of leptin secretion (361), a direct action is supported by the finding that a CNTF derivative corrects the obesity and metabolic disorders of mice deficient in leptin or its receptor and also of diet-induced obesity models unresponsive to leptin (358). Further evidence supporting the involvement of NPY in cytokine effects is obtained in anorexic, tumor-bearing rats, which show a reduction in NPY levels or release, NPY-induced feeding, and NPY receptor affinity in association with anorexia and weight loss (353,365).

Whereas cytokine-induced anorexia may also involve other neurochemicals, such as CRH, CCK, and 5HT, that suppress feeding and modulate NPY (88,361,366), there is compelling evidence supporting a key role for the melanocortin system that provides a bidirectional tuning necessary to maintain energy stability under different conditions (367,368). This includes the finding that anorexia and weight loss induced by sarcoma growth are both reversed and prevented by administration of AGRP, the endogenous melanocortin antagonist. Further, both genetic and pharmacologic blockade of central melanocortin receptor signaling prevents the complex cytokine response and the weight loss that accompanies lipopolysaccharide injection. Whereas a close relationship is known to exist between leptin and the melanocortin system, the effects of melanocortin blockade occur independently of this hormone.

Since the discovery that CNTF produces severe anorexia and weight loss in rodents and humans, further studies have been conducted to more fully characterize this effect (358,366). A CNTF derivative, CNTF<sub>AX15</sub>, is highly effective in correcting obesity and resulting metabolic disorders in mice, apparently with minimal side effects. It is believed to act by penetrating the blood brain barrier and impacting on the alpha subunit of the CNTF receptor complex in the hypothalamus. It mobilizes intracellular signal transduction pathways that are similar to those activated by leptin, but not the prototype cytokine, IL-1. Like leptin, CNTF reduces NPY-induced feeding and NPY mRNA and peptide in the ARC and PVN. However, it functions independently of leptin, as well as the melanocortin system. In fact, it is effective in diet-induced obesity models that are resistant to leptin (358). The ability of CNTF to produce weight loss and improve insulin sensitivity in humans makes this compound an attractive agent for obesity treatment, given that certain side effects can be controlled (366,369).

### C Cocaine- and Amphetamine-Regulated Transcript

Cocaine- and amphetamine-regulated transcript (CART) was originally identified by differential display polymerase chain reaction as a novel mRNA stimulated after acute administration of psychomotor stimulants (370). The predicted protein product of CART mRNA has a leader sequence and several pairs of basic amino acids, suggesting that it is processed and secreted. The mature peptide contains several cleavage sites, indicating that CART may be posttranscriptionally processed into long and short fragments, with both forms of CART peptides found in the rat and only the short-form peptide found in humans (370,371). In the rat, CART mRNA and the short-form CART peptide (amino acids 42–89) are found in various nuclei of the hypothalamus, including the ARC, PVN, and LH, as well as in extrahypothalamic areas (372–374). Moreover, CART coexists with peptides involved in the control of energy balance. Virtually all CART neurons in the ARC also express POMC (375), as well as the long-form leptin receptor (376). Hypothalamic CART neurons outside the ARC coexpress DYN and MCH and, as in the ARC, are direct targets of leptin (376). Further, in the PVN, 25–50% of CART-expressing neurons express GAL (377,378), and CART coexists with GAL or MCH in neurons of the PFLH (377,379).

A number of studies suggest that CART has a role in eating behavior and obesity. Administration of this peptide produces a dose-dependent decrease in food intake and reduces feeding stimulated by NPY (380,381). Moreover, antibodies that block CART increase nocturnal feeding, suggesting that this peptide has a tonic inhibitory effect on food intake (382). Other effects of CART include a stimulation of uncoupling proteins (383) and inhibition of gastric acid secretion (384). Chronic administration of CART leads to a marked decrease in body weight in rats (385).

Investigations of the endogenous peptide show that CART expression is regulated by leptin (380). It is stimulated by leptin administration and is reduced in genetically obese *fa/fa* rats, leptin-deficient *ob/ob* mice, and food-deprived rats. Whereas this decline in CART may contribute to the hyperphagia characteristic of these animals, overeating and obesity induced by a high-fat diet is similarly associated with elevated levels of leptin, together with CART in the hypothalamus (386), in particular the ARC and PVN (387). Since obesity induced by a high-fat diet is less marked than that of genetically obese rodents, this higher expression of CART on a fat-rich diet may function in limiting the level of body fat accrual. Supporting this idea are recent studies showing that targeted deletion of the *CART* gene in mice on a high-fat diet induces hyperphagia and increased body weight and fat mass compared to wild-type mice on the same diet (388). Other genetic studies provide further evidence that variation in the *CART* locus may influence fat distribution and variables related to syndrome X (389).

#### D Corticotropin-Releasing Hormone

A well-known role of corticotropin-releasing hormone (CRH) is to control the HPA axis, exerting powerful regulatory effects on the release of ACTH and glucocorticoids. In addition, however, this peptide has been implicated in the mediation of the integrated physiological and behavioral responses of stress, which are largely independent of the activation of the HPA axis and involve a direct action of CRH on brain receptors.

Included in the responses of endogenous CRH are changes in eating behavior and metabolism, involving a constellation of effects favoring a state of negative energy balance (88,390–394). The specific effects observed with CRH injections into the MH or PVN include a marked suppression of spontaneous or fasting-induced feeding. This is coupled with stimulation of sympathetic outflow, which increases lipolysis and energy expenditure and raises blood glucose, while

inhibiting any increase in insulin secretion. Chronic central CRH administration causes a sustained reduction in food intake and body weight. Urocortin, an endogenous peptide related to CRH, is considerably more potent than CRH in suppressing feeding, and is more selective in binding to the CRH<sub>2</sub> receptor subtype, which may mediate the anorexic and thermogenic responses (395). Studies in knockout mice suggest that the feeding-suppressive effect induced by urocortin may actually have two phases, with the early phase mediated by the CRH<sub>1</sub> receptor and the long-term phase by the CRH<sub>2</sub> receptor (394).

A role of endogenous CRH or urocortin in energy balance is suggested by evidence showing an increase in feeding after pharmacological blockade of CRH receptors, expression, or synthesis (88,394,396). This receives further support from the finding that food intake is reduced by chronic administration of a CRH-binding protein inhibitor, which increases CRH/urocortin availability in the hypothalamus (397). In states of glucocorticoid insufficiency induced by adrenalectomy, CRH expression in the PVN is enhanced, and this neurochemical change is associated with a decline in eating and body weight, impaired recovery of weight loss after food deprivation, and the prevention of experimentally induced obesity (392). Circulating glucocorticoids normally released by CRH may provide the feedback signal for inhibition of CRH and regulation of adipose tissue. Other studies have suggested the involvement of CRH or urocortin in the anorexic effects induced by restraint stress, treadmill running, E<sub>2</sub>, and caffeine and in the thermogenic actions of 5HT agonists (394). Possible sites of action include the PVN and MPO (31,398). The finding that MC4-R-deficient mice are hypersensitive to the anorexic effects of CRH provides evidence for crosstalk between the melanocortin and CRH pathways (399,400).

There is further evidence supporting the possibility that CRH has a role in the development of obesity. Chronic injections of CRH or an inhibitor of the CRH-binding protein reduce weight gain in genetically obese rats with normally reduced CRH content in the hypothalamus (397). Moreover, the expression of the CRH<sub>2</sub> receptor in the VMH is reduced in obese rats, and leptin suppresses the synthesis and release of CRH (394). A variety of evidence focuses attention on CRH as an important mediator of the actions of leptin. The behavioral and metabolic effects of CRH are similar to those produced by leptin, and the anorexic effects of leptin are attenuated by CRH antagonists (394,401). In addition, central injection of leptin increases hypothalamic CRH content (401).

A variety of evidence demonstrates a close, inverse relationship between CRH and the feeding-stimulatory peptide NPY (396,402,403). Administration of CRH reduces NPY-elicited feeding as well as NPY gene expression in the ARC (404), and CRH antagonists enhance NPY feeding (396,402). In addition, adrenalectomy, which enhances CRH expression in the PVN, suppresses NPY mRNA in the ARC, and these effects are reversed by glucocorticoids (405,406). Thus, conditions associated with changes in eating behavior and body weight have opposite effects on CRH and NPY. These studies support the possibility that the effects of CRH may be mediated, in part, by inhibition of endogenous NPY, whereby a reduction in CRH release mediates the stimulatory effect of glucocorticoids on NPY. A role for leptin in this relationship between CRH and NPY is suggested by the evidence demonstrating a negative feedback loop between leptin and glucocorticoids (406).

Central CRH blockade also inhibits anorexia evoked by stress, such as physical restraint, suggesting a direct relation between endogenous CRH and stress-related changes in feeding (407,408). The actions of CRH on metabolism and energy balance, as well as gastric emptying, may also involve alterations in immune signals, particularly cytokines (393,409). This is reflected in the similarity of their effects, in the stimulatory effect of cytokines, such as IL-1, on CRH release and HPA axis, and in the essential role of CRH in the hypophagic effect of IL-1 and its impact on fever, thermogenesis, and ACTH release. The possibility of bidirectional communication is suggested by the influence of CRH on immune and inflammatory responses. Thus, the role of this peptide in energy balance must be evaluated in a broader context, as an integrator of the physiological responses to stress in relation to immunity and infection.

## E Enterostatin

Enterostatin (ENT) is the intestinal amino-terminal pentapeptide that is released from pancreatic procolipase in response to fat intake, with the remaining colipase serving as an essential cofactor for pancreatic lipase during the digestion of fat (410). Procolipase gene transcription and ENT release into the lymph and circulation are increased by high-fat diets. Also, systemically or centrally injected ENT selectively inhibits voluntary intake of fat as opposed to carbohydrate. This pentapeptide acts through sites in the brain as well as the periphery, and peripheral responses to ENT are dependent on an afferent vagal signaling pathway to the

brain (145,411,412). Systemically administered ENT activates neurons in the PVN, where injections of this peptide also reduce food intake, performing a function that parallels its actions in the gut (413).

An ENT circuit in the brain causes satiety through both serotonergic and opioid interactions in the brain (410). It inhibits the opioid system that promotes fat ingestion (282). Enterostatin antagonizes kappa agonists that stimulate fat intake, and, conversely, a kappa agonist (U50488) at low doses can interfere with the suppression of fat intake normally caused by ENT. Also, both ENT and kappa antagonists suppress an animal's choice of fatty food. Thus, York and Lin (413) propose the existence of a kappa opioid system in the PVN that controls appetite for fat and that is inhibited by ENT. They also demonstrate that ENT reduces the consumption of a fat-rich diet induced by GAL, whereas it has no effect on NPY-elicited feeding (414). This is consistent with the evidence showing endogenous GAL to be stimulated by high-fat diet consumption, while NPY expression is reduced (see Sec. III). As described below, the GAL-ENT-kappa system supported by this evidence may control the balance between DA and ACh in the NAc for the promotion and inhibition of instrumental responses for fatty food (see Sec. VI).

A possible role for ENT in obesity is indicated by evidence that chronically administered ENT reduces fat intake and body fat accrual (415). This effect may result from multiple metabolic actions of ENT. These include a decrease in insulin secretion, activation of the sympathetic nervous system and stimulation of the HPA axis. Studies show low ENT production or responsiveness in rats that are fat preferring and become obese. In humans, there is some evidence that obesity is associated with reduced secretion of pancreatic procolipase (410) or ENT (416) after a test meal.

## F Neurotensin

Neurotensin (NT), a 13-amino acid peptide, increases in the plasma of humans after eating a meal, and the increase is significantly larger if the meal is hot and palatable rather than cold and poorly accepted (417). When NT is injected peripherally in rats, there is no compelling evidence that it causes satiety by itself (418), although large doses are reported to inhibit feeding and grooming behaviors (419). Peripheral NT may act physiologically in synergy with other satiety peptides normally released at the same time.

When injected into the PVN-MH region, NT decreases food intake, provided the active portion of the

peptide chain is used (418,420). It also inhibits the orexigenic effect of MCH, but has no impact on NPY (421). Neurotensin is expressed and synthesized in the ARC, PVN and DMN. Its expression in the hypothalamus is elevated in rats consuming a high-carbohydrate diet (422) and is reduced in association with the development of obesity in *ob/ob* mice and *fa/fa* rats (423,424). There is evidence that NT may be involved in mediating the central effect of leptin on feeding. Both NT antiserum and NT receptor antagonist completely block the inhibitory effect of leptin on food intake (425). Further, leptin injection stimulates NT expression in the hypothalamus (426) and potentiates NT's satiety-producing effect (427). In fat-preferring rats, NT concentrations in the PVN are increased and positively correlated with elevated levels of leptin (427).

This peptide interacts closely with the monoamines, which are reviewed in more detail in Section V below. Neurotensin modulates hypothalamic NE release (428) and inhibits feeding induced by NE (420). In the mesolimbic system, NT is colocalized with DA in neurons that project from the VTA to the NAc. Neurotensin iontophoresed into the VTA increases DA cell firing rate. These clues have led to the demonstration that rats self-inject NT into the VTA (429). Repeated NT injections in the VTA sensitize animals to the hyperactivity produced by subsequent injections, due to increased responsiveness of DA neurons (430). In the posterior, medial NAc where NT is coreleased with DA, injections of NT are like CCK in potentiating self-stimulation (431). On the other hand, NT in parts of the NAc can prevent dopaminergic effects and, thus, alter motivation. Glucocorticoids may also affect motivation by acting on peptide expression in the NAc (432).

## G Apolipoproteins

Apolipoprotein A-IV (apo A-IV) is a glycoprotein produced by the small intestine and released into the blood in response to a lipid meal (433–436). The increased synthesis of apo A-IV in response to fat absorption, rather than related to the uptake or reesterification of fatty acids to triglycerides, is induced by the formation of chylomicrons. It may also be responsive to a factor from the ileum, probably peptide tyrosine-tyrosine (PYY). The evidence that other apolipoproteins in the intestine are unresponsive to fat consumption indicates a specific role for apo A-IV in relation to dietary fat. After systemic or central administration, apo A-IV causes a significant, dose-dependent suppression of feeding. Since the secretion of apo A-IV is rapid, this protein

may play a role in the short-term control of food intake, acting as a circulating satiety signal produced specifically by a high-fat meal. Apo A-IV may also be involved in the long-term regulation of food intake and body weight. Chronic ingestion of a high-fat diet blunts the intestinal apo A-IV response to lipid feeding, in conjunction with a rise in leptin. This suggests a possible mechanism whereby a high-fat diet promotes obesity. Pharmacological studies show that apo A-IV synthesis is reduced by leptin administration (436).

De novo synthesis of apo A-IV in the brain is under investigation (437). Studies support the possibility that apo A-IV released by the small intestine traverses the blood brain barrier, enters the cerebrospinal fluid, and is taken up by astrocytes (436). A recent investigation, however, has revealed apo A-IV mRNA in the hypothalamus, particularly in the ARC, and has demonstrated an increase in expression after consumption of a high-fat diet (438). The existence of apo A-IV in the ARC suggests a possible relationship with neuropeptides, such as NPY, in the control of feeding. This receives support from the finding that NPY injection stimulates the expression of apo A-IV in the hypothalamus (438). This is interesting in light of the evidence (436) that apo A-IV synthesis and secretion in the intestine are stimulated by PYY, a member of the peptide family that includes NPY. This peptide is believed to mediate the stimulatory effect of a high-fat diet on apo A-IV and possibly to act centrally by sending signals through the vagus nerve.

There is evidence that another apolipoprotein, apo D, may also have a role in body weight regulation. In contrast to other apolipoproteins, apo D is heavily expressed in the brain, most abundantly in the hypothalamus, and it exists at low levels in peripheral tissues (438). To clone genes that regulate food ingestion and body fat accrual, a recent study (438) used both representational difference analysis to identify genes responsive to dietary fat and the yeast two-hybrid system to isolate proteins that interact with the leptin receptor, Ob-Rb. This report demonstrates that apo D mRNA in the hypothalamus is stimulated by consumption of a high-fat diet. Moreover, this protein interacts with the cytoplasmic portion of Ob-Rb and not with the short-form receptor, Ob-Ra. Anatomical studies show that apo D and Ob-Rb are coexpressed in neurons and other cell types in the ARC and PVN (438). In addition to being stimulated by dietary fat, hypothalamic apo D mRNA is elevated in rats and inbred mice that become obese on a high-fat diet. This phenomenon may occur in response to changes in leptin and body fat, which are also

increased and strongly, positively correlated with apo D mRNA. This positive association with body fat, however, is lost in obese *ob/ob* and *db/db* mice, which exhibit markedly reduced levels of hypothalamic apo D mRNA compared to that of wild-type mice. This suggests a role for apo D in obesity on a high-fat diet.

Although designated an “apolipoprotein,” apo D is atypical in that it actually belongs to the lipocalin family of proteins that bind and transport small hydrophobic ligands (5,439–441). However, the specific ligand to which apo D binds has not been unequivocally identified. Numerous reports suggest that it may bind to a variety of small molecules (5,442). That apo D binds with progesterone in breast cyst fluid (443) and with an axillary odorant in apocrine glands (444) suggests that the ligand may be specific to the tissue or cell type where apo D is expressed. In hypothalamic neurons, apo D may have a specific ligand where it exerts signaling functions similar to that of other apolipoproteins (445). This putative ligand may be produced as a consequence of the leptin stimulation of Ob-Rb. In fact, previous work has suggested the existence of a ligand generated following the activation of Ob-Rb (446). This apo D-specific ligand may be either a small molecule that functions as a paracrine signal within particular hypothalamic nuclei or a hormone that enters the circulation, possibly via the pituitary, where both apo D and Ob-Rb are expressed in moderate levels. Pregnenolone may be one such candidate that deserves further investigation as a specific ligand that binds apo D in the hypothalamus and participates in body weight regulation. This steroid is present in the brain and associates with apo D with high affinity (447,448). Further, its production is modulated by leptin (449), and high plasma levels of pregnenolone are associated with hyperphagia in rats (450) and obesity in humans (451). Taken together, this evidence suggests that apo D in the hypothalamus is involved in the leptin/Ob-Rb signal transduction pathway and that a deficiency of apo D protein contributes to the development of obesity, particularly on a high-fat diet (438). This proposed function of hypothalamic apo D is consistent with previous reports that a *Taq I* apo D polymorphism is linked to obesity and hyperinsulinemia, as well as to non-insulin-dependent diabetes mellitus, a condition commonly associated with obesity in animals and humans (438).

## H Glucagon

Glucagon is released from the pancreas during a meal (452,453). Pharmacological studies indicate that portal

vein administration of glucagon reduces the size of spontaneous meals, whereas highly specific glucagon antibodies increase meal size, suggesting a physiological role in controlling food intake. The mechanism for glucagon's satiety action may involve signals within the liver, as well as the hepatic branch of the abdominal vagus. Further studies are needed to determine whether glucagon acts via stimulation of hepatic glucose production or fatty acid oxidation. The finding that this pancreatic peptide interacts synergistically with other gut-brain peptides, such as CCK, suggests that it may contribute in a complex manner to the array of peripheral signals controlling meal size. There is evidence that hyperglucagonemia in the tumor-bearing state may be the most important hormonal alteration causing anorexia and abnormal carbohydrate metabolism, effects reversed by inhibiting glucagon secretion (88).

## I Glucagon-like Peptide 1

The peptide hormone, glucagon-like peptide 1 (GLP-1), results from posttranslational processing of proglucagon in the gastrointestinal tract (454). It is secreted into the circulation, in a vagal-dependent manner, in response to the ingestion of meals, primarily fat and carbohydrates. This peptide, functioning through several diverse but complementary physiological systems, plays an important role in the control of blood glucose levels (454). It lowers circulating glucose by stimulating insulin secretion and inhibiting glucagon secretion, thereby decreasing hepatic glucose production. It also inhibits gastric emptying and gastric acid secretion.

Whereas circulating GLP-1 may have central effects through receptors in the area postrema and subfornical organs, recent studies indicate that GLP-1 is also synthesized in the brain (454–456). Neurons expressing GLP-1 exist in the brainstem, mainly the solitary tract, and send projections to different nuclei of the hypothalamus, where its receptors are concentrated. Central administration of GLP-1 inhibits feeding, while a GLP-1 antagonist stimulates feeding, enhances NPY-elicited feeding, and blocks leptin-induced inhibition of food intake, suggesting a physiological role (457, 458). A possible site of action is the PVN, where the peptide's receptors are concentrated and the immediate early gene, *c-fos*, is stimulated by GLP-1 (457,459). This and other evidence has led to the hypothesis that GLP-1 is a natural mediator of satiety, possibly responding to the postmeal rise in circulating glucose levels. This idea is supported by the finding that the feeding-suppressive effect of this peptide is strongest in rats fed a high-carbohydrate diet, which raises

glucose levels (460). In addition, acute onset of anorexia occurs in animals receiving transplantable glucagonoma tumor lines, which produce highly elevated levels of proglucagon mRNA and plasma GLP-1 and glucagon (461).

A possible role for GLP-1 in obesity is suggested by evidence that chronic administration of GLP-1 reduces feeding and body weight, and a GLP-1 antagonist produces the opposite effect (409,456,462). Also, obese subjects exhibit lower levels of GLP-1 in response to a meal (463). However, the involvement of this peptide in normal body weight regulation is not substantiated by genetic studies (454,464). Targeted disruption of the GLP-1 receptor gene has little effect on feeding and weight gain in mice, even after several months on a high-fat diet, despite fasting hyperglycemia and reduced insulin secretion. Moreover, a combined disruption of leptin and GLP-1 action produces mice of comparable body weight to those with leptin deficiency alone. Also, transgenic mice with sustained elevations in circulating exendin-4, a potent GLP-1 agonist, eat normally.

An alternative possibility is that GLP-1 acts on neurons involved in the stress response (454,465). Central administration of GLP-1 produces conditioned taste aversion and has aversive side effects. It induces similar patterns of neuronal *c-fos* activation to that caused by lithium chloride, which can be blocked by a GLP-1 receptor antagonist. Further, deletion of the GLP-1 receptor gene results in an exaggerated CORT response to restraint stress. The available evidence indicates that different central pathways mediate GLP-1 induced satiety and taste aversion (465). This peptide is a likely candidate in mediating cancer-induced anorexia (88).

## J Cholecystokinin

As an integrative peptide for satiety, CCK has parallel functions in the gut and certain brain regions, such as the PVN-MH (466–471). This peptide also has roles in the mesolimbic DA system, which provides a challenge to any simple overall explanation of function (472).

Although CCK-8 is the form of the active peptide that is typically studied in paracrine and neurotransmitter research, CCK-33 is more effective in the periphery due to its endocrine actions at distant sites including the liver (473). This peptide can stimulate the release of OT, which in rats is involved in nausea (474,475). However, CCK satiety without nausea has also been demonstrated (461,472,476,477). The overall effect of CCK at an appropriate dose in humans is to suppress

food intake without nausea (478,479). As further evidence for CCK satiety, CCK antagonists can increase food intake when given peripherally or locally in regions, such as the PVN-MH (480).

Functioning as a paracrine hormone, CCK is released from secretory cells and nerve fibers in the upper intestine, where it works locally to stimulate pancreatic secretion and gallbladder contraction. The peptide also inhibits gastric emptying by constricting the pyloric sphincter (470). Receptors for CCK involved in feeding suppression exist, for example, in the pyloric sphincter, the sensory vagus nerve where they are transported to vagal nerve terminals, and the PBN and PVN. These sites may all be part of a CCK pathway involved in the control of feeding. The sequence of events after a meal to promote satiety may include the release of peripheral CCK, which acts on vagal nerve endings in the gut, followed by signals to the hindbrain and hypothalamus through central CCK neurons.

To suppress feeding, CCK in the PVN may act by counteracting the  $\alpha_2$ -noradrenergic feeding response, synergizing with 5HT (481,482) or leptin (14,471), and interacting with  $E_2$  during the estrous period (439,483). There is evidence that CCK's satiating action increases during estrus in female rats (484) and is attenuated by consumption of a high-fat diet (485). The hypothalamic output under the influence of CCK is presumably biased to adjust the hindbrain centers to stop feeding reflexes. The PVN projects back to the vagal motor nucleus, where there are cells excited by CCK. This may involve a hindbrain DA-CCK interaction (486). The vagal output, in turn, projects back to the gastrointestinal tract. Technical approaches used to demonstrate this circuit include CCK suppression of sham eating, sphincter extirpation, selective vagotomy, CCK receptor binding, local CCK brain injections, receptor antagonists, c-Fos immunoreactivity, and electrophysiological recording (469,470,487–490). Thus, CCK acts in both the body and the brain, and it sends neural information from one to the other but does not seem to cross the blood brain barrier. The primary receptor for CCK satiety is the CCK<sub>A</sub> subtype, which has the same sequence and overall function in the brain and body (491,492). Mice lacking the CCK<sub>A</sub> receptor are hyperphagic, diabetic, and obese (493). An antagonist of the CCK<sub>A</sub> receptor can attenuate satiety without affecting preference conditioning, suggesting separate mechanisms (494).

Cholecystokinin can inhibit the learning of food incentives (495). Rats perform fewer responses for food if they have prior experience performing the response under the influence of CCK injections. Apparently,

CCK can devalue the incentive properties of food in hungry animals, and this is manifest later when the animals work for less of that food. Similarly, CCK is more effective at suppressing the intake of a flavored solution if the flavor is linked to a caloric reward, ethanol (496). Given that a flavor paired with calories can release DA in the NAc (497), CCK through the circuitry of Figure 2 may inform the brain of “nutritive expectations” (496). The hypothalamus may be one region where CCK can inhibit conditioned mesolimbic DA release. When injected into the PVN, CCK inhibits DA release in the NAc. It also synergizes with 5HT to release accumbens ACh, which apparently contributes to satiation by counteracting DA (498).

Some of the mesolimbic DA neurons contain CCK as a cotransmitter. Thus, CCK is a neurotransmitter in some DA projection sites, such as the NAc (499). The NAc has intrinsic CCK neurons as well. There are studies showing the effects of satiety peptides on dopaminergic reinforcement processes, as reflected in hypothalamic self-stimulation (500). Ventricular injection of CCK-8 decreases self-stimulation as one might predict for a satiety factor when self-stimulation is related to appetite. However, the same dose of CCK increases self-stimulation rate when injected into the posterior, medial NAc, where CCK is a DA cotransmitter. One may speculate that CCK potentiates some of the reinforcing effects of DA when the two are released together in the NAc. Thus, CCK in the posterior, medial shell of the NAc is probably involved in locomotion and in some aspects of the primary or secondary reinforcement of eating (501).

### K Bombesin

Soon after bombesin (BBS) was found in the mammalian gut, the satiety properties of this peptide were discovered (502). The evidence suggests that BBS-like peptides fit most of the criteria for an integrative peptide with parallel functions in the body and brain (503). Peripheral BBS shortens meals and lengthens the time to the next meal, without behavioral or subjective signs of illness (504). Central injection of BBS into different sites of the hypothalamus and forebrain also reduces feeding (505,506). There exist several BBS-like peptides, such as gastrin-releasing peptide and forms of neuromedin, which may act within the brain or body (507). Peripherally administered BBS can stimulate the release of gastrin, CCK, insulin, and other gut peptides that contribute to satiety. When given chronically on an appropriate schedule, BBS can cause weight loss (508). Evidence that BBS receptor knockout mice become

obese (509) suggests a role for this peptide in body weight regulation.

### L Neuromedin U

Neuromedin U (NMU) is a neuropeptide that is distributed throughout the gut and brain (510). Peripheral activities of NMU include regulation of adrenocortical function and stimulation of smooth muscle. Two NMU receptors have recently been identified. These are G-protein-coupled receptors, with NMU1R expressed predominantly in peripheral tissues and NMU2R in specific regions of the brain, including the PVN and the ependymal layer of the third ventricle (510). Neuromedin U is expressed in the VMH, and fasting downregulates NMU mRNA. Moreover, intracerebroventricular injection of NMU markedly suppresses food intake and body weight in rats (510,511), while anti-NMU antiserum increases feeding (512). Central injection of NMU also stimulates activity level, body temperature, and heat production (511). These findings suggest that NMU, a potent anorexic peptide, is a catabolic signaling molecule in the brain, possibly involving neural mechanisms in the ventromedial region of the hypothalamus.

### M Amylin

Amylin, also known as islet amyloid polypeptide, is a 37-amino acid peptide with extensive sequence overlap with calcitonin gene-related peptide (513). It is coreleased with insulin from pancreatic  $\beta$ -cells in response to a variety of stimuli. These include meal ingestion and elevated blood concentrations of glucose, arginine, and  $\beta$ -hydroxybutyrate.

Amylin has multiple biologic actions related to glucose (513,514). Although it is coreleased with insulin, it inhibits insulin secretion and counteracts insulin's metabolic actions. In vivo studies indicate that amylin alone stimulates glycogenolysis, decreases glucose uptake, enhances blood glucose and lactate levels, and induces insulin resistance, although these effects generally require supraphysiological concentrations. In addition to altering glucose homeostasis, peripheral injections of amylin reduce food intake in rodents (514). Unlike the satiety actions of CCK, this effect of amylin is not altered by abdominal vagotomy, nor is it mediated by a change in gastric emptying. Precise meal pattern analyses reveal a specific action of amylin on the satiety processes at the end of a meal, rather than on feeding rate or on the size and duration of subsequent meals (515). Amylin and insulin, cosecreted by pancreatic

$\beta$ -cells in response to a nutrient stimulus, interact to reduce food intake and, ultimately, body weight (516).

Amylin, like insulin and leptin, is synthesized peripherally and is rapidly and efficiently transported across the blood brain barrier into discrete brain regions, including the hypothalamus, where amylin binding sites are located (517–519). Central injection of amylin suppresses feeding behavior (520,521). Moreover, repeated intracerebroventricular injections of this peptide potently and dose-dependently reduce daily food intake, weight gain, and body fat accrual (522). Insulin and amylin combine synergistically to reduce food intake, leading to the proposal that amylin, like insulin and leptin, is a circulating adiposity signal to the brain (520). Systemic administration of amylin causes a rise in hypothalamic concentrations of 5HT, and it reduces forebrain DA metabolism (523). Thus, amylin may act centrally, through these and other neurochemical changes, in the long-term regulation of food intake and energy balance. This hypothesis receives further support from the finding that repeated injections of an amylin antagonist into the third ventricle increase feeding, adiposity, and circulating insulin levels (522). In addition, targeted deletion of the amylin gene, resulting in amylin deficiency, also stimulates weight gain (524).

Amylin function is disturbed in both type I insulin-dependent and type II insulin-independent diabetic conditions (513). This peptide is the predominant component of the amyloid deposits in the pancreatic islets of type II diabetic patients. These excess peptide concentrations may contribute to disordered glucose homeostasis, e.g., glucose intolerance and insulin resistance, suggesting that amylin antagonists may be potential therapeutic agents in these patients. Type I diabetes, however, is associated with decreased production of amylin and decreased release after a meal. In this condition of insulin insufficiency, intravenous infusion of an amylin analog may help to reduce postprandial hyperglycemia.

## N Calcitonin

Calcitonin belongs to a family of peptides that include calcitonin gene-related peptide (CGRP), adrenomedullin, and islet amyloid polypeptide. These peptides are each found to reduce food intake when centrally injected (521,525–528). The hypothalamus is a main target site for calcitonin-induced anorexia, and it contains high concentrations of calcitonin receptors. As indicated above, CGRP is structurally similar to amylin, and these peptides have similar biological effects, including feeding suppression. Consumption of a high-

fat meal causes a significant rise in circulating CGRP levels. In obese women, plasma CGRP concentrations are found to be elevated (529).

## O Prolactin-Releasing Peptide

Until recently, the hypothalamic peptide hormone regulating the secretion of PRL from the anterior pituitary was unknown. A new peptide, prolactin-releasing peptide (PrRP), has been identified which is proposed to perform this function (530). This peptide, however, is not found in the external layer of the ME, precluding its role as a classical hypophysiotropic hormone. Additional studies, however, suggest that this peptide has other functions related to energy homeostasis. The expression of PrRP is concentrated in the DMN and brainstem, with PrRP receptor mRNA highest in the DMN and PVN (531). A recent study shows that PrRP and mRNA is reduced in obese Zucker rats (532) and in situations of negative energy balance, including fasting and lactation (516), when leptin levels are low. Moreover, central administration of PrRP reduces food intake and weight gain, producing its strongest effect after injection into the DMN (516,533). Further, *in vitro* studies demonstrate a stimulatory effect of PrRP on the release of  $\alpha$ -MSH and NT, two feeding-inhibitory peptides (533), suggesting possible mechanisms through which this peptide may act to control feeding behavior.

## P Oxytocin and Vasopressin

An oxytocinergic pathway for the inhibition of feeding has been suggested (474,534). Pituitary OT in rats inhibits food intake under conditions other than normal satiety, e.g., in states of nausea or dehydration. Central OT injections reduce food intake as well as sodium appetite (535–537). Also, OT receptor antagonists stimulate feeding (538). Arginine vasopressin replaces OT for these functions in primates and, like OT, inhibits feeding in rats (539,540). This feeding-suppressive effect of AVP is not affected by vagotomy, indicating that its peripheral mechanisms of action are different from those of CCK and ENT (541).

Evidence suggests the involvement of other neuromodulators in OT's action. These include 5HT, which has a stimulatory effect on the release of OT. d-Fenfluramine increases pituitary OT release via the PVN and inhibits it via the DMN (542), suggesting a possible function of OT in the action of this serotonergic anorexic compound. The peptide CRH also stimulates OT, which may be an additional factor

underlying its feeding-suppressive effect (543). Conversely, brain GAL, which stimulates feeding, plays a role in inhibiting pituitary OT release (544).

### **Q Acidic Fibroblast Growth Factor**

Acidic fibroblast growth factor (aFGF) is one of several growth factor peptides that do more than promote mitosis and tissue repair (545). It facilitates learning and memory and, in addition, inhibits eating behavior (546). Proof of a role in satiety comes from an increase in nighttime eating in rats given aFGF antibodies. This peptide is found in both the body and brain, where it is synthesized and released from storage sites in ependymal cells of the gut and ventricular walls. When aFGF is released into the CSF by a meal, it permeates the hypothalamic structures and inhibits the same glucose-sensitive cells in the LH that are inhibited by glucose itself. Evidence suggests that blood glucose stimulates both insulin release from the pancreas and aFGF release from the ventricular lining, with both cooperating in the inhibition of eating via hypothalamic mechanisms. There is evidence that an aFGF increases the release of CRH which, in turn, activates sympathetic outflow after feeding (547). This idea is consistent with the fact that exogenous and endogenous aFGF both induce reactions similar to the integrated physiological responses induced by CRH (see above).

### **R Cyclo(His-Pro)**

Cyclo(His-Pro) is a dipeptide derived from TRH. It is distributed widely throughout the brain and gastrointestinal tract (548). This dipeptide at high doses reduces food intake and causes a reduction in body weight (548). Levels of cyclo(His-Pro) are increased in the LH of obese Zucker rats, and these elevated levels are reduced by dehydroepiandrosterone, which itself reduces feeding and weight gain (549). Plasma levels are altered by oral glucose ingestion, and administration of cyclo(His-Pro) causes higher insulin levels, possibly by decreasing hepatic insulin clearance (550). There is evidence (551) that decreased levels of cyclo(His-Pro) may contribute to the hyperinsulinemia of obesity.

## **V BIOGENIC AMINES IN THE CONTROL OF EATING BEHAVIOR AND METABOLISM**

The peptide systems in the hypothalamus, reviewed in Sections III and IV, are modulated by the biogenic amines. Apparently, the monoamines potentiate or

“prime” different systems at different times. For example, one major role is to impose a circadian rhythm on the feeding systems. Biogenic amines may also selectively potentiate subsystems for selection of specific macronutrients, which vary across the light-dark cycle. Norepinephrine has another feature of particular interest. This monoamine can modulate opposing systems depending on which noradrenergic pathway is active and which receptors are upregulated at the time. Remarkably, changes in receptor binding and gene expression can occur in a matter of hours and perhaps minutes. These and other mechanisms of action are reviewed below.

### **A Norepinephrine**

There is support for a strong circadian rhythm of hypothalamic norepinephrine (NE) and its receptors, suggesting that it plays an important role in the animal's overall state of arousal. Measurements of NE release, receptor activity, and neuronal firing demonstrate a peak at the onset of the natural feeding cycle (420,552). The more excited the animal becomes, the faster noradrenergic neurons fire (553). While this suggests a general role for NE in brain arousal and selective attention, NE additionally modulates specific types of motivation, such as food consumption.

Hypothalamic injections of NE can have very specific behavioral effects (554–556). When injected into the PVN, it enhances lab chow intake, and when a choice of macronutrients is allowed, NE causes a preferential increase in the ingestion of carbohydrate, compared to fat or protein. This catecholamine induces feeding via  $\alpha_2$ -noradrenergic receptors concentrated in the PVN. Local injections of antagonists of  $\alpha_2$  receptors reduce feeding. The strongest effect of NE can be seen at the onset of the natural feeding cycle, showing that natural rhythms are critical in understanding its function. The same is true for peptides, notably NPY, with which NE coexists.

The arousal effect of NE is consistent with its close interaction with the adrenal steroid, CORT (42,556). Blood levels of this glucocorticoid rise just prior to the active cycle when it has an important role in arousal. It also activates the NE system in the PVN by potentiating  $\alpha_2$ -receptor binding and increasing NE-induced feeding responses. The rise in circulating CORT coincides with a natural rise in extracellular NE in the PVN at the onset of the active period (552,557), in association with an increase in appetite for carbohydrate (51). Also, CORT fosters a rise in blood glucose as it potentiates carbohydrate intake (42), which in turn

has a stimulatory effect on  $\alpha_2$ -receptor-binding sites in the PVN (558).

As a consequence of this relationship with CORT and perhaps other feeding-stimulatory neurochemicals, NE injections in the MH region have effects that are similar to those produced by lesions in this region, including increased food intake, parasympathetic activity, and body weight gain. Therefore, it appears that NE inhibits, and MH lesions destroy, various satiety signals (559) and sympathetic functions (560). The dorsal noradrenergic bundle may be a source of the NE that acts via  $\alpha_2$ -receptor sites to inhibit satiety and increase eating (559).

There are several studies suggesting that NE stimulation of hypothalamic  $\alpha_2$  receptors contributes to the development of obesity. Norepinephrine increases body weight in rats after repeated injections into the PVN, which cause hyperphagia for carbohydrate (561). Moreover, in a recent study (562), chronic NE infusion in the VMH produces a full set of changes characteristic of obese, insulin-resistant animal models. Norepinephrine increases feeding and body fat accrual, causes marked endocrine changes, including hyperinsulinemia, hyperleptinemia, and hypertriglyceridemia, and affects metabolism, producing increases in white adipocyte activities, whole body fat oxidation, and glucose intolerance. In obesity-prone Sprague-Dawley rats, a variety of disturbances in the hypothalamic noradrenergic system are evident, supporting its role in obesity (563,564). Obesity-prone subjects have higher levels of circulating NE, reflecting a decline in NE turnover and low sympathetic nervous activity, an increase in glucose-stimulated NE, and an altered ratio of  $\alpha_2/\alpha_1$  noradrenergic receptors in the hypothalamus (565). In an animal model of the Dutch famine during World War II, male rats born of mothers deprived of food early in pregnancy grew up to be overweight and have increased NE in the PVN (566). Disturbances in the hypothalamic noradrenergic system are also detected in genetically obese *ob/ob* or *fa/fa* rodents. Compared to their wild-type controls, they have higher levels of medial hypothalamic NE, reduced NE turnover, increased  $\alpha_2$ -receptor binding, and greater responsiveness to the feeding-stimulatory effect of NE or the  $\alpha_2$ -agonist, clonidine (567–571). Increased VMH noradrenergic activities are also associated with other glucose-intolerant conditions that accompany seasonal, genetic or experimentally induced obesity (562).

In contrast to NE's feeding-stimulatory action on  $\alpha_2$ -noradrenergic receptors, the  $\alpha_1$ -receptor subtype in the PVN mediates feeding suppression (555,572). Injections of  $\alpha_1$  agonists reduce food consumption, while specific

$\alpha_1$ -receptor antagonists stimulate feeding. A notable example of a drug that acts on these receptors is phenylpropanolamine. It is effective in the short term in reducing body weight (573) and inhibiting feeding by acting on  $\alpha_1$  receptors in the PVN (574). The density of both  $\alpha_1$  and  $\alpha_2$  receptors can vary with body weight (565), which provides support for their role in weight regulation. Radiolabeled anorexic drugs can be used to mark sites in the brain where they bind (575). AMPH and mazindol bind particularly well in the PVN and VMH. This binding is reduced by food deprivation in association with a decline in blood glucose. The phenomenon is similar to a glucose-dependent decline reported for  $\alpha_2$ -receptor binding in the PVN (78). Based on this, it was hypothesized that anorexic drug binding inhibits  $\alpha_2$  receptors, thereby reducing carbohydrate intake (575). AMPH is also effective in the LH via other monoamine receptors, as discussed below.

Whereas the focus of these studies has been on NE's action on  $\alpha_1$ - and  $\alpha_2$ -noradrenergic receptors in the MH, there is evidence that the LH responds differently. In the PFLH, NE or epinephrine suppresses feeding behavior via  $\beta$ -adrenergic receptors (576,577). Destruction of a subset of noradrenergic and adrenergic neurons, which project in part to the hypothalamus, causes hyperphagia and body weight gain (573,578). This selective lesion of the ventral noradrenergic bundle also disinhibits LH self-stimulation and reduces AMPH-induced anorexia (579). Thus, adrenergic inputs can have different effects on feeding depending on the site of innervation and the receptors that predominate. As a general rule,  $\alpha_2$  receptors foster feeding, while  $\alpha_1$ - and  $\beta$ -adrenergic receptors reduce feeding. This pattern of control in the brain may have its counterpart in the periphery, where the net lipolytic effect of catecholamines is dependent on a similar functional balance between  $\alpha_2$ - and  $\beta$ -adrenergic receptors in fat cells (580). Whereas genetically obese rodents show greater responsiveness to the feeding-suppressive effects of a  $\beta_3$ -agonist, they exhibit reduced activity of the  $\beta_2$ -adrenergic receptors that decrease feeding (571).

## B Serotonin

As with NE, circadian changes in the firing rate of serotonergic neurons suggest that they also play an important role in the animal's overall state of arousal and feeding pattern. An animal's level of excitement rises as 5HT neurons fire faster (553). Serotonergic activation is most evident at the onset of the natural feeding cycle. Central injection studies show that 5HT, specifically at this time, suppresses food intake, prefer-

entially carbohydrate intake, by an action on MH nuclei, including the PVN and VMH (581,582). There is evidence that serotonergic drug treatment can also reduce intake of dietary fat (583). Microdialysis studies show a significant increase in extracellular 5HT release during the meal (584), as well as before the meal in response to the sight and smell of food (584,585). Additional 5HT is released as the animal consumes the food, but it declines over the next 30 min to baseline levels. This time course is consistent with an anticipatory and short postingestive satiety effect for 5HT, rather than a long-lasting action.

Evidence strongly suggests that 5HT potentiates systems that respond to postingestive signals. Microdialysis in the PVN/VMH region demonstrates that a carbohydrate meal is particularly effective in releasing 5HT, whereas a protein or fat meal has the opposite effect (586). Serotonin and DA release are related to satiety in normal rats and Zucker rats (587–589). A conditioned aversive taste releases hypothalamic 5HT as part of a life-saving reaction to poisonous food (584). Hypothalamic 5HT also increases in response to peripheral tryptophan, d-fenfluramine, fluoxetine, and a low-dose AMPH challenge after lithium treatment. The results indicate roles for 5HT in pharmacotherapy for appetite, depression, and bipolar disorder (590–592). Disturbances in the serotonergic system in relation to overeating and obesity are indicated by the finding that obese rodents have decreased hypothalamic levels of the 5HT metabolite, 5-hydroxy-3-indole acetic acid and they exhibit decreased responsiveness to 5HT administration (567–570,593,594).

Biogenic amines often have effects that depend on other local neurochemical signals. Hypothalamic 5HT may act in synergy with other peptides that produce satiety (595), acting when postingestive signals are present to release cofactors, such as CCK, in the hypothalamus. This peptide may come from serotonergic neurons as a cotransmitter and have longer-lasting effects on feeding than the monoamine alone. CCK may also be released in the hypothalamus in response to vagal inputs that are relayed from the stomach to the hypothalamus (578). The proposal that 5HT and CCK work together is further supported by the finding that 5HT receptor blockers antagonize CCK's anorexic effect (439,472), and conversely, a CCK antagonist blocks 5HT's effect (596). Serotonin and CCK injected together into the PVN have a superadditive effect in the NAc by releasing ACh that inhibits eating behavior (498).

The compound d-fenfluramine is an anorexic drug that is a 5HT reuptake blocker at low doses and a

releaser of 5HT at higher doses (597–599). Consistent with results obtained with 5HT, the feeding-suppressive effect of d-fenfluramine is attenuated by various 5HT receptor antagonists (600). Thus, the actions of d-fenfluramine, or its active metabolite nor-fenfluramine, may involve specific 5HT receptors that provide some degree of behavioral specificity. d-Fenfluramine additionally increases background metabolism by enhancing utilization of the body's fuels (601). This increased metabolism contributes to weight loss. Owing to the toxicity of d,l-fenfluramine in combination with phentermine (602), attention has shifted to sibutramine. This NE and 5HT reuptake blocker fosters the sympathetic state, while attenuating NPY production and affecting the melanocortin system (603).

Serotonin may act, in part, via an inhibitory action on the  $\alpha_2$ -noradrenergic system of the MH (447,555). Serotonin and d-fenfluramine reduce the hyperphagic actions of NE in the PVN. This may explain why serotonergic drugs are used to treat carbohydrate craving and related obesity (448). The interaction between NE and 5HT may also be a mechanism through which these drugs inhibit a component of the self-stimulation system related to feeding reinforcement (449), thereby contributing to their appetite-reducing properties (450). However, in hamsters, long-term excess of NE and 5HT in the VMH leads to hyperinsulinemia and insulin resistance (604).

It is clear that there are other sites, besides the MH and LH regions, where 5HT acts in the control of feeding behavior and metabolism. For example, diets with an amino acid imbalance cause primary anorexia and conditioned taste aversion. This effect, which is blocked by 5HT antagonists, is mediated in part through actions in the piriform cortex (451). Serotonin also contributes to postingestive onset of satiety through brainstem structures (605), as well as through its potent actions in the periphery (606). In a genetic model of obesity, 5HT2C mutant mice overeat and gain weight in adulthood (97) and display reduced sensitivity to d-fenfluramine (607). Confirmation by pharmacological studies (608) has focused attention on this 5HT receptor subtype as a therapeutic target. However, there is abundant evidence that attacking multiple DA, NE and 5HT targets affords a better strategy for suppression of the appetite for food and drugs, if a safe combination can be found.

## C Dopamine

Dopamine and AMPH-related compounds have long been known to suppress feeding through their action in

the hypothalamus. However, the full story of DA's actions in the brain is only beginning to unfold. Dopamine has effects in the LH and MH. It also has powerful actions related to feeding behavior in other brain regions, notably the NAc where it is a behavior reinforcer and generates incentive motivation (Fig. 2).

### 1 Dopamine in the Hypothalamus

Hypothalamic DA contributes to AMPH-induced anorexia (609–611). This is of renewed interest due to the recent upsurge in the use of phentermine, which is a dopaminergic and noradrenergic drug (612). A variety of DA-related effects may occur in the hypothalamus, depending on the site of intervention and experimental technique used. Hypothalamic DA is released, in part, from an incertohypothalamic cell group, also MH neurons intimately involved in the control of pituitary functions (613), and from one or more DA cell groups (A8, A9, A10) with branches that ascend from the midbrain. Injections of DA in the LH suppress food intake, an action blocked specifically by DA receptor antagonists (609,610). Anorexic doses of AMPH injected in the LH increase extracellular DA, although NE and 5HT are also increased (614). All three monoamines may suppress feeding and mediate the actions of AMPH under different conditions (559, 577,584,611,615).

As further evidence of a DA satiety function in the LH, some compounds that block DA receptors stimulate eating behavior. This was demonstrated with the nonspecific receptor antagonist chlorpromazine and with the specific D<sub>2</sub> receptor antagonist sulpiride (559,616). Chronic peripheral injections of sulpiride cause hyperphagia and obesity in rats, analogous to the effect sometimes seen in schizophrenic patients undergoing antipsychotic treatment with D<sub>2</sub> antagonists (610,616). This effect may be due, in part, to dopaminergic control of pituitary functions, such as E<sub>2</sub> release (617), or to disinhibition of a behavior reinforcement system that leads to overeating. Sulpiride in the LH has locomotor and reward effects. Remarkably, rats will even self-inject sulpiride into their own LH (616). This suggests that DA agonists can act at hypothalamic D<sub>2</sub> receptors to inhibit instrumental responses, including responses involved in the reinforcement of eating.

In studies using microdialysis, the release of DA in the MH is positively correlated with eating behavior (618). It is proposed that taste and smell may enhance the release of hypothalamic DA at the start of a meal, to

organize autonomic reflexes for receiving food (619). Diabetic rats that are hyperphagic also exhibit enhanced DA turnover in the VMH (620). Thus, DA release may influence eating as well as satiety, depending on which DA system is activated and the state of their multiple receptor subtypes.

Recording studies in monkeys find taste-responsive cells in the hypothalamus that are sensitive to DA (621). Some of these cells are tuned to features of the animal's external environment. Other cells that are glucose sensitive are for monitoring the internal state (621). Cells in the hypothalamus, some of which are responsive to DA, influence feeding via an output that connects to the mesolimbic DA system. The mesolimbic system passes through the hypothalamus on its way to the NAc (Fig. 2). As a clear demonstration of this, a DA antagonist, sulpiride, injected in the LH causes the release of DA in the NAc (622).

### 2 Dopamine as a Behavior Reinforcer in the Mesolimbic System

Neurons projecting from the VTA to the NAc can reinforce behavior and are involved in generating the incentive to eat (622–626). This seems to be based on a dual role in instrumental and classical conditioning. Dopamine is released in the NAc by behavior, such as self-stimulation, psychostimulant self-administration, and eating (275,627–630). Self-stimulation or stimulation-induced feeding in the LH releases DA in the NAc, with or without food present (631). When food-deprived rats eat a meal, DA release in the NAc may be especially salient because the DA baseline level is low (382,386,632). In addition, DA can be released in the NAc by classically conditioned stimuli, as discussed below. As a meal continues, DA release diminishes, suggesting that it plays a larger role in initiating the meal and responding to food novelty than in maintaining a meal (264,633).

An increase in extracellular DA in the NAc can be a positive reinforcer. This is shown in rats with NAc cannulas for self-injection of AMPH or DA directly into that region (634,635). When rats self-administer cocaine intravenously, they respond in a manner that raises extracellular DA whenever it falls to a trigger level (636). Neurochemicals are reinforcers if they stimulate DA cells in the VTA, the prime examples being opiates, nicotine, and NT (637–640). This means that the mesolimbic DA system activates a reinforcement process (by definition, a reinforcer increases instrumental responding). Therefore, DA is probably a reinforcer when it is released by self-stimulation, drugs, or natural

behavior such as eating, mating, aggression, and associated stimuli. It appears from a teleological point of view that animals perform voluntary behavior in order to get the effects of DA release in the NAc and perhaps in other forebrain sites such as the PFC (641). Recording from VTA cells in the awake monkey suggests that neural activity signals a salient change in the environment (642). The debate as to whether DA creates a simple error signal, a reward (pleasure and liking), or an incentive (motivation and wanting) seems to hinge on which component of the ascending DA system is being addressed. Evidence is accumulating to indicate that DA in the NAc shell region generates "wanting," or what in the feeding field is usually referred to as appetite (625,643).

Dopamine in the NAc is also involved in reinforcing behavior to escape an aversive stimulus. Extracellular DA increases during MH stimulation escape behavior, but not during the same stimulation when it is inescapable (622). Thus, DA may be a negative reinforcer for active escape, as well as a positive reinforcer for active approach in feeding situations. Its role in these reinforcement processes could be incentive motivation.

### 3 Taste Reactions and Dopamine

Dopamine antagonists administered systemically or directly into the NAc block locomotion, instrumental behavior, and sucrose intake (241). Results with the DA antagonist raclopride are particularly interesting. An animal drinking sucrose, with a fistula so it never gets full, acts as if the sucrose has been diluted when treated with this DA blocker. The avidity for sweet taste diminishes when raclopride is given systemically or locally into the NAc (644). Reinforcement may involve both  $D_1$  and  $D_2$  receptors. The literature is not clear on this, due to the discovery of new receptor subtypes, the nonspecificity of some pharmaceutical agents, multiple facets of reinforcement, and multiple actions in many brain regions such as the hypothalamus and NAc (645).

A definitive role for mesolimbic DA has been demonstrated by neural recordings from DA cells in the VTA of awake monkeys. Some of the neurons that project to the NAc increase their firing rate during eating (646). As the monkey gains practice at the feeding task, neural activity precedes food presentation, coinciding with discriminative stimuli that are a sign of forthcoming food. Thus, with experience, DA release becomes allied with conditioned stimuli and perhaps with secondary reinforcers. This

suggests that mesolimbic DA in primates is involved in learning what, where, and when to eat, more than in the act of eating. Dopamine is an anticipatory signal that reflects novelty, and it may be one factor that makes satiety "sensory specific." A new taste can reinstate eating with the help of renewed DA release (647). The taste and anticipation may release DA in the NAc shell and core differentially (648).

### 4 Body Weight and Dopamine

Microdialysis shows that basal extracellular DA may be as low as half normal in rats at 80% of free-feeding body weight (382,386). Given the demonstration that rats respond for cocaine when accumbens DA decreases to a certain level (636), it is quite possible that animals also respond for food when DA reaches a low level. Drug self-administration, self-stimulation, and eating are all potentiated by food deprivation (273,649,650), and they all can increase extracellular DA in the NAc. It is therefore likely that animals or people with diminished amounts of DA, for any reason, may have a tendency to take foods or drugs that restore synaptic DA.

Although DA depletion in the nigrostriatal pathway causes aphasia and weight loss (651), rats can still eat when DA is depleted in the NAc. For example, 6-hydroxydopamine was used to deplete accumbens DA to 16% of normal, but the rats could still swallow a normal amount of sucrose when delivered directly into the mouth (486). Dopamine-depleted animals eat normally when the food is easy to get, but they opt not to perform difficult tasks (652). Rats that bar-press for cocaine and food pellets in alternation stop responding for the dopaminergic drug when DA is depleted, but they still bar-press for food (653). Apparently, accumbens DA serves partly as a priming signal that activates the systems needed for difficult tasks, for learning or switching behavior (654,655). For simple tasks, other areas such as the striatum, hypothalamus, midbrain, and brainstem may be sufficient. A decerebrate rat, with no forebrain at all, can still swallow food put in its mouth and reject it when full. Thus, the caudal brainstem participates strongly in neural control of feeding (656).

### 5 Classical Conditioning of Neurotransmitter Release

Dopamine that is released by a conditioned stimulus, such as a taste, a special place or even an advertisement, may prime instrumental behavior leading to more DA release. When DA is low, as during food restriction, a

conditioned stimulus is needed to release the initial DA and help start the behavior. Dopamine release in the NAc can be conditioned with food flavors. A flavor associated with intragastric feeding becomes a preferred flavor (657) that releases DA in the NAc (585). Conversely, a flavor that reminds the animal of lithium-induced nausea causes extracellular DA to decrease (658). Thus conditioned DA release in the NAc may play an important role in the animal's decision to approach or avoid food.

There are several components to behavior reinforcement. These include the facets people think of as motivation, drive, wanting, incentive, or willingness to work. In addition, they include the hedonic aspect involved in liking and pleasure and other related concepts, such as satisfaction. Researchers are currently engaged in the fascinating enterprise of dissecting out the roles of DA, as well as opioid peptides and other neurotransmitters, in these different aspects of the total reinforcement process (623,624,641,659–661).

## D Histamine

Histamine, which is synthesized from histidine, is well known for its role in regulating body temperature and stimulating drinking (662,663). Neuronal histamine, in addition, is involved in the regulation of feeding, mastication, and circadian rhythms (662,664–667). Peripheral histidine injections which increase brain histamine levels cause a concomitant decrease in food intake. Peripheral or ventricular administration of drugs which block histamine receptors enhance feeding. In the hypothalamus, food-deprived rats show increased levels of endogenous histamine, and obese rats exhibit reduced levels (668,669). Pharmacological activation of hypothalamic histamine suppresses feeding through the  $H_1$  receptor subtype. Sites of action include the PVN and VMH, areas richest in histamine and  $H_1$  receptors. Iontophoretic application of  $H_1$  antagonists suppress neuronal activity in these areas.

Sakata et al. (670,671) propose a role for hypothalamic histamine in the homeostatic control of energy stores. Fasting and 2-deoxy-D-glucose, as well as insulin-induced hypoglycemia, all stimulate the turnover of histamine. The essential stimulant is a reduction in glucose utilization and a consequent histamine-dependent decrease in brain glycogen to maintain brain glucose availability. A further role for histamine may be reflected in the impact of high ambient temperatures, which elevate hypothalamic histamine and suppress food intake (669). Histamine injected into the preoptic

area reduces body temperature (672). This process of histaminergic thermoregulation raises the possibility that this biogenic amine is also involved in the changes in ingestive behavior and body temperature induced by EL-1 $\beta$ , which is released in response to infection, injury and inflammation (669). Ventricular injection of the cytokine suppresses food intake and induces thermogenesis (673,674). These responses, which are accompanied by a rise in histamine turnover, are attenuated by depletion of neuronal histamine in the hypothalamus (675). Histamine may mediate the anorexic action of some peptides, such as amylin (676). The finding that Zucker fatty rats have lower hypothalamic levels of this biogenic amine and are unresponsive to the feeding-stimulatory actions of histamine receptor antagonists (668,677) provides support for a role of central histamine in obesity.

## VI ACETYLCHOLINE AND AMINO ACIDS IN FEEDING-RELATED CIRCUITS

It has long been known that nicotine in cigarettes suppresses appetite, and smoking cessation leads to increased body weight. Thus, acetylcholine, acting on nicotinic receptors, is particularly relevant to the discussion of obesity. Amino acids are very important in several contexts, including neurotransmission that controls meal size in the hypothalamus. In addition to their direct actions, new evidence suggests that the brain can detect amino acid imbalance in the diet and, thereby, affect food choice.

### A Acetylcholine

Acetylcholine (ACh) has several roles at nicotinic as well as muscarinic receptors in the circuits that control eating. In the LH, the muscarinic agonist carbachol potentiates eating and drinking (395,678–680), and cholinergic drugs influence locomotion related to eating (681). Hypothalamic stimulation that supports self-stimulation or stimulation-bound eating causes the release of ACh in the VTA (682). Figure 2 shows this circuit by which cholinergic cells of the midbrain project onto DA cell bodies of the VTA. When injected into the VTA, antisense to the M5 muscarinic receptor blocks LH self-stimulation, and atropine also suppresses self-stimulation and feeding (682,683). Nicotine in the VTA, as well as the NAc, stimulates the release of DA in the NAc (639,640,684,685), showing that the VTA has nicotinic as well as muscarinic receptors. Thus, cigarettes have a double dopaminergic action,

by activating the mesolimbic DA projection at both its origin and terminals.

Acetylcholine interneurons in the NAc may contribute to the inhibition of eating behavior. Most, if not all, of the ACh in the NAc comes from interneurons that play a special role in gating motivated behavior output. As a working hypothesis, it is suggested that these ACh interneurons act as gates that control instrumental behavior for reinforcers such as food (686). Just as striatal DA/ACh balance is a factor in Parkinson's disease and Huntington's chorea, accumbens DA/ACh balance may be a factor in disorders of motivated behavior, such as anorexia and binge eating. Measurements of ACh during a meal show that the highest levels coincide with the slowing of eating (686). Neostigmine infused into the NAc to elevate endogenous ACh can stop an ongoing meal. This suggests that accumbens ACh is involved in a "no-go" command that counters the DA "go" signal.

A conditioned taste aversion releases ACh in the NAc when the taste stops the animal from ingesting a flavor associated with nausea. Thus, the conditioned stimulus raises extracellular ACh at the same time as it lowers the release of DA (687). This may contribute to inhibition of behavior output such as eating. The DA/ACh imbalance, with low DA and high ACh release, is very different from what occurs with a normal satiating meal that can raise first extracellular DA and then ACh at the same time (686). A nicotinic antagonist injected in the NAc can block the conditioned taste aversion caused by a cholinergic agonist (688). This supports the hypothesis that ACh in the posterior, medial NAc, through nicotinic receptors, can contribute to stopping eating behavior.

ACh in the major projection system to the neocortex and hippocampus is probably involved in all kinds of cognitive behaviors, including memory formation and retrieval, foraging, and social factors in eating (689, 690). Four ACh system components have been described above, in the hypothalamus, midbrain, accumbens, and cortex. The hypothalamic and midbrain components may have similar cells of origin, whereas the others are totally separate systems. This is one reason that systemic cholinergic drugs have not yet found a use in treating eating disorders, other than nicotine, which is addictive.

## B Amino Acids

The metabolism of energy in the brain is coupled to the formation of several amino acids, including glutamate and GABA, which serve neurotransmitter roles. This

may confer on them a special role in brain mechanisms for eating and body weight regulation. Obese Zucker rats have disturbances in brain GABA that may contribute to their overeating (691). They are refractory to the anorexic effects of the GABA-transaminase inhibitor EOS, which elevates GABA levels in the brain. Moreover, transgenic mice that ubiquitously overexpress GABA transporter subtype I exhibit heritable obesity, which features increased body weight and fat deposition (692).

The role of GABA in feeding varies in different brain areas. The PVN is the most sensitive site to the feeding-stimulatory effects induced by injections of GABA agonists and the feeding-inhibitory effect of a GABA antagonist (693–695). In the VMH, mixed results with injections of GABA agonists have been obtained (693–696). GABA is released during hypoglycemia (697). There may be a metabolically distinct GABA-ergic system that exerts inhibitory control over feeding (696). This is based on the finding that levels of endogenous GABA are high in the VMH during the light phase when natural feeding is low (698). Other conditions associated with decreased feeding also cause enhanced levels of VMH GABA (699). The release of GABA in the LH correlates with the end of a meal and may have a very different function than in the PVN (700).

As indicated in Figure 2, complex sensory inputs to the NAc arrive on glutamate pathways from the PFC, amygdala, and hippocampus. Output signals leave the NAc on GABA pathways of the extrapyramidal motor system to the VTA, GP, and LH. Glutamate projections to the NAc shell stimulate feeding that can be blocked by GABA antagonists in the LH (701,702). There are also glutamate inputs directly to the LH that stimulate feeding (703–705), and these may be inhibited by GABA agonists (702). Microdialysis coupled to capillary electrophoresis was used to measure glutamate and GABA simultaneously in the LH every 30 sec during a meal. Glutamate peaked near the start of the meal and then decreased, while GABA peaked at meal's end. This strongly supports the hypothesis that glutamate helps start the meal, and GABA participates in satiation (700). In the NTS, glutamate has been implicated in the suppression of feeding by CCK and by glucose-induced satiety (706). A benzodiazepine-GABA system is involved in responses to palatable tastes (707).

Further evidence demonstrates that the anterior piriform cortex can detect and respond to indispensable amino acid imbalance. One of the responses to threonine injection in the piriform cortex of threonine-depleted rats is an increase in neural activity in the

LH. Under natural conditions, this may initiate life-saving ingestive behavior (7).

## VII BRAIN AND BEHAVIOR: REINFORCEMENT SYSTEMS AND OVEREATING

Motivation to eat is a major factor in the development and maintenance of obesity. Neural mechanisms have evolved to anticipate the animal's energy needs and to avoid past mistakes. The brain learns and remembers a myriad of responses for finding, storing, and rationing food supplies. The animal is both consciously and unconsciously aware of fuel sources within its ecological niche and its own body. It uses innate reflexes plus classical and instrumental conditioning to get food, to know how hard to work for it, and to know how much to eat. Responses that engage the environment are particularly clever when they involve motivation and learning of complex and arbitrary motor sequences that must be chained together from the animal's repertoire of simpler responses. To survey the chemical neuroanatomy of classical and instrumental conditioning of feeding behavior in a few pages is to leave out most of the available information. Nonetheless, some basic principles can be drawn from the above discussion during a brief tour of the feeding reinforcement circuit, as we now know it (578,641,708).

An overview of Figure 2 indicates that sensory signals from vision, audition, somesthesia, and the chemosenses are entered separately or as multimodal signals into the inputs of two major circuits or loops. One loop from PFC to NAc (the vertical oval) uses sensory information to generate motor output patterns. Thus, the NAc is often referred to as a sensorimotor interface (709). The other loop from the LH to the NAc (the horizontal oval) reinforces output from the sensorimotor interface.

### A Sensory Inputs

Chemosensory inputs for taste, olfaction, metabolism, and fuel storage are fed into the NTS, PBN (710,711), hypothalamus, and amygdala (239). Glucoreceptors are widespread in a network throughout much of the brain (712,713). The prime example of chemosensory processing is the taste signal that has been traced from the tongue to NTS, where some of it combines with hepatic vagal inputs representing glucose and amino acids in the liver (714). This signal travels on to the PBN and thalamus (directly to the hypothalamus in rodents)

and, then, taste sensory cortex, where more cells respond to stimuli on the tongue. Electrophysiological studies in monkeys follow this trace from the classic taste cortex to the orbital PFC, where cells respond to tastes as a function of appetite and satiety. As a monkey eats a flavorful food and gradually becomes satiated, the PFC cells gradually stop responding to the flavor. This effect is specific for the flavor of a particular food (6). The animal, like the cells in its PFC, no longer responds to one food when satiated, but it still responds to another. This neurological phenomenon corresponds to sensory-specific satiety.

### B Behavior Generator System

As shown in Figure 2, complex sensory information that enters the NAc on glutamate neurons is gated by ACh neurons and leaves the NAc on the GABA neurons of the motor systems. The PFC is involved in making choices, including choices of foods. It projects strongly via glutamate neurons to the NAc and other parts of the striatum. The NAc has various rostral-caudal and shell-core inputs and outputs with functionally distinct neuronal ensembles (715,716). Acetylcholine interneurons in the NAc may act as gates that stop instrumental motor output (686,687). These gating neurons are modulated by DA and other transmitters, including 5HT (717) and certain opioids (53) as well as other peptides. Excitatory influences on the GABA output neurons cause downstream excitation of the instrumental motor output. The output from the NAc goes, in part, to the ventral GP, then to the thalamus, and out to motor systems (718,719). The information also loops back from the thalamus to the PFC (75,720), as shown in Figure 2.

### C Behavior Reinforcement and Inhibition Systems

The hypothalamus is part of a system that evaluates the sensory outcomes of behavior and, then, reinforces behavior. These functions are important for maintaining a normal body weight. As indicated in the lower center of Figure 2, cells sensitive to insulin and leptin in the ARC influence feeding-related cells in the PVN. Figure 2 further suggests that the PFLH feeding reinforcement path descends (260,627,721) and connects to the VTA, PBN, and NTS. Recording studies show that PFLH stimulation, which is capable of inducing eating and brain stimulation reward, has effects on NTS cells that mimic the effects of palatable tastes on the tongue (722). The descending components of these systems may connect to the ascending ACh path that stimulates the

VTA cells of the mesolimbic DA system, as discussed above (682,723). The VTA projects to forebrain limbic structures, including the NAc, ventral globus pallidus, amygdala, hippocampus, and PFC, which have inputs back to the LH (702,724). Overall, these projections can be viewed as a behavior reinforcement circuit that increases the rate or force of ongoing behavior and recruits responses to associated signals for incentive motivation (623). Both positive and negative reinforcement of behavior can release DA, as shown by the increased extracellular DA in the NAc during LH self-stimulation or stimulation escape (725,726). This is a major portion of the system for reinforcing eating behavior and for appetitive and aversive motivation. Thus, it is very likely to play important roles in eating disorders (8,727).

In the NAc, DA helps to reinforce behavior in a variety of ways (623,728,729). The time course of DA release in the NAc fails to fit a simple notion of a feeding reward. Microdialysis experiments have found both DA release and decrease while the animal is still eating but often DA remains elevated for up to an hour after the meal is over (631,730). The synaptic overflow of DA into the extracellular space revealed by microdialysis is functional DA. It can have synaptic actions on dopaminergic receptors and at uptake sites some distance from the release site in the manner of "volume transmission" (731). Sometimes DA is released in anticipation of eating, as reflected in a conditioned rise in extracellular DA before a meal (497,732). This agrees with recording studies in monkeys, showing that "naïve" DA cells in the VTA fire during eating but later "learn" to fire during the presentation of discriminative stimuli that signal forthcoming food (646). Therefore, as described in the section above, these cells can release DA in response to conditioned discriminative stimuli that predict food.

#### **D Hypothalamic Control of Reinforcement**

It has been known for 30 years that the hypothalamus influences complex responses for food, but only now is the mechanism becoming clear. The above discussion depicts a pathway from the LH to the NAc by which the hypothalamus influences operant eating responses. As evidence for this idea, GAL injections into the PVN cause a significant increase in DA release in the NAc (733). This occurs in the absence of food and only in animals that, in a separate test with food present, exhibit a GAL induced-feeding response. Thus, it is feeding behavior that is likely to be reinforced by the DA-activated circuit in the NAc. Eating or associated

stimuli can release more DA, which further reinforces the behavior. This positive feedback may contribute to bingeing on the kinds of foods, rich in fat and carbohydrate, which are enhanced by GAL (69). As mentioned in the earlier dopamine section of this review, hypothalamic injection of GAL not only releases DA that may accelerate eating; it also decreases extracellular ACh in the NAc. This is thought to disinhibit eating (733). Conversely, CCK and 5HT injected in the PVN cause satiation and, in separate tests, inhibit accumbens DA while synergizing to release ACh (498).

Hypothalamic injection of the D<sub>2</sub> antagonist sulpiride is another way to induce eating (734). When injected in the LH, sulpiride causes the release of DA in the NAc in the absence of food, much like GAL. In this case, we have direct evidence of the reinforcing effect, as rats self-inject sulpiride into their own hypothalamus (616). Perhaps any hypothalamic manipulation that releases accumbens DA, without also releasing accumbens ACh, can motivate the animal to repeat its behavior. This may contribute to hyperphagia when there is no natural satiety factor sufficient to stop it.

In the course of eating a meal, a rise in ACh release in the NAc very likely contributes to the stopping or switching behaviors (735). When hypothalamic stimulation is aversive, one finds that stimulation releases ACh in the NAc. If the rats are allowed to work to escape the stimulation, they succeed in lowering the ACh (725). Apparently, ACh not only inhibits feeding, but, if ACh is excessive relative to DA, this creates an aversive state. This condition is seen under natural conditions when experiencing a conditioned taste aversion or drug withdrawal (285,687,736). It also occurs during withdrawal from sugar in the animal model of sugar addiction described below.

#### **E Models of Food Addiction**

The neural systems for reinforcing eating are the same as those involved in addiction (8,625,737–739). This suggests that certain foods might be addictive under appropriate conditions. There are remarkable overlaps between the effects of palatable foods and addictive drugs. Food deprivation potentiates consumption of food and self-administration of drugs (740,741). Hypothalamic self-stimulation that is sensitive to hunger and appetite also responds to drugs of abuse (3,740,742). In a model in which young rats undergo periods of deprivation-induced weight loss and refeeding (743), there is a proclivity to drug self-administration (744). Animals will even substitute a sweet flavor for an addictive drug that is in short supply (745,746). There are also

“gateway effects” such as motivation for sugar that is engendered by sensitization to AMPH (747). Some animals are born with a proclivity to drink sweet fluids and take drugs of abuse (748,749). Dopamine release in the NAc is clearly one of the underlying substrates that is common to the reinforcement of food and drug intake (750). Opioid receptor activation is another. Sweet flavors can suppress pain (751) and potentiate morphine-induced analgesia (427). Likewise, morphine can potentiate ingestion of sweet foods, and naloxone blocks it (239). Naloxone can also precipitate withdrawal with somatic symptoms, such as teeth chattering and shakes, in rats fed a cafeteria diet or a sugar-enhanced diet (422,752,753).

This suggested that some foods might have addictive properties under certain conditions. It has been hypothesized that long-lasting changes occur in the brains of rats on a cycle of fasting and refeeding. These may be similar to the changes caused by intermittent intake of drugs of abuse. To test this hypothesis, rats were deprived for half of each day and given highly palatable glucose to drink with chow a few hours after they would normally have started eating. With this paradigm, they gradually double their daily sugar intake and develop a binge pattern of glucose ingestion. This excessive sugar intake results in increased  $D_1$  receptor and mu receptor binding in the NAc shell (422). Moreover, opioid receptor blockade with naloxone causes withdrawal symptoms, including teeth chattering, anxiety, and disruption of DA and ACh balance. During withdrawal, extracellular DA is low and ACh is high, similar to withdrawal from morphine. These animals also show signs of craving, such as reinstatement of excessive sugar intake after 3 months of sugar abstinence (unpublished). Given this evidence for three stages of addiction, namely, sensitization with receptor changes, withdrawal with neurochemical imbalance, and craving in terms of memorized motivation, one can conclude that animals may become addicted to highly palatable food, as hypothesized earlier (8,752).

This may apply to some cases of binge-eating disorder or bulimia in humans (754–759). Sugar-dependent rats and obese people both show decreased  $D_2$  receptor binding in the striatum (422,760). Binge eaters also have decreased 5HT transporter binding (761). Opioid antagonists have been tested in humans with obesity, binge-eating disorder, or bulimia, with limited success in certain cases (762–767). The therapeutic paradox in using opioid antagonists lies in blocking the motivation to abuse palatable food, without precipitating withdrawal symptoms that promote relapse.

## VIII SYMPATHETIC AND PARASYMPATHETIC NERVOUS SYSTEMS

The sympathetic nervous system is defined as primarily an energy output system that is activated in times of stress (“fight and flight”). The parasympathetic system, in contrast, is considered on the input side of the equation (“rest and digest”). It is not a simple matter to classify feeding, which involves both energy output to find food and energy input during ingestion. The proper distinctions may come with full understanding of these systems, which have many components that can be activated separately or all together. For example, the sympathetic system has a subdivision for the body extremities and another for the visceral region that, in turn, is further subdivided (768). The subcomponents can be activated by the appropriate spinal sympathetic afferents, and the larger units can be activated by adrenal catecholamine hormones, epinephrine, and DA. For the sake of clarity, this discussion focuses primarily on the sympathetic system; although as a general rule the parasympathetic system plays an equally important and opposite role.

### A Three Components of Sympathetic Output

Sympathetic energy output on a given food ration can be divided into the thermic effect of food (body heat production), physical exercise, and metabolic rate, all of which affect body weight. A person or animal that is eating normally but gaining weight might have low levels of any of these three outputs. The thermic effect of food refers to the amount of heat produced (thermogenesis) above and beyond the basal metabolic rate (769). This changes with the animal’s weight and is closely related to body fat. When a normal animal or person gains weight by overeating and depositing fat, the thermic effect of a meal increases. This allows the subject to adapt to the extra fat by squandering heat and curtailing further weight gain. Prostaglandin-E1 is partially responsible for activating the sympathetic system and causing thermogenesis via the VMH (770). During the dynamic phase of overeating after VMH lesions, the thermic effect of food remains low, while the animals gains weight rapidly. This low heat production may signal an impaired sympathetic state that occurs in cases of impending obesity (771). High body temperature not only gets rid of unneeded calories; it also inhibits food intake via a histaminergic system in the hypothalamus (772). A hot rat usually eats less (773), and histamine and its receptors may play

a role in producing this response, providing a pharmacological avenue to control appetite.

Second, physical activity accounts for a large amount of energy expenditure. Low physical activity is a major factor in obesity (774). Hyperactivity contributes to weight loss, whereas a sedentary life can lead to obesity. Food-restricted rats conserve energy by becoming less active and more reactive (775). With the availability of a running wheel, underweight rats may display hyperactivity that exacerbates their weight loss (776). When food is restricted to achieve ~80% of normal body weight, rats exhibit marked changes in the brain, such as a decline in basal levels of DA in the NAc (382,386), leading them to engage in behaviors that release DA. Low basal DA is also observed in the NAc of genetically obese Zucker rats (777). Both the underweight rat without the opportunity to run and the obese rat are hypoactive compared to normal rats.

The third factor on the output side is basal metabolic rate. With a computerized metabolism cage that corrects for temperature and activity, a decline in background metabolism can be detected just before a meal (601). Blood glucose also falls before a meal, and as the body's metabolism changes and glucose levels start to rise, the animal initiates the meal (778). Under controlled conditions, the nadir in blood glucose level is so reliable as a predictor of a meal that one must assume the brain can respond to glucose dynamics or, more likely, to the chemical factors that reverse the decline in glucose. This is a revival of Mayer's glucostatic theory (779). However, the liver plays a powerful role in responding to fat, as well as glucose, and it creates "metabolic sensations" via vagal signals that are transformed into brain perceptions (780). Ghrelin, a newly discovered peptide from the stomach wall, varies in the bloodstream in accordance with meals; it predicts meals accurately and is closely associated with insulin and glucose metabolism (303,305,781). Measurements of the immediate early gene product, *c-fos*, as an indication of cellular activity, confirm that the hypothalamus is one of several brain areas that change their activity in response to decreased utilization of either glucose or fat (782). In an attempt encompass both glucostasis and lipostasis, it is proposed that fuels for the brain are monitored in the hypothalamus as a microcosmic representation of the whole body (601). The LH may sense its own intermediary metabolism, and this may be related to the DMN, which is an important locus of the CRH output pathway that is part of the sympathetic system (75,783). It is clear that the hypothalamus exerts control over the various components of the multifaceted sympathetic nervous system.

## B High Sympathetic (Low Parasympathetic) Tone

High sympathetic tone in the brown adipose tissue system is associated with loss of the urge to eat. In the MH, electrical stimulation can increase sympathetic neural output to brown adipose tissue and stimulate glucose uptake in skeletal muscles (784). Stimulation tends to be aversive, and it inhibits or interrupts eating. Lesions in the LH have some of the same effects as stimulation of the MH. Depending on the exact size and location, LH can cause various aspects of the well-known syndrome of aphagia, sensory neglect, and motor impairment (440,785) and can disinhibit sympathetic signs, such as peripheral NE release. Leptin from the adipose tissue has similar effects to MH stimulation or some excitotoxic LH lesions. This hormone heightens some facets of satiation and stimulates the component of the sympathetic system that projects to brown adipose tissue. It does this, in part, by indirectly exciting and disinhibiting the CRH and/or TRH satiety output, as shown in Figure 1. It also tends to indirectly inhibit a feeding system. It is interesting that regulation of leptin release may itself be a function of the sympathetic system, as well as of the amount of adipose fat (38). The hypothalamic peptide components of this sympathetic satiation system include a variety of satiety-producing peptides, namely, CRH, CART, CCK, BBS, ENT, and  $\alpha$ -MSH (768). Bombesin, for example, acts via the CRH system to promote activation of the HPA axis to cause a rise in plasma ACTH, CORT, epinephrine, and glucose (786). Also, sympathetic activity and satiation are potentiated by 5HT, acting at 5HT<sub>1B/2C</sub> receptors, and by NE, acting at  $\beta_2$ - and  $\beta_3$ -adrenergic receptors. These influences cause lipolysis and provide fuel while augmenting sympathetic tone (787).

## C Low Sympathetic Tone

Lesions of the MH region or PVN do the opposite of MH stimulation and leptin. The MH lesions cause overeating and an elevated plateau for body weight maintenance (561,788), with low sympathetic activity occurring during the dynamic weight gain phase. Ventromedial hypothalamic damage may also destroy neurons necessary for inhibition of peripheral insulin secretion (789). This leads to hyperinsulinemia that is proportional to the elevated level of body weight (790). Thus, these lesions unsettle the autonomic nervous system by creating an animal with low sympathetic tone, which is accompanied by an increase in parasympathetic tone (443). A similar state of

parasympathetic dominance occurs in the obese state, as shown in animals that are genetically obese (791) and in obese men (792). They deposit excess fat with or without overeating, although they generally do overeat, and this hyperphagia further exacerbates their obesity. Spontaneous food intake is usually inversely correlated with the sympathetic activity that is measured in terms neural activation of brown adipose tissue (560). Paradoxically, low sympathetic tone can be found in both underweight and overweight animals. One possible explanation is that the "overweight" animals may actually be "underweight" in relation to their weight plateau. This is the familiar description of VMH-lesioned animals, which in their dynamic phase are overeaters and gain weight but are actually underweight relative to their own eventual weight level (788). Thus, low sympathetic activity in brown adipose tissue and related systems reflects not only high food intake but also the tendency or "potential" to eat (771). Perhaps any animal that is under its preferred weight level for a given diet can have a large feeding potential coupled with low sympathetic activity. This may include food-deprived animals, VMH-lesioned animals in the dynamic phase, genetically obese animals, or dietary obese animals that are denied their palatable diet.

Some of these effects can be seen with electrical stimulation of the PFLH region. Self-stimulation of this site can promote eating to the extent of causing obesity (793). Stimulation also causes parasympathetic functions in peripheral tissues, as evidenced by increased cholinergic tone (442–444,784). The LH stimulation site most relevant to this discussion is in the PFLH, where orexin and MCH cell bodies are located. Orexin neurons extend, in part, to medullary sympathetic outputs and may play a role in the control of cardiovascular sympathetic responses (225,794). However, this pressor response system is different than the brown adipose thermogenesis system, even though both are part of the sympathetic nervous system. Thus, the complex orexin system may be involved in both parasympathetic feeding processes as well as sympathetic arousal via the spinal cord. There is evidence that CCK, bombesin and leptin can inhibit the self-stimulation reward system (795,796). This may occur through the connection to the orexin/DYN system shown in Figures 1 and 2.

## IX CONCLUSION

As evident from the new references in this review, the study of ingestive behavior and obesity from the neuroscience perspective is a burgeoning field. There are many

exciting discoveries, including the revelation of peptides for eating and satiation that were hitherto unknown. Two examples serve to illustrate the panoply of interactions that are described above. The first "feeding peptide" discovered was NPY. This peptide not only induces a strong appetite; it causes vital metabolic adjustments. A variety of endocrine signals feed back to regulate NPY and its receptors. For example, leptin and insulin control the production of NPY, and CORT controls NPY receptors. Now, NPY is known to be colocalized with AGRP, which acts as an endogenous antagonist to block a CART/ $\alpha$ -MSH satiety system and induce increased food intake over a period of several days. This long-lasting effect, which may occur through some yet-to-be-discovered change in gene expression, involves the newly discovered orexin pathway, which induces feeding with its axons that travel from the LH to both the hindbrain and frontal cortex. Orexin is colocalized with the opioid peptide DYN. Therefore, this orexin-DYN path may be a major component of the classic LH feeding systems that subserve appetite and reinforcement, as displayed in stimulation-induced eating and self-stimulation.

The behavior reinforcement pathway is a circuit that includes both the hindbrain centers for the taste and visceral integration, and the forebrain centers for cognitive integration. For example, in the NAc, DA potentiates eating, and ACh potentiates satiation. Release of these neurotransmitters is part of a learning process that allows the animal to plan ahead to acquire nutritious food, coded as palatable, and avoid poisonous items coded as unpalatable. The output is motivation to eat, conditioned cephalic reflexes for eating, and adjustments of the autonomic nervous system for energy homeostasis. The most palatable and, therefore, preferred foods cause the release of opioids that prolong a meal and may even create signs of dependency.

The remarkable aspect of all that is reviewed above is the wealth of information about neural mechanisms that extend all the way from the gut and liver that send signals to the hindbrain and then to the motivational centers for feeding in the accumbens and the cognitive processes in the frontal cortex. The hypothalamus serves as "base of operations" that receives much of this neural information, plus its own hormonal signals and energy-rich molecules, and coordinates an output that sustains the energy needs for life. A major miscalculation at any step can lead to starvation or obesity. The unfolding beauty and intricacy of the neural and hormonal systems is a thing of awe. However, its application in modern times is impossible without parallel appreciation of the enormous impact of the envi-

ronment, food availability, and food taste. The neural-hormonal system of energy homeostasis evolved in an environment of scarcity. It needs sociopolitical help in coping with problems created by refugee migrations on the one hand, and advertised superabundance on the other. An understanding of the neuroscience of ingestive behavior and obesity must bring with it a sensible food distribution and education system. Otherwise, it will just be science for the sake of treatment, without all the benefits that could accrue from prevention of starvation and overeating.

## ACKNOWLEDGMENTS

Some of the research described in this review has been supported by U.S. Public Health Service grants MH 43422 (S.F.L.) and MH 30697 and DA 10608 (B.G.H.). We thank Ms. Kate Sepiashvili, Henrietta Enninfuleghian, and Nicole Avena for their assistance in the preparation of this review chapter.

## Experimental Studies on the Control of Food Intake

**Henry S. Koopmans**

University of Calgary, Calgary, Alberta, Canada

### I INTRODUCTION: INTERNAL SIGNALS CONTROL FOOD INTAKE

The amount of food eaten is an essential component of the control of body weight. Food provides the chemical energy required for metabolism and for the storage of nutrients for later use. If the amount of ingested food is inadequate for the body's needs, the animal will burn its endogenous stores of fat and protein and will lose weight. If food is eaten in excess of needs, some of that food will be stored in fat, muscle, and liver for later use. Thus, the proper control of food intake is essential for maintaining a healthy body composition and avoiding obesity.

There is little doubt that daily food intake is controlled by internal signals. If rats are force-fed for a period of time until they become obese, they will reduce their food intake, when allowed to do so, and will bring their body weight back down to normal levels (1). Conversely, when the rat's food intake is restricted for a period of time so that they lose weight and become thin, they will increase their food intake, when they are allowed to do so, and will again bring their body weight up to normal levels. Although several studies clearly show that there are internal mechanisms that will adjust daily food intake following changes in body weight, they do not show how the task is accomplished. During force-feeding and partial starvation there are changes in the degree of stimulation of the gastrointestinal tract, in the internal metabolic pathways of the liver and other

organs, in the nutrients present in the blood and transferred to tissue, and in the storage of nutrient in muscle and fat. When force-feeding or starvation stop, any or all of these organs could be responsible for generating an internal signal that brings cumulative food intake and body weight back to normal levels.

Since food intake is a behavior, it must be mediated by the brain. Although many regions of the brain are involved in the control of daily intake, several important studies have shown that two major regions, the paraventricular or ventromedial hypothalamus and the lateral hypothalamus, are critically involved in the control of daily food intake and body weight (2). If lesions are made in the ventromedial hypothalamus or in the paraventricular nucleus, an animal will begin to eat soon after coming out of the anesthesia, will gorge itself for several hours, and will continue overeating for weeks or months until a new level of body weight has been achieved. Thereafter, food intake is stabilized and the new level of body weight will be defended (3). As with normal rats, if these lesioned, obese rats are overfed and forced to reach a new level of body weight, they will voluntarily reduce their daily food intake and bring body weight back to the previous obese levels (see Fig. 1). If they are starved, they will subsequently increase their food intake until they again reach their previous level of obesity. These obese rats are no longer as accurate in their control of food intake: they become finicky, that is, they respond to improved food quality by overeating and to food adulteration by undereating.

**Figure 1** Body weight and food intake of rats given ventromedial hypothalamic lesions, allowed to reach a new level of body weight, and then force-fed or starved. After being force-fed or starved, the rats alter their food intake and bring their body weight back to their new obese level. (From Ref. 3.)

Thus, they are more likely to change their food intake and body weight in response to changes in the quality of their diet than are normal rats. They are also less willing to work for food: if they are required to press a lever several times to get access to food, they will eat less and lose some of their body weight.

Lesions to the lateral hypothalamus cause animals to eat less and lose weight. If the lesions are large, the rats have to be nursed back to health by feeding or intubing liquid diets (4). If the lesions are relatively small, the rats reduce their food intake for a period of time until they have arrived at a lower body weight, and then they eat to

maintain that weight. Lesions that limit or inhibit food intake are difficult to interpret since the absence of a behavior can have several causes. The lesion may have damaged a regulatory center and reset body weight at a new lower level. Alternately, the lesion may have destroyed the motor capabilities that underlie feeding or a sensory quality that makes feeding attractive. The possibility that a motor or sensory deficit may result from a lesion can be explored by depriving the rat of food and lowering its body weight before the lesion is performed (5) (see Fig. 2). Rats that are starved before the lesion increase their food intake after the brain

**Figure 2** Body weight of rats that were free-fed or starved before being given two different sizes of lesions in the lateral hypothalamus. The rats reach a level of body weight related to the size of the lesion and the starved rats increase their food intake after lesion. (From Ref. 5.)

surgery showing that the lesion did not affect their ability to eat or the attractiveness of food. These deprived rats actually ate more than normal after the surgery and stabilized their body weight at the same lower level as nondeprived rats with the same-size lesion. These studies demonstrate that the lesion acts by changing the set point for body weight. The combination of the results from VMH and LH lesions show that there are two major regions of the brain that respond to internal signals in a way that controls daily food intake. In fact, the internal circuitry regulating food intake is quite complex (6,7). Again, it is important to remember that the relationship of these brain regions to peripheral signals generated in the gut, through metabolism or in storage organs, has not been clarified by these lesion studies. The overfeeding or underfeeding of the rats has affected all of the body's organs and all of the processes involved in digesting, absorbing, transporting, metabolizing, and storing food. It has also altered a large number of endogenous signals.

Internal regulation of food intake is also demonstrated in nature (8). Rodents that hibernate gain weight during the summer and autumn and then gradually lose weight during the winter as their body temperature drops to just above freezing. Bears also gain weight in the autumn and then retire to their dens where they lower body temperature by a few degrees and slowly lose weight. Some birds gain weight twice a year before their biannual migrations and arrive at their destinations with little body fat. Deer and walrus gain weight before mating season and then make little effort to eat and lose weight throughout their courtship period. Some birds and mammals reduce their intake during periods when they are incubating eggs or looking after young. Thus, the signals that control daily intake and the deposition of fat are under internal control and vary with external conditions. However, none of these natural experiments demonstrate which internal changes involved in causing the readily observed changes in food intake and body weight. These internal signals have been shown to be regulatory because birds incubating eggs eat very little of the food fat that is made readily available, and they continue to lose weight until the season is at an end (9). After forced starvation, they will eat more to put themselves back on a standard, predetermined pattern of weight loss.

Other types of external challenges have been shown to cause large changes in daily food intake to limit loss of body weight. When there is a large need for calories, daily food intake can be doubled. Lactating

mammals more than double their food intake to provide milk for their young (10). Rats exposed to the cold show large increases in food intake to provide the heat needed to maintain body temperature (11,12).

Internal regulation of food intake can also be demonstrated in pairs of parabiotic rats in which a 30-cm segment of one rat's upper small intestine is disconnected from its own digestive tract and sewn into the intestine of its partner (see Fig. 3). This surgery requires three transections of the small intestines in two rats, but none of the major nerves or blood vessels are cut. As a result of this surgery, one rat in the pair continually loses some of its ingested food into the crossed intestinal segment and into the bloodstream of its partner. The partner, on the other hand, has its own digestive tract shortened by connecting its upper duodenum end-to-end to its lower jejunum. All of the food eaten by the partner is retained in its own gut and is absorbed into its own bloodstream. One consequence of this surgery is that the rat that loses food into its partner's small intestine

**Figure 3** Diagram of a one-way crossed-intestines rat. The stippled gut belongs to the rat on the left. The right rat is continually losing food into the intestine and bloodstream of its partner. No major nerves or blood vessels are cut. (From Ref. 11.)

**Figure 4** Daily food intake of one-way crossed-intestines rats. The surgery was done on day 9. The rat on the right in Figure 3 that lost food or chyme into the partner's crossed intestinal segment showed a large increase in daily food intake while its partner reduced its daily intake. These large changes in daily food intake are sustained for the rest of the animals' lives.

and bloodstream exhibits a large 50% increase in daily food intake, while its partner reduces its daily food intake by about the same amount (13) (see Fig. 4). The pair as a whole continues to eat the same total quantity of food and to gain weight at the same rate as controls. The threefold difference in daily food intake between the two rats in a crossed-intestines pair is sustained for the rest of these animals' lives. This study clearly shows that daily food intake is internally regulated. The rats show large and sustained changes in daily food intake due to relatively minor surgery. The surgery involves only three transections and reconnections of the small intestines, which in themselves would not cause a sustained change in food intake (14). The altered feeding results from the rerouting of food through the gut, the altered stimulation of the rats' internal organs, and the change in the amount of ingested food that has been absorbed into each animal's bloodstream.

## II TYPES OF INTERNAL SIGNALS

The most convenient way to describe the possible internal signals that are involved in the control of food intake is to trace the route that the food moves through the body from the moment when it is first touches the tongue until it is excreted as waste by the kidney or

rectum, or is reduced through metabolism to water and carbon dioxide, or is stored in tissues for later use. When an animal becomes hungry, it begins to search for food and often uses strategies that minimize its cost in obtaining the food (15–16). Once food is encountered, it is explored through smell and taste. Once identified, the sensory qualities of the food can be compared to previous experiences, and an estimate can be made of its satiating properties (17). If the food is found to be acceptable, it is ingested and comes into contact with the mucosa of the tongue, where it stimulates taste receptors. At the same time, volatile substances in the food excite odor receptors in the nose. When the food is swallowed, it passes from the mouth through the throat and esophagus into the stomach, and can stimulate various stretch and chemoreceptors in these organs. These neural messages may provide part of a short-term signal for the control of intake during a meal. Some of the food in the stomach passes rapidly as a small bolus into the upper small intestine (18). The presence of food in the intestine inhibits and controls stomach emptying (18–19). Within a few minutes after the beginning of a meal, glucose derived from laboratory chow is absorbed from the gut and is present in the bloodstream (20) (see Fig. 5). This leads to a shift in the release of gut hormones and, once the critically important pancreatic hormone insulin has been released (21), to the transport of some of the

**Figure 5** Changes in plasma glucose and free fatty acid levels occur within minutes of the initiation of a laboratory chow meal in 24-hr-food-deprived rats. These changes begin well before the meal has come to an end. (From Ref. 20.)

absorbed nutrient into tissues. Since most of these changes occur within the first few minutes after feeding and since animals usually require 5–30 min to complete a meal, a large number of internal changes provide possible short-term satiety signals. Our major task is to determine which of these signals are needed to cause the termination of a meal. After a meal ends, the ingested nutrients are transferred slowly from the gut to the bloodstream and then to the tissues, where they enter various metabolic pathways and provide energy for the cells. Changes in the rate of nutrient transfer may provide signals that terminate one meal or initiate another, and may control the subsequent meal patterns throughout the day. Excess nutrients are stored mainly in liver, muscle, and fat, and these tissues may provide possible long-term signals that control daily food intake and energy balance.

In short, there are three main types of internal signals that may be involved in the control of food intake. Signals will arise quickly from the gastrointestinal tract due to the stimulation of the mucosa with food and the absorption of nutrients across the gastrointestinal wall. These signals could be involved in the termination of a single meal. Both short-term and medium-term signals can arise from the presence of absorbed nutrients in the bloodstream and their depo-

sition into tissues where they can be used for metabolism or for storage of excess food. Long-term signals that are involved in controlling food intake over several days are more likely to arise from shifts in metabolism and from the storage organs. The relative importance of all of these types of signals for the control of meal and daily food intake is still in considerable dispute. There are a wide range of theories about food intake regulation with some supporting evidence for each possibility, but there are few definitive explanations of the underlying control mechanisms.

### III SIGNALS ARISING IN THE GASTROINTESTINAL TRACT—TASTE AND SMELL

The nose and mouth are the first organs to come into contact with food. The neural messages generated by the smell and taste of food are sent to the olfactory bulb or to the brainstem and are relayed up to higher centers of the brain. Taste and smell are usually thought to provide chemical messages for the decision about whether and how much to ingest, but they can become rewards in themselves and lead to overeating and obesity. While stimuli from the gut and from other internal organs are certainly involved in the control of feeding behavior, there is definitely a cognitive component. Animals need to decide when and where to feed and to remember their past encounters with food. The particular flavors and textures can then be used to guide feeding behavior. Collier and his collaborators have been the major contributors to laboratory studies that examine the decisions that are made about the cost requirements of finding food and ingesting it. They have shown that increasing the cost of obtaining food by increasing the number of lever presses needed to gain access to a food source leads to a decision to reduce the number of meals each day (22) (see Fig. 6). While meal number goes down, the size of the average meal increases so that total daily food intake is held fairly constant (22,23). If the tasks become very complex or require too much effort, the animal may choose to eat somewhat less than its normal daily portion and, thereby, trade off the amount of effort in obtaining food against its level of body weight. Daily food intake may decrease to 80–90% of its previous level. Collier has argued that there is too much emphasis upon a depletion-repletion model of the control of food intake (24). He notes that changes in external requirements cause large changes in meal patterns, but not in daily intake. He questions whether there are fixed internal

**Figure 6** Number of daily meals taken by each of three rats (1, 2, 3) when they are free-feeding (FF) or when they have to press one (CRF) or more times to gain access to food. As the lever-pressing requirement increases, the rats take fewer but larger meals. They maintain their normal level of daily food intake until they reach the highest levels of bar pressing, when they reduce daily intake a little. (From Ref. 22.)

signals controlling meal intake and believes that the choice of meal size has a large cognitive component. The counterargument is that a hungry animal with free access to food will eat much more food when the food is removed at the same time from the esophagus, stomach, or intestine (13,25). Some internal signals from the gastrointestinal tract or elsewhere in the body must be involved in terminating a meal. Thus, the amount eaten may depend on cognitive estimates of the food's calorie value and availability as well as on tentative satiety signals generated in the gastrointestinal tract or beyond. The cognitive component would be influenced or conditioned by subsequent information generated by the metabolism and storage of absorbed nutrients. The cognitive component would have to be controlled by some unconditioned stimulus which, in the case of food intake, is probably the same signal that controls the amount of food eaten.

#### IV ESOPHAGEAL AND GASTRIC FISTULI

Once a decision has been made to swallow food, it passes down through the throat and esophagus to the stomach. The early physiologists, Bernard and Pavlov,

did experiments using an esophageal fistula that allowed food that was eaten to pass out of the body before it could reach the stomach. They were trying to determine whether internal signals led to the termination of feeding behavior. They discovered that dogs and horses with esophageal fistuli greatly overate (26). These experiments have been replicated on other types of animals in more recent times and have been given clearer definition. Hull et al. (27) did an experiment on a single dog and showed that on the first and second sham feeding session, the dog greatly overate. Their 10-kg dog ate nearly its body weight in food before pausing for 5 min. This group also showed that the dog was gradually able to realize that it was losing the ingested food (sham-feeding) during the experimental test and, by the eighth day, the dog refused to eat in the experimental cage. However, when returned to its home cage and offered food, the dog sham-fed, showing that there was a cognitive component the dog's previous cessation of sham-feeding behavior. This result of excessive feeding after an esophageal fistula was confirmed by Janowitz and Grossman, who found that dogs sham fed four to five times their normal intake (28).

The sham-feeding paradigm has also been demonstrated in rats. Mook created an esophageal fistula in

rats and fed them glucose, sucrose, and saline solutions (29). He found that when the nutrients were prevented from reaching the stomach, intake was greatly increased in a 1-hr test. In addition, the rats showed a preference for higher concentrations of the ingested solution. After doing a gastric fistula in rats, Smith et al. (30) found that the rats continued feeding for more than 2 hr. A rat with an open gastric fistula will eat at a normal rate for 15–20 min and, thereafter, will continue to feed over the next 100 min at a rate that is about half its previous rate (see Fig. 7). The fact that the well-trained rat continues to feed suggests that distension or chemical cues arising in the stomach, in the small intestine, or beyond are important for the inhibition of intake during a single meal. The decrease in the rate of food intake after 20 min shows that mucosal stimulation inhibits the rat's avid desire for food or that the animal tires of the motor movements involved in feeding.

There are advantages and disadvantages to the use of either esophageal or gastric fistuli. With an esophageal fistula, the esophagus is transected, usually in the neck, and both ends of the esophagus are externalized, or, alternatively, the end leading to the stomach is closed and a gastric tube is inserted. Thus, the food eaten by the animal as well as its salivary secretions pass entirely out of the animal and do not reach the stomach or intestine. Sufficient food and water can be given to the animal by

putting the food into the externalized lower esophagus or through the gastric tube. The major advantage of the esophageal fistula is that one can be certain that only the mucosa of the mouth, throat, and upper esophagus is stimulated by food: none of the food can stimulate the wall of the stomach or pass into the intestine and be digested and absorbed.

The main drawbacks of the esophageal fistula preparation is that the feeding procedure is often quite messy, the animal must be fed by tube, and the fluid and electrolyte content of the saliva must be appropriately replaced. If replacement is inadequate, then subsequent intake may be affected by deficits that the animal cannot correct for itself. The gastric fistula does not suffer from these difficulties because most of the time the fistula is closed and food moves through the digestive tract in its normal fashion. Only at the time of the experiment is the fistula opened, the stomach flushed, and the experiment begun. If the animal is fed a liquid diet, most of the food will drain out of the gastric cannula, preventing the distension of the stomach and the associated neural or hormonal signals. However, two studies have shown that some of the nutrient ingested is emptied through the pylorus into the intestine and is absorbed into the bloodstream (31,32). Thus, the weakness of the gastric fistula is that the stomach and the rest of the gut will receive some stimulation of the mucosa by food which makes the results more difficult to interpret. Of course,

**Figure 7** Food intake of rats that have a gastric fistula that is either open or closed. When the fistula is closed, a 17-hr-deprived rat will complete its meal in 15 min and then take a few small meals in the next 2 hr. When the fistula is open and the food drains out of the body, the rat will continue to feed throughout the 2-hr period. (From Ref. 30.)

the bulk of the food has been lost through the fistula, and the intensity of downstream signals is greatly reduced. The use of both the esophageal and the gastric fistula leads to considerable overfeeding, called sham-feeding. The sham-feeding animal receives taste stimuli but little or no postingestive stimuli. Sham feeding will continue well beyond the usual time when feeding ceases in an intact animal.

All of the experiments agree that signals arising from stimulation of the mucosal lining of the mouth, throat and esophagus by food are not enough to stop feeding behavior. Some additional signals must arise at the level of the stomach or the small intestine to inhibit intake during a single meal. These results are entirely consistent with the results from the crossed-intestines rats mentioned above (13). After the intestinal surgery (see Fig. 3), these rats exhibit a threefold difference in daily food intake. Since all of the food necessarily passes through the mouth, throat, and esophagus, these upper gut organs are stimulated three times as much in one rat as in its partner. If stimulation of these organs were the main signals controlling daily food intake, then the large differences in food intake would not have been seen in these rats. The large, long-term differences in food intake of these one-way crossed intestines rats show that these mucosal signals can play only a minor regulatory role in the control of daily food intake.

## V SIGNALS ARISING IN THE STOMACH

The stomach has been thought to be a storage site for food and an inhibitor of food intake since the ancient Greeks understood the anatomy of the gastrointestinal tract (33). In man and large animals, the bulk of the meal eaten over a relatively short period of time remains in the stomach for more than an hour. After a short period of adjustment following the beginning of a meal, the rate of gastric emptying becomes steady, and a fixed number of calories is delivered to the small intestine per unit time (18,34,35). Because the bulk of the ingested food stays in the stomach after a meal, gastric distension is one obvious mechanism for the short-term inhibition of food intake. An assessment of the total amount of food eaten during a meal would appear to depend to a large extent upon two types of signals: (1) the degree of distension of the stomach, and (2) the activation of chemoreceptors in the gastric or intestinal wall.

Distension can not be the only signal involved in the regulation of food intake. Animals will increase their food intake when nonnutritive diluents are added to the diet. Adolph found that rats will adjust their food intake

to compensate when the amount of dilution was not too large (36). At higher concentrations of diluents, the rats compromised by reducing intake. Janowitz and Grossman showed a less complete and gradual adjustment to the addition of diluents in the food of dogs and cats (37). A recent study using a liquid fiber that gels in the stomach found diminished reports of hunger in human subjects, but food intake was only slightly reduced and then only after a delay of several hours (38). Thus, gastric distension by itself, without activation of chemoreceptors, is not a major regulator of food intake. The determination of the nutritive characteristics of the food is also essential.

Davis and Campbell (25) did studies that focussed on the role of the stomach in the inhibition of food intake. They placed a tube in the stomach of 4-hr food-deprived rats fed a liquid milk or elemental diet and then withdrew the food during the time when the rats were feeding or at various times after the meal was complete. They found that on the first day of continual withdrawal of diet and sham-feeding, the rats nearly doubled their 30-min intake. Some food must have remained in the stomach to allow continued removal of the liquid diet by suction, and some may have emptied into the duodenum. On subsequent days, their intake increased even further until the rats ate four to five times their usual amount of liquid food in a 30-min period. In a second experiment, the rats ate about 17 mL of an attractive liquid diet, sweetened condensed milk. When 8–10 mL of their stomach contents were withdrawn at 10, 30, or 50 min after the meal, the rats responded by eating a nearly equivalent amount of food, which showed that the rats noticed the withdrawal of food and compensated for it by eating more. There are two difficulties with this experiment. Even though the rats were only 4 hr deprived, they ate 17 mL of this attractive, high-energy diet: an amount that should either match or exceed stomach capacity. Perhaps the animals were eating to reach full distension and they were not concerned about the number of calories ingested. Furthermore, some of the ingested food would have moved into the duodenum, making it impossible to conclude that the signals that inhibited food intake arose solely in the stomach. There may have been an added intestinal component. Nevertheless, these experiments did point to gastric distension as having an important role in the inhibition of a single meal.

Deutsch et al. (39) extended and clarified these studies through the use of a pyloric cuff which was intended to prevent the food from leaving the stomach. In addition, they added a gastric tube that could drain stomach contents so that the level of gastric pressure

would not exceed the normal level after a meal. They fed 12-hr-deprived rats a milk meal while measuring gastric pressure with a water manometer. The rats drank 13.6 mL with the pyloric cuff open and 11.5 mL with the cuff closed. These values were not significantly different and showed that the rats stopped feeding on the basis of gastric distension and chemoreception and did not appear to require stimulation of the duodenum with food. However, the rats drank to stomach capacity, which was demonstrated in overflow experiments to be  $\sim 13.6$  mL. Thus, it was not clear whether the intake was regulatory for calories eaten or was inhibited by the limits of gastric distension. In a subsequent study, Deutsch and his associates showed rats could eat smaller meals of a liquid diet without noticing the surreptitious delivery of saline into the stomach (40). This study showed that the calories present in the stomach were somehow sensed by the animal. Deutsch (41) claimed that there were nutrient receptors embedded in the wall of the stomach, which would become exposed to the luminal contents as the gastric volume increased. The combination of gastric distension and the caloric concentration, as determined by exposure to the "nutrient receptors," would provide information to the brain to inhibit feeding behavior.

One difficulty with the Deutsch theory is that it pays little attention to the anatomy of the stomach when describing the hypothetical nutrient receptors. Neural receptors are not likely to be present in the lumen of the stomach or in the lumen of the gastric glands or pits. First of all, the gastric contents are highly corrosive and nerve terminals would be readily destroyed. Moreover, there is a constant turnover of mucosal cells throughout the digestive tract, and these rapidly dividing cells migrate continuously along the basement membrane. They would override nerve terminals that might be aimed toward the lumen. Furthermore, there have been no descriptions of nerve terminals beyond the lamina propria, the support tissue for the gastric mucosa. Thus, nerves would be able to sense the presence of food in the gastric lumen only if the food was absorbed into the wall of the stomach. Relatively little nutrient is absorbed through the gastric mucosa (42). It remains possible that the food could release gastric hormones from cells that have villus tufts projecting into the gastric lumen and that these hormones would stimulate vagal afferents (see below).

Recently, Kaplan et al. (43,44) have challenged the interpretation of the pyloric cuff experiments. They confirm that rats eat the same amount of food whether a pyloric cuff is open or closed, which is the fundamental observation in previous studies (31,39,45). However,

they have shown that during the first meal of a food-deprived rat there is a rapid emptying of the stomach that may be as much as 25–40% of the meal (46). When they measure the amount of nutrient in the stomach after a meal with the cuff either open or closed, they find that the gastric contents were 30% greater in the rat with the cuff closed. They conclude that although the rats with a closed cuff eat the same amount of food as rats with an open cuff, they require a larger gastric distension signal to terminate a meal. In short, they believe that the amount of food in the gastrointestinal tract, not just the amount of food in the stomach, controls short-term food intake.

Phillips and Powley (47) looked more closely at whether gastric volume or nutrient sensing occurred in rats with pyloric cuffs. They found that when the cuffs were closed, the rats showed an equivalent reduction of food intake when 5 mL of either saline or 10%, 20%, or 40% glucose was delivered to the stomach before injections. Furthermore, it did not matter whether the infused substance was 40% glucose, fructose, or sucrose with different chemical structures, metabolic pathways, and caloric values. However, when the cuffs were open, the nutritional content of these sugars as well as of the more balanced liquid diet, Isocal, did inhibit food intake. They conclude that gastric distension inhibits food intake, not gastric nutrient sensing, while ingested nutrients work at the level of the intestine to inhibit gastric emptying and to limit food intake.

The role of the stomach in the inhibition of food intake has to be affected by the rate of stomach emptying. As food empties, there is less food in the stomach and less gastric distension. McHugh and Moran have done a series of experiments on gastric emptying in rats and monkeys (48–50). They have found that saline empties rapidly in an exponential way from the stomach. On the other hand, nutrients empty rapidly from the stomach for the first 4–5 min, but, thereafter, the presence of nutrient in the small intestine slows down the emptying rate to a steady state until the meal is gone. A fixed number of calories empty from the stomach per unit time regardless of the composition of the food placed in the stomach (34,48). They argue that the intestine inhibits stomach emptying and that distension of the stomach inhibits food intake. Both stomach and intestinal signals are important.

Although there is general agreement that the stomach provides part of the signal that inhibits food intake during a single meal, we still do not know the nature of the signal or how it is transmitted to the brain. Nerves are the most likely route of transmission. The information about the degree of gastric distension

or the presence of nutrients in the gastrointestinal walls could be transmitted to the brain through either nerves or hormones. Paintal (51) and Iggo (52) have shown that there are vagal stretch receptors in the stomach. These nerves increase their discharge rate as a linear function of the degree of gastric distension (see Fig. 8).

In a recent review paper, Phillips and Powley (53) describe two distinctly different types of afferent receptors in the stomach wall. One type has characteristics of an "in-series" tension receptor, and the other appears to be a stretch receptor. While the current electrophysiological evidence does not establish the presence of more than one receptor type, the nerve cell anatomy strongly supports the conclusion that there are two types of receptors. In another paper, Powley has suggested that one sensor might respond to small changes in gastric volume, while the other would respond as a stretch receptor responding to large, sustained changes in gastric contents (54). Gonzalez and Deutsch have argued that vagotomy eliminates the satiety signals that results from gastric distension after a very large meal, but that gastric nutrient content of the stomach can still be sensed (55–56).

A study in which the stomach and upper intestine was transplanted from one inbred rat into another suggests that an unidentified gastric hormone may inhibit food

intake (57). Four rats given multiple feeding tests showed a compensatory reduction of food intake when food was infused at the standard feeding rate into the completely denervated and supplementary stomach and upper small intestine. At the time of the feeding test, the rats' natural digestive tract was intact, empty, and normally innervated. Recently, two new peptides have been discovered in the stomach—ghrelin (58) and leptin (59). Both peptides affect food intake when given centrally (7) and may play some role in the peripheral inhibition of food intake. Ghrelin is a peptide of 28 amino acids that is a growth hormone secretagogue and is quite distinct from growth hormone–releasing hormone (GHRH) (58). Its sequence differs between rat and human by only 2 amino acids, which indicates a highly conserved structure during evolution. Its highest concentration is in the stomach, where it is found in X/A-like endocrine cells in the oxyntic mucosa (60). These cells do not make contact with the lumen of the glands (61). Serum concentrations of ghrelin are increased by fasting and reduced by refeeding (62,63), suggesting that the presence of food in the stomach may inhibit ghrelin release. Ghrelin is also found in a few cells in the arcuate nucleus of the hypothalamus and the upper small intestine. Intracranial injection of ghrelin stimulates food intake, gastric acid secretion and releases growth hormone

**Figure 8** Rate at which single fibers isolated from the vagus nerve of a cat fire as the amount of air in an intragastric balloon is increased to the designated volume. (From Ref. 51.)

(64,65). It is possible that increasing secretion of ghrelin during fasting induces food intake and that its decreased release after feeding augments the feeling of satiety generated by other gastric and intestinal signals.

Leptin is a peptide discovered by cloning the defective gene in *ob/ob* mice (66). It is a secretion product of adipocytes (see section on Storage Signals) and is known to inhibit food intake and increase energy expenditure when given intraperitoneally or intravenicularly (67,69). It is also present in the gastric mucosa (59,69) and is released into the bloodstream. It appears to be present in both the chief cells which make contact with the gastric lumen and secrete pepsinogen as well as in a specialized endocrine cell, called a P-cell. Leptin is secreted into the gastric lamina propria from which it is absorbed into the bloodstream (70,71). Its plasma levels have a circadian rhythm with low levels during the day and high levels at night (63,72). Leptin levels appear to fall just after a meal and then rise gradually as the meal is digested and absorbed. The diurnal pattern is quite similar to that of ghrelin (63) with smaller changes for leptin just before and after meals. Leptin receptors have recently been found on the afferent and efferent terminals of the vagus nerve (73,74). Since IV leptin inhibits and IV ghrelin stimulates food intake, it is possible that their modulated release from the stomach might fine-tune the changes in food intake during meals.

While hormones and nerves may provide gastric signals that alter meal intake, it is unlikely that changes in intragastric pressure are major determinants of satiety since the relaxation reflex prevents an increase in pressure beyond a fixed level (75,76). However, increases in abdominal pressure may inhibit meal intake, as shown in one human study (77). Since there is relatively little absorption of food from the stomach (42), a gastric signal is unlikely to be an absorbed nutrient, but could be neural or hormonal.

There are at least two limitations to a gastric theory of the control of food intake. It is well known that most animals have a circadian rhythm of feeding behavior with meals occurring at times that are appropriate for the animals' nocturnal or diurnal orientation. Rats eat heavily during the early dark phase (78). As implied above, if food empties from the stomach at a fixed caloric rate, then repeated bouts of food intake during the early part of the dark phase should greatly distend the stomach. New meals would have to be initiated while the stomach remains relatively full.

This prediction has recently been confirmed using a noninvasive technique for measuring gastric filling and emptying over a period of several hours. Van der Velde and Koopmans (79) added a radioactive tracer, technetium 99m sulfur colloid, to a standard liquid diet and

were able to view three regions of interest within the rat's body every 2 min using a gamma camera. The regions were the stomach, measuring gastric nutrient filling or, indirectly, distension; the intestines, measuring gastric emptying; and the total rat, measuring cumulative food intake. They found that the rats ate five or six meals over 6.5 hr. Four meals were analyzed in detail: the first and second meal after a 7-hr fast, a meal just after the middle of the 6.5-hr period, and the last meal eaten. All meals were of approximately the same size. In accordance with Kaplan et al. and others (46,80), they found that the gastric contents emptied during feeding at more than three times the average rate and that ~25% of the ingested food emptied from the stomach during the meal. This was true not just of the first meal but of all meals analyzed over 6.5 hr. In the 10 min following a meal, there was a significant reduction of emptying rate as intestinal signals kicked in. One of their most interesting findings was that rats initiated new meals at times when the stomach was still quite full and, therefore, inhibition of food intake required even greater distension of the stomach for later meals. In the later part of the 6.5-hr feeding session, the rats initiated meals when gastric nutrient filling was greater than it was at the termination of the first meal. Thus, the degree of gastric distension necessary to provide an inhibitory signal for feeding behavior has to vary throughout the day. Most of the experiments on stomach emptying have been done on deprived rats, dogs, pigs, or monkeys at a fixed time of day. This procedure would tend to show that food intake is inhibited by gastric distension while studies done over 24 hr show that the degree of gastric distension necessary to inhibit food intake depends on the time of day. These new results using a gamma camera in conscious, free-feeding rats undoubtedly complicate the theory that gastric distension is a major inhibitor of food intake and shift attention toward the brain as an interpreter of the importance of gastric distension relative to time of day.

Another limitation of a gastric theory can be seen from the results of the one-way crossed-intestines study previously described (see Fig. 3). Following the surgery, one rat in the pair eats three times as much as its partner and this change persists for the rest of the animals' lives. This means that three times the amount of food passes through the stomach of the rat that eats more relative to its partner that eats less. If the stretch or nutrient receptors in the mucosa or in the muscular wall of the stomach were sensing the total caloric value of the food passing through the stomach and using this information to control daily

food intake, then the food intake of these rats would not change after the surgery. Instead, the food-losing rat would lose weight while its partner would gain weight. Since daily food intake did change dramatically and body weight changed only a little, the stomach must not have a way of sensing the total amount of food passing through it. However, gastric distension could retain its importance in the control of food intake if there were changes in the rate of stomach emptying in these rats. If, for example, there were a threefold difference in the rate of gastric emptying for the two rats in a pair (matching the observed difference in food intake), then the degree of distension and chemical stimulation of the two rats' stomachs might remain the same. Preliminary data suggest that there are large changes in the rate of gastric emptying in these rats and, thus, gastric signals may still be partially responsible for the control of daily intake. However, the intestinal mechanisms involved in the control of gastric emptying would become important regulators of daily food intake.

The results of the crossed-intestines study show that the ultimate control of daily food intake must occur at the level of the small intestine or beyond. It is not yet clear whether intestinal or metabolic signals influence food intake by controlling stomach emptying or by some other response to the absorbed food. Neural or hormonal signals generated in the small intestine may act directly on the brain to inhibit food intake, or they may act indirectly on food intake, by changing the rate of gastric emptying. These neural or hormonal satiety signals would be generated as the food comes into contact with or is transported into the absorptive cells of the intestinal mucosa or as the absorbed nutrients or released hormones come into contact with the nerves that terminate in the wall (lamina propria) of the small intestine (54).

## VI SIGNALS ARISING IN THE INTESTINE

The studies cited above indicate that gastric distension is an important short-term signal that inhibits food intake. However, it is possible that other signals are involved in the termination of a meal. Messages arising in the intestine or in other organs may also be involved in generating satiety signals. Some early studies have shown that the intestine can be a source of signals for the inhibition of food intake (81,82). These investigators found that the delivery of hyperosmotic nutritive and nonnutritive solutions to the duodenum reduced meal size in the rat. One interpretation of the results of these

early infusion experiments is that the intestine is a source of satiety signals during a meal. Another interpretation is that the infusions cause some discomfort or intensify signals in an abnormal way.

Many of the recent studies of intestinal satiety have used the paradigm of the sham-feeding rat. A gastric fistula is implanted into the animal and it is opened during the feeding test. At various times before or after feeding, an infusion of glucose or some other nutrient is made into the duodenum. One rat study found that infusing 2.25 kcal of an elemental liquid diet over 6 min into the duodenum reduced sham-feeding most effectively when the infusion began 12 min after the rat began eating (83). This delay may correspond to the time when a rat normally begins to end a feeding bout. Oddly enough, the same substantial infusion of the diet 6–12 min into the duodenum before the rat began sham-feeding had no effect on its feeding behavior. This result suggests that the intestinal signal is quite transient and that oral, gastric, and intestinal signals must occur at the same time for feeding to be inhibited.

Most of the intestinal satiety studies have been done in rats and monkeys. In one rat study, Liebling et al. (84) infused a liquid diet with a caloric value of .375 kcal/mL directly into the duodenum of rats. They found a small reduction in sham feeding when 3 mL was infused over 3 min and a larger reduction when 6 mL was infused over 6 min. This rate of infusion is double the normal rate of nutrient delivery to the intestine. In a similar study in rhesus monkeys, 20, 40, and 60 mL of a liquid diet containing 1 kcal/mL was delivered into the duodenum at a rate of 5 or 7.5 mL/min (85). The 20-mL infusion produced a small significant inhibition of sham feeding, which increased with increasing doses. In most of these sham-feeding studies, feeding continues throughout the test period in part because gastric distension is not available as a signal to inhibit food intake.

Most of these studies suggest that there is an intestinal signal that inhibits food intake. Such a satiety signal could be transmitted to the brain through the peripheral nerves. Several investigators have recorded from the vagus and from mesenteric nerves. They have found that there is an increased firing rate when glucose or amino acids are placed in the lumen of the intestine (86–89). Other studies have shown that vagotomy prevents the reduced food intake caused by intestinal infusions (82,90). In recent years, Yox et al. have continued the exploration of the way in which intestinal satiety is communicated to the brain. They used an infusion rate that they determined was the equivalent of the gastric emptying rate of their rats.

The infusion of 10 cc of maltose or oleic acid at a rate of 0.13 kcal/min reduces food intake while octanoic acid and casein hydrolysate has minimal effects. The effects of maltose and oleic acid on sham-feeding can be blocked by capsaicin treatment or by vagotomy (91,92), which again shows that the intestinal signal may travel through the vagal afferents to diminish food intake.

In a very interesting study, McHugh and Moran (93) allowed monkeys to drink 150 mL of a 1 kcal/mL glucose solution and found that 21.6 mL passed into the duodenum in the first 5 min. Then, they infused the 21.6 mL into the intestine of fasted monkeys over 3–5 min and observed their feeding behavior for the next 4 hr. The monkeys with glucose infused directly into their intestine showed a substantially reduced food intake during the first hour compared to monkeys that had delivered the same amount of glucose into their own intestine through normal gastric emptying. Only after 3–4 hr did their food intake return to the same levels as the controls. Thus, the delivery of an appropriate amount of glucose directly into the intestine, but in a less than physiological way, caused an extra large suppression of food intake. The authors conclude that an intestinal infusion, without the stimuli associated with the taste and swallowing of food and without gastric distension, may have reduced food intake in an abnormal way. They question whether the infusion of nutrients into the intestine produces a normal satiety. If the delivery of food to the intestine makes the animal feel discomfort or malaise, then the reduction of food intake cannot be accurately ascribed to internal mechanisms that normally produce satiety.

What would be a physiological mode and rate of delivery of food into the small intestine? It is obvious that food normally arrives in the intestine after it has been mixed with saliva and partially digested by acid and digestive enzymes in the stomach. The release of food from the stomach is periodic and results from a pressure differential between the gastric antrum and the duodenal bulb (76). A small spurt of food is delivered into the upper duodenum at the end of some of the gastric contractions depending on local pressure levels. This food is then distributed along the upper small intestine by repeated constrictions of the intestinal circular muscles, which mix the chyme rapidly with bicarbonate and digestive enzymes secreted from the pancreas and with bile secreted from the liver and gallbladder. Thus, under normal physiological conditions, the food is already partially processed before it reaches the duodenum, and then it is immediately mixed with the current intestinal contents. The food must

arrive at the duodenal bulb in a predigested state for delivery to be considered normal. Complex foods such as plant or animal tissues would be most changed by the digestive process while simplified foods, such as pure sugar or amino acid solutions, would change little. These latter simple foods are most often used in experiments but they rarely occur in nature and are even limited in the kitchen cupboard. Most importantly, the food must be delivered at a rate that is within the normal physiological range. That rate can be estimated by examining the total food intake of a rat or any other animal during a 24-hr period. Adult rats eat between 60 and 100 kcal/d depending upon the strain and the physical conditions of the experiment. If this amount of food were delivered to the duodenum at a constant rate throughout the day, then 0.04–0.07 kcal would arrive per minute. As discussed above, the rate of gastric emptying increases during a meal to a level that is three to four times the average rate between meals and then slows to about half the normal rate in the 10 min after the meal ceases. A reasonable estimate of the rate of delivery of food to the small intestines of the rat is 0.14–0.25 kcal/min during a meal and 0.02–0.04 kcal/min in the 10 min thereafter. Deliveries of liquid food to the small intestine at a much higher rate are common in the feeding behavior literature.

An important test of the value of an food intake experiment is whether the delivery of food to the intestine has approximated physiological conditions. Many studies in the literature deliver food at a rate that goes beyond normal physiological limits and, in almost all studies, the infused food has not been processed by the digestive tract. The study that comes closest to using physiological procedures to assess the importance of intestinal satiety has been done with crossed-intestines rats (94). These rats are parabiotic pairs that have a further intestinal surgery in which a 30-cm segment of lower duodenum or upper jejunum is isolated from the small intestine of each rat in the pair and then surgically connected to the intestine of its partner (see Fig. 9). After the surgery is complete, the food eaten by each rat in the pair arrives in the rat's own stomach, travels through a 5-cm segment of upper duodenum that includes the entrance of the common bile and pancreatic duct and then passes into the 30-cm crossed segment of its partner. Thus, the food ingested by these rats has been mixed with saliva and gastric secretions before entering the small intestine, where it is also mixed with pancreatic and hepatic secretions before it crosses into the intestinal segment of its partner. Some of this food is digested and absorbed in the partner's upper small intestine, and then the remaining food passes back into

**Figure 9** Diagram of two-way crossed-intestines rats. A 30-cm segment of lower duodenum and upper jejunum is isolated from the gastrointestinal (GI) tract of each rat and is connected to the intestine of its partner. The preparation is symmetrical. Each rat loses food into the upper small intestine of its partner, and some of that food returns to its own lower jejunum. The stippled GI tract belongs to the rat on the right.

the lower jejunum of the rat that fed and travels down along the rest of the length of that rat's small intestine and lower gut. The surgery is symmetrical, so that each rat loses some of the food that it eats into the upper small intestine of its partner.

The short-term experiment testing the role of the intestine in the termination of a meal, is done by feeding one rat in the pair 10 or 30 min before the partner and then measuring the partner's intake after the crossed segment has been stimulated by food. A rat will normally complete its first meal after a 7-hr fast in 6–8 min. The results of several experiments show that the food intake of both rats is not affected by having a delay of 10 or 30 min (94). The rat allowed to feed first does not overeat even through its own lower duodenum and upper jejunum have not come into contact with ingested food. The unfed partner does not reduce its food intake

when allowed to eat even through the ingested food of the feeding rat can definitively be shown to be present in the crossed segment and some of it has been absorbed into the bloodstream within minutes after the beginning of the first rat's meal. Thus, endogenous signals arising in a 30-cm segment of the small intestine do not alter food intake during a meal after a 7-hr fast, especially when the food has been processed by the gut in a highly physiological way.

The major limitation of the crossed intestines experiment is that the 30-cm crossed segment is only part of the normal length of the rat's small intestine, which has a total length of 100–110 cm. Of course, the top third of the small intestine sees the ingested food more rapidly and is a major site for the absorption of nutrients (95). Nevertheless, it could be argued that it is necessary to stimulate a longer length of intestine to show "intestinal satiety." On the other hand, the experiment is exceptional in its physiological delivery of food into this critical upper intestinal segment. The food has been processed through the mouth, stomach, and upper duodenum and has been mixed with digestive enzymes and other salivary, gastric, pancreatic, and intestinal secretions. Experiments have shown that the rate of gastric emptying is slightly higher during the first 10 min after a meal in the crossed-intestines rats than in control parabiotic pairs (94). Thus, feeding one rat in the pair should have delivered slightly more food than is normal to the crossed segment of the partner. Still, there was no effect on the partner's food intake when measured at 10 or 30 min. Measurements were made of the rate of absorption of radioactive glucose and amino acid that were added to the diet, and it was found that at 10 min there was significantly more radiolabel in the bloodstream of the unfed and hungry rat than in the bloodstream of the fed and satiated rat (94). The conclusion from this experiment is that the combined signals arising in the 30-cm crossed-intestinal segment, including neural, hormonal, and metabolic signals, were insufficient to inhibit short-term food intake. Since the upper small intestine is a major site for the absorption of ingested food, these results suggest that the upper intestine may not generate signals that inhibit food intake. If intestinal signals are normally involved in the control of food intake during a meal, then it is also puzzling that a free-feeding crossed-intestines rat that lacks signals arising in its own 30-cm crossed-intestinal segment does not overeat, since "satiety" signals are missing in this animal.

The reader might be confused by the seemingly contradictory conclusions drawn between the results from the above study (94) (see Fig. 9) and from the one-way crossed-intestines experiment (13) (see Fig. 3) in

which there was a large change in the daily food intake of both partners in a parabiotic pair when one rat continuously lost food into the crossed segment of its partner. It is important to note that the study described in this section used a symmetrical surgical preparation and was designed to investigate changes in short-term food intake, while the second study (Fig. 3) was designed to investigate changes in daily food intake due to the continuous loss of calories from one rat into the intestine and bloodstream of the other. The seeming contradiction about the role of the intestine in the control of short- and long-term intake can be readily investigated in the left rat of the one-way crossed-intestines model (Fig. 3). By feeding the rat on the right 30 min before or after its partner, the rat on the left, which receives nutrients into its 30-cm crossed-intestinal segment, either can have its crossed segment stimulated by predigested food when it begins to feed or the intestinal segment can remain empty during feeding. If the signals in the crossed-intestinal segment were to inhibit food intake during a meal, then the rat on the left, which has its crossed segment stimulated with food, should eat less while the same rat with an empty crossed segment should eat more. In fact, these rats ate the same amount of food whether fed before or after their partners (13). Thus, we can conclude that even in this one-way crossed-intestines preparation where the rats have dramatically changed their daily food intakes, there is still no effect of the physiological stimulation of the 30-cm crossed-intestinal segments on short-term food intake. Indeed, the two crossed-intestines experiments are consistent in providing data from which one can draw the conclusion that the physiological stimulation of the 30-cm crossed segment does not alter short-term food intake.

Another important conclusion from the one-way crossed-intestines experiment is that the short-term and the long-term controls of food intake are clearly different. In the same animals that show large and sustained changes in daily food intake, there is no effect of intestinal stimulation on short-term intake. In other words, the same surgery that alters daily food intake in a dramatic and long-lasting way has no effect on meal intake after a 7-hr fast. The results from this model strongly argue for two separate physiological mechanisms: the first involved in the control of short-term or meal intake, and the second, in the control of long-term or daily food intake.

In summary, several experiments have shown that infusion of nutrients into the small intestine can inhibit food intake during a single meal. This inhibition is often blocked by vagotomy. When nutrients are infused into

the duodenum of rhesus monkeys at the same rate that it is normally released from the stomach, there is an inhibition of food intake that is much greater than when the same amount of food is delivered to the intestine by gastric emptying. In addition, when nutrients are delivered to a limited segment of the upper small intestine in a physiological way, there is little change in short-term food intake. Furthermore, most studies that deliver food directly to the intestine do so at nonphysiological rate and in a nonphysiological form. Thus, the presence of a short-term "intestinal satiety" signal during normal feeding remains possible but has not been adequately demonstrated. The results of the one-way crossed-intestine studies show that there are signals arising at the level of the upper small intestine and/or resulting from the absorption of food that have no effect on short-term food intake, but that do control daily food intake in a very large and significant way. The importance of "satiety" signals arising in the stomach and small intestine can also be assessed by observing the effect of the infusion of intravenous nutrients that bypass the gut. These studies will be reviewed in a later section of this paper on Metabolic Control of Food Intake.

## VII EFFECT OF GASTROINTESTINAL HORMONES ON FOOD INTAKE

The issue of whether the stomach and small intestine are sources of short-term satiety signals also has direct implications for the role of gastrointestinal hormones in the control of food intake. If an organ generates signals that induce satiety, then the hormones it releases may also be part of the that signal.

During a normal meal, the ingested food is delivered to the stomach, which allows some food to pass rapidly into the duodenum until intestinal mechanisms inhibit gastric emptying (18). Thus, soon after the beginning of a meal, the mucosal surface of the gut from mouth to mid-ileum has been partially stimulated with nutrients. As previously mentioned, plasma glucose and fatty acid levels change within minutes after the beginning of a meal of laboratory chow (20). Plasma insulin levels also increase rapidly, in part due to cephalic insulin release (96) and in part due to the sustained absorption of glucose and the release of intestinal hormones, such as gastric inhibitory peptide (GIP) and glucagon-like peptide 1 (GLP1) (97). Thus, food has been digested and absorbed and gut hormones have been released long before the end of a meal. This fact leaves the distinct possibility that hormones released by the small intestine during the

absorption of food could be part of the signal that terminates a meal.

The gut is the largest endocrine organ in the body (98). After a meal, a large number of gastrointestinal hormones are released including gastrin, somatostatin, secretin, cholecystokinin (CCK), GIP, neurotensin, GLP-1, GLP-2, and peptide YY (PYY) (99). Any of these hormones, especially those arising in the stomach or upper small intestine, would be considered prime candidates as possible gastrointestinal satiety signals. The first gut hormones to be examined for a role in the control of food intake during a meal were secretin and cholecystokinin (CCK). Glick et al. (100) injected secretin and CCK separately or together into the peritoneal cavity or into the aorta of rats and found that neither hormone produced a significant reduction of food intake. There was a tendency for the IP injection of CCK to reduced food intake, but the result with multiple tests on six rats was not significant at  $P = .05$ . Koopmans et al. (101) injected CCK into the peritoneal cavity of mice and found that the mice reduced both their food and water intake, suggesting that the dose of CCK was not specific to feeding behavior and may have been causing malaise in the animals. Thereafter, Gibbs et al. (102,103) injected CCK and its octapeptide into the peritoneal cavity of rats and found a dose-dependent reduction of food intake for both forms of CCK. Secretin alone or in conjunction with CCK had no effect on food intake. They injected an intermediate dose of CCK, 20 U/kg IP, and found no effect on water intake.

To test the possibility of malaise resulting from the CCK injection, they used a relatively weak test. A one-bottle conditioned aversion paradigm was used with the attractive substance, saccharin, added to water paired with the injection of CCK. They found that a high dose of CCK, 40 U/kg, failed to generate a conditioned taste aversion in these rats, although lithium chloride, a nauseating poison, was very effective. Deutsch and Hardy (104) challenged these results by doing a more sensitive, two-bottle conditioned aversion test with different neutral flavors associated with CCK and vehicle administration. They found that intake of the flavored water associated with the 40 U/kg CCK injection was reduced from 9.4 mL to 3.3 mL for the flavor paired with CCK injection. Thus, at the highest dose, they found a mild conditioned taste aversion which can be interpreted as due to either malaise or the aversive side of excessive satiety.

The importance of CCK as a satiety signal remains controversial. CCK injected into the peritoneal cavity causes an inhibition of gastric motility and an excitation

of duodenal phasic activity (105). A meal usually generates an increase in gastric motility and an inhibition of duodenal activity. Thus, exogenous CCK could be causing unusual gut motility patterns that are communicated by nerves to the brain to inhibit food intake. It is now well established that exogenous CCK requires an intact vagus nerve to cause an inhibition of food intake (106–108). There is also evidence that doses of CCK that inhibit food intake produce plasma levels that are an order of magnitude higher than normal postprandial CCK levels (109). Moreover, IV infusion of a monoclonal antibody to CCK blocked CCK-stimulated pancreatic enzyme secretion, but had no stimulatory effect on food intake (110).

One of the most convincing pieces of evidence that endogenous CCK acts to reduce food intake is that specific CCK antagonists cause an increase in food intake (111–113). Since these antagonists cause an increase in feeding behavior, it is unlikely that the change can be due to some nonspecific cause. There are two known types of CCK receptors: (1) CCK-A receptors that are present in the pancreas, gallbladder, pyloric sphincter, afferent vagal fibers (114,115), and specific brain regions, including the area postrema, the nucleus tractus solitarius, and the hypothalamus, and (2) CCK-B receptors that are distributed widely in the brain and in the stomach (116). Specific blockade of type A receptors, but not of type B receptors, attenuates the inhibition of food intake caused by CCK (117,118). However, these antagonists cross the blood brain barrier, are distributed throughout the body, and could have their effects either in the periphery or in the brain. Since CCK-A receptors are found in both the brain and the periphery, it is not yet clear where the antagonists act (119). It is possible that CCK-A antagonists act in the brain to increase food intake and not in the periphery. Another indication that the CCK-A receptor is involved in the inhibition of food intake is the existence of OLETF rats that have been shown to have a deletion in the CCK-A receptor that makes it nonfunctional (120). These rats are hyperphagic, have an overexpression of NPY in the dorsomedial hypothalamus, and become moderate obese (121). As mentioned above, the role of the mutant CCK-A receptor could be either central or peripheral.

The ability of the upper gut peptides gastrin, secretin, and GIP to reduce food intake has been tested using a sham-feeding paradigm on rats with open gastric fistuli (119). It was found that even at relatively high doses, none of these peptides had an inhibitory effect on feeding behavior. However, CCK and CCK octapeptide were effective in inhibiting sham feeding.

Another peptide that has been reported to reduce food intake is bombesin. Its intraperitoneal delivery induced a dose-dependent reduction of food intake (122,123) (see Fig. 10). Bombesin is isolated from amphibian skin and has some sequence homology with the mammalian neurotransmitter, gastrin-releasing polypeptide (GRP). It normally does not circulate in mammals, but its injection into the bloodstream causes the release of several pancreatic and gut hormones (124), making it difficult to assess the specific action of GRP. Injection of bombesin into the lateral ventricle reduced food intake and produced an increase in grooming and resting at a dose below that needed to inhibit food intake (125). There is controversy about the way in which bombesin inhibits food intake. One study disconnected all the nerves to the gut by doing a vagotomy and cord transection. They found that complete denervation, but not vagotomy alone, inhibited bombesin's effect on food intake (126). However, the rats were 18-hr food deprived and ate more than normal stomach capacity. This study suggests that bombesin acts peripherally to inhibit food intake. On the other hand, other studies suggest that bombesin may act on the central nervous system. Bombesin-like peptides are present in the paraventricular nucleus, drop during feeding behaviour, and rise after the meal is finished (127). In addition, the reduction of food intake induced by peripheral bombesin can be blocked

by the intraventricular injection of a bombesin receptor antagonist (128). A bombesin antagonist administered at high doses had no effect on normal food intake but was able to block bombesin-induced satiety (129). It appears to act independently of CCK.

Serotonin is present in many endocrine cells in the gut (ECL cells) and is released by a wide variety of stimuli (130). Its major effect is local since serotonin is rapidly inactivated in the bloodstream. It appears to stimulate afferent vagal neurons that terminate in the intestinal mucosa and project to the brain (131). Recent work has shown that CCK and serotonin activate different vagal afferents (132) and that glucose stimulates 5HT release while peptides stimulate CCK release from endocrine cells (133). Serotonin has also been shown to inhibit the intake of all the major macronutrients when injected IP (134). Its precursor, tryptophan, also reduces food intake in humans (135). Both of these studies delivered serotonin (or its precursor) to the periphery, making it difficult to determine whether the effects were central or peripheral because brain serotonin also inhibits food intake (7).

Another set of hormones are present in endocrine cells of the lower gut, and some of these have been shown to inhibit food intake. The hormones, neurotensin (NT), peptide YY (PYY) and glucagon-like peptide 1 and 2 (GLP-1 and GLP-2), are present in endocrine cells that have an increased frequency as

**Figure 10** Percent suppression of food intake during the first 15 min of food presentation as increasing amounts of the gut peptides cholecystokinin octapeptide (CCK8) and bombesin (BBS) are injected into the peritoneal cavity of rats. (From Ref. 122.)

one moves down the small intestine (97). A description of these hormones will be presented in the section on Signals Arising in the Lower Gut (see below).

### VIII EFFECT OF PANCREATIC HORMONES ON FOOD INTAKE

When nutrients stimulate the surface of the small intestine, GI hormones are released. Two hormones, one from the upper small intestine, gastric inhibitory polypeptide (GIP), and another from the lower small intestine, glucagon-like peptide 1 (GLP-1), have been shown to be incretins for the release of the pancreatic hormones, insulin and amylin, and to indirectly inhibit the release of glucagon (97). Thus, after a meal containing carbohydrate, plasma insulin and amylin levels rise and glucagon levels fall. Glucagon may continue to be released if there is protein in the diet since it helps to mediate amino acid disposal (136).

The pancreatic hormone glucagon has long been known to suppress food intake in man and rodents (137,138). This suppression can be blocked by vagotomy (139) and, more specifically, by hepatic vagotomy (140). Glucagon is the hormone of starvation and catabolism, and its plasma levels increase during a fast. It falls soon after a carbohydrate meal or an oral glucose tolerance test, but can remain elevated or even go up slowly after a meal containing protein and fat (136,141). Sometimes it even goes down after a mixed meal (142). If it has a role in satiety, it must be rather specific for the noncarbohydrate macronutrients. The most convincing piece of evidence that glucagon may be acting as a satiety agent is that the injection of glucagon antibodies causes an increase in food intake (143,144). Glucagon reduces food intake when it is infused into the portal vein (138) and is less effective when it is infused into the vena cava (145). All of these results suggest that the glucagon acts on the liver to inhibit food intake and that the information about the presence of glucagon is sent to the brain through the hepatic vagal nerve. Whether its effect is the result of normal physiology or malaise is not clear. The major difficulty with the glucagon hypothesis is that glucagon is the hormone of starvation, provoking both glycogenolysis and gluconeogenesis, and glucagon has its highest concentration in the blood during a fast when the animals are usually hungry.

Another pancreatic hormone, insulin, has long been thought to be involved in the control of food intake. Insulin rises after a meal and gradually declines as carbohydrate absorption diminishes (21). The “gluco-

static” theory originated by Jean Mayer in the 1950s asserted that rats became satiated when there was an arteriovenous difference in blood glucose levels, indicating that there was a significant uptake of glucose by peripheral tissues and that they became hungry when the A-V difference disappeared (146). Since insulin is the main hormone that moves glucose out of the bloodstream into cells and, thereby, causes an A-V difference, the theory was essentially an insulin theory of the termination of food intake. Woods and Porte (147) extended this theory and claimed that the average plasma insulin level feeds back on the brain to inhibit food intake. Investigators have noted that blood insulin levels tended to increase with increasing obesity, demonstrating the phenomenon of insulin resistance (148,149). Woods and Porte postulated that these elevated blood insulin levels provide a feedback signal that informs the brain about the amount of adipose tissue and, if adipose tissue is excessive, inhibits food intake. One difficulty with this theory is that obese individuals tend to eat more, rather than less, than their lean counterparts (150), so well-documented increases in plasma insulin could not be inhibiting their food intake. The Woods and Porte theory is supported by a number of studies that have shown that insulin delivered intracranially causes a reduction of food intake and a loss of body weight (151,152).

However, the critical question is whether peripheral insulin crosses over into the brain to inhibit food intake. It has been shown in dogs that peripheral insulin crosses slowly into the brain and appears in the cerebral spinal fluid (153). Does this insulin alter food intake? There is conflicting evidence. Vanderweele et al. (154) infused 1, 2, and 6 units of insulin in the peritoneal cavity of rats by osmotic minipump and found a small reduction of daily food intake, but it was not dose dependent. In diabetic animals that had been allowed to become hyperphagic, increasing doses of insulin reduced daily food intake but failed to bring food intake back to normal levels (155). In another rat study, very low doses of insulin, either 1 or 2 mU, were infused into the hepatic portal vein during each voluntary meal throughout the daylight hours (156). Meal size decreased in a dose-dependent manner while there was no change in the number of meals. Daily intake was not measured. In contrast, Willing et al. (157,158) continuously infused 2–4 units of insulin into the vena cava of rats that had been made diabetic 1 day before infusion. The rats’ food intake increased with increasing dose until it reached 30–40% above baseline levels (see Fig. 11). During this time, urinary glucose was gradually reduced to zero, showing that the insulin was

**Figure 11** Daily food intake of rats made diabetic after the baseline infusion of saline and, thereafter, infused intravenously with increasing daily doses of insulin. The open bars indicate the amount of glucose lost in the urine of these rats. Daily food intake increases at the lower doses of insulin even though there is an elevated blood glucose and substantial loss of glucose through the urine.

effective in moving glucose into cells. Overfeeding occurred before glucose had been cleared from the urine and while blood glucose levels were greatly elevated. The same increases in intake were observed whether insulin was infused in the vena cava or into the portal vein. To test whether insulin might cross the blood brain barrier to affect food intake, Walls and Koopmans (159) continuously infused insulin into the carotid artery leading to the brain. Since blood flow to the brain is 2–3% of cardiac output, blood insulin levels enhanced by the infusion would be greatly elevated while passing through the brain. They found that carotid insulin was no more effective in altering food intake than vena cava insulin, and in both cases, food intake was significantly increased.

When human studies are examined, insulin infusion during a meal either produced no effect or caused an increase in food intake. Woo et al. (160) infused both insulin and glucose to mimic their postprandial levels before the meal began. They found no change in meal size even with substantially elevated insulin levels. Rodin et al. (161) infused insulin while maintaining plasma glucose levels. They recorded increased hunger ratings with a high insulin infusion and a substantially increased meal at the end of the infusion. Holt and Miller (162) tested different types of rice meals and found that those meals that allowed rapid absorption

of glucose and high plasma insulin levels produced higher hunger ratings and increased food intake at the end of the 2-hr session. Most clinical studies have found that insulin infusion leads to a gain in body weight (163). In short, human studies have tended to find that insulin increases rather than inhibits food intake.

A third pancreatic hormone, amylin, is cosecreted from the beta-cells with insulin and has been shown to inhibit food intake in mice and rats (164,165). Amylin reduces basal and glucose-stimulated insulin secretion (166) and is normally released after a meal. Amylin also decreases food intake when injected intraventricularly (167,168). High-affinity binding sites have been found for amylin in several brain regions (169). Recent work has shown that peripheral amylin inhibits food intake and gastric emptying at close to physiological doses (170). Subdiaphragmatic vagotomy does not block peripheral amylin's effect (171).

Another islet hormone is somatostatin, which is a 14- or 28-amino acid peptide that was originally isolated from sheep hypothalamus (172) but is present in many of the organs of the gut, including stomach, pancreatic islets, and small intestine (97). Somatostatin (SOM) has been found in the CNS and enteric nerves as well as endocrine cells (173) and cells with short paracrine processes that terminate on other endocrine cells (174). Its main effect is to inhibit the release of other

hormones or to inhibit various physiological functions, such as gastric acid and pepsin secretion (175,176), pancreatic exocrine secretion (177), endocrine secretion (178), and intestinal absorption (179). When injected IP, SOM has been shown to inhibit food intake in rats (180). This result is very hard to interpret since one would expect that SOM injection would alter the plasma levels of several brain or gut hormones, including growth hormone, gastrin, cholecystokinin, insulin, and glucagon, all of which could have effects on food intake, not to mention a lot of other changes in gut activity and function. A recent study reports that a somatostatin analog reduced the rate of gastric emptying during the period of time when the stomach was being filled (181).

## IX UNUSUAL GUT-RELATED PEPTIDE HORMONES

Several unusual peptides have been shown to have an effect on food intake. These peptides are generated during the processes of digesting and absorbing food and could provide an indirect signal to the brain of the amount and type of food that has been absorbed. The previous studies on one-way crossed-intestines rats (see Fig. 3) have shown that the absorption of food provides the major signal that controls long-term food intake. The three gut-related peptides that affect food intake are enterostatin, B-casomorphin, and apo A-IV.

Enterostatin has been shown to inhibit food intake when injected into the stomach, intestine, or peritoneal cavity (182). It is a pentapeptide that is released by the cleavage of procolipase by trypsin in the lumen of the digestive tract to produce enterostatin and colipase (183). Enterostatin's amino acid sequence is well preserved across many animal species. Procolipase is secreted from the pancreas in response to CCK and specifically inhibits fat intake if animals are given a choice of diets or dietary components (184). If fat is a sustained portion of the diet, more procolipase is secreted and could inhibit feeding behavior. One difficulty with the belief that enterostatin inhibits food intake under normal circumstances is that enterostatin is degraded by membrane peptidases in the intestinal brush border (185) and is, therefore, unlikely to be absorbed intact unless some special transport mechanism exists. However, Mei and Erlanson-Albertsson (186) have shown that plasma levels of enterostatin increased significantly after a meal and respond to the fat content of the meal. An interesting finding is that mRNA for procolipase and the procolipase protein are

present in endocrine cells in the fundic region of the stomach as well as in the antrum and duodenum (187). The gastric procolipase was cloned, sequenced, and found to be identical to pancreatic procolipase (188). Colipase has been found in the lumen of the stomach (189), and it is possible that cleaved enterostatin could be released into the bloodstream. Injection of small amounts of enterostatin into cerebral ventricles suppress fat intake. There is reasonably strong evidence the enterostatin inhibits the intake of fat after a fast, but the role of enterostatin in the long-term control of food and fat intake under the free-feeding conditions has been questioned (190).

Another peptide, beta-casomorphin, is a cleavage product of milk casein that stimulates food intake when delivered intraperitoneally. This septapeptide was first discovered from a digest of milk because of its morphine-like activity (191). It has been found to increase fat intake, to inhibit intestinal motility (192,193), and to stimulate sleep in neonates (194). It appears to interact with enterostatin by preventing enterostatin's usual suppression of fat intake. Indeed, based on their feeding behavior curves, White et al. (195) hypothesize that beta-casomorphin may be an enterostatin receptor antagonist. The role of beta-casomorphin in the control of food intake has the same explanatory problem as enterostatin: How does the peptide avoid digestion and get transferred into the GI tissue or the bloodstream in order to have a systemic influence? Of course, its importance for the control of food intake is based on the presence of milk in the diet. Since beta-casomorphin stimulates food intake, it is possible that its main role is to override satiety signals in the early stages of life, when milk is a large part of the animal's diet and when rapid growth is important for survival. Indeed, it has been known for a long time that satiety signals are quite limited in neonatal rats (196).

The third gut-related peptide that affects food intake is a glycoprotein (with a molecular weight of ~ 46,000) that is attached to newly synthesized fat particles, called chylomicrons, in the intestinal absorptive cell (197). The apoproteins, apo A-I and apo A-IV, are added to the surface of the chylomicron in order to solubilize it for transport through the lamina propria of the intestine and through the intestinal lymph ducts before these chylomicrons enter the bloodstream near the heart. Apo A-IV is readily displaced from chylomicrons to other lipoproteins, such as HDL, in the bloodstream, and 80% of it circulates in the bloodstream as a free protein. Only the intestine makes Apo A-IV (198,199). Patrick Tso and colleagues have shown that Apo A-IV is effective in reducing food intake (200,201). They

collected intestinal lymph before and at 6–8 hr after a meal and then infused it intravenously into rats that had been deprived of food for 24 hr. They found that postmeal lymph caused a substantial reduction of food intake in the first 30 min of feeding compared to rats that had a saline or a fasting lymph infusion. An infusion of the equivalent amount of lipid and phospholipid (2% intralipid infusion) had very little effect on short-term food intake which is consistent with the long-term lipid infusion studies (see Metabolic Signals below). However, infusion of three increasing doses of apo A-IV demonstrated a clear dose-dependent inhibition while infusion of Apo A-I had no effect on food intake. Immunoprecipitation of Apo A-IV in postmeal lymph returned food intake back to normal levels, demonstrating a very specific Apo A-IV effect. Apo A-IV was also effective in inhibiting intake when infused in small amounts intracranially, while antirat Apo A-IV delivered ICV increased food intake (202). Intracisternal Apo A-IV also increased gastric acid secretion and motility (203,204). Apo A-IV or a related fragment has been found in cerebrospinal fluid (202). It is difficult to understand how such a large peptide as Apo A-IV would enter the brain unless actively transported. Although IV infused Apo A-IV has effects on short-term food intake, the normal stimulus and route of entry of Apo A-IV into the bloodstream suggest a regulatory effect on long-term food intake, which is supported by the fact that IV infusion of Apo A-IV decreases food intake in ad libitum rats (201,205).

## **X CYTOKINES AND INFLAMMATORY PEPTIDE REGULATORS OF FOOD INTAKE**

Not only do various gastrointestinal peptides alter food intake during a meal, but cytokines released in the gut wall or elsewhere as a result of infection, inflammation, or malignancy also tend to inhibit food intake (206–208). These cytokines are released by leukocytes and surrounding tissue. The most prominent cytokines that produce anorexia are interferon- $\alpha$  (IFN $\alpha$ ); interleukin 1, 6, and 8 (IL-1, IL-6, IL-8); and tumor necrosis factor- $\alpha$  (TNF $\alpha$ ). They can have multiple peripheral effects including changes in hormone levels (209), GI motility (210), and metabolic pathways (211), as well as changes in neurotransmitter levels in the hypothalamus (212). They may also elevate temperature and induce sleep. These cytokines can act on specific receptors in the central nervous system. IFN $\alpha$  and IL-1b excite the glucose sensitive neurons in the ventromedial hypo-

thalamus and suppress neuronal activity along with TNF $\alpha$  in the lateral hypothalamus. The intracerebral injection of a specific IL-1 receptor antagonist blocks food intake suppression induced by IL-1b (213), showing that the site of action of IL-1 was in the brain.

Cytokines rarely act alone because they stimulate the release of other cytokines (214). Often, they enhance each other's effectiveness in producing anorexia or, in more serious conditions such as cancer, in producing cachexia, a type of wasting syndrome that includes reduced food intake. Studies have shown that IL-1 and TNF $\alpha$  act synergistically to reduce food intake (215). There are several ways to limit anorexia. Feeding n-3 polyunsaturated fatty acids (216), giving cytokine receptor antagonists or antibodies (213), or administering hormones, such as glucocorticoids or, more specifically, megestrol acetate (217) seems to limit the mild nausea and lack of interests in food. Another peptide closely related to IL-6, called ciliary neurotrophic factor (CNTF), has been added to the list of cytokinelike molecules that inhibit food intake (218).

Although cytokines have now been clearly shown to have direct effects on the inhibition of food intake, these effects are probably not intended to limit body weight. The more likely goal is to limit the animal's desire for food which, if acted upon, would expose the animal to the risk of predation at a time when it is not capable of peak physical activity. The long-term need for calorie balance may be temporarily set aside for the more immediate goal of survival. There may also be some benefit to recovery by having elevated temperature or a limited use of joints, muscles, and bone (219,220). The effect of these peptides on intake should not be thought of as regulators of energy balance, but as defenders from further tissue damage.

## **XI CROSS-CIRCULATED RATS AND GUT NERVE SECTIONS**

All of the above studies show that many gut-related peptides or hormones play a role in the inhibition of food intake. Another way of testing the role of hormones in the control of food intake is to cross the circulation of two rats in a parabiotic pair. This can be done by connecting the abdominal aorta of each rat with the ascending vena cava of its partner (see Fig. 12). After this surgery, the blood of the two rats is completely mixed every minute (221). The role of blood factors in the control of feeding behavior can be tested by feeding one of the rats in a pair 10 or 30 min before its partner after a 7-hr deprivation. Rats deprived for 7 hr

**Figure 12** Diagram of conscious rats with continuous cross-circulation of the blood between the two rats. Grafts from other inbred rats are used to connect the descending aorta of one rat to the ascending vena cava of its partner. Thirty percent of cardiac output crosses in each 15-sec circulation time, and the blood is completely mixed every minute. The stippled vessels are those that carry only arterial blood.

will normally stop eating after 6–8 min based on their own internal satiety signals. The rat fed first will have all of its released hormones and absorbed nutrients diluted into twice its normal amount of blood and removed by twice the amount of tissue. This should lower the plasma levels of the hormones released by the meal and of all the absorbed nutrients. If these humoral factors are important in the control of meal intake, the rat fed first should eat a larger-than-normal meal in order to bring these humoral signals up to some specified level. On the other hand, its partner fed 10 or 30 min later will already have elevated hormones and nutrients present in its blood. If these humoral signals are important in the termination of a meal, these rats should eat a smaller meal. The results of this experiment were that the rats ate the same size meal regardless of whether they ate first, and had a low plasma level of hormones or nutrients or ate second when they were already stimulated by these humoral

signals. The natural conclusion from this study is that the combination of released hormones and absorbed nutrients is not an important signal in the termination of a meal when these substances flow through the systemic circulation from one rat to the other. Hormones and nutrients may have an effect on food intake by stimulating the liver, since all gut hormones released and all water-soluble nutrients absorbed by the intestine must pass through the liver before entering the general circulation. Thus, released hormones could act on the nerves in the wall of the gut or on nerves terminating in the portal vein and liver. However, once these humoral substances have passed into the vena cava which leads to the heart, they have already been diluted by the blood of the partner which has also been arriving into the ascending vena cava. Thus, the results of this study limit the possible satiety signals derived from a meal to neural signals generated in the gastrointestinal tract and the liver. These neural signals could be generated in the gastrointestinal tract and the liver. These neural signals could be generated by the local presence of hormones, for example, the high levels of hormones released into the lamina propria of the GI tract.

The results of the cross-circulation studies do challenge many of the theories that argue that nutrients or hormones present in the blood are involved in the control of meal intake. In fact, the results show that the combination of hormones released by the meal and nutrients absorbed as a result of feeding do not affect short-term food intake. Theorists with a different point of view may argue that results from parabiotic rats are not typical of normal, single animals. While it is true that these rats are restrained in their movement by the presence of the attached partner, the parabiotic surgery is relatively minor and there is no interference with any of the rat's internal organs other than end-to-side connections to their major blood vessels. No drugs or exogenous hormones have to be given to these animals at the time of testing; there are no worries about dose, site of action, type of injection, or possible malaise. The only change is  $\sim 30\%$  of their cardiac output is lost into their partner's bloodstream during each 15-sec recirculation time and, of course, 30% of the partner's blood returns continuously to the first rat. In short, the cross-circulated rats are normal parabiotic rats that live for more than a year without special attention. This surgical preparation has the enormous advantage of testing the role of not just one nutrient or hormone at a time, but of testing the role of all of the hormones released from the gut into the bloodstream after a meal and all of the absorbed nutrients at the same time. Since these substances are released or absorbed by normal body pro-

cesses that follow a meal, their plasma levels should remain within the normal range although levels are likely to be below normal concentrations. Although these rats have some restricted movement, their daily food intake is normal and they do provide a critical test of the role of all gut hormones and absorbed nutrients on the termination of a meal.

One difficulty in interpreting the cross-circulation is that these results seem to imply that nerves provide the only signals that inhibit food intake during a single meal. In many ways, an important role for nerves in the termination of a meal is a reasonable hypothesis. The bulk of the food eaten during a meal remains in the stomach and only empties slowly into the intestine. The combination of gastric distension receptors and intestinal neural chemoreceptors would be needed to inform the brain about the amount of food ingested. Since the stomach of a free-feeding rat is rarely empty, new food eaten can only be recognized by increased gastric distention or intensified signals from intestinal chemoreceptors. Thus, the expected internal changes suggest that neural messages are involved in the termination of food intake. On the other hand, there are many studies in which vagotomies have been done with no major long-term effect on food intake. Animals with vagotomies usually lose some weight and have changes in stomach emptying depending on their diet (222,223). However, their food intake usually does return to and stabilize at near normal levels. If the vagus nerve is not essential for production of a satiety signal and humoral signals play no role in the control of intake, then how does the animal know when to stop feeding? Are the splanchnic nerves essential? Or can the animal shift its attention from one type of signal to another when the internal signals do not produce the expected changes that normally follow feeding?

Very few studies have attempted a complete gut denervation which requires extensive surgery. There are four reports that claim that all nerves to the GI tract have been severed. Grossman et al. (224) did a three-stage operation over several months on dogs that had complete section of the vagus and sympathetic nerves. After recovery of several months, food intake was measured and they found that denervated dogs ate the same-size meals as intact dogs. When the dogs were given insulin injections, food intake for both dogs increased by the same amount. Harris et al. (225) followed the same surgical procedure and confirmed that there were no lasting results of nerve section on feeding behavior, and found that amphetamine caused a similar decrease in food intake in denervated and intact dogs. Both of these studies showed that the recovered

dogs ate normally and responded to substances that alter food intake in the same way as normal dogs. However, neither group of experimenters reported a postmortem confirmation that the surgery was complete and that nerve regeneration had failed to occur in the many months between surgery and behavioral testing.

More recently, Stuckey et al. (126) did a two-stage operation on rats doing dorsal rhizotomy and cord section first, allowing the rats to recover for 2–3 weeks, doing some behavioral tests and thereafter doing bilateral vagotomy with another week of recovery. The main objective of this study was to determine how bombesin affected food intake, so no data on meal pattern or daily intake were presented although the authors state that grossly normal feeding behavior was maintained. It was mentioned that the rats initially lost weight and then maintained it at a reduced level. This is not surprising since the spinal cord section would have eliminated movement in the back limbs, making both eating and exercising difficult. At postmortem, nerve section was confirmed with the aid of a dissecting microscope, but no histochemical or functional tests were done. These studies suggest that several months after complete denervation surgery, dogs and rats will feed in a grossly normal way. All of these studies required considerable recovery time.

To reexamine this important question, we have recently done a complete gut nerve section in rats (226). Four groups of rats had either bilateral vagotomy, bilateral splanchnectomy (elimination of the sympathetic nerves to the gut tissue), the combination of these two surgeries, or complete sham surgery including mobilization of the nerves and preparation for section but without an actual transection. We were determined to transect all of the accessory branches to each set of bilateral nerves. Because the nerves branch into fibers that are barely visible under a dissecting microscope, our procedure included the cutting of the mesenteric membranes through which these nerves are known to travel as well as the visible nerves themselves. The rats were fed the liquid diet Ensure for 17 overnight hours per day, and the results were quite interesting. The vagotomy produced a large reduction of daily food intake (sustained at 20% below normal) and a substantial loss of body weight, which remained depressed by 25% below the level of controls at 26 days when we sacrificed the rats and took blood and tissue samples. The splanchnectomy had no effect on food intake or body weight when done alone even though we cut all of the four or five branches of the splanchnic nerve that leave the celiac and mesenteric ganglia on each side and travel toward the sympathetic ganglia and spinal cord.

Splanchnectomy combined with vagotomy was no different from vagotomy alone, showing once again that the sympathetic gut nerves did not alter energy balance, but section of the vagus nerve was very effective in lowering food intake and body weight. Our study of vagotomy produced a larger effect than that found in most other studies in the literature (222,223). We also tested the size of the first meal after a 7-hr fast and found that 15-min meal size was not different across any of the surgical groups even though vagotomy caused a large reduction in daily intake. Apparently, the section of both extrinsic afferent and efferent gut nerves had no effect on short-term intake. We also measured the rats' response to a 50% dilution of the liquid diet by water. The rats adjusted both the size of their first meal and their daily intake on the first day so that caloric intake did not change. This result suggests that vagotomized rats were somehow regulating ingested calories and not just responding to food volume.

The dramatic effect of our vagotomies on energy balance and body weight loss can be interpreted in one of two ways. Either we were very effective in cutting all the branches of the vagus nerve and the resulting complete vagotomy led to a substantial reduction in food intake and body weight relative to other studies in the literature, or our cutting of the mesenteric membranes supporting the esophagus, stomach, and liver led to changes in the rats' comfort that exacerbated the reduction in food intake and body weight after vagotomy. In the later case, the changes would be nonregulatory. We used a histochemical method at the end of the study for verifying that the nerves had been sectioned: the calcitonin gene-related peptide (CGRP) fibers disappeared from the gastric wall and the duodenal mucosa after total nerve section, showing that afferent nerves had been destroyed. The observed large decrease of food intake and body weight following vagotomy is complicated from a theoretical perspective. If transection of the nerve simply cut vagal sensory fibers that increase their firing rate to inhibit food intake [as seen in Paintal's gastric distension vagal nerve fibers (51)], then vagotomy would be anticipated to cause an increase in food intake. If, on the other hand, the transections cut nerves that stimulate food intake when activated or reduce their firing rate to signal inhibition [as found in Nijijima's hepatic nerve recordings to portal glucose infusion (227)], then one would expect that food intake would decrease as has actually been found after most studies of vagotomy. These alternate explanations require further research with more selective afferent or efferent nerve sections. In fact, both vagotomies and sympathectomies cause large changes in the sensory

nerve cells found, respectively, in the nodose and dorsal root ganglia. These cell bodies actually change their dominant neurotransmitters (228,229), which suggests that peripheral nerve section may be followed by a large central nervous system reorganization.

At the present time, the conflicting results from the cross-circulation and denervation studies suggest that animals may be able to shift their attention from one signal to another. The cross-circulation studies do not interfere with any of the possible communicating signals within the body because no major nerves or blood vessels are severed and blood flows continuously throughout the bodies of both rats. However, there is about a week of recovery from the time of surgery until the behavioral testing begins. During this time, the rats could learn to ignore changes in blood levels of hormones or nutrients and rely only on intact neural messages to inhibit food intake. In contrast, the denervation studies interfere with one of the major signal systems in the body, but the animals survive and recover over several weeks or months. Even with probable total gut denervation, dogs, cats, and rats are able to feed in a fairly normal way although the level of food intake and body weight may be reduced, especially after vagotomy. Perhaps during this long adjustment period, they learn to pay attention to mouth and throat signals or to the changes in the blood levels of hormones and nutrients. A possible shift over time to different internal signals seems to be one way to reconcile the two sets of studies.

Another way to reconcile the results is to examine whether some combination of signals is needed to inhibit food intake. A number of studies have shown that a combination of neural and hormonal signals may together produce an effective signal that inhibits food intake. Neither signal alone would be enough. Davison and Clarke found that there were CCK receptors on gastric afferent nerve terminals and that the combination of CCK release by the intestine and gastric distension might together produce satiety signals (230). These studies were extended to show a clear increase in nerve activity when CCK and gastric load were increased together (231). Some studies have shown that peripheral CCK and intraventricular leptin interact to produce a larger inhibition of food intake (232,233). More recently, it has been shown that intraventricular leptin enhances satiety caused by a gastric nutrient preload (234). These studies suggest that a complex combination of neural and hormonal signals may be needed to produce satiety and that focusing on just one or the other signal system independently may fail to demonstrate a major effect on short-term or daily food intake. Further investigation is needed to obtain a clear

understanding of the nature of the signals that inhibit food intake after a meal. It has recently been shown that there are leptin receptors on some of the gastric afferent neurons of the vagus nerve (74). It would be interesting to know if ghrelin released into the gastric lamina propria could also inhibit food intake by attaching to receptors on vagal afferents.

## **XII SIGNALS ARISING IN THE LOWER GUT**

Jejunioleal bypass surgery has been one of the most successful ways of causing weight loss in morbidly obese patients. In this surgery, the upper jejunum is connected to the lower ileum so that the food bypasses 80–90% of the length of the small intestine, and as a result, the ingested food is not fully digested and absorbed. Following this surgery, obese patients lose 40% of their body weight and retain this weight loss after 2–5 years (235–237). The original theory behind the surgery was that, by shortening the length of the small intestine, one would reduce the absorptive surface of the gut and prevent the absorption of much of the ingested food. The patients could eat as much as they wanted, but most of the food would pass right through the digestive tract before it could be absorbed. Presumably, patients who were unable to control their food intake would still lose weight. In fact, a major consequence of the surgery was that the patients chose to eat less which contributed to the substantial weight loss (238,239). This effect has also been observed in rats (240). In fact, the weight loss was largely caused by reduced food intake and not by malabsorption. Part of the reason for this reduction of intake may have been the discomfort of their lower gut symptoms. These jejunioleal bypass patients experienced severe diarrhea, bloating, and flatulence and were running frequently to the toilet to relieve their recurrent discomfort. Thus, there may have been some aversive conditioning that led to their reduction of food intake.

Jejunioleal bypass surgery induced a large number of medical complications due to malabsorption or to the large segment of bypassed bowel, and, because of these complications, the surgery is no longer done in major medical centers. Instead, the surgeons have focussed on gastric restriction or gastric bypass operations (241,242). These surgeries attempt to restrain food intake by producing a small gastric pouch that provides strong distension cues if the right food is eaten. Both of these operations do cause an initial major loss of body weight, but, in the case of gastroplasties or gastric ver-

tical binding, the weight loss depends on patient compliance in food selection. If the selected foods can pass easily through the narrowed opening of the stomach pouch, as can milk shakes or blenderized meals, then the patients rapidly regain their lost weight. In recent years, obesity surgeons have returned to the gastric bypass operation (243), which combines the restriction of a stomach pouch with the stimulation of the lower gut. In the gastric bypass surgery, a small isolated pouch of upper stomach is connected through a restricted outlet to the upper jejunum. This procedure bypasses the usual controls of gastric emptying and spreads the emptied food more rapidly into the lower gut (244). Indeed, the plasma levels of lower gut hormones following a meal in gastric bypass patients (245–248) were quite similar to those found after jejunioleal bypass. The 15-fold integrated postprandial enteroglucagon response after gastric bypass was comparable to the 14-fold increase found after j-i bypass (249). Thus, the current surgery of choice, gastric bypass, has a large lower-gut component. New experimental surgeries are following the same strategy of greater stimulation of the lower gut (243).

Greater stimulation of the lower small intestine could cause reduced food intake and increased weight loss by stimulating the nerves in the ileum or by greater release of lower gut hormones. The role of ileal nerves in long-term weight loss has not yet been investigated. There are four hormones that are released from the lower small intestine and might play a role in the inhibition of food intake. Neurotensin (NT) is a tridecapeptide that was originally isolated from the hypothalamus and has the same structure in rat, dog, and human. It is found in the N-cells of the gut, which are present in increased frequency as one moves down the small intestine (250). The N-cells have microvilli that make contact with the lumen of the small intestine and may thus directly sense luminal contents. Neurotensin is released after a normal meal or after the infusion of fat into the duodenum (251). Gastric secretion and motility are inhibited by high doses of NT (97). When injected IP, neurotensin causes a reduction of food intake and grooming and an increase in drinking (252), but plasma levels were not measured and an effect on gut motility cannot be ruled out as an explanation of reduced feeding. A recent study involving the IP injection of a novel neurotensin analog also appears to inhibit food intake (253). When NT is injected into the hypothalamic paraventricular nucleus, it causes a dose-dependent reduction of food intake without associated changes in water intake, grooming, or sleeping behavior (254), but these investigators found no effect of IV infusion.

There are three other hormones originating in the lower gut, and all are found in endocrine cells, labeled L-cells, which have microvillous tufts that protrude into the intestinal lumen and, thus, could be stimulated by lower gut contents. Like N-cells, L-cells increase in number as one progresses down the small intestine, and large amounts of PYY are found in the ileum and colon (255). Pancreatic peptide YY (PYY) is a 36-amino acid peptide that was first discovered using a chemical method that detected amide groups (256). It is released after a normal meal and after oleic acid is infused into the duodenum and, in much higher amounts, after a large meal (257). It inhibits gastric acid and pancreatic enzyme secretion and causes gallbladder contraction (97). PYY also limits gastric emptying and inhibits intestinal motility, acting as an ileal brake (258). Recent work has shown that peripheral PYY acts on the dorsal vagal complex to inhibit gastrointestinal motility (259). Hormonal PYY has not been shown to alter food intake, although its close cousin, neuropeptide Y, greatly enhances food intake when injected into the cerebral ventricles or the hypothalamus (260,261). Several studies have shown that injection of PYY into the ventricles enhances food intake (262,263), in contrast to increased lower gut stimulation, which reduces food intake (264) and releases hormonal PYY. If peripheral PYY gains access to the hypothalamus, it probably works on NPY receptors in the brain to increase intake.

The two other identified lower gut hormones, the glucagonlike peptides 1 and 2 (or GLP-1 and GLP-2) are produced by alternate processing of the proglucagon gene in the small intestine and colon (265,266). When released, GLP-1 acts as an incretin in the stimulation of insulin release (267). It interacts with both glucose and GIP to enhance insulin release. GLP-1 also inhibits stomach emptying and thereby lowers blood glucose levels (268). Recent studies have shown that the intravenous infusion of GLP-1 will reduce food intake and lower plasma glucose in humans (269,270), but there is also evidence that GLP-1 may cause visceral malaise (271,272).

The other major enteroglucagon is GLP-2. GLP-1 and GLP-2 are released by the same cells in equimolar quantities (265,267). GLP-2 increases the activity of brush border enzymes and increases the rate of absorption of peptides and fats (273). It may also act as an ileal brake, inhibiting the delivery of food to the lower gut (274). The specific receptor for GLP-2 has been cloned and identified (275). It has been found only in the stomach, small intestine, hypothalamus, and brainstem. In the small intestine, the receptors appear to be present only on other endocrine cells (276). A recent study

involving the central injection of GLP-2 demonstrated a small, 2-hr reduction of food intake that was not associated with conditioned aversion using a weak one-bottle saccharin aversion test (277). These authors identified the presence of GLP-2 neurons originating in the nucleus tractus solitarius of the brainstem and projecting to the dorsomedial nucleus of the hypothalamus. They argued that GLP-2 was acting as a neurotransmitter to decrease food intake, but their evidence does not exclude the possibility that peripheral GLP-2 may also act centrally as an inhibitor of food intake.

All of the lower-gut peptides can be released by glucose, 5% peptone solution, and oleic acid delivered to the lumen of the small intestine (278,279). Recent studies have shown that they all may play some role in the peripheral control of food intake, although direct evidence for a role of peripheral PYY on intake is not available. In addition, a physiological effect of NT, GLP-1, and GLP-2 on the inhibition of food intake is not yet certain. At present, the internal signals that cause the sustained lower level of daily food intake and body weight after jejunoileal and gastric bypass are not fully understood.

Another way to test the importance of the lower small intestine in the inhibition of food intake is to move a segment of the lower small intestine to the upper regions of the gut without causing any change in the length of the small intestine. In one experiment, a 10- or 20-cm segment of lower ileum was isolated from the lower small intestine and was reconnected to the mid-duodenum or upper jejunum (264,280). These rats with ileal transposition showed a decrease in food intake that led to a substantial loss of weight. The ileal transposition surgery was more effective in obese than in lean rats, although the effect was significant in both. These data suggest that overstimulation of the ileum might lead to a reduction of food intake by intensification of lower-gut signals.

The ileal transposition studies have shown that malabsorption and its associated discomfort were not the essential components of the reduction of food intake that followed jejunoileal bypass (280). Increased lower-gut stimulation was sufficient to cause a large reduction of food intake. However, these studies failed to prove that the intensification of ileal signals was reducing food intake through a normal physiological mechanism. It was still possible that the intensified signals were causing a reduction of intake by making the animal uncomfortable, that is, by generating physiological signals that were outside their usual range. One suggestion that the level of stimulation was abnormal was the large number of morphological changes that resulted from the inten-

sified ileal stimulation. There was a 50% increase in the wet weight of the stomach, pancreas, and remaining jejunum, as well as a fivefold increase of the transposed ileal segment (264,281). These changes in organ size could be interpreted as an hard-wired attempt by the body to reduce ileal stimulation. In a normal rat, similar changes could increase the holding capacity of the stomach, provide more digestive enzymes for the processing of food in the upper small intestine, and increase the absorptive surface of the gut. In addition, ileal stimulation would reduce intestinal transit leading to less stimulation of the lower gut (282,283). Reduced food intake could be interpreted as another way in which the organism could prevent food from reaching the lower small intestine (281). However, all of these signals might still be outside the usual physiological range: the intense stimulation of the transposed ileal segment could be making the animal sick. After all, almost all of the ingested food had to pass through this ileal segment before it could be absorbed, which was far from the normal level of stimulation by  $\sim 3\text{--}5\%$  of the ingested and digestible food. Was there a way to reduce the stimulation of this ileal segment and bring it closer to the normal physiological range?

The degree of the stimulation of the lower gut could be altered by using surgery on another type of parabiotic rat pair. In this surgical preparation, the small intestine of one rat in the pair was transected at the jejunoileal junction or about halfway down the length of the small intestine. The upper jejunal end of this rat's small intestine was connected end-to-side to the partner's small intestine at the same level (see Fig. 13). The lower ileal end was simply closed so that no more ingested food could enter into its lumen. The result of this surgery was that one rat in the pair (the rat on the right) no longer has its ileum, cecum, and colon stimulated by exogenous food, while its partner had its lower gut doubly stimulated. Instead of the 20- to 30-fold increase in the amount of ileal stimulation that might be expected in the ileal transposition rats, these rats had their full lower gut either unstimulated or doubly stimulated by chyme that had been appropriately processed for the level of intestinal stimulation (284). Of course, in this preparation, there was also a continual loss of food from the intestine of one rat into that of its partner. The rat that lost food into its partner and that had its lower gut unstimulated increased its daily food intake by 30–40% while its partner that had its lower gut doubly stimulated reduced its own intake by about the same amount. On the surface, this result would suggest that food intake is controlled by the lower small intestine, but the results need to be inter-

**Figure 13** Diagram of rats with doubly stimulated lower guts. The rat on the right has its small intestine transected at the junction between jejunum and ileum. The jejunum is connected end-to-side to the partner's intestine at the jejunoileal junction. The stippled GI tract belongs to the rat on the left. After the surgery, the rat on the left has its lower gut doubly stimulated with chyme while the right rat has no further food enter its ileum, cecum, or colon. (From Ref. 284.)

preted carefully. Is the change in daily food intake due to the loss of food from one rat to the other or due to the change in lower-gut stimulation? To answer this question, one needs to look at the changes in body weight that occur over an extended period of time. When the rats were sacrificed 24 days later, it was found that the two rats did not differ significantly in body weight or in the size of their retroperitoneal fat pads. Therefore, the adjustments of daily food intake were appropriate for the amount of food lost from one rat into the intestine of its partner. This result showed that doubling or reducing to nil the exogenous stimulation of the lower gut had no specific effect on the daily food intake of the rats. The changes that were observed could be attributed to the loss of chyme from one rat to the other. The major controller of food intake was the amount of absorbed food and not the stimulation of the lower gut. From these results, one can conclude that stimulation of the

lower gut has only a minor role in the regulatory control of food intake. At greatly elevated levels, it may be effective in causing reduced food intake and sustained weight loss, but, at near normal levels, it does not appear to be a major peripheral controller of food intake.

### XIII SIGNALS ARISING IN THE LIVER

The liver originates as an outgrowth of gut tissue and plays a significant role in the secretion of bile and the absorption of fat. One of its major functions within the body is the control of the metabolism of glucose, amino acids, and fat. Therefore, the role of the liver in the control of food intake could be seen from the perspective of a gut organ coming in early contact with food or as a mediator and regulator of metabolism. It is appropriate to review its role in the control of food intake in a section that moves from gut signals to metabolic signals.

The liver is the only organ, other than the gut, that comes into direct contact with a substantial amount of the ingested food. All of the absorbed water-soluble nutrients, including sugars and amino acids, pass through the liver on their way into the general circulation. The liver removes many of these nutrients during the absorptive phase and works to control their levels in the bloodstream. Thus, the liver would be in a position to assess or monitor the total amount of carbohydrate and protein entering from outside, which could be as much as 60–90% of ingested calories. However, the liver does not come into direct initial contact with most of the absorbed fat, since ingested long-chain fatty acids are resynthesized into triglycerides and formed into fat particles called chylomicrons. These fat particles do not enter the portal vein, but instead pass into the intestinal lymphatics, travel through the thoracic duct, and enter the blood at the level of the large veins leading into the heart (285). Thus, the absorbed fat bypasses the liver before it enters the bloodstream at the heart, where it is diluted in all of the blood. Some of the absorbed fat will go directly to muscle and adipose tissue for use or for storage and never pass through the liver, making it impossible for the liver to determine the total amount of absorbed long-chain fat by direct contact. Of course, the liver could still have some indirect way to count absorbed fat calories by assessing some change in internal signals or changes in specific metabolic pathways.

Russek was the first person to propose that the liver was a major organ involved in the regulation of food

intake (286). He suggested that hepatic nerves respond to changes in the metabolic activity and the resulting hyperpolarization of the hepatocyte membrane. He argued that these changes were communicated to the brain through the hepatic vagus nerve. Nijima has shown that the nerves in the hepatic branches of the vagus decrease their firing rate in an inverse relationship to the glucose concentration in the portal vein (227). Novin and his collaborators infused isotonic glucose into the portal vein of free-feeding rabbits and found that it had little effect on meal intake, but when the glucose was infused into the portal vein in 17-hr-deprived animals, it did reduce food intake over a period of 3 hr (287,288). In contrast, infusion of glucose in the duodenum reduced food intake in free-feeding rabbits but had little effect in deprived rabbits. These data are confusing because glucose infused into the duodenum should be very rapidly absorbed into the portal vein and, thus, ought to act in a similar way as direct portal vein infusion. Like portal infusion, duodenal infusion should have reduced the food intake of the deprived rabbits, unless a duodenal signal somehow blocks a later hepatic signal.

The role of the liver in the control of food intake has been more recently investigated by Tordoff and associates. They infused glucose into the portal vein and found that it was more effective than equimolar concentrations of NaCl only at the lowest concentration of 0.3 M (289,290). As the dose doubled and quadrupled, the 2-hr food intake of the rats infused with salt continued to decrease, while those infused with glucose remained at the same level (see Fig. 14). In comparison, infusion of the same amount of glucose into the jugular vein had relatively little effect on 2-hr food intake. They also found that the rats with portal glucose infusion had lower plasma glucose levels and increased hepatic glycogen compared to jugularly infused rats. This result is consistent with the fact that the infused portal glucose was altering hepatic metabolism and was being stored as glycogen. One puzzling aspect of these data was that increasing the dose of glucose caused no greater reduction of food intake even though the highest dose was the equivalent of 104 kcal/day or more than a rat would normally eat. The hepatic sensor did not seem to be measuring the amount of water-soluble nutrient passing through the liver during this short time frame. It registered the presence of glucose, but not the amount.

A more recent study has measured daily food intake over a 17-hr period when only 10 or 20 kcal of glucose (0.57 or 1.15kcal/hr) was infused into the portal or the jugular vein. It was found that using these slow infusions of relatively small amounts of glucose pro-

**Figure 14** Food intake of rats infused with increasing concentrations of glucose and sodium chloride into the portal vein. \*Food intake is significantly different from the control mock infusion. †The two treatments at a single dose differ significantly. There is no dose dependence of glucose infused into the portal vein. (From Ref. 289.)

duced a significant 5- or 10-kcal reduction of food intake but there was no difference in intake between the portal or vena cava infusions (291). Plasma levels of glucose or amino acids passing through the liver would be very different in these rats because only ~20% of cardiac output goes directly to the liver. Thus, the elevation of infused glucose passing through the liver would be five times greater in the portal than in the vena cava-infused rats. This result suggests that the liver does not sense the total amount of glucose absorbed from the intestine and use this information to control daily intake.

One way to assess the role of the liver in the control of meal intake is to allow a substantial amount of water-soluble nutrient to pass through the hepatic sinusoids and see whether the nutrient has a direct effect on food intake during a single meal. This objective can be achieved by feeding one rat in the two-way crossed-intestines rat pairs, a symmetrical preparation in which

a 30-cm segment of each rat's intestine is connected to the intestine of its partner (see Fig. 9). This preparation was described above (under intestinal signals), but can be briefly described again to explore its implications for the role of the liver in the control of short-term food intake. Following this surgery, either rat in the pair has its ingested food move into its own stomach, pass through its upper duodenum, and then travel into the crossed segment of its partner's intestine at a level just below the bile duct (94,284). Some of each rat's ingested food will be digested in the partner's upper small intestine and absorbed into the partner's bloodstream, and some will continue to travel down the digestive track back into the lower jejunum of the feeding rat. Water-soluble nutrients will be digested in and absorbed from the crossed intestinal segment and will be delivered directly to the portal vein of the partner. The effect of these water-soluble nutrients on the hepatic control of food intake can be assessed in these rats by feeding only one rat of a pair after a 7-hr fast. The rat fed first has a lower delivery of absorbed nutrient into its own bloodstream and less stimulation of the liver by food during the 10 min following the beginning of a meal because its own crossed 30-cm segment of the upper intestine remains unstimulated by food. Nevertheless, its food intake does not increase, but remains at the same level as unfed control rats with no hepatic nutrient stimulation. The partner rat fed 10 or 30 min later has already had its liver stimulated by the absorbed food, but these rats ate the same amount as their partners fed earlier or as control rats without their intestines crossed. In fact, when the absorption of glucose-3H or of amino acids-3H was measured in rat pairs where one of the rats was fed a normal diet with these radioactive tracers, it was found to be significantly higher at 10 min in the rat that had not yet fed and was hungry than in the feeding partner that had completed its meal and was satiated. These results suggest that the passage of water-soluble nutrients through the liver in a physiologically controlled way does not inhibit food intake during meal. The liver does not appear to monitor the amount of absorbed nutrient passing through its sinusoids and use this information to alter meal intake.

An alternative way of testing the capacity of the liver to measure the amount of absorbed nutrient passing through its sinusoids and to use this information to alter food intake is to divert the blood coming from the gut into the systemic circulation before it reaches the liver. This can be done by use of a portacaval shunt. In this surgery, the portal vein is clamped and tied just below the liver. The vein is transected on the gut side of the tie,

and the loose end is sutured end-to-side to the ascending vena cava. As a result of this surgery, all of the blood leaving the gut passes directly into the systematic circulation and does not go through the liver on its first pass into the body. The liver is supported only by blood arriving through the hepatic artery, and over the next 10 days it is diminished by 30% in wet weight (292). If the liver were monitoring the total amount of water-soluble nutrient that was entering through the gut and using this information to control food intake, one would predict that the shunted rat would overeat on its first meal after the surgery and would continue to overeat until hepatic signals to the brain had adjusted for the reduced caloric load passing through the hepatic artery. In fact, it was found that the rats ate  $3.6 \pm 0.7$  kcal on their first meal compared to  $6.2 \pm 1.6$  kcal for the controls ( $P = .18$ ).

These results did not change in subsequent meals. During the first night, the portacaval shunted rats ate an average meal size of  $5.1 \pm 2.4$  kcal while the controls ate  $5.5 \pm 1.9$  kcal ( $p = .90$ ). The shunted rats also ate  $7.4 \pm 1.7$  meals while the controls ate  $8.1 \pm 2.2$  meals ( $p = .80$ ). During the next 8 days of recovery, the shunted rats tended to eat less than controls and they lost somewhat more weight (see Figs. 15, 16). These results show that the shunted rats ate less food than controls even though their livers were deprived of contact with some of the absorbed nutrient. Some of the absorbed food would pass from gut to muscle or adipose tissue without ever coming into contact with the liver. An increase in food intake by shunted rats would be predicted by a theory that argues that the liver measures or monitors the total

**Figure 15** Daily food intake of rats provided with a portacaval shunt or given sham surgery. Measurements of meal patterns were made on the first day after surgery and during the last 6 days, when the rats had returned to the baseline intake.

**Figure 16** Body weight of rats with either portacaval shunt or sham surgery. Rats with the portacaval shunt lose more weight after surgery, but their subsequent weight gain is comparable to that of controls.

amount of exogenous water-soluble food arriving from the gut and sends a message that controls food intake.

To make sure that we were testing rats at their best performance, measurements were also made of meal patterns during the last 6 days of the study when the rat's daily food intake and rate of body weight gain had stabilized for both the shunted and controls rats (154). The rat's first meal after a 7-hr fast was  $10.7 \pm 1.4$  kcal in shunted rats and  $10.8 \pm 1.2$  kcal in controls ( $p = .98$ ). For their average meal during the day, the shunted rats ate  $5.1 \pm 0.5$  kcal while controls rats ate  $5.9 \pm 0.8$  kcal ( $p = .26$ ). Their number of meals were  $15.8 \pm 1.6$  versus  $14.7 \pm 1.0$ , respectively ( $p = .70$ ). Clearly, the food intake of the shunted rats was not larger than and, in fact, not significantly different from, that of controls. This results suggested that the liver does not use information that it may obtain about the amount of absorbed food passing through it to control food intake.

Russek has argued that the diversion of the blood away from the liver through the use of a portacaval shunt does not change the stimulation of the liver by absorbed food: within one circulation time, he argues, the absorbed nutrients have passed into the hepatic artery and elevated plasma levels (293). However, in shunted rats, a substantial amount of the absorbed nutrient will never pass through the liver. Some portion of the absorbed glucose and amino acids will go directly from the systematic circulation to muscle, fat, and other tissues and will be taken up by these tissues before it can ever reach the liver. Thus, the liver fails to have contact with the full amount of water-soluble nutrient absorbed from the intestine in these portacaval shunted rats and, therefore, should not be able to assess the total content of absorbed nutrient.

These last two studies show that the liver does not determine the amount of absorbed nutrient and pass

this information to the brain to control food intake. In the first study, there was a physiological delivery of a substantial amount of nutrient from the upper small intestine into the portal vein leading directly to the liver. This delivery over a period of 10, 30, or 60 min did not reduce food intake and, in fact, had no effect upon the size of the first meal after a 7-hr fast. In the second study, the diversion of the nutrient-containing portal blood away from the liver did not cause an increase in the first meal after the surgery, in the meals throughout the first day, in the first meal after a 7-hr fast over the last 6 days or in the meals taken throughout a 6-day period when daily food intake and body weight gain had stabilized 10 days after the surgery. Thus, both studies show that the liver does not monitor the amount of absorbed food and convey that information to the brain to alter food intake.

Although the liver does not appear to sense the total amount of nutrient absorbed from the gut, it could be involved in relaying information to the brain about metabolic changes taking place in the body, such as the type of nutrient being used for fuel or the fasting-refeeding state. This information may influence and alter food intake. If the liver were involved in the control of food intake, it would need to send messages to the brain to produce a change. These messages would have to be sent by nerves or through the bloodstream. A partial denervation, hepatic vagotomy, has been done in free-feeding rats and produced mixed results. Friedman and Sawchenko (294) found a shift in the day/night rhythm with increased feeding during the day and reduced feeding at night. There was a small change in daily intake but only in male rats. On the other hand, Del Prete and Scharrer (295,296) have shown that hepatic vagotomy caused no change in day/night feeding but the pattern of daytime feeding was altered. These are relatively minor effects of partial denervation of the liver. When a total hepatic denervation is done, the changes in meal pattern completely disappear (297, 298, 299, 300). A recent liver transplant study showed only a small night-time decrease in daily intake in liver-denervated and transplant rats (298). Thus, hepatic denervations appear to have little effect on spontaneous food intake, and the hepatic nerves are not much involved in the control of meal patterns. On the other hand, hepatic vagotomies have been shown to affect food intake when intake is altered by external treatments, such as infusion of total parenteral nutrition (301) or glucagon (140). Thus, hepatic nerves may play a role in unusual, external challenges, but they do not have much of a role in the normal control of food intake. The other possible way in which the liver could

inform the brain about peripheral changes in metabolism is by the release of some humoral factor. The type and quantity of food eaten has an effect on the release of somatomedins or insulinlike growth factors that alter metabolism and enhance growth (302). A specific inhibitor of food intake secreted from the liver has not been identified, but remains a possibility.

#### XIV METABOLIC SIGNALS

Although the liver does not seem to monitor the amount of water-soluble nutrient passing through it from the gut and use this information to control intake, it still responds to changes in the plasma levels of glucose, amino acids, and fats by removing or releasing these nutrients to maintain their blood levels within a well-defined range. That the liver can release glucose in the blood has been known since the days of Claude Bernard. In fact, the liver and various regulatory hormones are very effective in maintaining plasma glucose levels: they are able to substantially limit the surge in plasma glucose that follows a CHO meal and to maintain plasma glucose levels even under conditions involving extensive exercise when glucose is rapidly being used by the muscles (303). Thus, the liver could acquire some information about the flow of energy through the body without having to monitor the total amount of absorbed nutrient.

It is possible that the liver or some other tissue in the body monitors the plasma levels of the macronutrients and sends this information to the brain to alter food intake. Indeed, there are many theories that claim that plasma nutrient levels are important in the control of food intake. The early version of the "glucostatic" theory stated that elevated plasma levels of glucose inhibit food intake (304,305). When it was noted that diabetic rats had very high plasma glucose levels and were nevertheless hyperphagic, the theory was modified to claim that the use of glucose by the tissues, which produced an arteriovenous (A-V) difference in plasma glucose, controlled daily food intake (305,306). Because increased levels of plasma insulin are needed to generate an A-V difference in plasma glucose levels in peripheral tissues, the glucostatic theory has been closely associated with a theory that insulin inhibits food intake (see section on Pancreatic Hormones above). One argument against the glucostatic theory is that a meal of meat, which contains mostly protein and fat, is highly satiating, suggesting that regulation of glucose transport into cells cannot be the only mechanism involved in control of meal intake. Grossman and associates have reported

that the short-term injection of glucose into veins or the peritoneal cavity in calorically significant amounts had no greater effect on the food intake of dogs than a control saline injection, but no evaluation of A-V differences was made (307,308).

In a complementary approach, the “aminostatic” theory states that increased levels of plasma amino acids are associated with decreased appetite in man (309). Amino acid levels were found to vary inversely with ratings of hunger. A major argument against the aminostatic theory is that increased protein content of the diet leads to substantially lower levels of plasma amino acids but no major increase in food intake (310,311). Thus, amino acid levels themselves are unlikely to control food intake. The final classic theory, the “lipostatic” theory, states that the amount of body fat controls daily food intake (312) and will be discussed in greater detail under Storage Signals.

One way of testing whether metabolic signals control food intake is to infuse nutrients directly into the bloodstream and to determine whether the infusion reduces daily food intake. Such an infusion bypasses the gut and tests the relevance of specific nutrients for the reduction of daily food intake. All relevant studies have shown that the slow, chronic infusion of nutrients into the

bloodstream produces a substantial reduction of daily food intake (313–316). These studies show that the presence of these nutrients in the bloodstream or the metabolic consequences of their uptake into the body’s tissues generates a signal that feeds back to the brain to inhibit feeding behavior. Each of these nutrients has its own specific effect on daily food intake (317) (see Fig. 17). If 34 kcal of glucose is infused slowly and continuously over a 17-hr feeding period, the rats show a reduction of intake in 1 day that is equivalent to 55% of the calories infused. When the infusion stops, the rats return in 1 day to their previous baseline levels of intake. In contrast, infusion of 10 or 20 kcal of an amino acid mixture causes a complete reduction of intake relative to the number of calories infused. Daily food intake is decreased during the first day of infusion and returns within a day to normal at the end of the infusion. Finally, infusion of 20 or 40 kcal of IV lipid has no significant effect on daily food intake during the first day and, then, provokes a gradual reduction over 2–3 days that stabilizes at a lower level after 4–6 days. The long-term compensation averaged only 42% of the calories infused, showing that IV lipid was the least effective in reducing voluntary food intake. When the infusion ceased, daily food

**Figure 17** Average daily food and energy intake of rats infused intravenously with saline, glucose, amino acids, lipids, and an IV diet that had the same composition as the oral diet. Slashed bars are the voluntary daily food intake; open bars are the total number of calories infused. The total height of the bar is the total amount of calories ingested and infused. Rats show a 50% compensation for glucose and lipids, nearly complete compensation for amino acids, and 75–80% compensation for the IV diet. (From Ref. 317.)

intake barely increased on the first day and then rose very slowly over the next several days showing that the pattern of response to fat infusion was greatly delayed and very different from the patterns resulting from the infusion of the water-soluble macronutrients. Since the infusion of each of these macronutrients separately might lead to a less than complete compensation because of a change in the relative amounts of the macronutrients available to the tissues, we also included an infusion condition in which all of the nutrients were infused in the same proportion as the nutrients in the diet. Infusion of 20 and 40 kcal of IV diet produced reductions of daily food intake that were  $\sim 77\%$  of the calories infused. In short, there was a better adjustment for all three nutrients together than for the sum of the nutrients infused separately (317,318). The body was responding partly to the altered macronutrient composition of the infusate. In addition, the infusion of all three nutrients did not produce full compensation showing that either signals originating in the gut or signals associated with the circadian pattern of food delivery were important in providing the full signal for the inhibition of food intake. One study showed that the circadian infusion pattern was important, with infusion during the normal feeding hours being the most effective in reducing daily intake (319).

All of the infusion studies show that the presence of the infused nutrients in the blood or their metabolism and storage in the tissues provides the major signal that controls daily food intake. These infusions of nutrients cause a reduction in food intake without there being a concomitant change in metabolic rate. When glucose is infused into the vena cava, the rats show an immediate reduction of daily food intake, but metabolic rate remains the same (320). There is, of course, a shift in respiratory quotient which reflects the increase in the amount of glucose that is being burned by the tissue. There is also a small increase in metabolic rate on the fourth day of glucose infusion, when there has been a sustained increase in carbohydrate calories delivered to the body, but the increase in metabolic rate was only 5% of baseline levels. On the other hand, when fat is infused in the form of an intravenous intralipid, there were gradual changes in food intake but no change in metabolic rate before, during, or after the infusion. Even if infusion of nutrients doesn't change metabolic rate, it leads to the deposit of excess calories in body fat (321).

Since the infusion of nutrients into the bloodstream is a very effective way of reducing daily food intake, there must be one or several sites within the body where the infused food is translated into a signal that is sent to the brain to alter food intake. One of the most likely sites for

the measurement of plasma levels of nutrients would be the brain itself. Several studies have shown that there are neurons in the ventromedial and lateral hypothalamus that are responsive to glucose and amino acids as well as insulin and other hormones (322). These neurons could sense the plasma levels of these nutrients or hormones and use this information to initiate and control the feeding behavior of the animal. To test the role of these brain sensors in the control of daily intake, infusions of glucose or amino acids were made directly into the internal carotid artery (323). Infusions of water soluble nutrients directly into the carotid artery would greatly elevate their plasma levels during the first pass of blood through the brain, because the infused nutrients are diluted into the 2–3% of the cardiac output that goes to the rat brain. The infusions are made continuously for 24 hr. Calculations based on blood flows show that plasma glucose levels in the brain should be increased by 44 mg% above background, which was confirmed by direct glucose measurements made in the jugular vein. Once the blood with the infused nutrients has passed through the brain, it gets diluted by other blood entering from the descending and ascending vena cava and has a nutrient composition that is the same as the nutrient content after nutrient infusion directly into the vena cava, which is the control comparison condition. This study found that the rats with carotid infusions of glucose and amino acids showed the same reduction of food intake as rats with vena cava infusions. Therefore, substantially elevated glucose or amino acid levels in the blood flowing through the brain did not alter food intake any more than when the same nutrients were infused into the vena cava and diluted in the total volume of blood before reaching the brain. Plasma levels of glucose and amino acids flowing through the brain do not appear to alter food intake.

Another way to assess the effects of nutrients on the control of daily food intake is to draw nutrients that have already been absorbed out of the bloodstream. This can be done with the cross-circulated rats described above (see Fig. 12). One rat in a cross-circulated pair can be deprived of food for 4 days while the food intake of its partner is observed. If nutrients are important in the control of daily food intake, the feeding rat that loses half of its ingested food into the bloodstream and tissues of its partner should increase its daily food intake. We observed that the rats did not significantly change their food intake for 2 days and, thereafter, increased food intake on the 3rd and 4th day by  $\sim 30\text{--}40\%$ , which was less than compensatory for the amount of food lost (221). The feeding rats should have doubled their daily food intake to sustain both

animals. As a result, the rats lost weight. When food was again available to both rats, the long-term feeding rats reduced their intake to baseline levels on the first day, showing that the rats were capable of sensing increased nutrient content within 1 day.

The overall result suggests that, in cross-circulated rats, a decrease in the blood level of nutrients and the amount of nutrient transferred into tissue fails to be noticed by the mechanism that controls daily intake for 2 days. This result challenges the hypothesis that metabolism controls daily intake. However, it is in conflict with the results from studies using direct nutrient infusion where water-soluble nutrients reduce daily food intake within the first day of infusion (317,318). It is possible that nutrients are more effective in causing a reduction in food intake than in causing food intake to increase. In any case, the cross-circulation studies show that food absorbed from the gut has little effect on meal intake and that daily food intake increases only slowly when plasma metabolites are lost into the bloodstream of the partner of a cross-circulated pair.

Another way to approach the search for a metabolic signal that controls food intake is to block various metabolic pathways and see whether the blockade causes a change in food intake. Since metabolism is very central to the survival of the organism, one has to be careful to select agents that do not make the animal sick or uncomfortable. Indeed, the most convincing metabolic blockers should cause an increase in food intake showing that the agent works specifically on feeding behavior and that the animal is healthy enough to respond to the internal stimulus. A series of studies using metabolic blocking agents have suggested that there are metabolic signals that can alter food intake.

The first metabolic blocker that was shown to cause an increase in food intake was 2-deoxyglucose (2-DG), which is taken up by cells and interferes with glucose utilization (324). 2-DG causes an increase in food intake, activates the sympathoadrenal system, and substantially increases plasma glucose, FFA, epinephrine, and glucagon levels (325, 326, 327). Small amounts of 2-DG injected into the brain stimulate food intake (328). There are conflicting data about whether 2-DG acts on the liver to reduce food intake. Some studies claim that hepatic branch vagotomy attenuates the effect of peripherally injected 2-DG (329) while others claim that it enhances the feeding response (330). Still others find no effect of hepatic vagotomy (331,332) or total hepatic denervation (333) on 2-DG-induced feeding. The main effect, however, is that slowing down the cellular use of glucose causes increased feeding behavior.

Another blocker, 2,5-anhydro-d-mannitol (2,5-AM), also interferes with glucose metabolism and increases food intake in a dose-dependent manner (334). 2,5-AM inhibits glycogenolysis and gluconeogenesis (335). It also produces a small decrease in plasma glucose and a significant increase in plasma fatty acids, glycerol, and ketone bodies (336). It is as effective in increasing food intake in diabetic as in normal rats, suggesting that elevated blood glucose and low blood insulin levels are not detrimental to its effect. Low doses of 2,5-AM probably act in the liver. When infused intraperitoneally, it has a faster and larger capacity to increase food intake than when infused intravenously. The effects of small doses of 2,5-AM are eliminated by hepatic vagotomy, although higher doses are still effective in increasing food intake. 2,5-AM also affects metabolism: it causes an increase in metabolic rate during the first hour after injection but has no long-lasting effect on whole body energy expenditure. It does lower RQ with a decrease in carbohydrate metabolism and an increase in fatty acid oxidation (337). 2,5-AM lowers hepatic ATP, which may provide a signal that increases food intake (338). On the other hand, infusion of 100% TPN reduces food intake by 85%, but there are no associated changes in hepatic ATP or ATP-to-Pi ratio. Thus, this ratio doesn't seem to control food intake during intravenous infusions of nutrients (339). On the 5th day of this study, voluntarily daily food intake increased considerably but there still no changes in hepatic ATP.

There are also a couple of inhibitions of fatty acid metabolism that cause an increase in food intake. Mercaptoacetate (MA) causes an increase in food intake during the day in rats fed a high-fat diet but not a low-fat diet (340). MA impairs mitochondrial beta-oxidation of fatty acids (341) and causes elevation of plasma free fatty acids, no change in plasma glucose, and a reduction of the ketone, 3-hydroxybutyrate (340). The effects of MA can be blocked by subdiaphragmatic vagotomy and by capsaicin destruction of vagal afferents (331), suggesting that the effects of MA are transmitted through the vagus nerve. MA activates the sympathetic nervous system and increases plasma levels of norepinephrine, fatty acids, and glucose (327).

Another fatty acid oxidation inhibitor, methyl palmitate (MP), also causes an increase in food intake (342). MP lowers fatty acid oxidation by inhibiting carnitine palmitoyltransferase I, which transports long-chain fatty acids into mitochondria (343). It elevates plasma free fatty acids and glycerol while lowering ketone bodies (344). MP also interacts with 2-DG which blocks glucose utilization to cause an increase in food

intake at doses that are not effective when only MP was given (see Fig. 18). MP causes an increase in food intake when the rats are fed a high-fat diet rich in long-chain fats but not when they are fed a high-fat diet rich in medium-chain fats (345). Neither MP nor 2-DG alone or together was able to cause an increase in food intake in Syrian hamsters (346).

That these metabolic blockers are effective in increasing food intake does not necessarily imply that the metabolites with which they interfere are normally involved in the control of meal size, meal patterns, or daily food intake. It is clear from the studies cited above that several metabolic blockers act in a specific way to elevate food intake, but they also put unusual stress on the animal and, in the process, elevate stress hormones (327). It is certainly possible that these metabolic blockers could elevate food intake by activating an infrequently used escape pathway that is present only for unusual circumstances when it is necessary to rapidly boost plasma metabolite levels. Food intake may be

initiated as a last resort whenever metabolites fall to very low levels at some regulating site. After all, when other sources of metabolic fuel fail, feeding will provide some rapidly absorbed nutrient (20), and can contribute to maintaining an adequate metabolic rate. However, sudden reductions in the availability of metabolic fuels are not common in animals, and most meals are eaten in a relatively relaxed state without metabolic stress. The increase of food intake provoked by metabolic blockers may provide more of an escape from a severe metabolic deficit than a regular mechanism for the control of food intake.

## XV STORAGE SIGNALS

Early studies by a number of investigators have shown that body weight is regulated. If an animal is force-fed to obesity, it will, when given free access to food, reduce its food intake and return its body weight back toward normal levels (1). In contrast, when an animal is starved or its food intake is restricted, it will slowly lose weight, but, when it is given food *ad lib* again, it will increase its daily food intake and decrease its energy expenditure to bring its body weight back up toward normal levels (347). Since the major change in these overfed or underfed animals is the amount of stored fat, several investigators have argued that there is some internal mechanism that measures the amount of body fat and that adjusts food intake and energy expenditure to bring body fat back to its usual level. Unfortunately, these studies show only the presence of internal regulation; they do not show where or how a corrective signal is generated and transmitted. Indeed, as mentioned in the Introduction, the overfeeding or underfeeding of an animal causes changes in the stimulation of the GI tract, in delivery of soluble nutrient to the liver, in the metabolic pathways that are used by the body, and in the short- or long-term storage of nutrients in various tissues. The response to any of these changes could be responsible for bringing food intake and body weight back to normal levels.

The idea that body fat could control food intake was first proposed by Kennedy as a result of his studies on weight change after VHM lesions. The "lipostatic" theory states that the amount of body fat controls daily food intake in some way (312). However, the theory doesn't specify the nature of the signal system that brings body weight back to normal. It could be a metabolite, such as a fatty acid or glycerol, or a hormone released by adipose tissue or a chalone, defined as a negative humoral feedback signal controlling tissue size.

**Figure 18** Two-hour food intake of rats injected with the combination of 2-deoxy-d-glucose (2-DG), an antimetabolite for glucose, and methyl palmoxirate (MP), an inhibitor of fatty acid oxidation. The drugs given together have a much larger effect than either alone on increasing food intake. (From Ref. 344.)

A number of theorists have tested the role of glycerol by injecting it subcutaneously (SC) or intracerebrally (IC). Glycerol has received considerable attention because glycerol is released by adipose tissue during lipolysis in a one-to-one relationship with the breakdown of stored triglyceride. It is also released in an amount that is directly proportional to the amount of body fat and to adipocyte size (348,349). When injected SC or IC, it causes a reduction of food intake and a decrease in body weight (350). Glycerol has been fed to rats and causes a somewhat more than compensatory reduction of food intake (351,352), but high levels of glycerol in the diet are highly unusual and adaptation to a new diet would necessarily take time. Only one study has infused glycerol into the bloodstream to try to mimic plasma levels and investigate its effect on daily intake. Glick found in 1980 that a 1-day intra-arterial infusion of glycerol caused a reduction of daily intake that was three times the amount of calories infused (351). If his results are accurate, they argue for a role for glycerol in the control of daily intake. These results, however, have not been replicated.

One way to study the role of body fat in the control of food intake is to remove some of the fat in one group of rats and see whether these rats adjust their food intake and energy expenditure to bring body fat back to normal levels. Two studies have found that lean rats that have the inguinal and epididymal fat pads removed will bring their total amount of body fat back to control levels in 3–6 weeks (353,354). Only one of these studies measured food intake under very special conditions in which Osborne-Mendel rats were fed a high-fat diet that tended to make the rats obese. The reduction in the amount of body fat did not produce an immediate increase in food intake, as one might expect if the amount of body fat were directly inhibiting food intake. Instead, the investigators found that after ~ 20 days of rapid weight gain, the lipectomized rats began to reduce their daily food intake relative to controls (353). It was clear that it took several weeks to change their food intake due to the loss of body fat. Indeed, the reduction of intake after 20 days may have resulted from a decreased capacity for storage: these high-fat-fed, lipectomized rats had large fat cells that were the same size as those of the controls on the same high-fat diet, but had less body fat at postmortem. The fat cells may have reached a maximum size which led on to an earlier reduction of food intake in lipectomized rats. Another study did lipectomy of inguinal, retroperitoneal, and epididymal fat pads or sham-surgery in ground squirrels just before they began their increase in body weight prior to hibernation (355). The authors found that 4

months later there was no difference in body composition and no significant change in cumulative food intake in the lipectomized squirrels relative to sham controls. Indeed, the lipectomized ground squirrels ate slightly less food and gained slightly more weight than their sham controls, but neither result was significant. Again, this study shows some regulation of body fat, but no necessary connection between changes in body fat and changes in food intake.

Many studies have shown that the energy balance regulating mechanism has the most difficulty recognizing the caloric content of fat: people eating high-fat diets tend to gain weight, and low-fat diets help them to diet and lose weight (356). These well-established phenomena are probably due to their body's inability to recognize fully the fat calories in their diets. The lipid infusion studies (cited above under Metabolic Signals) have shown that the adjustment to intravenous body fat is slow and incomplete with rats reducing their daily food intake by only 42% of the calories infused after 4 days of slow adjustment (317). A more recent study has shown that both intragastric and intravenous infusion of glucose was more effective in reducing food intake than the same caloric amount of fat (70% compared to 40% of calories infused, respectively) (357). Intragastric infusion caused a greater reduction of intake than intravenous infusion for both macronutrients. Control rats overate on a high-fat diet by 25 kcal/day (compared to a baseline intake of ~ 77 kcal). These studies suggest that there is not as good a satiety mechanism for the fat component of the diet as for the water-soluble macronutrients regardless of route of delivery.

Another possible way in which food intake could be disconnected from the amount of body fat is through the deposition of ingested fat into adipose tissue before it is noticed by the food intake regulating system. The ingested or infused fat could be transferred into fat or muscle by an enzyme, lipoprotein lipase (LPL), present on the capillary linings of these (358,359) and other tissues, such as mammary glands (360), before the food's caloric value has been recognized. This theory actually assumes that once circulating metabolites are moved into storage tissues, they are no longer recognized as having been ingested. It also postulates that activation of LPL should lead to overeating and obesity (358,359). The expression of LPL in adipose tissue is controlled and elevated by increased plasma insulin levels (361,362), which, in the context of this theory, suggests that insulin should increase rather than decrease food intake (see discussion in Pancreatic Hormones above). Greenwood (363) has argued that lipoprotein lipase acts

as a gate keeper, directing ingested fat into adipose tissue and away from other issues. She claims that the level of adipose tissue LPL activity could alter feeding behavior in both rodents and man by sequestering some of the ingested fat away from organs that might sense the amount of ingested food. One piece of supportive evidence is that there are elevated LPL levels in young fatty (fa/fa) rats before they become hyperphagic and hyperinsulinemic (364). We now know that these rats are leptin receptor deficient. Furthermore, obese women have been found to have 3.5 times the level of adipose tissue LPL than age-matched leans (365). Even after the loss of 13 kg, or about half of their excess weight, the obese women's level of LPL in adipose tissue was still three times higher than that of their lean counterparts, suggesting that elevated LPL might move some of the ingested fat into adipose tissue and thereby maintain their obesity.

The idea that the fat component of ingested food might be moved into adipose tissue before it can be sensed by food intake regulating mechanisms has become a central component of another theory of the metabolic control of food intake (366,367). Friedman claims that the oxidation of metabolic fuels in the liver generates a signal that controls feeding behavior. If ingested food bypasses these oxidative pathways, which he believes take place in the liver, then this food will not be noticed by the regulating system. He believes that changes in the intramitochondrial oxidation of metabolic fuels govern feeding behavior (368). If fuel is partitioned so that more fuel moves into adipose tissue, less fuel will be available for oxidation and the excess fat moved into adipose tissue will thus not be noticed by the system that regulates food intake. One problem with this "oxidation" theory is that the intravenous infusion of either glucose or fat into rats produces large changes in daily food intake but no measurable changes in the overall metabolic rate (320). Both of these theories are in conflict with theory that leptin release from adipose tissue is a major controller of daily food intake and body weight (see next section).

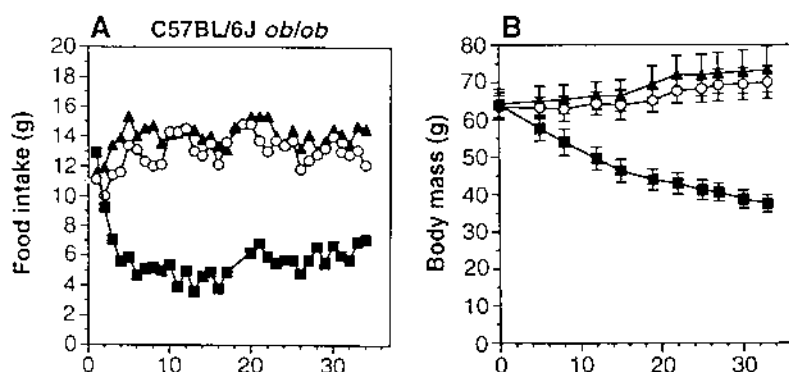

## **XVI ANIMAL MODELS OF OBESITY AND NEW PEPTIDE REGULATORS**

Another way to gain insight into the control of the amount of body fat is to investigate the characteristics of genetically obese mice and rats. There are several strains of obese mice including ob/ob, db/db, agouti, tubby, and fat, as well as several strains of obese rats, fatty (fa/fa), corpulent, and OLETF (120,369,370). All

of these obese rodent strains occur because of the presence of a recessive gene that leads to obesity. The ob/ob and db/db mice have many characteristics in common: hyperphagia, hyperglycemia, hyperinsulinemia, and marked obesity. ob/ob mice are infertile and have difficulty maintaining body temperature under cold stress (371). The first attempt to understand the physiological signal system that was responsible for the genetic obesity that was occurring in these obese rodents was done with parabiotic mice. Coleman surgically connected combinations of ob/ob, db/db, and normal mice together into parabiotic pairs to see whether the slow exchange of blood through the parabiotic union would lead to changes in food intake and body weight (372). Parabiotic connections of two normal, two ob/ob, or two db/db mice produced pairs that grew well and exhibited no changes in intake. In contrast, when db/db mice were connected to either normal or ob/ob mice, these latter mice reduced their food intake, had reduced plasma insulin and glucose levels, and continually lost weight. Some of these normal or ob/ob partners eventually became so thin that they apparently died from malnutrition and starvation. Coleman hypothesized that the db/db mice produced a bloodborne satiety factor that the db/db mice themselves could not sense, but which inhibited the food intake of their partners and led to their slow emaciation. In addition, Coleman found that when normal mice were parabiosed with ob/ob mice, the ob/ob mice reduced their food intake and rate of growth, suggesting that normal mice also produced a satiety factor which was lacking in ob/ob mice. In short, Coleman concluded that the ob/ob mice failed to produce an effective bloodborne satiety factor and that db/db mice failed to sense its presence. With unusual prescience, Coleman thought that the genetic defect in db/db mice might be caused by a deficient sensor in the hypothalamus.

Several investigations have used molecular biology techniques to explore the character of the ob gene. These interesting studies have shown that the ob gene codes for an mRNA that is present in adipose tissue and this mRNA translates into a protein that is released into the bloodstream. Several studies have shown that when this protein, called leptin, has been injected ip into mice, there is a large reduction in food intake and body weight (see Fig. 19). These reductions are most striking in ob/ob mice that don't make a functional protein themselves, but they also occur in normal mice (67). ob/ob mice normally have a lower body temperature and lower metabolic rate, but injection of leptin brings these values back up to normal levels, showing that leptin is working

**Figure 19** Food intake and body weight of *ob/ob* mice given a daily IP injection of ob protein for 34 days. ■, rats receiving 5  $\mu$ g/day of ob protein; ○ and ▲, rats receiving vehicle or no treatment. Similar treatment of *db/db* mice produced no effect. (From Ref. 66.)

on both food intake and energy expenditure to bring body weight back to normal. Leptin also lowers serum insulin and glucose, but these effects could easily be the result of the reduced food intake.

As predicted from the parabiotic experiments of Coleman, the injection of leptin into *db/db* mice had no effect on food intake, showing that the *db/db* mice do not have a functional receptor for leptin and are thus not affected by the elevated blood leptin levels presumed to be present because of their obesity (66). Studies have shown that there is a splicing error in the processing of the gene of the leptin receptor in *db/db* mice (373). Leptin receptors have been isolated from the choroid plexus and from the hypothalamus which has a special long form of the receptor. Leptin is released by adipocytes and appears to act on the brain, most probably the hypothalamus. Injection of one-third of the intravenous dose of leptin into the ventricles of *ob/ob* mice produced similar reductions in food intake, suggesting that a brain region was sensing the presence of leptin (68).

As previously mentioned (see section on Gastric Satiety Signals), leptin has recently been found in endocrine cells of the stomach (59). Plasma leptin levels increase following a meal, and decline before the onset of the next meal (63). There is an increase in plasma leptin levels during the day, with the highest levels in man at night (63,72). The relative proportion of plasma leptin originating from stomach and adipose tissue has not been determined.

Not long after the discovery of an ob gene protein (66), researchers measured the expression of the ob gene mRNA in the adipose tissue of obese and normal human subjects and found that it was elevated in the

obese (374,375). More recently, measurements of immunoreactive leptin have been made in the blood of normal and obese humans (376). These investigators found a significant fourfold increase in the serum levels of leptin-like molecules in obese individuals compared to normal weight subjects, and there was a strong positive correlation between serum concentrations of a leptinlike molecule and the percentage of body fat ( $r = .85$ ). It is not clear whether these leptinlike molecules are restraining food intake in these obese patients or are altered and ineffective. When seven these patients were given a low-calorie diet (800 kcal/d), there was a drop in both serum leptinlike material and in the expression of ob mRNA in their adipose tissue. Both of these changes rebounded, in part, when the patients were put on a weight maintenance diet and ate more food.

The physiological triggers of leptin release have been explored by changes in the expression of the ob gene in the adipose tissues of mice and rats. Fasting led to a substantial fall in the ob mRNA in the epididymal fat pad of *ob/ob* mice, and refeeding brought it back toward normal levels (377). This result was confirmed in Sprague-Dawley rats and was shown to have a circadian rhythm with the ob gene expression doubling during the 12 hr of dark when the rats were fed (378). Fasting prevented this cyclic fluctuation. A single large injection of insulin (1 IU) into fasted rats led to an increase in ob mRNA expression to the levels of fed controls. Thus, insulin may play some role in ob gene expression and leptin release. Injection of hydrocortisone also led to an increase in ob mRNA and a corresponding decrease in food intake and body weight (379). Although these studies are based only on gene expression and not on blood leptin levels, they suggest

that release of leptin may be controlled by hormones as well as by absorbed food.

After the initial discovery of the leptin gene, there was tremendous excitement about the possibility of finding a medical treatment for human obesity by manufacturing a hormone analog of leptin. Some cases of leptin deficiency were discovered in England and Pakistan and were associated with severe human obesity beginning soon after birth (380). These patients were excessively hungry and highly aggressive in obtaining food. A Turkish family with three obese members was also identified with a leptin mutation, but only a small number of patients have been found worldwide with the type of leptin deficiency that occurs in ob/ob mice (381). In contrast, a French family had three female siblings with excessive morbid obesity which was caused by a mutation in the leptin receptor gene, related to the receptor gene defect in db/db mice (382). These sisters had very high plasma leptin levels, reduced growth hormone and thyrotropin levels, and no pubertal development, showing that leptin is involved in many endocrine functions. Although there are only a small number of confirmed cases of mutation of leptin or its receptor in man, leptin is effective in human subjects. In a randomized double-blind placebo-controlled human trial, subjects were given increasing doses of leptin (383). The investigators found that weight loss occurred in a dose-dependent way and that most of the loss was caused by reduced body fat.

The leptin results have provided some validation for the "lipostatic" hypothesis (312) with the identification of a possible blood factor released by adipose tissue and which also inhibits food intake. There are, in fact, several other factors released by adipose cells, but none of these have the same clear-cut relationship to food intake and energy expenditure as leptin (384). Adipose tissue releases a number of complement related factors, such as adipsin or adiponectin, as well as inflammatory cytokines, such as TNF $\alpha$  or IL-6, which have been shown to inhibit food intake when infused into rodents (385) (see section on Cytokine and Inflammatory Peptide Regulators of Food Intake, above). Several other factors are released by fat cells, but only leptin appears to act in a coordinated, physiological way by decreasing food intake and increasing energy expenditure, both of which limit body weight. Although leptin inhibits intake in man, a large amount of data shows elevated leptinlike material in the blood of obese human subjects, who normally eat more and exercise less than their lean counterparts. This contradictory phenomenon has been called leptin resistance and provides a

challenge to the belief that leptin normally acts to regulate body weight. Whether blood levels of ob protein are a result of release from stomach or adipose tissue and whether these blood levels are involved in the day-to-day control of food intake and energy expenditure need further exploration.

## XVII RELATIONSHIP OF FOOD INTAKE AND OBESITY

Obesity occurs when food intake exceeds energy expenditure for an extended period of time (386). One cause of obesity is the ready availability of a large variety of food. The alluring tastes of attractive foods seem to override the internal signals that normally inhibit food intake. Rats are known to become obese when given an attractive supermarket diet (387,388). Diets that are high in both fat and carbohydrate have been shown to cause overfeeding and weight gain (389,390). This result is also true of modern man.

Mixed meals that have a high fat content tend to cause overeating (390). Meals of high caloric value and high fat content also prevent the oxidation of the fat component of the diet. Fat oxidation is inhibited by carbohydrate-containing meals because the absorbed glucose releases insulin which, at low levels, inhibits fatty acid release (391). Insulin also activates lipoprotein lipase which moves some of the fat into adipose tissue for storage rather than allowing the fat to be transferred to tissues for oxidation (392). In addition, ingested fat is stored at a lower energy cost than is fat synthesized from carbohydrate and protein. The cost of storing fat in adipose tissue is only 3% of the ingested calories while the cost of converting carbohydrate into fat requires 23% of the calories consumed (393). When mice are given an increased percentage of their diet as fat, their body fat content increases and a larger percent of the mice have >30% of their body composition as fat (394). When human subjects have fat removed from their diet, they lose weight (395). These studies suggest that fat calories are less effective in inhibiting food intake than are carbohydrate or protein calories. This is confirmed in studies in which glucose and lipids were infused intragastrically or intravenously in rats (317,357). The lipid infusion by either route was less effective in the inhibition of daily food intake. One way to counteract a high fat content of the diet is to burn fat calories by exercising (396).

The large increase in the proportion of people in North America who have been identified as obese in the past decade (397) shows that the recent increases in the

percentage of body fat are not due to our genes but to our behavior and lifestyle. These observations suggest that the ready accessibility and pleasant taste of the wide variety of foods available in developed countries and their relatively high fat content play a large role in the development of obesity. In addition, the decrease in exercise resulting from desk jobs and television viewing contributes to the reduced calorie output and to the storage of excess energy. A similar phenomenon is seen in laboratory rats that are fed a supermarket diet in a small cage that restricts activity (387). To gain weight, humans and rats must overeat, and most override the internal signals that are normally involved in the control of food intake.
